About the Editors

Arie W. Kruglanski, PhD, is Distinguished University Professor of Psychology at the University of Maryland–College Park. He is a recipient of the Donald T. Campbell Award for Outstanding Contributions to Social Psychology from the Society for Personality and Social Psychology, the Distinguished Scientific Contribution Award from the Society of Experimental Social Psychology, and the Senior Career Award from the National Institute of Mental Health. Dr. Kruglanski is widely recognized for his distinguished research contributions, disseminated in over 200 articles and chapters, which focus on how people form judgments, beliefs, impressions, and attitudes, and the consequences for their interpersonal relations, group interactions, and intergroup relations. He has served as editor of the *Journal of Social and Personality Psychology: Attitudes and Social Cognition* and of the *Personality and Social Psychology Bulletin*. He is now a codirector of the START National Center for the Study of Terrorism and the Response to Terrorism at the University of Maryland.

E. Tory Higgins, PhD, is the Stanley Schachter Professor of Psychology, Professor of Business, and Director of the Motivation Science Center at Columbia University. He has received a MERIT Award from the National Institute of Mental Health, the Thomas M. Ostrom Award in Social Cognition, the Donald T. Campbell Award for Outstanding Contributions to Social Psychology from the Society for Personality and Social Psychology, and the Lifetime Contribution Award from the International Society for Self and Identity. Dr. Higgins has also received the Distinguished Scientist Award from the Society of Experimental Social Psychology, the William James Fellow Award for Distinguished Achievements in Psychological Science from the American Psychological Society, and the American Psychological Association Award for Distinguished Scientific Contributions. He is a Fellow of the American Academy of Arts and Sciences and a recipient of Columbia University's Presidential Award for Outstanding Teaching.

Preface

More than 10 years have gone by since the first edition of *Social Psychology: Handbook of Basic Principles* made its appearance. It has been an exciting decade for social psychology, with dynamic developments transforming the conceptual and empirical landscape of our field. New topics and principles have been discovered and vigorously explored. Classic issues have been approached from novel vantage points and via new methodologies.Young generations of social psychologists have emerged whose work has ushered in fresh, often boldly irreverent, perspectives on traditional issues. And, amidst all the excitement of progress, along with the strong winds of scientific change that have been blowing, some fundamental constancies have not only remained but have become increasingly rich in their implications. The rigor of social psychological research and the self-critical attitude that has become our stock in trade have continued to characterize our work. Another constant presence that we editors have certainly felt has been the need to take stock of the teeming, positively accelerated research activity in our field, and to clarify to ourselves what principles of social behavior seem to emerge out of the fast-flowing stream of effects, phenomena, and results that our research endeavors bring forth. Accordingly, the aim of the second edition of our handbook has been to capture the unfolding shifts in ways and means of social psychological research and to distill to the extent possible the principles of human social behavior that lurk beneath the surface of our manifold empirical observations.

Whereas the emphasis on principles is what ties the present edition of the handbook to its predecessor, the present contents, as well as the contributors, were unconstrained by their earlier counterparts. Of the 41 topics in the present handbook only 14 were represented in the previous volume. And of the 81 contributors to the present handbook only 10 contributed to the former project. In part, that is because the 1996 volume left out some research endeavors that were only beginning at that moment and that now have actualized their potential, having matured to full-fledged areas of active inquiry. In such a category belong the topics of "goals," "social metacognition," "the role of impulse," "information ecology," and "dynamic systems approach" or "social cognitive neuroscience." Other topics, though by no means novel historically, had been neglected by social psychologists for a period but now appear with a fresh impetus and with the benefits of theoretical and methodological developments that have visited our field in the meantime. In the latter category belong such topics as "value," "social power," "basic human needs," and "psychological distance."

To the extent that our choice of topics reflects the ongoing research activities in the field, it is apparent that the cognitive approach continues to grow as a significant presence in social psychology. Twelve contributions reflect this perspective—more than any other category. This strong showing is indicative of the richness and diversity of social psychological topics approached these days from the cognitive perspective. Still, the personal motivational emphasis continues to grow as well, suggesting its fruitfulness and utility for understanding social psychological phenomena.

A significant innovation in the present edition is the inclusion of chapters dealing with the applications of social psychology to a variety of applied domains such as "health behavior," "clinical psychology," "organizational behavior," "politics," "marketing," "law and the justice system," and "social action." Indeed, it is encouraging to witness how useful and influential social psychological principles have been across wide swaths of practical domains, attesting once again to the wisdom of Kurt Lewin's famous dictum that "there is nothing as useful [to applied concerns] as a good theory"—good theoretical social psychological principles, that is.

As in the prior edition of our handbook, all our contributors were asked to orient their discussions toward principles and issues rather than toward a detailed examination of specific studies. Indeed, it is our impression that they have done so quite admirably, tempered by the degree to which clear principles or issues were naturally emerging in the specific domains being reviewed. At least in spirit, then, the quest for social psychological principles was apparent in all our varied contributions. We feel and hope that such a quest will offer valuable blueprints to interested students and researchers, indicating where the field is at the moment, and where it needs to go to gain the kinds of insight that would *make a difference* to science and society. In this sense, then, we are pleased to offer our readers a handbook that holds a mirror to social psychology as we have begun our voyage into the 21st century and that reflects the state of our discipline and its exciting research directions.

PART I
BIOLOGICAL SYSTEM

Evolutionary Theory for Social and Cultural Psychology

Linnda R. Caporael

Humans are a fundamentally social species. They are unable to reproduce and survive to reproductive age without a group. They lack natural defenses such as slashing canines, bodily armor, or fleetness of foot; they have an extended infancy followed by years of further development before they reach reproductive maturity. Many of the evolved characteristics that have permitted humans to adapt to a wide range of physical environments, such as omnivory and tool making, create dependence on collective knowledge and cooperative information sharing among individuals and between generations. Humans are an *obligately interdependent* species (Brewer & Caporael, 2006a; Caporael & Brewer, 1995). Our evolution is a product of the coevolution of genetic endowment, social structure, and culture (Boyd & Richerson, 1985; Caporael, 2001a; Fiske, 2000; Janicki, 1998; Li, 2003; Mesoudi, Whiten, & Laland, 2006).

The dominant metaphor in the human sciences, "selfish gene theory" (Dawkins, 1976) or the "gene's-eye view" of evolution, has limited resources to theorize groups and the consequences of group living for the human mind. Human sociality is largely conceived in terms of Machiavellian intelligence, deception, exploitation, and coalition formation for intergroup conflict (Alexander, 1989; Byrne & Whiten, 1988; Dawkins, 1976; Flinn, Geary, & Ward, 2005), primarily because the gene's-eye view uses familiar economic explanations tied to a genetic currency that cannot be cashed out. This approach can still broaden our understanding of human cooperation, and a movement to do so is under way in a number of related disciplines such as economics (Gintis, Bowles, Boyd, & Fehr, 2003) and anthropology (Henrich et al., 2005), as well as in social psychology (Baumeister & Leary, 1995; Sedikides & Skowronski, 1997; Simpson, Schaller, & Kenrick, 2006).

This chapter aims to expand such approaches by drawing on multilevel selection theory, which offers a framework more appropriate than genes for psychological levels of analysis. *Coordination*, rather than the evolution of biological altruism (genetic self-sacrifice), is the central problem of a human psychology informed by biology and culture (Brewer & Caporael, 2006a; Caporael & Baron, 1997; Kameda & Tindale, 2006). Coordination refers to the skillful integration of diverse elements into a harmonious operation. This could mean, literally, a surgical operation, with its diverse artifacts, human skills, body movements, and the plan for the surgery. However, a broad range of human activities involves coordination from knowledge creation to walking down an urban street, attending a dinner party, or training a dog. Similarly, exploitation, intergroup conflict, and coalition formation presuppose highly developed coordination skills. While there is a sense in which all coordination benefits "selfish genes," a genetic level of explanation skips over the psychological and social processes that compose human cognition and behavior.

The following sections offer an evolutionary framework drawing on the implications of multilevel evolutionary theory. An expanded evolutionary theory has a crucial advantage in the human sciences: It enables us to point at recurrence without getting embroiled in nature–nurture controversies. A vocabulary for the repeated as-

sembly of diverse elements does not require making unsupportable claims about specific genetically based adaptations. Following the evolutionary framework is a cursory review of current knowledge about the "ancestral environment." In view of that research, drawn primarily from paleoanthropology, I propose a model of core configurations in face-to-face groups as the selective environment of uniquely human mental systems and the reorganization of earlier evolved "building blocks." If the model is valid, we should expect human mental systems to correlate with core configurations. We should also expect that capabilities specialized for specific configurations can be extended and recombined for novel behavior and situations, including life in the modern world.

Many psychologists will find a fit between their research and the core configurations model (Caporael, 1997). An important advantage of the model over other adaptationist approaches (Andrews, Gangestad, & Matthews, 2002; Schmitt & Pilcher, 2004) is that it can enable greater precision in psychological theory. One could argue not only that some particular feature is functional but also that it is functional with respect to particular configurations of structure and activity. The model also has the connective tissue to extend the scope of psychological theory and research. Brewer and Caporael (Brewer, 1997; Brewer & Caporael, 2006b; Caporael, 2001b) have illustrated such integration and extension for research and theory on social identity. Finally, the model rejects the traditional reductionist view of biology as the basis for psychology, which in turn is the basis for culture. These three arenas are more reasonably viewed as coconstructive in human evolution. Human evolution—and human psychology—is mediated by artifacts and situated in sociohistorical contexts (Cole, 1996, 1997). An interesting result of such coconstruction is that *it is human nature to invent human nature*, most visibly in terms of locally distinctive folk psychologies (Lillard, 1998). The researcher's job is to understand how humans invent and coordinate mind and activity. Analytically, our three arenas–biology, psychology, and culture—must lean on each other for validation, correction, and inspiration.

In short, this chapter is broadly synthetic. It draws on diverse disciplines far from psychology for a generalized framework constructed with the conviction that social and cultural psychology have a great deal to give back to the evolutionary efforts to understand humankind in other disciplines (Brewer, 2004, 2005).

MULTILEVEL EVOLUTIONARY THEORY

The gene's-eye view of evolution is based on a technical definition drawn from population genetics—changes in the frequency of alleles (genes) in a population. The major goal of the gene's-eye view of human evolution is to identify adaptations—gene-based traits that evolved through a process of natural selection in the evolutionary past. To use the gene's-eye view of evolution in any scientifically respectable way, psychologists would have to shoulder certain "burdens of proof" from biology

(Lloyd, 1999). These include specifying a well-defined trait, eliminating other explanations for the trait such as genetic drift, developmental constraints, correlated traits, and, in the case of humans, cultural explanations. The most critical evidence, however, is the demonstration that variations in the phenotypical trait are correlated with variations in reproductive or genetic fitness. Although biologists have a variety of methods for determining such covariation, few are practically or ethically possible with humans, and the most successful cases have been made for physiological characteristics such as sickle cell anemia or lactose intolerance (Durham, 1976). Demonstrating covariation between a human psychological trait and fitness would also be a logical challenge.

Certainly one major difficulty in the population geneticists' view of Darwinism is that it has little to say about development, environment, or culture. It lacks the theoretical resources to engage psychology because the gene's-eye view works *below* the level of the organism. Its generality is such that it works equally well for oysters, ants, birds, and humans because it is about changes in gene frequencies. Crucially, it tells us little about human (or oyster, ant, and bird) phenotypes in the absence of what we already know or think we know about them. Evolution then becomes an explanatory project (Smith, 2006) that might add another layer of understanding (DeKay & Buss, 1992), but could fulfill little in the way of Darwin's revolutionary promise of a new foundation for psychology or light on human origins. Moreover, the gene's-eye view is blind to the distinction between social and asocial species, a critical distinction for hypothesizing sociality at the phenotypical level (Brewer, 2004; Caporael, Dawes, Orbell, & van de Kragt, 1989). This is not to say that the gene's-eye view of evolution is false; merely that for Darwinism to be productive in psychology, we need an expanded view of evolution appropriate to our current levels of analysis.

Multilevel Selection Theory

In 1987, evolutionary biologist Leo Buss published a groundbreaking book, *The Evolution of Individuality.* Evolutionists going back to Darwin had recognized that selection could occur at different levels of the biological hierarchy wherever there was heritable variation and differential replication (Brandon, 1990; Buss, 1987; Campbell, 1974; Gould, 1980; Wilson & Sober, 1994). What the gene's-eye view overlooked (or rejected [Dawkins, 1982]) was that levels of biological hierarchy—chromosomes, cells, and multicellular individuality—also had to evolve. Buss's (1987) contribution was to detail the evolution of multicellularity, that is, how individuals composed of reproductive gametes and nonreproductive somatic cells that "gave up" reproduction could evolve.

This work ushered in a new era in biological theory. Levels of biological hierarchy roughly represent major transitions in the evolution of life on earth, especially in the way that information is stored and transmitted (Maynard Smith & Szathmáry, 1995; Szathmáry & Maynard Smith, 1995). They are also represented in the

bodies of multicellular organisms (Buss, 1987) and serve as rough guides to levels of analysis. The major characteristics of such transitions are that entities that were capable of independent reproduction prior to the transition are able to reproduce afterward only as part of a larger unit. Cellular mitochondria, for example, are believed to have been independent cellular organisms that continue to have their own DNA lineage. Selection on multiple levels is associated with increased task specialization (energy production by mitochondria in the cell) and new forms of information relevant to evolution and development (e.g., the genetic code, sexual reproduction, epigenetic inheritance, and human language) (Jablonka & Lamb, 2005; Szathmáry & Maynard Smith, 1995). At each level, the environment for an entity is the next level, which can also have downward causal effects (Campbell, 1974). For example, the environment for genes is the cell, and cellular products influence which part of the gene will be active. Humans, as individuals and as groups, constitute two levels of biological organization of major interest to social and cultural psychologists.

All such transitions pose the same "free-rider" question. What prevents lower-level entities from "defecting" and disrupting higher-level organization? The giving up of reproduction *can* be explained in terms of genetic self-interest. But far more predictive power is gained from considering conflicts and synchronies over different levels of organization, where there are different types of payoffs, obstacles, path dependencies, and locked-in systems (Caporael, 2003). Sex, for example, is ubiquitous, not for the single reason of benefiting the genes but because it is multiply synchronous, selected at the genic, cellular, individual, and group levels (Buss, 1987, p. 181, fn). What once seemed to be competing alternative explanations for the evolution of sex, taken together, are the discovery of synchrony over different levels of organization. In addition to synchrony, we should expect conflict among levels as well. Cancer is one example: A cell lineage reproduces itself at a cost to the organism. In effect, it has defected, although at a cost to itself in the end.

Multilevel evolutionary theory offered insights for an evolutionary theory at a psychological level of analysis. First, it provided a view of evolutionary processes as hierarchically structured; the process of selection is *situated*, *relational*, and *embodied* in specific contexts (Eldredge & Grene, 1992; Endler, 1986). The situated environment for genes is the cellular machinery with which DNA and its products interact. The situated environment for humans is the face-to-face group, through which they are able to interact with the habitat. Stressing "situatedness" in a context focused on selection as the statistical result of *relations* between entity and ecology (Caporael & Baron, 1997; Endler, 1986) in place of the anthropomorphic metaphor of selection favoring a trait, a locution that obscures the conditions from which selection may result. To take a psychological example, there is no basis for assuming, as the trait view implies, that a dominant individual will be so across interactions. An individual may act socially dominant in a dyad but not in a group of five people working on a shared problem. The situated context of behavior is reliably different, and the func-

tional relation between dominant behavior and the context may well differ, too (Mischel & Shoda, 1995). Functional relations refer loosely to the fit or match between entity and context in achieving certain ends (e.g., movement and nutrition). The focus on relations also opened the door to artifacts as part of the relation. In humans (and some other animals; Dawkins, 1982) functional relations can be achieved artificially. Humans can have disabilities that in other species would be terminal, but they can also use "artificial traits" (e.g., wheelchairs, canes, and eyeglasses) to achieve basic functional relationships such as locomotion or vision. The functional relations of an organism and environment are also *embodied*, that is, available to empirical investigation (Andrews et al., 2002; Caporael & Baron, 1997; Levins & Lewontin, 1985).

Multilevel evolutionary theory also accommodates groups as a level of organization. Darwin (1871/1981) and later Williams (1966; whose book is an extended argument against group selection and for the logic of costs and benefits accruing to the gene) believed that humans might have traits resulting from group selection and informally worked out the argument. However, Williams's (1966) book might have been too successful. By the early 1970s, group selection was not merely dropped; it was passionately damned (Pollock, 1989). Unfortunately, psychologists have followed suit, although Brewer and Caporael (2006a) have urged reconsideration. Wilson and Sober (Sober & Wilson, 1998; Wilson & Sober, 1994) formally worked out the argument for the evolution of "altruistic genes" from the perspective of multilevel selection.

Briefly, subgroups ("trait groups") of a larger group vary in the proportion of altruists and nonaltruists. Some groups will have low ratios of altruists to nonaltruists; other groups will have high ratios. Within all the groups, the nonaltruists increase relative to the altruists. However, if groups with higher proportions of altruists also produce more offspring, then the total number of altruists in the global population will increase when groups disperse and form new groups. In other words, within-group selection favors the evolution of self-interest whereas between-group selection favors the evolution of cooperation (because altruists benefit themselves as well as others). The important difference between a gene's-eye view of altruism and the multilevel evolutionary view is really in the next step. The selfish gene theorist seeks an explanation in terms of genetic self-interest. The multilevel theorist looks further for the evolution of individual mechanisms for developing and maintaining group memberships and group-level mechanisms for enforcing groupish behavior in the face of individualism. (Some readers may want to interpret the distinction as a parallel to the distinction between ultimate evolutionary causes and proximate causes. However, this dichotomy is insufficient. The ultimate cause will typically be an explanation about how some particular piece of behavior benefits the genes of an individual. The proximate explanation is typically about the stimulus that activates an adaptation [e.g., dust or some other stimulus causes the sneeze] rather than about the mechanism that responds

to the stimulus, which presumably has an evolutionary history [Kitcher, 1985].)

Repeated Assembly

One of the difficulties of evolutionary language is that it lacks a good vocabulary for waffling. An adaptationist vocabulary makes it impossible to avoid sounding like a genetic determinist. By definition, calling a trait an adaptation is a commitment to genes as a primary explanation of its recurrence and operation. Even for most descriptions of gene–environment interactionism, the possible alternatives for the trait are in the gene, and the environment merely fills gaps in "open programs," "shapes" innate proclivities, or "shunts" behavior from one option to another (Buss, 1999; Crawford & Anderson, 1989; Tooby & Cosmides, 1992). One reason social and cultural psychologists have been reluctant to turn to evolutionary theory is an uneasiness about making genetic claims when they are not biologists. At the same time, the phenomenon of recurrence, between generations and across cultures, is one of the appeals of an evolutionary approach.

Multilevel selection helps to solve this problem. Expanding neo-Darwinism calls attention to organisms' interaction with the environment and to phenotypical development. Phenotypes repeatedly assemble generation after generation from constructive interactions among multiple recurrent resources, including genes, cellular machinery, social resources, and the reliable presence of critical features of the habitat, from caregivers to oxygen in the air (Gottlieb, 2002; Lickliter & Honeycutt, 2003; Oyama, 1985). As a result, the concept of heritability is expanded to include a range of resources that mediate phenotypical outcomes (Cole, 1996; Griffiths & Gray, 1994). As humans, we inherit genes, but also attitudes, practices, place, nationality, expectations for behavior, and so forth. There may be change (e.g., in traditions) within lifetimes, but this simply indicates low reliability of recurrence. Heritability itself is thus no indicator of the universality, fixity, or difficulty of changing organism–environment relations.

A vocabulary of *repeated assembly* (Caporael, 2003) points to recurrences that we can observe—recurrences from generation to generation as well as recurrence across cultures. Not only do organisms repeatedly assemble, but so also do the products of organisms, including human ideas, artifacts, and cultural practices (Dawkins, 1982). Repeated assembly enables us to escape the dichotomy of biology and culture, nature and nurture, genes and environment; it does not require us to make commitments about genes in the absence of hard evidence; and it is consistent with the Darwinian model of selection, variation, and retention. More specifically, repeated assemblies are recurrent entity–environment relations composed of hierarchically organized, heterogeneous components having differing temporal scales and cycles of replication (Caporael, 2003). That description is quite a mouthful: The following discussion is meant to provide a brief sense of the nature of repeated assemblies.

Recurrence is fairly obvious, although we are most interested in a particular kind of recurrence, that which is recursive, where the seeds of the next cycle are part of a current cycle. Entity–environment relations are, at the psychological level, organism–environment relations, where the environment may be features of the physical habitat or configurations of conspecific groupings. Hierarchical organization (actually, heterarchical because causal effects may be downward and upward) is built into the evolving, jury-rigged structure of living organisms. Heterogeneous components refer to the multiple resources that compose a repeated assembly, although which resources are the objects of research depends on the focus and perspective of the research question. Components can be heterogeneous partly because they recur over different time scales. DNA recurs over macro-evolutionary time; at the other extreme, social rituals can rise and fall within a lifetime (affecting phenotype, but having no systematic selective effects).

As an example, consider the fertilized egg or zygote. A zygote is composed of multiple resources. There are two sources of DNA from the gametes, centrosomes from the sperm, maternal information in the egg cell, and an appropriate setting in the body. If all these resources are in the right place at the right time, a zygote automatically results. There is no genetic program; in fact, the genes are inactive during the first few cell divisions of the fertilized egg. The difference that matters for the differentiation of structure and specialization of tissue in the first cell divisions is time and space—recall, all DNA in cells are the same. Cells in the zygote adhere to each other, the lose adhesion, and migrate to different regions. The cellular activity influences genetic activity, which in turn affects cellular activity.

The zygote is a repeated assembly, and like other repeated assemblies, it is inherently interactionist. It emerges from the constructive interaction of genes, temporal and spatial relations, and the changing cellular machinery. Its continued development and existence depends on the reliable recurrence of appropriate contexts—from cellular machinery to social events to regularities in the habitat to persistent resources such as gravity and atmosphere (Griffiths & Gray, 1994). Genes are always part of the repeated assembly of an organism, but so also (in the human case) are group memberships, customs, artifacts, learned skills, languages, and worldviews (see Figure 1.1). These resources may vary wildly in their specifics but are nevertheless critical to human survival and reproduction.

Within historical, ecological, and developmental constraints, repeated assemblies are almost infinitely variable. Change in any repeating component of an assembly, whether genetic or epigenetic, can increase or decrease the probability of future assembly. This is because repeated assemblies are concretely situated in specific flows of interaction. The situatedness of activity makes the unit of analysis the organism-in-setting, where the focus is on the relation between entity and context, or person and setting. To illustrate the variability of concretely situated activity, consider any everyday routinized activity—say going to a supermarket (Lave, 1988). The su-
FIGURE 1.1. Recurring multiple resources having different scales of time contribute to the repeated assembly of unique individuals. Resources (which are usually repeated assemblies themselves) differ in their scale, meaning how long they have been repeated (e.g., the DNA code has been repeated far longer than any particular cultural resource), and their cycles of generation.

permarket has a more or less invariant set of practices and structure of shelves, aisles, and grouping of products. Yet, despite the routine, each trip is unique. The unit of analysis is the pattern of the assembly (shopping), until some feature that makes the pattern unique is picked out. Repeated assemblies are like Eleanor Rosch's (1977) prototypical categories. They have components with varying degrees of membership. Some components, however, will be more prototypical or central than others.

Although some traits of organisms do inspire marvel for their complexity of design and are designated as adaptations, evolutionary theory is ultimately a theory about the history of use and not design (Millikan, 1984). The same is true for repeated assemblies. Some recur because in the past, some components, in some specific relation to their contexts, contributed to the replication of the assembly. Specialized functions describe what an assembly is "supposed to do" under historically ideal conditions. (This is not to say that they cannot serve other functions as well.) For example, a function of sperm is to fertilize an egg cell, even though ova are rare in the world of sperm and most fail to fulfill their function. Nevertheless, because some ancestor sperm did find and fertilize ova, sperm are repeatedly assembled. Historically ideal conditions are not necessarily statistically average or modal conditions.

Specialized functions may be quite awkward, inefficient, and clumsy, far from optimal design, and even constrain the spread of better designs should they appear. They reflect the meandering path dependencies that occur in history. A cultural example of the result of such path dependencies is the QWERTY keyboard. Its design originated as a way of fitting the striking mechanisms for the keys into the machine to reduce jamming by slowing down fast typists (e.g., by separating TH). As the machine constraints were altered, other keyboard designs with better ergonomic features for users were developed. However, these better designs were unable to invade the keyboard niche. We know (or are able to know) much more about the recent past than the ancestral past, which serves as a caution. Claiming that a particular psychological mechanism or process has a specialized function depends on our best guesses about history. All things considered, we may be more like the QWERTY keyboard than the more optimally designed Dvorak layout.

Some repeated assemblies have no function; they are like the superstitious behavior of Skinner's circling pigeons. Some can result from illusory contingencies or once useful behavior. Other repeated assemblies, including biological adaptations, may have had a function at one time but become dissociated from it. Langer (1989) tells the story of a woman who would always cut a slice off the end of a roast before placing it in the oven. To make a long story short, the woman said she did this because her mother did it; mother said she did it because her mother did it; and grandmother did it because the pan she used for roasting was too small to accommodate the whole piece of meat. Of course, such dissociations can occur in evolutionary time (then they are vestiges) or, as Boyd and Richerson (1985) argue, in cultural–historical time, resulting in practices that have no function or are even costly.

Repeated assemblies can be characterized in terms of scales of time (i.e., persistence, cycles, and the frequency of repetition). Some components, such as the DNA code, have been parts of repeated assemblies since the beginning of life. Other components, such as a cultural environment, have a temporal scale measured in historical terms. Still others recur on the scale of a lifetime. "In the past" does not necessarily refer to a dichotomy between the Pleistocene and the urban present. It may refer to time measured in terms of ontogeny (in "habits of a lifetime"), to cultural–historical time (as in "2,000 years of Western civilization"), or to geological–evolutionary time (the temporal scale of DNA). Paradoxically, time expands the notion of heritability; we inherit genes but also attitudes, practices, place, nationality, expectations for behavior, and so forth. Assemblies may persist in evolutionary time, among Americans, in the Smith family, or in J. Smith. A more extensive discussion of reproduction, development, and culture on different scales is in Wimsatt and Griesemer (in press).

What is *not* a repeated assembly? The answer often depends on level of analysis and perspective. Every individual—even one of a monozygotic twin set—is unique. No twin has precisely the same experiences as the other. However, organisms in general are repeatedly assembled. Often the product of a repeated assembly with specialized functions is unique. For example, the processes involved in the healing of wounds are repeated assemblies in organisms. However, the specific scars that result are the unique results of an individual's history.

By definition, errors would not be repeated assemblies. Despite considerable redundancy in biological systems, errors do occur in development and produce organisms unable to survive or reproduce. Hence, their lineages cease to repeatedly assemble. At first glance, it seems that there should be few errors that repeatedly assemble in artifactual systems because these can be corrected when discovered. However, the poor design of artifacts can cause undesirable outcomes to repeatedly assemble because of ignorance or even outright deceit, as in the cases of the Ford Pinto's faulty gas tank and the

Dalkon shield. As in biology, complex, poor design can persist, although the mechanisms will be clearly and identifiably different from those sustaining artifacts.

An adaptive response to a novel event may be unique; but even though it is useful, it may fail to repeatedly assemble. In his examination of "cognition in the wild," Hutchins (1996) observed the failure of a ship's navigational systems. Through a process of trial and error, two men eventually solved the problem of plotting location; however, the innovation was not saved in the cultural system. The situation for using the solution again is rare because the failure of redundant navigational systems is rare.

Rethinking Evolution, Sociality, and Psychology

An expanded evolutionary theory immediately generates a set of interesting predictions and guidelines. Because of group selection and downward causation, we should expect the evolution of a variety of specialized processes for coordination among group members. (Unlike cooperation, coordination does not necessarily imply prosocial behavior—nor does it exclude it.) Some coordinating processes will have to do with motor coordination (Boinski & Garber, 2000), interactional synchrony (Bernieri, Davis, Robert, & Knee, 1994), and other phenomena related to rhythmicity, coordination, and body movement. Research in automaticity may also point to another system or set of related systems of general social coordination. For example, in a well-known study by Bargh, Chen, and Burrows (1996), priming students with words such as *Florida* evoked a stereotype of the elderly that reduced the speed of students walking down a hallway compared to students who did not receive the prime. The phenomenon of *stereotype threat*, when high performance is lowered when a group stereotype is made salient, illustrates tacit control of behavior (Fiske, 1993; Steele & Aronson, 2003). Such research suggests the types of mechanisms that function as a coordinated/coordinating stream of behavior.

Multilevel selection also suggests that there should be conflicting individual and social motives that result from selection on those levels. Humans are ambivalently social because both individual and group levels are under selection. The psychology of optimal distinctiveness and group-oriented motivations (Brewer, 1991; Brewer & Roccas, 2001) makes a great deal of sense as a regulator of individual and groupish behavior.

The emphasis on selection arising from relations between organism and environment maps to a growing emphasis in cognitive science on embodiment and adaptive responding to the environment (Agre, 1997; Clark, 1997; Hendriks-Jansen, 1996), the evolution and operation of socially situated cognition (Caporael, 1995; Smith & Semin, 2004), and a revival and reassessment of Gibson's (1979) concept of affordances (Norman, 1990; Zebrowitz & Montepare, 2006; Zhang & Patel, 2006). Dijksterhuis and Bargh (2001) posit a "perception–behavior expressway" that might also be part of this revival (given further consideration about the role of representation in cognition and action). Affordances originated in evolutionary considerations (unlike the computational metaphor) and bring with them concepts such as attunement and action boundaries that could deal with humans and their interactions with objects (Fajen & Devaney, 2006; Fajen & Turvey, 2003; Núñez & Freeman, 1999).

THE MIND'S NATURAL ENVIRONMENT

The previous sections established a general warrant for sociality and sketched an evolutionary approach that is suitable for psychological levels of analysis. In evolutionary biology, that might be enough. The details about genotypical variation and selection history of a single species tend to be sparse. The usual assumption is that the current traits of an organism evolved in the past and are maintained in the present by stabilizing selection, which shifts the problem from history to ecology. The field biologist can then demonstrate natural selection through a variety of methods, including covariation between trait and reproductive fitness (Rose & Lauder, 1996).

Things are tougher in the human case. We are well aware from sciences such as geology, climatology, paleoanthropology, and archaeology that the lives of modern humans are different from what they were before the rise of urban ultrasociality (Campbell, 1983). One clear consensus is that humans lived as foragers, and another is that the physical constraints of the body's evolved interaction with the habitat (e.g., the mechanics of vision or caloric requirements) would remain the same between the ineffable past and the present. Not all such characteristics necessarily would be *human* adaptations. Some would be adaptations of an ancestral organism (e.g., color vision); others would be the result of developmental constraints that arise from highly conserved regulatory genes. Other characteristics of humans that are adaptive and do show measurable variation, such as reading, are recognized as having appeared so recently as to not enter into an evolutionary explanation (although some of the components of reading probably would). These issues aside (and they are nontrivial), the big question is, what was life like in the evolutionary past, or more to the point, what was psychology like?

Life in the Pleistocene

Donald Symons (1992) wrote that life in modern industrial societies looks like unplanned evolutionary experiments. In fact, the whole of human evolution looks like unplanned experiments (Caporael, 2004; Potts, 1998; Tattersall, 1995). Ancestral populations contracted, expanded, appeared, dispersed and became extinct against the turbulent background of global climate change. Today some paleoanthropologists recognize as many as 23 species.[1] Deep-sea drilling for sediment cores shows dramatic climate changes beginning about 50 million years ago, when a major cooling phase began leaving the temperatures of today about 12–15° C cooler. This was not a smooth transition. There were major climate reversals, the polar ice caps formed, and the Mediterranean Basin dried up and refilled. Regional climates were affected by

the Earth's orbital peculiarities, the advance and retreat of glacial ice, and geological activity such as volcanoes, faults, uplifts, and rain shadow. During this period an enormous variety of Miocene apes became extinct. One surviving lineage included the common ancestor of chimpanzees and bipedal apes, including the australopithecines. These were small-brained animals whose locomotor specializations (splayed toes, curved fingers) indicated adaptation to both walking and climbing. Turbulent climatic change continued through the period of human evolution, which occurred primarily in glacial conditions, interspersed with shorter, warmer interglacials (the most recent beginning about 10,000 years ago).

The phylogenetic pattern (a phylogeny is a diagram depicting ancestor–descendant relationships in geological time) for human evolution is quite unlike the widely depicted image of uphill evolutionary progress that begins with a knuckle-dragging ancestor. Instead, the pattern shows branching and overlaps. About 2 million years ago, as many as five bipedal species may have coexisted, one (perhaps even one yet to be found) is ancestral to humans. One nonancestral species had an amazingly rapid 30% expansion of the brain in less than 700,000 years, an event that would occur again in the *Homo* lineage, between 600,000 and 200,000 years ago, when brain size approximates the modern size, but with considerable variation.

A later rash of lineages, sometimes collectively called archaic *Homo sapiens*, ebbed and flowed through Africa and Eurasia, and eventually Europe. Arguably, all modern humans are descended from a limited population, perhaps as small as 10,000 breeding individuals of *Homo sapiens* that survived a major population crash about 130,000 years ago (Lahr & Foley, 1998). Although there are important exceptions in Africa, *Homo sapiens* were behaviorally (based on artifactual data) indistinguishable from Neanderthal populations until about 50,000 years ago (Klein, 1999). Then there is an inexplicable outburst of modern behavior in art, personal ornamentation, cultural variation in tool use, and the working of materials, such as shells, previously unseen in the archaeological record. Modern humans eventually replaced the Neanderthals in Europe about 30,000 years ago, spread through Asia, probably constructed watercraft for several migrations to Australia and crossed the Bering Strait. Inconceivably, we modern, industrialized humans overlapped for 75% of our evolutionary history with another intelligent species.

In the view of evolution that sees it as an uphill march of progress, new stages in human evolution were expected to have greater intelligence and, of course, would have the latest new tools. That view dropped away when new techniques for dating materials became available. Humans were bipedal for approximately 2 million years before the earliest known stone tools. New tools do not appear at the same time as new hominins, which makes sense—tools have to appear within species that already exist (Tattersall, 2000). One way of characterizing ancient tools is by characteristic modes of production (Foley, 1987). Early artifacts are remarkably stable though time.

The same mode of tool production is used by different species with little variation and over long distances. The first tool user, *Homo habilis*, was essentially an australopithecine with a slightly larger brain, used Mode 1 (Oldowan) choppers and handaxes. Although the form is refined through time, Mode 1 tools were produced for over 1 million years and are found from the southern tip of Africa to the eastern reaches of China to the western edges of the British Isles.

In Africa, these are eventually replaced with bifaces (flakes removed from both sides of a stone core). Their use persisted, again with some refinement, for another million years. In the Far East, however, Mode 1 tools are replaced directly by Mode 5 tools, which may be evidence that *Homo sapiens* replaced existing *Homo erectus* populations. In Africa and Europe, the changeover in modes of production begins to speed up with Mode 3 (Mousterian). These tools are usually associated with large-brained (1,200 cc) hominins,[2] especially the Neanderthals. There was a shorter period of production, about 100,000 years, and a greater variety of form. Modes 4 and 5 are associated with modern humans, have a high turnover of different types of tools, none lasting more than 5,000–10,000 years. Some of this later variability may be attributed to stylistic differences between groups. Stone transport, diet, hearths, structures and eventually pigments, ornaments and composite tools (tools made with two materials, for example, obsidian flakes set into a wooden haft to make a knife) also appear in the fossil record. How to relate artifacts in the archeological record to psychological function is unclear, largely because, with few exceptions (Cole, 1997; Hutchins, 1996), artifacts have not played a major role in psychological theories until recently and represent a vast area for future research.

To sum up, research on the last 3 million years of human evolution indicates shifting habitats, with different regions responding differently to large-scale climatic changes. Fragments of populations would become isolated. They might reunite after long periods of time (if they had not become reproductively isolated); speciate from the parent population through gradual selection to a new or changing environment; stay unchanged by following their preferred habitats; or simply become extinct (Lahr & Foley, 1998). Globally, humans lacked the stable habitats supporting ever more complex cognitive adaptations. For psychology, the fossil evidence suggests that we should expect the evolution of small-grained adaptations, more like Lego blocks (Bechtel, 2003; Scher, 2004) than large-grain, informationally encapsulated adaptations that would require exceedingly long periods of environmental stability for their genetic evolution.

The conventional wisdom since Darwin was that the lack of natural defenses such as claws and canines meant that bipedalism implied tools used for defense, and tools implied intelligence. (It was partly this deeply held assumption that made the Piltdown Hoax so successful for so long.) Fossil finds of the 1970s overturned the conventional wisdom. "Lucy" (*Australopithecus afarensis*) lacked natural and artificial defenses and was bipedal. Whatever the details, australopithecines must have lived in groups;

in a remarkable find, at least nine adults and four juveniles who may have died at the same time, perhaps in a flash flood, were unearthed. Group living also formed the context for the changes between *Homo habilis*, and *Homo erectus*. There was an important shift to hunting, and higher-quality nutrition may have allowed the redeployment of energy from a large gut to a growing brain (Aiello & Wells, 2002). There is some evidence of group buffering (individuals with injuries that would have required support to survive). A reduction in sexual dimorphism appears to be the result of females growing bigger (Klein, 1999); no data seem to exist as to whether the change was accompanied by a reduction of male conflicts. Considerable evidence exists for the manufacture, transport, and use of stone tools and even raw materials. Presumably stone tool technology was repeatedly assembled and refined in group contexts; however, the sheer stability, especially of mode of manufacture in earlier hominin species, is difficult to explain or grasp with our current psychological understanding. There are also few fossil data that tell us about social organization, parenting, sexual preferences, mating behavior, division of labor, and so on until quite recently in the archaeological record.

Some of these questions might be resolved by turning to the ethnographic literature on hunters and gatherers. There are certainly some universals, for example, food sharing (Gurven, 2004) and other behaviors closely tied to ecology. When these can be connected to material remains, such as a pattern of waste materials from chipping stone tools (Binford, 1972), ethnoarchaeology offers additional insight about practices in the past. However, even this approach is not as fruitful as hoped because the archeological record of hunter–gatherers is itself so variable (Kusimba, 2005). Moreover, the closer foragers come to issues of keen interest (e.g., sex and gender) to the early missionaries and anthropologists who first studied their lives, the more bias can be expected from the data (Leacock, 1981). Later studies of traditional hunter–gatherer groups are frequently of peoples "tethered" to water, missions, welfare rations, government posts, agricultural plots of their own or their neighbors, and sources of cigarettes and alcohol (Kelley, 1995). Finally, recent research (Henrich et al., 2005) shows that indigenous peoples are surprisingly variable in their economic choices (measured in structured games) and frequently fail to choose strategies and outcomes in the self-interested ways predicted by traditional game theory.

A Minimalist Scenario

The "bones and stones" of the human past provide important negative evidence, in that paleoanthropological research fails to support the assumptions that most people make about the evolutionary past and, if anything, should make us wonder where wonderfully detailed claims about the past do come from. Research by Landau (1984) and Moser (1998), both anthropologists, suggests that narrative and imagery have played a long and unrecognized role in scientific and popular conceptions of the past, and the work by Green and her colleagues on transportation in narrative and imagery may provide the relevant psychological processes (Green & Brock, 2000; Green, Strange, & Brock, 2002). For the present, the best scientific strategy appears to lie in constructing minimalist scenarios that are transparent with respect to their idealized and fictional origins and in apposition to popular narratives and images. (This strategy is similar to one common in social psychology, where scientific research is tacitly in apposition to folk psychology, and may often raise our "discomfort index" [Fiske, 2003].) Given the considerable individualism that infuses selfish gene theory, and the undervalued significance of group living as a selective factor in coordination, focusing on face-to-face groups in human evolution is a good start (Byrne & Whiten, 1988; Geary, 2005).

Evolutionists often write as if organisms calculated genetic costs and benefits and made individual choices about whether or not to group. Nonetheless, most animals are group living (Pulliam & Caraco, 1984), even if for no other reason than the failure of kin groups to disburse for some part of their life history. However, there is considerable variability across species in the intensity of interdependence of group living (Avital & Jablonka, 2000; Boinski & Garber, 2000). Quite often, sociality may consist of little more than a group of opportunistic and individualistic cooperators (Norris & Schilt, 1988; Williams, 1966). Schools of fish or herds of fleet deer are *aggregate* groups. There may be safety in numbers, and the risks of predation might be spread out among a group of animals. In some species, individuals that form aggregates are adaptively specialized for knowing when to group and when to be solitary. Other kinds of groups cannot break up. The individuals that form such groups *must* be part of a group in order to reproduce and survive to reproductive age. These intensely *social* groups organize individual efforts, communicate within the group, have tasks and roles for group members, and definable boundaries (Brewer, 1997). In extreme cases, such as wolf packs, naked mole rats, and meerkats (a social mongoose), only a single pair of individuals in the group reproduces, somewhat like the "germ line" of the body. Other group members (usually relatives) may help care for the offspring by feeding, guarding, and tutoring them in hunting skills. Human sociality is nowhere so extreme as to have a single breeding pair within a group. Nevertheless, human sociality is at the extreme end in that humans are unable to reproduce and survive to reproductive age without a group context. Grouping is an appropriate starting point for constructing a minimalist scenario.

Given their morphology and ecology, the ancestors of evolving hominins must have survived as groups rather than as individuals. Finding food, defense from predation, moving across a landscape—these matters of coping with the physical habitat—would have been largely group processes that began among the earliest arboreal primates, possibly as a result of changing patterns of dispersal in response to climatic and ecological changes. Over time, if exploiting a habitat is more successful as a collective group process than as an aggregate group or

individual process, then not only would more coordinated groups persist but so also would individuals better adapted to group living. Because local ecologies limit group size, the number of "niches" in a group are also limited, resulting in a feedforward ratchet and group fission when groups become too large to exist on the local ecology.

If individual humans cannot survive outside of groups, then the structural requirements for sustaining groups create systematic constraints on individual biological and psychological adaptations. Such downward causation (Campbell, 1974, 1990b) across system levels operates whenever structural requirements at higher levels of organization determine or shape some aspects of structure and function at lower levels. Thus, individual human cognitive systems do not have to be—nor can they be— fundamentally self-interested under all conditions. Humans are frequently motivated by outcomes of purely personal value; however, a variety of preconscious, conscious, group-level, and institutional mechanisms curb self-interest, albeit not always successfully. In the latter instance, when self-interests cannot be curbed, a group itself may disintegrate and be replaced by better coordinated groups.

The result of downward causal processes would be a shift to face-to-face groups as the selective context for uniquely human mental systems. Selection within groups would lead to the evolution of perceptual, affective, and cognitive processes that support the development and maintenance of membership in groups (Caporael et al., 1989). Without a group, the probability of reproduction and survival to reproductive age is lowered for humans. To say that humans are a social species is much more than saying that they aggregate or form alliances for the mutual exchange of benefits; they are a group-living, obligately interdependent species.

The psychological implications of just this minimalist scenario are profound. Rather than individuals simply perceiving "reality" and then compromising or conforming their different versions, processes of social verification make reality valid, reliable, and objective (Hardin & Higgins, 1996). However, group-level and individual processes might still conflict. Campbell's (1990a) reinterpretation of Asch's conformity studies illustrates how they might. He argued that these studies should be viewed in terms of the dependence we have on others for knowledge. Accordingly, the Asch studies should be seen as a structural conflict between the respect we have for each other's reports (group-level trust) and our duty to report our observations honestly (individual-level honesty).

So far I have sketched an oversimplified and general model of downward causation and its consequences for grouping. There are various dimensions of groups that can serve as theoretical foci to take a minimalist scenario further and in different directions. For example, Rodseth, Wrangham, Harrigan, and Smuts (1991) developed a theory of social structure based on phylogenetic data about mating patterns. Bugental (2000) and Fiske (1991) theorized domains of relationships, and Flinn and colleagues (2005) and Kurzban and Leary (2001), coali-

tion formation. The following scenario differs from these in that it draws on considerations of body, group size, and task.

The Evolution of Human Coordination: Core Group Configurations

The idea of so-called magic numbers for functional subdivisions of groups appears mostly in anthropology (Lee & DeVore, 1968) but is also mentioned independently in other literatures (Sale, 1980). Dunbar (1993) identifies three groupings drawing partly on ethnographic records of contemporary hunter–gatherers. Conversation groups of about four individuals evolved as a substitute for grooming as a means to service social relationships; "overnight camp groups" or bands with a mean size of 38; and "tribes" with a mean size of 1,150. An intermediate grouping of 150, the predicted group size based on the covariation between primate group size and neocortical size, is proposed as the cognitive limitation on the number of relationships an individual can personally maintain. With the exception of tribes (which are not face-to-face groups), Dunbar's groupings approximate the usual divisions in anthropology.

Two recent reviews of foraging peoples concluded that there was only support for one consistently recurrent group size, but these differed, with one approximating a small work group (Binford, 2001) and the other a small band (Kelley, 1995). Although there is some variation in subgroup size and in what subgroupings are called (e.g., a four- to six-person group may be a hunting group or a gossip group), various models and ethnoarchaeological data (Hassan, 1981) roughly converge on face-to-face groupings shown in Table 1.1, which adds the dyad as a subgrouping. What is significant about anthropology's magic numbers is that they can map on to considerations of body and task. Only one person at a time can hold an infant, and feeding one ensures a specific and constant view of the human face. About four or five people are the most that can closely view a small object in the palm of the hand or examine an animal track on the ground.

Table 1.1, it should be remembered, is an idealized model, a fiction, doing theoretical service. However, it is not a complete departure from human possibility. In their ethnoarchaeological research on the sociospatial organization and decision-making processes of subarctic Chipewyan Indians, Jarvenpa and Brumbach (1988) identified three recurrent spatiotemporal phases of organization: a concentrated summer band of about 300 individuals, winter staging and domestic settlements of 4–10 related families, and, from the latter groups, dispersed bands of hunters, usually two to three men, but also nuclear families or older husband–wife pairs. In their view, the decision-making dynamics of subgroupings is implicit structural organization. One implicit "rule" is a sine qua non for a conjugal pair or nuclear family to ally itself with any cluster of 20–50 people where they had kin in order to survive the long frozen winter.

The congruence between subgroup size, body, and task suggests the hypothesis of four core group configurations as the topography of the selective environment

TABLE 1.1. Core Configurations

Core configuration[a]	Group size	Modal tasks	Proper function
Dyad	2	Sex, infant interaction with older children and adults	Microcoordination
Work/family group	5	Foraging, hunting, gathering, direct interface with habitat	Distributed cognition
Deme (band)	30	Movement from place to place, general processing and maintenance, work group coordination	Shared construction of reality (includes indigenous psychologies), social identity
Macrodeme (macroband)	300	Seasonal gathering, exchange of individuals, resources, and information	Stabilizing and standardizing language

Note. From Caporael (1995). Copyright 1995 by Linnda R. Caporael. Reprinted by permission.
[a]Core configurations are a function of *both* size and task. Except for dyads, these numbers should be considered as modal estimates.

for humans. These are the dyad, task group, deme (or band), and macrodeme (or macroband), organized as a nested hierarchy, or *demic* structure (Hull, 1988). A core configuration is the *joint* function of group size and activity. Configurations provide a context for the evolution of adaptive social cognitive mechanisms. Each group configuration affords functional possibilities and coordination problems that do not exist at any other level. Table 1.1 lists the configurations, along with an approximate group size, examples of modal tasks for the configuration, and an example of a proper function that could have evolved given the configuration.

If uniquely human sociocognitive processes evolved (or earlier building blocks were reorganized) for dynamic coordination in core configurations, then traces of the mind's natural environment and the processes that evolved in that context should persist despite substantial differences in large-scale social organization (Caporael & Baron, 1997). Core configurations and associated processes are hypothesized to recur ontogenetically as a developmental system, in day-to-day life, and presumably in human evolutionary history. There are, of course, other types of human groupings, but they are not necessarily "core." Also, we would expect that a variety of different mechanisms—not just single mechanisms—would evolve because any configuration is suitable for a variety of recurrent tasks.

The smallest configuration, the dyad, is the most ancient of configurations, minimally necessary for all forms of internal fertilization (although mechanisms across species will vary). Among humans (and perhaps primates more generally), dyads are probably evolutionarily significant not so much because new capacities appear but because this configuration functions in (and is influenced by) the initial social organization and entrainment of biological clocks, rhythmicity, and temporal patterning (Jones, 1976; Jones & Boltz, 1989; McGrath & Kelly, 1986). Sometimes this synchrony of movement—or microcoordination—maintains "twoness," even when it is a problem. Imagine two strangers walking toward each other in a direct line. They dance and jerk trying to avoid bumping into each other until one or both manages to

break the coordination. Learning motor tasks from games such as golf or tennis to scientific tasks such as blowing a pipette or using a complex piece of equipment are frequently hands-on jobs.

The earliest cultural overlap between generations occurs in early development with joint attention, shared reality, and storytelling (Higgins, 2005; Nelson, 1993; Tomasello, 1999). Dyadic interaction is generatively entrenched in development, meaning that the dyad's proper functions are necessary conditions for processes that develop later (Wimsatt, 1999). Higgins (2005) argues that self-consciousness begins in dyadic interaction, and Nelson's (2003) work on children's talk to themselves before going to sleep shows them weaving emerging self-concepts against a background of cultural experiences. Some research suggests that adult "dyadic selves" exist as cognitive representations in which concepts of the self and other overlap (Aron, Aron, Tudor, & Nelson, 1991), as transactive memory systems (Wegner, 1986; Wegner, Raymond, & Erber, 1991), and in the coordination of bodily motion or interactional synchrony (Newbern, Dansereau, & Pitre, 1994). Interpersonal networks, such as friendship groups, also engage relational identification processes, as extensions of the basic dyadic unit (Brewer & Caporael, 2006b).

More than other configurations, the work/family or task group appears to be a major point of sense making of the material environment. It affords possibilities for distributed cognition; this means that cognitive tasks such as perception, classification, inference, and contextually cued responses are distributed over group members, particularly when the group is confronted with ambiguous or anomalous environmental information (Cole, Hood, & McDermott, 1980). In the idealized hunter–gatherer group, a task group might be a foraging party interpreting signs of animal movements over a landscape. A modern example would be control tower personnel at airports interpreting signs of possible danger from ambiguous signs on a radar screen. Group size alone does not determine a configuration. Consider a collection of five strangers in an elevator. Under typical conditions, they are an aggregation; each person is an individual ab-

sorbed in his or her own thoughts. If the elevator gets stuck between floors, the same five people form a task group configuration. They jointly explore the opportunities for putting the elevator in motion, recall previous incidences of and solutions for coping with stuck elevators, and point to buttons (shared attention) that might suggest different possibilities of danger and safety. For cognition to be functionally distributed in small groups requires not only a (somewhat) shared focus of attention and representation or schema but also a division of cognitive labor. Wegner (1995) points out that there can be progressive differentiation of memory "specialties" in a group over time. Liang, Moreland, and Argote (1995) found groups trained together to assemble radios outperformed individually trained subjects tested in newly formed groups. Group training enhanced not only recall about assembly procedures but also specialization for remembering distinct aspects of the procedure and trust in one another's knowledge about the task.

The task group is also a primary site for the repeated assembly of culture between generations, such as learning subsistence modes in hunter–gatherer cultures or polite dinner manners in modern cultures. Vygotsky (1978) coined the phrase "zone of proximal development" to describe how children participate with adults in activities slightly beyond the young learner's competence. This zone is a dynamic cognitive region of heightened responsiveness to the tools, skills, and practices in a culture, which children must learn to participate fully as adults (Rogoff, 1990, 2003).

The terms "deme" and "macrodeme" in Table 1.1 are used to indicate a greater generality than the anthropological terms "band" and "macroband" (although these are used here when the anthropological context is intended). Biologists use *deme* to refer to a breeding population; however, it derives from the Greek term, *demos*, which refers to a political unit defined by geography rather than kin ties. Hull (1988) used the term "demic structure" to refer to the organization of scientific communities, which is similar to the structure in Table 1.1. Demes are the locus of practical skills and common knowledge, some of which may be mythical, some of which may be acutely attuned to local conditions, from detailed knowledge of other people to the local ecology. It is also a locus for articulated social identity, "we-groupness" communicated in terms of stories and songs and the basic economic unit, the first configuration that can be self-sustaining for survival and childrearing (but not sexual reproduction). It is also the staging ground for domestic life, including task group coordination, local norm enforcement, and cooperative alliances, which are the basis for fissioning when the community exceeds resources or is fractured by conflict (Olsen, 1987).

In our hunter–gatherer fiction (and sometimes in real-life) related bands meet seasonally, forming macrobands that exchange marriage partners and disgruntled deme members, gifts, and information and perform rituals, competitive games, and stories. Macrobands are generally (and often loosely) related by common history, origin accounts, customs, and, most enduringly, language. They also complete the cycle of biological and social reproduction. A Monte Carlo simulation of paleodemographics by Wobst (1974, cited in Hassan, 1981) indicates that about 175–475 people, or seven to nineteen 25-person bands, are needed to maintain genetic viability by providing mates for members reaching sexual maturity in a population. Macrobands are also historically transitional. They were probably seasonal in the prehistoric past because of limitations of resources, but as agriculture took root, settled macrodemes simply became settlements. Macrobands are rare in the modern world, but macrodemes with analogous group structures are discernible. For example, scientific conferences are often seasonal meetings where information and young people are exchanged, and where the standardization and stabilization of distinctive terminology and the reaffirmation of group identity occurs.

The most important modern function of macrodemes is probably the construction of symbolic group identity (Brewer & Gardner, 1996), shared reality (Hardin & Higgins, 1996), social representations (Deaux & Philogène, 2001), stereotypes (Fiske, 1993; Steele & Aronson, 2003), artifacts (Norman, 1990), and the gathering of them all into worldviews, paradigms, or *social imaginaries*. Taylor (2002) writes of the social imaginary as the way that ordinary people imagine their social surroundings, a collectively shared landscape that makes common practices normative and possible and provides a widely shared sense of legitimacy. Imaginaries are the epistemic products of groups (Kruglanski, Pierro, Mannetti, & De Grada, 2006). For some peoples, the stars in the sky are holes in the floor of heaven; for others, stars are gaseous balls of flame. In both cases, the sensory experience of stars is presumably the same, but the explanatory paradigm differs.

There are a few general points to be made about the core configurations model. First, core configurations repeatedly assemble, in evolutionary time, in ontogeny, and in daily life. As infants develop, their widening scope of interaction increases demands for reciprocity, skills, memory, social judgment, and so on. Second, core configurations differ in how deeply entrenched they are (Wimsatt, 2001). Dyads are deeply entrenched; a change in their evolved functions should predict poor developmental outcomes. In contrast, macrodemes are shallowly entrenched and are relatively easy to modify. Second, humans have made dramatic changes in their lifestyles over the past 10 millennia, and especially in the last 300 years. Clearly the functions that evolve and develop in core configurations are capable of being extended, combined, and used in new domains. For example, a heart surgery team combines microcoordination and distributed cognition. Third, technology can also provide bridges between the functions of configurations. A group of 500 people given an order to march on a football field are likely to clump and straggle, but if a rousing marching song is broadcast, they can hardly avoid keeping time. In fact, artifacts are extremely important, not only for coordinating cognition and behavior (Hutchins, 1996) but also for their role in creating value-saturated environments (Berkowitz, 1997; Hodges & Baron, 1992).

Fourth, core configurations and their psychological correlates can operate independently of the demic structure in which they are hypothesized to evolve. This independence is especially characteristic of urban life where there may be multiple, cross-cutting groups, many assuming the functions of different demic structures. Demic structure is characteristic of certain bureaucratic institutions (e.g., military and clergy) and systems with self-organizing tendencies, like science and the firm, although more often corporate and bureaucratic institutions are likely to suppress self-organizing tendencies of lower-level groups (Campbell, 1982).

In summary, the model of core configurations is built on a set of constraints. It includes an evolutionary framework suitable to psychological levels of analysis; a vocabulary, repeated assembly, for grasping recurrence without making genetic commitments or creating the illusion that a phenomenon of interest has been explained, and an awareness of the limitations of its fictions. Although behavioral data about the past are limited, they do warrant an assumption that humans evolved to be obligately interdependent. Within that framework, there are a variety of ways in which individualism and interdependence may be played out, and the core configurations model is one of these. It organizes a range of experimental findings and lends itself to deriving additional hypotheses in diverse areas of psychology, including development, social cognition, and cultural psychology. It also organizes existing research in social psychology and generates hypotheses that can be tested, including tests of its assumptions through carefully designed experimental and naturalistic fieldwork.

CONCLUSION:
INVENTING HUMAN NATURE

In the 1970s, sociobiology burst onto the scene and into the living room with great fanfare, threatening to "cannibalize" the social sciences, psychology, and ethics (Wilson, 1975). Its proponents claimed that neo-Darwinism would explain self-interest, altruism, aggression, cooperation, knowledge, conflict, reciprocity, and sympathy among other human attributes (Hamilton, 1975; Trivers, 1971; Wilson, 1978). A rarely mentioned feature of this research is that most theorists failed to cite the empirical literature in psychology. What then, was being explained? *Not* the illuminating, albeit counterintuitive, data respected by psychologists (Ross & Nisbett, 1993). Sociobiologists offered the "gene's-eye view" of a widely shared and understood folk psychology. Everyday human experience served as circle of inspiration and evidence for easily decoded scientific categories, beginning with money (resource acquisition), sex (mating), and status (dominance hierarchy) and moving onto the "terrible twos" (weaning conflict), divorce (mate desertion), rape (forced copulation), adolescent rebellion (parent–offspring conflict), and declining reproductive value (menopause). Darwinism itself was tamed (Greenwood, 1984) by a biological rendition draped on a story skeleton (Schank & Abelson, 1995) from Christian theology:

Like the soul, the immortal genes are the essence of the individual, whereas the body, vessel of the soul or vehicle of the genes, is transitory and ephemeral (Caporael, 1994; Dawkins, 1976; Oyama, 1985). God "favors" and "acts" on preferred individuals and natural selection does the same; man was cast out of the Garden of Eden, a state of primitive innocence, and has "lost his natural environment." The meaning implications of this view of Darwinism are hardly lost on the brightest of students (Brem, Ranney, & Schindel, 2003).

In this chapter, I have adopted a view of evolution, psychology, and culture as leaning on each other for inspiration, validation, correction, and interpretation. None of these areas can be reduced to the other because human biology, psychology, and culture coevolved. Each research domain is essential for its contributions to understanding the evolution of human mental systems. Darwinism, conceived at an appropriate level of analysis, provides a theoretical framework that constrains and guides hypothesis development. Social psychology has an experimental methodology that is particularly effective for identifying deviations from conventional wisdom and raising our "discomfort index" (Fiske, 2003) with counterintuitive findings. Cultural psychology, in addition to its range of observational and interpretive methods, trains us to focus on and understand the construction of meaning (Bruner, 1986, 1990), which helps to distinguish evolution as it is used in scientific and social domains. Understanding both domains is both a goal and a significant contribution of social psychology for understanding humanity past, present, and future.

ACKNOWLEDGMENTS

NOTES

1. Caporael (2004) has a more detailed review based largely on Klein (1999). Other resources are Foley (1987, 1995), Tattersall (1995, 1999), and Potts (1996). Potts (1998) offers a brief primer particularly detailed with respect to climatic change. Other primers are Tattersall (2000) and Lahr and Foley (1998).
2. Most readers know *hominins* by the earlier nomenclature, *hominids*. The new taxonomic status of humans includes the australopithecines and *Homo*. Hominids now includes the hominins, plus the great apes and extinct members of their lineages.

Visceral and Somatic Indexes
of Social Psychological Constructs
History, Principles, Propositions, and Case Studies

JIM BLASCOVICH
MARK D. SEERY

It has long been customary for physiologists and behavioral scientists to acknowledge the potential
bearing of one discipline on the other, but only recently has there been a deliberate and
conscientious attempt to merge the two into an expanded science of behavior. There is little
question that the study of behavior in the matrix of general biology is now one of the major,
though fledgling, scientific enterprises of the day. A distinct subdiscipline within this general trend
is represented by research combining social–psychological and physiological research techniques in
the study of human interaction.

—SHAPIRO AND CRIDER (1969, p. 1)

PROPHETS AND PIONEERS

The appearance of Shapiro and Crider's seminal hand-book chapter, "Physiological Approaches in Social Psychology," in 1969 marked optimism on the part of the authors (and editors, Gardner Lindzey and Eliot Aronson, in choosing to invite such a chapter) that the study of human behavior, including social behavior, and biology would soon merge into a major interdisciplinary scientific enterprise. These authors implied that until the late 1960s, physiologists and social psychologists stayed mostly on their own side of an epistemological wall, but one they foresaw crumbling, presumably along with the remnants of Descartes's (1680) centuries old metaphysics of mind–body dualism. This was a bold assertion given that psychophysiology itself, a field attempting to unite the disciplines of general psychology and general physiology, was acknowledged by psychophysiologists themselves to be less than a decade old (Fowles, 1975; Sternbach, 1966). However, the assertion was prescient.

At the time they wrote their chapter, Shapiro and Crider noted that neither physiologists (nor psychophysiologists) on one hand nor social psychologists on the other were particularly well versed in the methodologies—to which we add theory and concepts—of

the other. They argued that a lack of cross-disciplinary expertise led investigators trained in physiological techniques to ignore proven methodological controls for social factors and individual differences. Indeed, these factors had been neatly labeled, even by psychophysiologists, as "situational response stereotypy" and "individual response stereotypy," respectively (Lacey & Lacey, 1958), inadvertently casting social psychologists' major categories of interest as uncontrollable noise in human psychophysiological experiments.

Shapiro and Crider were also quick to point out that social psychologists lacked sophistication in physiology. Their review of the relatively sparse social psychophysiology literature at the time indicated that most social psychological researchers using physiological measures apparently assumed that just about any visceral or autonomically controlled (i.e., visceral) response was interchangeable with any other. The clear conclusion was that social psychologists used unitary autonomic measures, particularly ones thought to be under sympathetic control (e.g., heart rate and skin conductance), interchangeably. A consequence of such naive interchangeability was that social psychologists used increases in sympathetically influenced physiological responses as though they were unambiguous measures of psychological states in

which physiological arousal played a theoretical or defining role (anxiety, tension, motivation, etc.). Hence, social psychological researchers who incorporated physiological measures often failed to define arousal constructs explicitly and, as a consequence, failed to consider both the role of physiological processes and social context restrictions when drawing inferences from physiological measures in their studies (factors contributing to a strong basis for inference when measuring physiological responses are discussed in more detail in subsequent sections).

The rise of neo-Jamesianism in the 1960s reinforced the idea that specification of physiological arousal constructs and the distinctions among physiological responses were unnecessary for social psychological researchers. For example, Schachter and Singer's (1962) classic paper, "Cognitive, Social, and Physiological Determinants of Emotional State," was based on the idea that emotions are not differentiated physiologically but, rather, cognitively and occur when a state of general visceral or autonomic "arousal" is labeled as a function of the social context. Valins (1966) went even further, concluding from his false-feedback studies that only the perception of such arousal was necessary, whether achieved veridically or nonveridically via interoceptive or external feedback. It should be noted that even now the search for "autonomic footprints" of basic-level emotions has proven quite difficult (Cacioppo, Klein, Berntson, & Hatfield, 1993). But the lack of such evidence should not be taken as negative evidence. We do know that at least visceral (e.g., Blascovich & Tomaka, 1996) and somatic (e.g., Cacioppo & Petty, 1981a, 1981b) footprints of superordinate emotional affective states have been identified.

Although the promise of the interplay between social psychology and physiology that Shapiro and Crider foresaw has not been fully realized in the 35 years since publication of their chapter, it has not proven an empty one either. Indeed, their seminal chapter played a role in motivating several social psychologists to become sophisticated in physiology and psychophysiology. These pioneers understood that the promise of social psychophysiology would be realized only if cross-disciplinary training took place. Paramount among these social psychophysiologists was John Cacioppo.

A quarter century after the first social psychophysiology handbook chapter, Cacioppo, a social psychologist by training, Gary Berntson, a biological psychologist, and Lew Tassinary, a cognitive psychologist, collaborated on a second handbook chapter, one appearing in the first edition of this handbook.[1] Cacioppo, Berntson, and Crites (1996) titled their chapter "Social Neuroscience: Principles of Psychophysiological Arousal and Response," in anticipation of the integration of social psychology within the broad new field of neuroscience.

These integrators brought sophistication and empirical substance to the merger foreseen by Shapiro and Crider. The sophistication was epistemological, physiological, social psychological, and educational. The substance included the use of physiological indexes of psychological constructs in empirical studies to advance social psychological theory, studies that incidentally provided model studies for others to emulate. Their educational efforts included an edited volume of social psychophysiological research (Cacioppo & Petty, 1983), which, with Waid's *Sociophysiology* (1984), consisted of the first two such contributions; training workshops[2]; and two edited comprehensive handbooks of social psychophysiology (Cacioppo, Berntson, & Tassinary, 2000; Cacioppo & Tassinary, 1990). Furthermore, it is fair to say that these contributions laid the groundwork for the more encompassing integration of social psychology and biology that today is labeled "social neuroscience."

MIND OR BODY VERSUS MIND AND BODY

Social psychophysiology fits within the context of mind–body interactions. Attempts to describe the relationship between the mind and the body, first explicitly labeled the "mind–body problem" by Descartes (1680), have occupied Eastern and Western philosophers of mind and other scholars for nearly 3 millennia and perhaps longer. In both hemispheres, scholars have proffered dualistic (i.e., mind or body) and monistic (mind and body) views. In Western philosophy, some suggest (e.g., Robinson, 2003) that Plato was the first dualist because he argued in *Phaedo* that the intellect is an immaterial part of the soul. Some (e.g., Ryle, 1949) suggest that Aristotle was the first monist or materialist because he argued that the soul is no more than the form or physical nature of one's body. These distinctions are remarkably similar in ancient Eastern philosophy lending even more credence to the universality of the mind–body problem among scholars.

Although other philosophers and scholars certainly addressed the issue, debates over the mind–body problem accelerated during the 17th century with the writing in 1650 and the publication in 1680 of Rene Descartes's *Six Metaphysical Meditations; Wherein It Is Proved That There Is a God. And That Man's Mind Is Really Distinct from His Body*. Although to this day, Descartes is seen by most (e.g., Damasio, 1994) as a strict dualist, separating the study of the mind from the body, he actually posited a singular connection between the mind and the body, one he placed at the pineal gland (Descartes, 1662/1972). During the 17th and 18th centuries, others attacked Descartes's position, including Spinoza (1677) and Leibniz (1695). The 19th century brought arguments from Carpenter (1874) and Lewes (1877) narrowing the mind–body problem to a "mind–brain" problem, but with mental states (e.g., consciousness) treated as epiphenomenal. William James (1890) attacked the notion of the epiphenomenalism of mental states, especially emotions, and essentially returned psychology to the mind–body connection albeit with the nature of the connections left relatively unspecified. James's work paved the way for work by physiologists such as Walter B. Cannon (1928) and Hans Selye (1950), who provided much of the early theoretical foundation for psychophysiology as a subdiscipline.

Thus, the dénouement of mind-body dualism began to accelerate by the beginning of the 20th century. However, the centuries long separation—the pineal gland notwithstanding—would take nearly 100 years to mend meaningfully and at first only in the scientific psychology and biology communities. Several modern scientific landmark studies forced the issue.

In the mid-1970s, Robert Ader and Nicholas Cohen, members of the psychiatry department at the University of Rochester, conducted a classical conditioning study using rats (Ader & Cohen, 1975). They paired water sweetened with saccharin (conditioned stimulus) with an injection of cyclophosphamide, an immunosuppressive agent (unconditioned stimulus). A few days after the conditioning, the rats were injected with an antigen, sheep erythrocytes, which would normally trigger the production of antibodies. However, Ader and Cohen found that rats that were exposed to saccharin for a second time produced lower levels of antibodies when the antigen was injected than rats that only received the initial saccharin pairing. This demonstrated that the immunosuppressive effects of cyclophosphamide had been conditioned to occur with exposure to otherwise benign saccharin.

Although studies (e.g., Solomon & Moos, 1965) of the relationship between psychological states and immunosuppression appeared prior to this one, there was no strong experimental evidence of a connection between the central nervous system and the immune system. Thus, it was Ader and Cohen's (1975) behavioral study that first provided an experimental basis for inferring a causal connection between the two, something that neither biologists nor other psychologists had achieved. Ader labeled the research area that grew out of his work "psychoneuroimmunology" and inspired many others, most notably Janice Kiecolt-Glaser and Ron Glaser (e.g., Glaser et al., 1987; Kiecolt-Glaser & Glaser, 1995), to study how the mind and nervous, endocrine, and immune systems influence one another.

At about the same time that Ader and Cohen published their paper, Milton Friedman and Ray Rosenman, cardiologists in joint practice, published their book, *Type A Behavior and Your Heart* (1974). On the basis of their own clinical and unobtrusive observations of heart patients as well as more formal study, Friedman and Rosenman concluded that a confluence of traits put certain individuals at increased risk for coronary artery disease. These individuals tended to be hard driving, competitive, time urgent, and hostile, a constellation that they labeled the coronary prone or "Type A" behavior pattern, which increased the risk of such individuals for heart disease. Their book was one of the first to close the gap between centuries of intuition and empirical evidence connecting personality and disease. More important for purposes here, the Type A construct stimulated a marriage between personality and social psychology on the one hand and cardiovascular psychophysiology on the other. Many social psychologists began their forays into social psychophysiology because of their interest in the coronary-prone behavior pattern.

These seminal studies also provided evidence that the merger of psychological and biological disciplines and subdisciplines could bear scientific fruit and advance science in ways unavailable to either parent discipline. By the end of the 20th century, major integrative and theoretical statements had been made including *Descartes Error: Emotion, Reason, and the Human Brain* (Damasio, 1994), *How the Mind Works* (Pinker, 1997), and *The Emotional Brain: The Mysterious Underpinnings of Emotional Life* (LeDoux, 1996). In terms of social psychology and physiology, three "social psychophysiological" chapters appeared in the first edition of this handbook (Cacioppo, Berntson, & Crites, 1996; Davison & Pennebaker, 1996; Zillman & Zillman, 1996), confirming Shapiro and Crider's original vision. These chapters as well as other seminal studies and books have also brought much media attention to the links between mind and body, attention that has increased markedly over the last quarter century.

Implications

The retreat from a Cartesian metaphysics of mind–body dualism to a more integrated, monistic view of mind–body relationships has several implications for combining psychological and biological disciplines. First, it requires real and practical acceptance of a background, metaphysical assumption sometimes labeled the "identity thesis" (e.g., Cacioppo & Tassinary, 1990). The identity thesis assumes that all mental and, hence, psychological, states and processes are embodied corporeally. Second, the monistic view implies that understanding bodily responses can inform our understanding of mental states and processes, and that understanding mental states and processes can inform our understanding of bodily responses. Hence, the monistic view implies that psychological (including social psychological) and biological (including physiological) levels of analysis cannot be separated if the mind–body relationship is to be understood. Third, the monistic view argues against biological reductionism as well as pure psychologism in all its forms (e.g., automatonism, cognitivism, and social constructionism). Fourth, it suggests that state-of-the-art training in social psychology should necessarily include training in biological methods generally and physiology and neuroscience more specifically, without abandoning its connections to other disciplines and subdisciplines such as sociology, cognition, and so on.

MIND SCIENCE AS AN OVERARCHING ORGANIZING CONSTRUCT

As Shapiro and Crider envisioned, social psychology and physiology would merge to form one subdiscipline, social psychophysiology, within the more general merger of psychology and biology. At the time, one could have imagined several such binary combinations within the more general merger. Yet, any binary combination of psychological and biological subdisciplines is not exclusive of any other. And combinations need not be bi-

nary. Multiple combinations (e.g., "social psychoneuro-immunology" and "social psychoendocrinology") can result from all sorts of multidisciplinary activities. The psychological–biological combinations have been subsumed somewhat under the label of "life science" for a relatively long time. Furthermore, combinations of psychological and biological subdisciplines have never really been limited to each other, though some of these extrapsychological and extrabiological linkages are newer (e.g., computational neuroscience) than others (e.g., psychosomatic medicine). The number of the linkages between psychology and biology and other disciplines has grown nearly exponentially (e.g., to any number of mathematics and science, engineering, social sciences, and humanities disciplines and subdisciplines).

An overarching label that has emerged for multidisciplinary approaches involving psychology, biology, and the many possible other disciplines is "mind science." Though 100 or even 50 years ago, many would have scoffed at the label and considered it an oxymoron (and some still do). Whether or not the descriptive label "mind science" takes hold, its mere advancement suggests the study of the mind is not limited to the behavioral, social sciences, and humanities but to the natural life sciences as well. Not unexpectedly, some territoriality seems to be involved among scientists claiming their subdiscipline is the "science of the mind" (e.g., Buss, 2004; Robinson-Riegler & Robinson-Riegler, 2004), but most recognize that some value to an overarching label and "mind science," or something akin to it, is likely to stick.

"Mind science" is not a new label. Indeed, the Mind Science Foundation, a nonprofit organization, has been supporting appropriate interdisciplinary research for many decades. However, trying to describe the exact nature of the interdisciplinary relationships underlying mind science is probably an exercise in futility because the underlying multidisciplinary structure is changing and growing too fast. However, the study of the mind has become more of a global multidisciplinary and interdisciplinary enterprise advancing what historically has been a theological, philosophical, and scientific question at least since Plato and probably earlier.

Mind science can be defined as the study of the antecedents, processes, and consequences of mental function in the context of the identity thesis. Mind science may well become the major scientific frontier for the 21st century. Scientific theory and technology have increased in sophistication so that models and tools have become available that allow investigators to move from the more hypothetical to the more truly scientific level of analysis (Harré, 1967) with regard to the mind.

Social Psychology and Mind Science

Multiple linkages exist among social psychology and other disciplines and subdisciplines within the context of mind science. Even the combinations between and among social psychology and biological disciplines are multiple. However, historically, the connection between social psychology and physiology is probably the oldest and most enduring one of a biological nature. Although social psychology and physiology can be relatively easily defined, neither can be as easily described.

Allport's (1935) classic definition of social psychology as the scientific investigation of "how the thoughts, feelings and behaviors of individuals are influenced by the actual, imagined or implied presence of others" (p. 800) remains accurate today. For didactic purposes, the subject matter of social psychological inquiry can be divided into intraindividual and interindividual processes. Historically, general categories of intraindividual processes have included the affective, cognitive, and behavioral ones noted in Allport's definition, while interindividual processes have included social interactional (e.g., group dynamics and prejudice) and social influence (e.g., persuasion) processes.

Clearly, the distinction between intra- and interindividual processes does not represent a realistic dichotomy as the so-called intraindividual processes do not take place in an interindividual vacuum, nor do interindividual processes exist apart from individuals. Consequently, despite the didactic value of these distinctions, limiting research domains to one or another category or subcategory of social psychological processes runs the risk of epiphenomenalism and lack of generalizability. For example, a consideration of motivational processes without integrating affect and cognition will necessarily lack external validity.

As a field, physiology has a much longer history than psychology and can be defined generally as the study of the functions or vital processes of living things, whether animal or plant, whole (e.g., living beings) or part (e.g., visceral organs and cells). Physiology is one (anatomy another) of the oldest of the biological subdisciplines. Given the reign of a dualistic perspective on mind and body that remained stronger in the biological than the psychological sciences, not surprisingly, subdisciplines such as psychophysiology and physiological or biological psychology evolved more within psychology than biology.

Historically, psychophysiology and physiological or biological psychology have been distinguished from each other in two ways. First, psychophysiology involved independent manipulation of psychological variables with measurement of physiological responses as dependent measures whereas physiological psychology involved independent manipulation of physiological variables (e.g., drug infusions and brain lesions) with behavioral responses as dependent measures. Second, psychophysiologists worked predominantly with human participants whereas physiological psychologists worked primary with animals. Thus, it not surprising that social psychologists would have more affinity with psychophysiologists than with physiological psychologists, although this preference is not as strong as it once was.

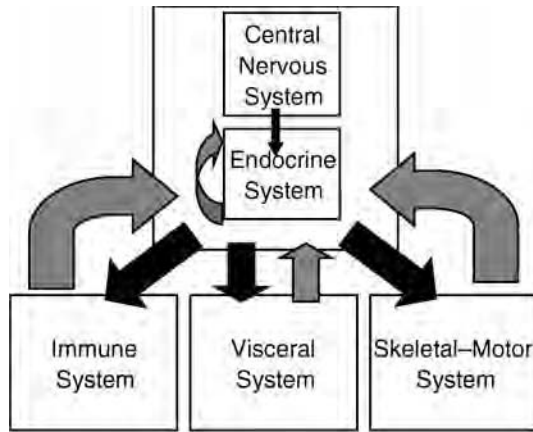
The subject matter of human physiology pertinent to psychophysiology can be and has been divided into control and operational systems for didactic purposes. In this vein, the major control systems include the central nervous system (CNS) and the endocrine system. Operational systems include the visceral system, the skeletal–


FIGURE 2.1. Cybernetic structure of physiological systems.

motor or somatic system, and the immune system. Clearly, the distinction between control and operational systems is a gross one as even the tiniest of physiological organs (i.e., cells), whether found in the CNS or the visceral system, have both control and operational functions.

The control–operational distinction subscribed to by physiologists and psychophysiologists is based on a cybernetic or feedback model (see Figure 2.1), allowing the continuous operation of bodily processes to deviate from and return to set homeostatic levels. A control system, such as the CNS, operates as a cybernetic model by transmitting operating instructions via efferent neurons and monitoring operational systems via afferent neurons. Similarly, the endocrine system transmits instructions and monitors operational systems via circulating hormones.

The major research questions guiding social psychophysiology, as well as social neuroscience more generally, involve the interaction of intra- and interindividual processes with physiological control and operating systems. Thus, the function or value of a social psychophysiological or neuroscience approach is twofold: understanding social psychological impacts on physiological systems and using physiological measures to understand social psychological processes. Most social psychologists have been more interested in the latter than the former. However, the view endorsed here is that the first function, understanding social psychological impacts on physiological systems, is necessary for the second; that is, to be able to use physiological responses to understand social psychological processes. Here, we focus on such understanding in terms of the interaction among social psychological, control (CNS, endocrine) and operational (i.e., visceral and skeletal–motor) physiological processes.

INFERRING PSYCHOLOGICAL CONSTRUCTS FROM EMBODIMENTS

We advocate a systematic approach to developing, validating, and using peripheral physiological markers of so-

cial psychological constructs. This approach includes a set of what we label and describe in some detail as "first principles" and a set of propositions for increasing the strength of inference drawn from physiological measurement of social psychological constructs. Following a relatively content-free discussion of first principles and propositions and a short discussion of general peripheral physiological measurement issues, we illustrate our approach content-wise by presenting two case studies of the development and validation of physiological markers based on these principles and propositions. One involves visceral and the other involves somatic physiological responses.

First Principles

To measure embodiments of social psychological processes, it is necessary to (1) specify the nature of particular social psychological constructs as precisely as possible; (2) specify the candidate physiological responses used to measure or index the constructs as precisely as possible; and (3) specify a valid or plausible theoretical physiological rationale for linking the constructs and physiological indexes as precisely as possible. Indeed, this logic can and should be used for indexes of any social psychological construct, whether those indexes are subjective (e.g., self-report) or objective (e.g., behavioral or physiological). Furthermore, it should be noted that the order of implementation of the second and third principles is often reversed.

Principle 1: Specifying The Nature of the Social Psychological Construct

Given the categories of processes that social psychologists study (e.g., relationships, emotion, and intergroup interactions), many social psychological concepts or constructs have proven "fuzzy" or difficult to define in social psychology. Part of the definitional difficulty is due to the seemingly ubiquitous use of common language labels for constructs in social psychology (e.g., attitudes, self-esteem, risk taking, compassion, racial prejudice, stigma, love, and liking). Such common language labels can lead researchers and investigators to rely on or be heavily influenced by common language connotations of the construct labels themselves rather than to rely on more precise conceptual analyses and explicit definitions of the constructs (Blascovich & Ginsburg, 1978).

Another conceptual difficulty derives from a tendency to define constructs with a focus on a single domain (e.g., affective, cognitive, or behavioral), sometimes leading to conceptual criteria for indexing these constructs in ways that fail to generalize across domains. For example, attitudes have been defined relatively narrowly depending on whether investigators are concerned with affect (i.e., defined in terms of liking), cognitions (i.e., defined in terms of associations of attitude objects with evaluations in memory), or behavior (i.e., propensity to respond). Hence, a set of physiological responses such as overt or covert facial electromyographic responses based on the muscles controlling smiling and frowning might have a

strong rationale if attitudes are defined as liking but little or no relationship if they are defined in terms of cognitions or behavior.

Such conceptual obfuscation creates several problems. First, it prevents the increasing clarity that comes with debate and refinement of explicit statements defining social psychological constructs. Second, without explicitly defined conceptual criteria, there is no conceptual or face validation check for manipulation of construct relevant independent variables. Third, such obfuscation promotes definitional operationism (Campbell, 1988b), wherein constructs are defined in terms of their measures (e.g., intelligence is what intelligence tests measure, or stress is a particular physiological response), a dangerous road inferentially (i.e., affirmation of the consequent) and consequently theoretically.

Precise specification of what an investigator means by a concept or construct avoids these issues, though it does not guarantee conceptual accuracy and acceptance. However, at least such specification does not finesse the problem of definition in the way that relying on the connotations of a common language label does. Rather, precise specification creates a point of departure for conceptual arguments, refinements, and, ultimately and ideally, conceptual clarity. As long as the conceptual criteria for a construct are stated, labels become less important. For example, one can define "risk taking" as behavior that puts something at stake for the actor, including both the possibility of gain and the possibility of loss, and for which there is a point in time when what is at stake cannot be withdrawn (Blascovich & Ginsburg, 1978). One can choose another label for the construct so defined such as "gambling" or even "X" without loss or change of meaning on the scientific level. And, one can argue the conceptual criteria explicitly.

Principle 2: Specification of Candidate Physiological Indexes

For human neuroscience, including social psychophysiology, we assume that the critical connection between mind and body occurs at the level of the CNS. However, this metaphysical assumption does not reduce the value of physiological responses controlled via peripheral visceral and somatic branches of the peripheral nervous system for understanding social psychological processes. Peripheral embodiments of psychological processes are driven by CNS embodiments of those processes as the latter controls the former. Hence, in theory, any psychological process that can be indexed via peripheral physiological responses should be distinguishable via CNS activity.

However, in many cases, the use of peripheral embodiments holds some practical advantages over CNS embodiments and, at least currently, some technological advantages. First, the costs of recording and scoring peripheral measures are much less than costs for recording and scoring central measures, especially those based on positron emission topography (PET) and functional magnetic resonance imaging (fMRI). Second, peripheral measures are typically less intrusive, though neither need be invasive. Third, compared to the technology for CNS measures (e.g., fMRI), the technology for peripheral measures, even ones requiring relatively sophisticated technology, does not restrict postures and movements, including speech, facial expressions, and so on, making even ambulatory measurement possible.

Fourth, at present, the predicted peripheral physiological patterns associated with certain psychological constructs are often open to precise measurement whereas the predicted CNS patterns associated with their underlying control processes are not. For example, specific physiological patterns of challenge and threat states (see below) can be distinguished peripherally via cardiovascular patterns. However, given the current state of technology, the hypothalamic differentiation underlying these peripheral patterns cannot be distinguished via brain imaging. Thus, functional brain imaging data may currently be able to demonstrate activation of the hypothalamus but not to distinguish between the oppositional motivational states resulting from that activation. Peripheral indexes are currently necessary for the latter.

Here, we are concerned with indexes derived from physiological responses controlled by the CNS via the peripheral nervous system. The major branches of the peripheral nervous system include the autonomic and somatic ones. The former provides neurological pathways allowing the brain and spinal cord to control the visceral organs via its sympathetic and parasympathetic branches. The latter provides neurological pathways allowing the brain and spinal cord to control skeletal muscles.

Many peripheral physiological responses manifest themselves in ways that can be assessed relatively easily, including pulse rate, respiration rate, and overt facial muscle movements, which can be assessed with little if any specialized technology. Not surprisingly, then, many investigators, buoyed by the false assumption that any autonomic response is as good as any other (see above), chose physiological responses as candidate indexes of psychological constructs based on convenience and on ease of measurement rather than specificity and, hence, validity.

With more advanced technology, many more peripheral physiological responses can be measured. Polygraphs advanced peripheral electrophysiological measures of biopotential signals—for example, those produced by cardiac activity via the electrocardiogram (ECG), covert skeletal muscle activity via the electromyogram (EMG), and gastric activity via the electrogastrogram (EGG). The advent of various electromechanical and electronic transducers made measurement possible for peripheral responses lacking endogenous biopotential signals such as eccrine sweat gland activity via skin conductance responses, stroke volume, and cardiac output via cardiac impedance responses, and so forth. In sum, the plethora of peripherally controlled physiological measures that present themselves as potential indexes of social psychological constructs have presented many opportunities for social psychophysiologists.

Principle 3: Specification of Theoretical Physiological Linkages between Social Psychological Constructs and Candidate Physiological Measures

Precisely specifying both the social psychological construct and the candidate physiological responses is a necessary but not sufficient step toward establishing valid physiological indexes of those constructs. Investigators must also specify a valid theoretical rationale for linking the two. Unlike many self-report and behavioral measures, a rationale of simple face validity is not sufficient to link physiological measures with psychological constructs. The absence of a plausible theoretical rationale limits a physiological index to speculation based purely on empirical correlation rather than demonstrable or putative causal connections. The strength of a physiological index rests on the validity of the rationale. If the rationale is questionable or purely speculative, the index is cast in doubt.

Generally speaking, there is a positive relationship between the complexity of the set of candidate physiological responses and the complexity of the theoretical rationale required for linking physiological responses to psychological constructs. In addition, given the increase in costs associated with the measurement of larger sets of physiological responses, it is not surprising that social psychologists and others have historically shown a propensity to index psychological constructs with unitary peripheral physiological measures. However, this trade-off makes it extremely difficult to avoid the problem of many-to-many relationships between constructs and unitary physiological indexes (see propositions earlier) even if the construct and the candidate physiological response are highly specific and the appropriate domain or context has been limited. Hence, the strength of inference is likely to be compromised by an approach to an index based on a unitary physiological response (Blascovich, 2000; Blascovich & Kelsey, 1990; Cacioppo & Tassinary, 1990).

For example, although reviewers (e.g., Landis, 1930) have long understood the lack of a one-to-one relationship between electrodermal activity and psychological constructs, pursuit of electrodermal activity as a more or less informative index of psychological and social psychological constructs has persisted long since. One can theoretically link the magnitude of a single electrodermal measure (e.g., skin conductance level) to a psychological construct (e.g., fear) based on an up-to-date model of autonomic activation of electrodermal activity. For example, Dawson, Schell, and Filion (2000) posit that electrodermal activity is elicited by affective stimuli that trigger amygdalar activation of the sympathetic branch of the autonomic nervous system.

Hence, theoretically, an increase in skin conductance response level can index fear. However, without ruling out alternative causes of other influences on electrodermal activity also posited by Dawson and colleagues (2000) (e.g., activation of the reticular formation due to increased muscle tone, hypothalamic activation due to thermoregulation, premotor cortex activity due to fine muscle control, and prefrontal cortical activity due to orienting and attention), one cannot guarantee a one-to-one relationship between the construct (i.e., fear) and the response (i.e., skin conductance level). One conceivably could restrict the psychosocial context to lessen possible influences of increased muscle tone, fine motor control, thermoregulation, and orienting and attention, thereby strengthening the inference provided by the electrodermal measure. However, even after ruling out these alternative causes, one would also have to rule out the possibility of alternative emotional constructs because amygdalar activation can be triggered by either positive or negative affect or emotions. All one could really infer is that an affective response occurred perhaps with an intensity indexed by the electrodermal response, hardly a strong basis for concluding that a psychological fear response had occurred.

It is important to note here that the physiological theory (i.e., Dawson et al., 2000) is not the cause of the problem of inference in this example—quite the opposite. Nor is it a problem of measurement technology. Rather, the problem is a failure to fully account for the complexity of the theoretical linkage by limiting the set of candidate physiological responses to a unitary one while ignoring other measures (e.g., electromyographic recordings of peripheral skeletal–motor activity, electrocortical measures, and blood flow patterns in the brain) that would help form a pattern of responses that together with electrodermal response would provide a stronger basis for inferring the operation of the construct (i.e., fear) when the specified pattern held.

Additional Inferential Issues

A perfect physiological index would have a completely transitive or invariant one-to-one relationship with the psychological construct so that one would not occur without the other (Cacioppo & Tassinary, 1990). Unfortunately, such completely transitive relationships are relatively uncommon in psychology, especially when physiological responses are posited as indexes of psychological constructs, including social psychological ones. However, steps can be taken to increase the likelihood of a one-to-one or invariant relationship.

Even specific physiological systems (e.g., cardiovascular and electrodermal) generally respond to multiple inputs (e.g., psychological and metabolic demands) in overlapping ways. For example, both motivational task engagement and physical exercise can increase cardiac responses in similar ways (e.g., heart rate and ventricular contractility). Such many-to-many relationships make it difficult to disentangle specific psychosocial inputs from specific physiological effects and, hence, to establish specific construct-to-physiological response relationships that can be used as the basis for invariant physiological indexes. Hence, the task of establishing the desirable one-to-one relationships involves being able to discriminate constructs on the one hand and patterns of physiological responses on the other.

Generally, the more one limits the social psychological construct and expands the set of physiological measures indexing it, the closer the construct and index can come to a one-to-one or "invariant index" (Blascovich, 2000; Cacioppo & Tassinary, 1990). Cacioppo and colleagues (2000) described a taxonomy of possible relationships between psychological constructs and physiological responses that helps clarify the nature of these relationships. Their scheme (see Figure 2.2) distinguishes categories of construct-measure relationships as a function of discriminant value or specificity and generality.

Cacioppo and Tassinary (1990) argue that limiting the psychosocial context helps increase the likelihood that a physiological index will discriminate between target and alternative constructs. For example, an investigator can be more certain that increases in heart rate and ventricular contractility are driven by, and therefore index, non-aerobic task engagement rather than aerobic task engagement (i.e., metabolic demands) if the context in which these responses are assessed is bound in such a way that does not permit physical exertion. Cacioppo and Tassinary also suggest ways in which investigators can decrease the plethora of possible many-to-one relationships—thereby increasing the possibility of one-to-one relationships between constructs and physiological responses—via fractionation of multiple physiological responses over time (see discussion below). Hence, the greater the psychosocial specificity and the construct-response specificity, the more likely a physiological index is to approach a one-to-one relationship with a construct.

An implication of this scheme is that social psychologists desirous of physiologically indexing constructs should aim for a bound context and a set of multiple physiological measures—thereby a "marker." In essence, markers are context-bound invariants. To the extent that the context or domain is limited, resulting use of the physiological markers will increase internal validity of experiments and be theoretically useful. To the extent that the bound context corresponds to a large category of psychosocial situations, the physiological markers will have external validity and generalizability in addition to internal validity. Blascovich (2000) incorporated and expanded on Cacioppo and Tassinary's (1990) suggestions in the form of propositions for increasing the discriminant validity of markers. In revised form here, these propositions include (1) *divergent validation*, (2) *patterns of overlapping multiple responses*, and (3) *assessment over time*. None of these propositions is unique to psychophysiological measurement. Indeed, they are propositions borrowed largely from the social psychological methodology literature and applied to psychophysiological measurement.

Proposition 1: Divergent Validation

Divergent validation is well-known in social psychology generally via, especially, the work of Donald Campbell (1988a), and Proposition 1 is an application of his argument. Hence, our proposition of *divergent validation* states that valid markers are more likely to be useful inferentially if physiological responses are shown to diverge between target and oppositional constructs rather than between the presence and absence of the psychological input or processes circumscribed by a singular construct. For example, the inference drawn from a physiological response, such as the amplitude of a skin conductance response, that occurs during an instance of a stimulus that induces avoidance, such as a snake, is more likely and convincing if the response does not occur during an instance of a stimulus that induces approach, such as a teddy bear, than if the comparison is between a stimulus-inducing avoidance and a neutral one (e.g., a book). It follows, then, that validation of physiological markers will be more likely for use in indexing constructs of a more rather than less superordinate nature. For example, attempting to develop discriminant physiological indexes for positive and negative affect should be easier than attempting to develop distinctive physiological indexes for happiness and joy, or fear and anger.

Proposition 2: Patterns of Overlapping Multiple Physiological Responses

The proposition of *patterns of overlapping multiple physiological responses* states that valid physiological markers are more likely to be achieved if the set of physiological responses targeted is more rather than less inclusive, and if the same set is used to index contrasting oppositional constructs; that is, if the set of responses differs in form but not substance. As illustrated previously, increased heart rate and ventricular contractility do not necessarily distinguish nonaerobic task engagement from aerobic task engagement. Both should cause increases in heart rate and ventricular contractility. However, oxygen demand and oxygen consumption should increase during exercise but not during a nonmetabolically demanding performance. Hence, expanding the set of responses in this example to include oxygen consumption provides a way of distinguishing nonaerobic from aerobic task en-

FIGURE 2.2. Categories of construct–measure relationships (Cacioppo et al., 2000).

gagement. Indeed, this has been shown to be the case (Rousselle, Blascovich, & Kelsey, 1995).

Proposition 3: Assessment over Time

The proposition of *assessment over time* states that valid physiological markers are more likely to be achieved if the set of physiological responses targeted is assessed continuously over time. For example, if one is using facial electromyography to assess positive affect, the intensity of zygomaticus major (i.e., the "smile" muscles in the cheeks) activity may not differentiate a genuine or automatic smile from an intentional forced one, whereas the time course of the activity may.

In sum, many-to-many relationships between social psychological constructs and indexes based on physiological responses appear to be the rule rather than the exception. However, investigators can increase the likelihood of achieving one-to-one relationships between their constructs and physiological indexes by carefully limiting the context within which they apply, by using a divergent validational approach, and by constructing indexes based on overlapping multiple responses over time. However, it must be stated that none of these strategies is logically necessary so that single physiological response indexes that provide a strong basis for inference, though less likely, are not logically impossible. Conversely, use of all these strategies does not guarantee valid indexes. Rather, the "devil is in the details" of the specification of psychological constructs, candidate physiological responses, and valid rationales linking the two.

Summary

Social psychologists can find much of value in psychophysiological and physiological theory on which to select candidate physiological response sets as indexes of theoretical constructs (see examples below). The pursuit of indexes based on unitary physiological measures, although appealing from an economic point of view, has not proven very successful in our view. However, neither past history nor logic absolutely rules out the establishment of valid unitary physiological indexes of social psychological constructs.

PERIPHERAL PHYSIOLOGICAL INDEXES OF SOCIAL PSYCHOLOGICAL CONSTRUCTS

General Issues

Physiological indexes of the operation of both intra-individual and interindividual social psychological processes can only be measured at the individual level. And, like other subjective (i.e., self-report) and behavioral measurement, physiological measurement is subject to individual differences, measurement error, and artifact. However, the measurement of physiological responses has some advantages over self-report and behavioral responses in this regard.

One advantage is due to the fidelity of physiological recording technology. Modern digital physiological measurement technology permits nearly noise-free, highly precise recording of physiological responses. An additional advantage stems from the relatively automatic and covert nature of physiological responses. Compared to self-report and behavioral measures, physiological responses enjoy relative immunity to demand characteristics and participant impression management concerns.

This immunity is illustrated in a review of self-report, behavioral, and physiological measures taken during perceiver interactions with physically and racially stigmatized others across several experiments by Blascovich, Mendes, and Seery (2002). They concluded that the theoretically predictable threat experienced by nonstigmatized participants interacting with stigmatized others (Crocker, Major, & Steele, 1998) was evidenced by physiological response patterns indicative of threat. Not only did corresponding self-report responses fail to indicate threat, but compared to participants interacting with nonstigmatized others, participants interacting with stigmatized individuals reported them as more intelligent, attractive, and so on, suggesting sensitivity on participants' part to impression formation concerns. Dambrun, Depres, and Guimond (2003) found similar fractionation between physiological and self-report responses to participants' contact with outgroup members.

In addition, advantages accrue to physiological measures by virtue of the relative ease with which they can be recorded continuously and online. Continuous recording not only permits increased reliability generally but also makes one-to-one relationships between physiological responses and psychological constructs more likely because continuous measurement is necessary for assessing physiological response patterns over time in line with the third proposition discussed previously. Online recording also avoids problems associated with prospective and retrospective self-reports because physiological responses are recorded conterminously with the operation of the psychological processes that they index without interrupting the flow of an experiment.

Peripheral Physiological Indexes of Basic Psychological Processes Underlying Social Psychological Processes

Social psychological phenomena and processes rest on and involve more rudimentary psychological processes, especially low-level perceptual and cognitive ones. Thus, psychophysiological indexes of these more basic processes (attention, perception, information processing, memory, etc.) can be valuable to social psychologists, as illustrated by the emergence and importance of dual-process theoretical models such as Wegner's (1994) model of ironic processing, Devine's (1989) automatic and control processes of prejudice, and Wilson, Lindzey, and Schooler's (2000) model of dual attitudes. When social psychologists are only interested in whether or not some stimuli or set of stimuli is perceptually or

cognitively processed at all rather than exactly how it is processed, even a unitary response can provide a reasonable basis for inference under proper conditions.

Perceptual Recognition

An interesting illustration involves perceptual (i.e., visual) aspects of person memory—specifically, whether or not an individual can respond to a previously known face even without any memory of it. Studies by Bauer (1984) and later Tranel and Damasio (1985) demonstrated that individuals who have lost the ability to recognize faces consciously (i.e., prosopagnosics) exhibited more frequent and larger skin conductance responses to pictures of familiar faces (e.g., family members) than to unfamiliar faces, even though they showed no evidence of conscious recognition. In this case, investigators can infer a basic or low-level recognition effect even though there is not a one-to-one correspondence between electrodermal activity and facial recognition.

Cognitive Processing

Another illustration involves pupillary responses, primarily pupillary dilations, as an index of cognitive processing load. Beatty and Lucero-Wagoner (2000) argue that autonomically controlled task-evoked pupillary responses (TEPRs) index brain processes associated with the intensity of human cognitive processing. They based this claim on research conducted as long ago as the 19th century (e.g., Heinrich, 1896; Schiff, 1875) as well as more recent research (e.g., Ahern & Beatty, 1981; Hess & Polt, 1964) showing that task difficulty is correlated with the intensity of TEPRs. Again, just as with the use of electrodermal activity as a unitary index of recognition, investigators can infer heightened cognitive processing from coterminous TEPRs even though there is not a one-to-one correspondence between pupillary responses and cognitive processing.

Summary

The types of inferences that can be drawn from physiological indexes based on unitary peripheral physiological correlates of basic perceptual or cognitive processes can be important to social psychologists. For example, in terms of dual-process theories, the strength of an electrodermal response as an index of perceptual recognition can provide the basis for the assumption that a low-level or automatic response exists to be controlled. Moreover, the strength of task-evoked pupillary responses can index cognitive load, which in turn would provide an inferential basis for whether or not cognitive control mechanisms were activated. Neither index, of course, would be very specific, about either the exact nature of the perceptual recognition in the case of the skin conductance index or the exact nature of the type of cognitive processing involved in control. To the best of our knowledge, a combination of such indexes has not been yet employed by social psychologists.

Peripheral Physiological Indexes of Social Psychological Constructs and Processes

The value of peripheral physiological indexes for social psychologists is not limited to indexes of basic perceptual and conceptual processes based on a simple notion of the identity thesis as described earlier. Rather, social psychologists have relied on more sophisticated physiological theoretical notions to validate and employ peripheral physiological markers of the operation of social psychological processes themselves. Several physiological models provide possible theoretical linkages for establishing peripheral physiological indexes of these higher-level social psychological constructs. These models include but are not limited to Cacioppo and Petty's (1981a, 1981b) linkages between affect and facial muscle movements, Obrist's (1981) general model of cardiovascular psychophysiology, Dienstbier's (1989) model of physiological toughness, Berntson, Cacioppo, and Quigley's (1991) doctrine of autonomic space, Porges's (1995) polyvagal theory, and Wright and Kirby's (2001) effort determination theory.

Page limitations for this chapter preclude an exhaustive general review of the use of peripheral physiological indexes in social psychology. Excellent general coverage can be found elsewhere (e.g., Gardner, Gabriel, & Diekman, 2000). Here, the focus is on two prototype examples or case studies illustrating, in depth, the use of peripheral physiological indexes according to the principles and propositions described earlier. In accord with the theme of this chapter, the first involves peripheral autonomic indexes of motivational processes and the other peripheral somatic indexes of affective processes.

PERIPHERAL AUTONOMIC INDEXES: A CASE STUDY OF CHALLENGE AND THREAT

Researchers have investigated motivation from a social psychological perspective for many years (see early review by Berkowitz, 1969). More than a decade ago, Blascovich and colleagues began to develop a biopsychosocial model of motivational processes integrating cognitive, social psychological, and physiological processes (Blascovich & Mendes, 2000; Blascovich & Tomaka, 1996). Their work fits the prototype criteria for physiologically indexing psychological constructs as discussed previously, including explicit definition of key constructs and specification of physiological response measures linked to the constructs via established physiological theory. Their work also illustrates the value of limiting the domain or context in which physiological indexes are applied and adherence to the propositions (i.e., divergent validation, patterns of overlapping multiple physiological responses, and assessment over time) discussed previously for increasing the likelihood of a one-to-one relationship between physiological indexes and psychological constructs.

Constructs, Candidate Physiological Indexes, and Theoretical Rationale

Principle 1: Construct Specification

The biopsychosocial model focuses on performance situations that are goal relevant to the individual. Challenge and threat processes involve deliberate and/or automatic influences on evaluations of resources (e.g., skills, knowledge, and abilities; various dispositions; and social support) relative to evaluations of demands (e.g., danger, uncertainty, required effort, various dispositions, and social evaluation). Challenge results from an overall assessment that one's resources meet or exceed the demands of the situation, and threat results from an overall assessment that the demands of the situation exceed one's resources. According to the biopsychosocial model, though seemingly categorically defined, challenge and threat actually represent anchors on a bipolar motivational continuum (Blascovich, Mendes, Tomaka, Salomon, & Seery, 2003).

As Cacioppo and Tassinary (1990) and Blascovich (2000) have argued, finding one-to-one (i.e., invariant, or general) physiological indexes of social psychological constructs that apply across all possible contexts is very difficult and, hence, unlikely. They suggest that this difficulty can be decreased and the likelihood of finding one-to-one correspondence increased by limiting the context in which the physiological index applies to the social psychological constructs. Consequently, any proposed physiological indexes are likely to enjoy a one-to-one relationship only in the empirically limited context even though the theory may be more generally applicable. Such a context limitation is not a limitation of the theory but rather an empirical limitation.

Blascovich and colleagues have limited the empirical context in which they typically have investigated challenge and threat in two ways. First, they restrict the context to non-metabolically demanding goal-relevant situations. This eliminates physically demanding situations, which would interfere with a one-to-one relationship between the candidate cardiovascular indexes (see later) and challenge and threat processes. The accompanying metabolic demands driven by large muscle activity would elicit cardiovascular responses that could obfuscate the relationship of the cardiovascular physiological indexes to the psychological demands that contribute to challenge and threat motivation.

Second, they limit the non-metabolically demanding goal-relevant situation to situations requiring active instrumental cognitive responses on the part of the individual (e.g., test taking, speech giving, game playing, negotiations, and singing). They term such situations "motivated performance situations" and contrast them to passive performance situations in which instrumental cognitive responses are not necessarily required (e.g., emotionally coping with the death of a loved one or watching a scary movie). Based on the work of Obrist (1981) as well as their own (e.g., Tomaka, 1993), Blascovich and colleagues concluded that their candidate cardiovascular indexes of challenge and threat do not hold in passive situations. As with the first, this limitation is an empirical one. It does not limit resource/demand assessments and, hence, challenge and threat to motivated performance situations. It only limits the validity of the physiological indexes of challenge and threat to motivated performance situations.

Principle 2: Specification of Candidate Physiological Responses

Blascovich and his colleagues focused on cardiovascular responses as candidate measures or markers of challenge and threat. Their initial consideration of cardiovascular measures was based on intuitions drawn from previous literature linking increases in various cardiovascular responses (e.g., heart rate reactivity and blood pressure reactivity) during stressful or threatening situations. Such cardiovascular reactivity research and theory came to the fore in personality and social psychology during the 1970s and 1980s as many investigators sought to find a link between the coronary-prone personality type and heart disease (see Blascovich, in press, for a more thorough discussion).

Principle 3: Specification of a Plausible Theoretical Physiological Rationale for Linking Candidate Physiological Measures to Social Psychological Constructs

Paul Obrist (1981) categorized cardiovascular reactivity patterns as relatively benign or malignant according to their antecedents. He argued that when cardiac responses are driven by somatic demands during aerobic exercise or when cardiac responses occur in passive coping situations, a benign pattern that he labeled "cardiac–somatic coupling" emerges. He argued that cardiac responses are not driven by somatic demands in active coping situations and that a potentially pathophysiological pattern that he labeled "cardiac–somatic uncoupling" emerges. Subsequently and not surprisingly, many cardiovascular reactivity researchers began limiting the experimental contexts in which they used cardiovascular reactivity indexes to investigate links between personality constructs and cardiovascular disease to active coping situations.

Less than a decade later, Richard Dienstbier (1989) published his *Psychological Review* article on physiological toughness and weakness. Relying nearly exclusively on investigations of cardiovascular responses of rodents, his work suggested that further clarification was necessary to Obrist's distinctions. Specifically, Dienstbier's work provided the basis for distinguishing benign from malignant patterns of cardiovascular reactivity within active coping situations. A year later, Kasprowicz, Manuck, Malkoff, and Krantz (1990) found evidence that distinguished "cardiac" from "vascular" responders during active coping situations. A few years later Manuck, Kamarck, Kasprowicz, and Waldstein (1993) suggested that vascular reactivity was the more malignant (with regard to cardiovascular disease) of the two.

Dienstbier (1989) concluded that physiologically tough animals, ones that survive and even thrive in potentially dangerous or threatening situations, exhibit a pattern of cardiovascular responses in such situations that is driven primarily by activation of the sympathetic–adrenomedullary (SAM) axis. According to Dienstbier, SAM axis activation mobilizes energy reserves in a benign way such that sympathetic neural stimulation of the myocardium increases heart rate and ventricular contractility while adrenal medullary stimulation quickly increases circulating catecholamines, including epinephrine and norepinephrine. The circulating catecholamines induce systemic vasodilation, thereby decreasing total peripheral resistance (TPR). This combination of cardiac and vascular stimulation increases blood flow (i.e., cardiac output; CO). Typically, such SAM activation has a quick onset and offset. Physiologically weakened animals, on the other hand, exhibit marked hypothalamic–pituitary–adrenal cortical (HPA) axis[3] activity in addition to SAM axis activation. The HPA axis activity increases the production of cortisol and inhibits the adrenal medullary release of catecholamines, thereby reducing the vasodilatory effects of SAM axis activation and, in turn, decreasing CO. Typically, HPA activation is slower to habituate. Figure 2.3 depicts both patterns.

Validation of Cardiovascular Physiological Indexes of Challenge and Threat

Dienstbier's model of physiological toughness provided the theoretical basis for the cardiovascular response patterns that Blascovich and colleagues would later establish as markers of challenge and threat processes in nonmetabolically demanding motivated performance situations. Within such a limited context, the specific responses (i.e., heart rate, ventricular contractility, CO, and TPR) could be used in accordance with the *propositions of divergent validation, patterns of overlapping multiple physiological responses, and assessment over time*, thereby increasing the likelihood of achieving one-to-one relationships between the indexes and the primary constructs underlying the biopsychosocial model of challenge and threat.

Correlational Validation

Tomaka, Blascovich, Kelsey, and Leitten (1993) conducted a series of correlational experiments to ascertain the relationship between self-reported evaluations of perceived demands and resources prior to active coping performance tasks and patterns of cardiovascular responses during subsequent performance. They hypothesized that an evaluation of resources exceeding demands (i.e., challenge) would be accompanied by the pattern of physiological toughness specified by Dienstbier (i.e., increases in heart rate, ventricular contractility, and CO, and a decrease in TPR; see Figure 2.3), and that an evaluation of demands exceeding resources (i.e., threat) would be accompanied by a pattern of physiological weakness specified by Dienstbier (increases in heart rate and vasocontractility, but little change in CO and little change or even increases in TPR; see Figure 2.3). These hypotheses were confirmed.

A within-subjects study encompassing four motivated performance tasks in succession was reported by Quigley, Barrett, and Weinstein (2002). Using hierarchical linear modeling (HLM) analytic techniques, these investigators demonstrated that within-subjects changes in pretask appraisals of demands and resources across tasks were statistically reliably related to changes in cardiovascular challenge and threat patterns during task performance. In other words, as pretask appraisals changed in the direction of challenge from threat, the patterns of cardiovascular responses became more challenge-like.

Experimental Validation

To strengthen the inferential basis for a causal connection between challenge and threat processes and the candidate cardiovascular indexes, experimental studies were

FIGURE 2.3. Dienstbier's (1989) cardiovascular patterns of physiological toughness/weakness.

conducted. For example, Tomaka, Blascovich, Kibler and Ernst (1997, experiment 1) manipulated instructional set in a manner likely to influence challenge and threat evaluations and, hence, patterns of cardiovascular responses via Dienstbier's model. Specifically, manipulations of the content of the task instructions; that is, practice (e.g., "This is just a practice run.") versus criterion (e.g., "This is an important run for you to do well.") coupled with vocal tone (i.e., friendly vs. hostile) during task instructions resulted in the hypothesized cardiovascular patterns of challenge and threat reactivity. Hunter (2001) also manipulated instructions such that participants were told that because they would be reading or singing the U.S. national anthem later during the experiment they needed to practice reading or singing the first couple stanzas. The predicted challenge and threat patterns of cardiovascular responses occurred such that significantly more of the individuals who sang evidenced the threat pattern than individuals who anticipated reading, and significantly more of the individuals who read evidenced the challenge pattern than individuals who anticipated singing.

Manipulated Physiological Studies

To determine whether interoceptions associated with the challenge and threat patterns of cardiovascular responses influenced the evaluations of demands and resources, Tomaka and colleagues (1997, experiments 2 and 3) manipulated participants' cardiovascular patterns mimicking the challenge and threat patterns physically (while engaged in moderate aerobic exercise, mimicking challenge in one experiment; while experiencing a warm pressor mimicking challenge in the other). During these manipulations, participants' self-reported evaluations of demands and resources for an upcoming serial subtraction task did not differ as a function of condition. These results suggested that overall challenge/threat evaluations were not likely caused by the physiological patterns themselves, but, rather, that the physiological patterns resulted from the evaluation or assessment mechanisms as postulated by the biopsychosocial model.

Predictive Validation

Recently, Blascovich, Seery, Mugridge, Weisbuch, and Norris (2004) conducted a study to determine the predictive validity of the cardiovascular indexes of challenge and threat patterns. Varsity baseball and softball players (position players other than pitchers; i.e., hitters) served as participants. Participants each gave two 3-minute speeches, a performance-irrelevant (control) speech (why I am a good friend) and a performance-relevant (predictor) speech (how I would approach a critical hitting situation). A unitary cardiovascular index derived from the set of multiple cardiovascular measures used to index challenge and threat was derived for each speech task. Controlling for the indexed cardiovascular responses during the performance-irrelevant speech, the cardiovascular challenge/threat index that occurred during the performance-relevant speech reliably predicted

major outcome measures of offensive baseball performance (the runs created index, batting averages, etc.).

Summary of Validational Studies

In aggregate, the aforementioned studies provide strong validation that challenge and threat are marked by specifiable and divergent patterns of cardiovascular responses across the same set of specific measures. They also attest to the value of grounding such candidate indexes in physiological theory (e.g., Dienstbier, 1989). Based on the validational studies alone, these markers appear to be robust.

The validational studies have also produced results that are remarkably consistent in at least two respects. First, no gender differences have ever been found that suggest that men and women evidence different cardiovascular patterns under either challenge or threat. Second, with one exception, better performance results were found under challenge rather than threat conditions. The one exception occurred in the study by Hunter (2001). She found that participant performance on a vigilance task was better under threat than challenge motivation. Indeed, one might expect better vigilance during threat as functional.

Application of Cardiovascular Indexes of Challenge and Threat to Theoretical Issues in Social Psychology

The validation of the cardiovascular indexes of challenge and threat was not the final goal of the proponents of the biopsychosocial model of challenge and threat. Rather, the goal was to be able to use such indexes to test social psychological theory. A corpus of work using these indexes to test various social psychological theories has paralleled the validational work. The basic rationale for this theory-testing work is based on a single argument. To the extent that challenge and threat motivational states can be predicted by a personality or social psychological theory, and the predictions can be tested in a nonmetabolically demanding motivated performance context, the cardiovascular indexes of challenge and threat can be used to test the theory. The conditions specified by this argument have proven remarkably attainable permitting tests of hypotheses drawn from a plethora of personality and social psychological theories.

Attitude Functionality

Allport (1935), Fazio (1989), Katz (1960), and others maintain that attitudes are functional in the sense that they facilitate decision making. Blascovich and colleagues (1993) predicted that during a motivated performance situation requiring rapid preference decisions, individuals with preexisting task-relevant attitudes are more likely to be challenged than threatened. For example, in one of the reported studies (Blascovich et al., 1993, Study 2), the investigators manipulated preexisting attitudes by having participants repeatedly rehearse attitudes toward abstract paintings in one of two 15-item subsets of abstract paintings in the first phase of an ex-

periment. In the second phase, they required participants to rapidly express preferences for one of two paintings in each of 34 slides of randomly paired paintings entirely chosen from either the rehearsed or the nonrehearsed subsets of paintings. During the second phase, the cardiovascular response measures underlying the challenge and threat patterns were continuously recorded. The results indicated that participants in the rehearsed paintings condition exhibited the challenge pattern of cardiovascular response, and participants in the nonrehearsed paintings condition exhibited the threat pattern.

Dispositions

The cardiovascular indexes of challenge and threat have enabled researchers to investigate dispositional influences on task performance in motivated performance situations. For example, Lerner (1980) and others (e.g., Lazarus & Folkman, 1984) hypothesized that dispositional belief in a just world allows individuals to adapt better to the demands of everyday life. Tomaka and Blascovich (1994) tested this notion in a correlational study. As expected, participants high in belief in a just world exhibited the challenge pattern of cardiovascular responses, whereas participants low in belief in a just world exhibited the threat pattern during the performance a mental arithmetic task in a motivated performance situation.

In a somewhat more complex set of studies, Seery, Blascovich, Weisbuch, and Vick (2004) utilized the cardiovascular indexes of challenge and threat to test predictions based on Kernis's theory (Kernis, 1993; Kernis & Waschull, 1995) that individuals with unstable high self-esteem are plagued by self-doubt and, hence, are likely to have low resource evaluation. The results indicated that individuals with unstable high self-esteem were threatened by failure feedback in a motivated performance situation and that individuals with stable high self-esteem remained challenged.

Social Facilitation

Social facilitation effects have often been described as the oldest experimental social psychological finding and, not surprisingly, have attracted the attention of theorists for more than a century. The basic findings are that the presence of others, whether coactors or members of an audience, facilitates individual performance on a well-learned task and inhibits performance on an unlearned or novel task. Based on the biopsychosocial model of challenge and threat, Blascovich, Mendes, Hunter, and Salomon (1999) hypothesized that the presence of others increases the goal relevance of task performance regardless of previous task experience. Furthermore, they hypothesized that, based on a relative lack of resources for performance, individuals attempting performance on a novel or unlearned task should be threatened during task performance, and individuals attempting performance on a well-learned task should be challenged. These hypotheses were confirmed by cardiovascular indexes of challenge and threat.

Social Comparison

Mendes, Blascovich, Major, and Seery (2001) examined challenge and threat processes during upward and downward social comparisons. They hypothesized that participants interacting with upward-comparison others should experience threat, whereas participants interacting with downward-comparison others should experience challenge. Their experiments provided a conservative test of these hypotheses because the investigators chose a motivated performance situation that involved a cooperative rather than a competitive task. In their first experiment, as predicted, participants cooperating with upward-comparison partners exhibited the cardiovascular pattern indicative of threat, and participants cooperating with downward-comparison partners exhibited the cardiovascular pattern indicative of challenge. In their second experiment, as predicted, attitudinal dissimilarity with their partners exacerbated this pattern of responses.

Stigma

Many theorists support the hypothesis that nonstigmatized individuals experience threat, based on a sense of uncertainty, discomfort, anxiety, and even danger, when interacting with members of stigmatized groups (Crocker et al., 1998; Goffman, 1963; Jones et al., 1984). However, until recently relatively little research has directly demonstrated this widespread assumption. Blascovich, Mendes, Hunter, Lickel, and Kowai-Bell (2001) and Mendes, Blascovich, Lickel, and Hunter (2002) conducted several experiments in which the cardiovascular indexes of challenge and threat confirmed this hypothesis. The effects held whether the interactant was stigmatized by virtue of disfigurement (i.e., facial birthmark), race, or socioeconomic status.

PERIPHERAL SOMATIC INDEXES: A CASE STUDY OF POSITIVE AND NEGATIVE AFFECT

Researchers have investigated affect and emotion from a social psychological perspective since William James's classic discussion of emotions (Bradley, 2000). Much work has focused on both the universality of basic emotional experiences (e.g., Ekman & Friesen, 1986) and possible autonomic footprints (i.e., physiological indexes) of the so-called basic-level emotions. Regarding the latter, there seems to be little agreement that such indexes exist (Cacioppo et al., 1993; Stemmler, 1989). However, there has been progress in the development of physiological indexes of the relevant superordinate states, positive and negative affect.

Constructs, Candidate Physiological Indexes, and Theoretical Rationale

Principle 1: Construct Specification

As discussed earlier, one cannot establish a meaningful one-to-one relationship between a social psychological construct and a physiological response without explicitly

defining the construct that is to be indexed. In the case of positive and negative affect, several definitions have been proffered. Most appear consistent with Shaver, Schwartz, Kirson, and O'Conner's (1987) definition that positive and negative affect are superordinate categories of feeling states with positive and negative valence, respectively. Positive affect encompasses specific states such as happiness and excitement, whereas negative affect encompasses states such as sadness and fear; the specific states under each category possess unique aspects, but they also share a common positive or negative element.

Principle 2: Specification of Candidate Physiological Indexes

Cacioppo and colleagues (e.g., Cacioppo & Petty, 1981a, 1981b; Cacioppo, Petty, Losch, & Kim, 1986) promoted the use of electromyography (EMG) as a way to quantify facial expressions, which they reasoned should vary with intrapersonal affective experience. Although not the only approach to identifying candidate physiological or even somatic indexes of affect, facial muscle movements underlying facial expressions have proven one of the most fruitful. In particular, Cacioppo and colleagues focused on muscles primarily involved with smiling (zygomaticus majori) and frowning (corrugator supercilii), reasoning that smiling and frowning obviously are associated with positive and negative affect, respectively.

Principle 3: Specification of a Plausible Theoretical Physiological Rationale for Linking Candidate Physiological Measures to Social Psychological Constructs

The theoretical roots supporting the use of somatic markers of positive and negative affect rest on Darwin's (1872/1965) arguments regarding the evolutionary significance of facial expressions. In the last several decades, a substantial body of literature has emerged that has illustrated the critical role of facial expression in social interaction and the expression of affect and emotion (e.g., Ekman, 1993).

Validation of Somatic Physiological Indexes of Positive and Negative Affect

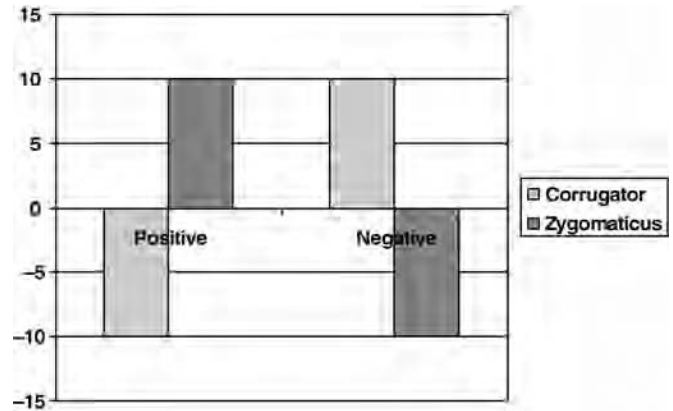
A potentially straightforward way to quantify facial expressions is to ask observers to rate them; indeed, much research has established the value of this approach, ranging from the collection of overall impressions of untrained observers to the use of video recording techniques to evaluate expressions that appear for only a fraction of a second (e.g., Ekman & Friesen, 1978). However, it is possible (and arguably common) for the muscle movements that create facial expressions to be so covert that no visible expression emerges to be coded (e.g., Cacioppo & Petty, 1979). Observational methods have little value in these situations, but somatic psychophysiological measures (i.e., EMG) can detect even minute muscle activity. This holds true even when individuals are motivated to consciously control their facial expressions (e.g., intergroup interactions); in spite of such efforts,


FIGURE 2.4. Facial electromyographic markers of positive and negative affect.

subtle leakage occurs that is accessible to EMG measurement.

For facial EMG, electrodes sensitive to muscle action potentials are placed over specific facial muscles (for procedural details and a more comprehensive review of EMG literature, see Cacioppo, Tassinary, & Fridlund, 1990; Tassinary & Cacioppo, 2000). Changes in muscle activity that occur with the onset of a relevant event (e.g., stimulus presentation, imagination, and social interaction)—regardless of whether or not visible facial expressions appear—are measured and used to index affective experience. Several elements of muscle activity can be recorded, including duration and intensity. Cacioppo and colleagues (1986) validated the use of the two candidate muscles to assess both valence and intensity of affect: zygomaticus majori ("smile muscles" in the cheeks) and corrugator supercilii ("frown muscles" in the brow). As depicted in Figure 2.4, during positive affect, zygomaticus activity increases and corrugator activity decreases, whereas during negative affect, zygomaticus activity decreases and corrugator activity increases. The theoretically based patterns of these somatic responses fit the propositions of *divergent validation, and patterns of overlapping multiple physiological responses*, thereby increasing the likelihood of achieving one-to-one relationships between the indexes and the primary constructs underlying the biopsychosocial model of challenge and threat.

In their study, Cacioppo and colleagues (1986) presented positively and negatively valenced images to participants and recorded participants' self-reported liking for each image along with EMG activity. Results confirmed the expected fractionation of zygomaticus and corrugator activity, which was also consistent with self-reported liking. In contrast, activity in unrelated muscles did not differ by image valence.

Application of Somatic Indexes of Positive and Negative Affect to Theoretical Issues in Social Psychology

Facial EMG has emerged as a valuable methodological tool in a variety of contexts. Recent examples in which

EMG was used to test social psychological theory regarding the role of affect in two research domains are described below.

Ease of Stimulus Processing

The mere exposure effect (Bornstein, 1989; Zajonc, 1968) is a robust finding in which increasing familiarity with a neutral stimulus (e.g., yearbook photos, Chinese ideographs, and polygons) breeds a more positive attitude toward it; in other words, merely being exposed repeatedly to a stimulus increases liking for it. Explanations for the mechanism that underlies the mere exposure effect fall into two general categories: cognitive explanations and affective explanations.

Cognitive explanations include the nonspecific activation model (Mandler, Nakamura, & Van Zandt, 1987) and the perceptual fluency/attributional model (Bornstein & D'Agostino, 1994). The nonspecific activation model holds that exposure to a stimulus creates a representation of it in memory, which is further activated by repeated exposure. When an individual is asked to evaluate the stimulus on a given dimension, the heightened activation associated with the stimulus's representation is applied to that dimension as long as it is relevant to the stimulus. This causes the individual to be more likely to judge that the stimulus possesses the given dimension. For example, Mandler and colleagues (1987) found that participants evaluated familiar black polygons as brighter, darker, or more likable than unfamiliar black polygons, depending only on which of the questions happened to be asked. According to the perceptual fluency/attributional model, a familiar stimulus is easier to process, which creates an affectively neutral experience of perceptual fluency. This fluency is then attributed to the most likely cause suggested by contextual cues, such as those provided by the items on a self-report questionnaire. Thus, in both cognitive models, the mere exposure effect does not depend on or include an affective component. Instead, greater liking after repeated exposure is merely an artifact of the questions posed to participants.

Affective models, in contrast, maintain that affect plays a critical role in the link between familiarity and liking. Biological and evolutionary theories suggest that an unfamiliar stimulus evokes fear innately, which is then habituated with repeated exposure (Zajonc, 1968). Hence, lack of familiarity is associated with danger and negative affect because it would be adaptive to avoid stimuli that have not demonstrated their benign nature over repeated interactions (Bornstein, 1989). Alternatively, the hedonic fluency model (Winkielman & Cacioppo, 2001) holds that the experience of fluency from cognitive models is necessarily positively valenced because it indicates that the individual possesses the skills to successfully reach a goal in the environment.

Harmon-Jones and Allen (2001) used facial EMG to pit cognitive and affective explanations against each other. After recording baseline zygomaticus and corrugator activity levels, 10 photos of women were repeatedly displayed to female participants. Participants were then shown these 10 familiar photos along with 10 unfamiliar photos of different women in a random order (the two sets of photos were counterbalanced, such that for half of the participants, the first set was made familiar, and for the other half, the second set was made familiar). Facial EMG responses were recorded during presentation and participants rated their degree of liking for each photo after its presentation.

Results revealed the typical mere exposure effect: Participants expressed greater self-reported liking for the familiar faces than for the unfamiliar ones. More important, participants exhibited greater zygomaticus activity while viewing familiar faces than while viewing unfamiliar ones, consistent with greater positive affect. Comparing these responses to baseline levels demonstrated that zygomaticus activity increased during exposure to familiar faces relative to baseline, whereas it did not differ from baseline during exposure to unfamiliar faces. There were no effects of familiarity on corrugator activity. These findings indicate that familiar stimuli engender a positive affective response that (1) is not an artifact of agreeing with self-report questions regardless of the stimulus dimension they assess and (2) does not reflect a relative difference driven by unfamiliar stimuli engendering negative affective responses. This supports affective explanations of the mere exposure effect over purely cognitive ones.

The mere exposure effect can be viewed as one example of a more general effect of stimulus processing ease: The easier a stimulus is to process, the more it will be liked, regardless of the specific presentation characteristics that facilitate processing. Winkielman and Cacioppo (2001) conducted an investigation similar to Harmon-Jones and Allen's (2001), manipulating ease of stimulus processing rather than stimulus familiarity.

In Study 1, Winkielman and Cacioppo (2001) presented participants with 20 black-and-white line drawings of common, neutrally valenced objects. Just prior to presentation of each stimulus, participants were subliminally exposed to a visual contour, created by removing all but the outer edge of a line drawing and then further degrading the image. Previous research has demonstrated that exposure to a contour that matches a subsequent target image facilitates processing of the target (e.g., Reber, Winkielman, & Schwarz, 1998); thus, for each participant, half of the targets were preceded by a matching contour and half were preceded by a mismatching contour (matching and mismatching stimuli were counterbalanced across participants). After each target presentation, half of the participants rated how positive their reaction was to the image and half rated how negative their reaction was. Facial EMG responses were recorded in the prepresentation period for each trial (baseline) and during presentation.

Results demonstrated that for participants who made the positively framed ratings, both zygomaticus activity and self-reported ratings were higher after matching contours than mismatching contours. This difference in zygomaticus activity was only significant immediately after stimulus presentation, not several seconds later. No effects emerged for corrugator activity or in the negatively framed condition.

In Study 2, Winkielman and Cacioppo (2001) conducted a conceptual replication, manipulating stimulus exposure duration instead of contour prime, with the logic that longer exposure time facilitates processing (Mackworth, 1963). The same stimuli from Study 1 were used in Study 2. Exposure duration condition (all less than 1 second) was manipulated within subjects. Instead of rating either how positive or how negative each stimulus was, all participants made a single bipolar judgment. Consistent with Study 1, results revealed that longer exposure duration resulted in both greater zygomaticus activity immediately after stimulus presentation (but not later) and more positive self-report ratings. Corrugator activity did not significantly differ by condition.

In sum, Winkielman and Cacioppo's (2001) studies demonstrate that manipulations that increase processing ease result in sudden and short-lived positive affect that is not limited to possibly artifactually self-reported responses. Together with Harmon-Jones and Allen's (2001) findings, the overall results suggest that purely cognitive explanations of the effects of processing ease are inadequate. Instead, positive affect in particular seems to play an important role. It is critical to note that this insight was made possible only with the theory-based application of facial EMG techniques, highlighting the utility of social psychophysiological methodology in general.

Prejudice and Discrimination

Facial EMG has also proven its value in the domain of prejudice and discrimination. Arguably, prejudice involves negative affect in the form of attitudinal bias toward a group of people, whereas discrimination refers to bias in behavior. A long-standing problem for researchers in this area is that people are reluctant to admit their own prejudices in the face of a social climate that values tolerance (McConahay, Hardee, & Batts, 1981). As discussed previously, physiological measures including facial EMG can avoid such self-presentation problems.

The work of Vanman and colleagues provides two illustrations of effective use of EMG in this context. In two scenario studies with white participants, Vanman, Paul, Ito, and Miller (1997) found that participants self-reported more positive affect for imagined black than white partners but exhibited EMG activity indicative of more negative affect for blacks than whites. In a third study with white participants, Vanman et al. administered the Modern Racism Scale (McConahay et al., 1981) and divided participants into high- and low-prejudice groups based on a median split. Participants then viewed a series of stimulus photos of black and white individuals, after each of which they rated the target individual's friendliness. Facial EMG was recorded during presentation of the photos. Consistent with the first two studies, results revealed that participants' self-reported friendliness ratings were higher for black targets than white targets, regardless of prejudice level. However, high-prejudice participants exhibited lower zygomaticus and higher corrugator activity during presentation of black target photos than white target photos, indicating lower positive affect and higher negative affect; in contrast,

low-prejudice participants did not significantly differ in EMG activity between target photo groups. These three studies demonstrate the value of facial EMG in measuring implicit affect underlying attitudes (i.e., prejudice), particularly when self-reported responses are likely to reflect self-presentational concerns.

Vanman, Saltz, Nathan, and Warren (2004) took an additional step, linking implicit negative affect assessed via facial EMG to discriminatory behavior. White participants first decided which of three applicants (two white, one black) should be selected for a prestigious teaching fellowship. Participants then completed the Implicit Associations Test (IAT; Greenwald, McGhee, & Schwartz, 1998), which is designed to assess implicit attitudes about race by comparing reaction times to various pairings of black/white-related words and pleasant/unpleasant-related words. Several weeks later, in an ostensibly unrelated study, participants rated the friendliness of black and white target photos while EMG activity was recorded. Vanman and colleagues computed bias scores for both zygomaticus and corrugator activity by subtracting values during exposure to photos of blacks from values during exposure to photos of whites.

Results indicated that higher zygomaticus bias (i.e., greater activity for white targets than black targets) was associated with selecting a white applicant over a black applicant, even after accounting for the higher probability of selecting a white applicant by chance. Corrugator activity and IAT score failed to predict discrimination. In combination, the findings from Vanman and colleagues (2004) not only establish facial EMG as an implicit measure of prejudice that reveals affect potentially obscured in self-reports but also support the notion that such affect may play a role in carrying out biases in behavior.

SUMMARY

The integration of social psychology and biology foreseen by Shapiro and Crider (1969) has increased markedly over time, particularly in the last decade. Furthermore, this integration has broadened from the connection between social psychology and peripheral physiology on which Shapiro and Crider focused to connections with CNS physiology and endocrine processes as well. In our view, social neuroscience including social psychophysiology is only now in its adolescent period. In our view, its further development will lead to major advances to both the psychological and biological sciences.

The connection between social psychology and peripheral physiology in particular remains viable and strong. The robustness of this connection derives from advances in many areas. The rejection of mind–body dualism and the resulting rise in a more monistic view have eliminated a major epistemological barrier between social psychology and physiology. A logical basis for drawing strong inferences from physiological indexes of social psychological constructs has been elucidated and continues to be refined. Additions to and improvements in existing technologies have enabled investigators to assess multiple peripheral physiological responses over time.

Plausible theories provide the justification for identification of peripheral physiological response patterns that reliably index social psychological constructs and processes. Finally, programmatic lines of research incorporating peripheral physiological indexes of constructs and processes have demonstrated the value of using such measures to test social psychological theories.

NOTES

1. Neither the third nor the fourth edition of the *Handbook of Social Psychology* included a social psychophysiology chapter, attesting to the perception of social psychophysiology as something less than mainstream by many in the field until recently.
2. Approximately 60 mostly social psychologists participated in these intensive, National Science Foundation supported, monthlong training sessions between 1985 and 1990.
3. Dienstbier actually used the pituitary–adrenal–cortical (PAC) axis rather than hypothalamic–pituitary–adrenal (HPA) axis nomenclature in his paper. Here we follow what we perceive to be the more modern nomenclature though we do not wish to imply anything more than PAC activity.

CHAPTER 3

Social Cognitive Neuroscience
Historical Development, Core Principles, and Future Promise

KEVIN N. OCHSNER

The supermarket checkout line provides interesting lessons about the human psyche. Beside the social norms that dictate that we stand in line and politely pay our bill, and before we encounter the disaffected teenage checker, there is the point-of-purchase magazine gambit. Strategically placed above the checkout conveyor belt are rows of magazines heralding the latest pop-culture happenings. Typically, two types of cover stories clamor for attention: those about the relationship hijinks of high-profile people and those about new businesses and technology that could "change the way we live and work." Since its emergence at the beginning of the 21st century, social cognitive neuroscience (SCN) has been purported to be both. At turns, SCN has been billed either as a hot new power coupling of social psychology and cognitive neuroscience or as a fast-growing research startup looking for investment capital.

The fact that we use relationship metaphors to describe SCN may not be that surprising. Indeed, the supermarket checkout line is a regular reminder that humans are fundamentally social beings (Fiske, 1991; Fiske, Kitayama, Markus, & Nisbett, 1998). Magazines capitalize on the facts that we care a great deal about our personal and our professional relationships and that stories and metaphors help us understand them (Lakoff, 1987, 1993). The beauty of metaphors is that when correctly applied they can help us intuitively grasp what something means. The danger of metaphors is that when incorrectly applied they can lead us to overlook important differences between the objects of comparison.

In this regard, using different relationship metaphors to describe SCN invites different types of questions about its nature. On one hand, a personal metaphor might lead to questions about how parent disciplines begat SCN, what they were thinking when they did so, and how SCN will develop and mature. On the other hand, a professional metaphor might lead to questions about SCN's business plan, principles for effective production, and growth potential.

The goal of this chapter is to address the nature of SCN. Toward that end, it uses the personal and professional relationship metaphors to organize discussion of questions about its practice, its principles, and its promise. The first section of the chapter takes the personal metaphor as a starting point for describing SCN's historical roots and developmental progression. The second section uses the professional metaphor to springboard consideration of core principles that govern its practice. The third and final section highlights promising directions for future work.

The goal of this chapter is not to describe basic psychological and neural principles that underlie a specific type of socioemotional ability. Rather, the goal is to describe the development and nature of basic principles that underlie SCN *as an approach* that can be applied to investigating any number of topics (Blakemore & Frith, 2004; Blakemore, Winston, & Frith, 2004; Ochsner & Lieberman, 2001). For principles related to specific types of ability, the reader is referred to other chapters in this volume, and to SCN work on social cognition and theory

of mind (Gallagher & Frith, 2003; Keysers & Perrett, 2004; Lieberman, 2003; Puce & Perrett, 2003; Saxe, Carey, & Kanwisher, 2004), self-reflection and self-perception (Heatherton, Macrae, & Kelley, 2004; Lieberman & Pfeifer, 2005), perception of faces and other nonverbal cues (Allison, Puce, & McCarthy, 2000; Calder et al., 2002; Haxby, Hoffman, & Gobbini, 2002), and emotion and self-regulation (Beer, Shimamura, & Knight, 2004; Ochsner & Feldman Barrett, 2001; Ochsner & Gross, 2004, 2005; Ochsner & Schacter, 2000).

WHAT'S IN A NAME?: TRACING THE HISTORICAL DEVELOPMENT OF SOCIAL COGNITIVE NEUROSCIENCE

The German psychologist Hermann Ebbinghaus (1908) once wrote, "Psychology has a long past, but a short history," by which he meant that the roots of modern psychological inquiry run long and deep, but the field operates as if current psychological research is a recent development. The same might be said of SCN: Amid attention to its recent growth and development, lessons from its long past may be overlooked. In this section, we chronicle some of the past and present debates and disciplines that have contributed to SCN's gene pool and some developmental milestones that have marked its growth. The goal is to understand the interdisciplinary origins of SCN, its relationships to allied fields, and how and why SCN has a distinct identity.

The Genealogical Tree: From Animal Models to Phineas Gage

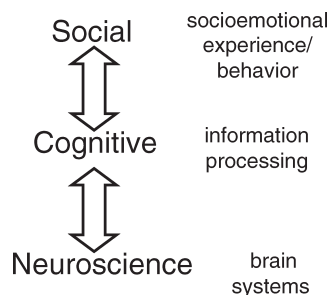
As illustrated in Figure 3.1, SCN is an interdisciplinary field that seeks to explain social phenomena at three levels of analysis: the social level of behavior and experience, the cognitive level of mental representations and processes, and the neuroscience level of brain systems. Although articles, laboratories, and conferences bearing the name "social cognitive neuroscience" have only appeared since the turn of the century, SCN has a long and important ancestry.


FIGURE 3.1. The three levels of analysis for social cognitive neuroscience.

SCN's Close Relatives

During the past century there have been a number of important findings in psychology and neuroscience that can be seen as precursors to SCN. The majority of this work has been done with animal models, with interest in human work growing during the past quarter century.

A LONG LINE OF ANIMAL MODELS

A great deal of work on the brain bases of social emotional behavior has employed animal models. In general, this work has followed two threads. The first concerns the study of prosocial behavior. Some of the earliest and best-known examples of this work came from Harry Harlow, whose studies of the effects of maternal deprivation on the development of social function in young primates is still cited an introductory textbooks today (Harlow, Dodsworth, & Harlow, 1965; Harlow & Harlow, 1962). In a similar vein, the classic studies of Kluver and Bucy purported to show that damage to the inferior temporal lobes resulted in a severe disruption of sexual, feeding, social, and maternal behavior (Kluver & Bucy, 1939). Modern work, however, has demonstrated that these effects are not wholly reliable. For example, Amaral and others have shown that the specific deficits observed in social function (e.g., showing either social disinhibition or fear of conspecifics) may depend on the specific location of cortical lesion in the temporal lobe, and in particular on the nature and extent of the damage to the amygdala (Amaral et al., 2003; Bauman, Lavenex, Mason, Capitanio, & Amaral, 2004a, 2004b). Consistent associations between impaired primate social behavior and damage to the amygdala and orbitofrontal cortex (among other regions) led Brothers (1990) to hypothesize that these systems together comprise a "social brain." Complementary work in rodents has less often concerned the amygdala, but more often other subcortical nuclei and neurohormonal factors important for mating, pair bonding, or maternal care. For example, Insel and colleagues have shown that oxytocin and vasopressin are important for promoting memory for and bonds with conspecifics (Insel & Fernald, 2004), and Meaney and colleagues have shown that early pup experiences of maternal licking and grooming set a threshold for subsequent responses to stress manifested at multiple levels of the neuroaxis (Meaney, 2001).

The second thread in animal research has emphasized the motivational and emotional, rather than the social, aspects of behavior. Some of the earliest work of this kind appeared during the first half of the century when numerous brain stimulation and lesion studies identified subcortical nuclei essential for the manifestation of various types of species-specific aggressive, fearful, and sexual behaviors (e.g., Davey, Kaada, & Fulton, 1949; Fangel & Kaada, 1960; Kaada, Andersen, & Jansen, 1954). This work was the impetus for some of the first "neural circuit" theories of emotion (e.g., Cannon, 1987; Papez, 1958). Building on this work, Paul MacLean later advanced the concept of the triune brain, alluded to above,

in which impulses for both prosocial (e.g., play and maternal care) and defensive (e.g., aggression and flight) behavior depended on evolutionarily old brain systems humans share with other mammals (MacLean, 1969). Higher neocortical systems were thought to control the expression of these innate drives, motivations, and emotions. Following MacLean's lead, Panksepp (1998) later described multiple subcortical neural systems dedicated to distinct motivated and/or emotional behaviors, ranging from play to maternal care to aggression and love. Then, in the late 1980s, emotion came to the fore in neuroscience with LeDoux's (2000) seminal work on the role of the amygdala in conditioned fear.

RECENT REEMERGENCE OF HUMAN RESEARCH

Interestingly, in comparison to animal work that has seen decades of concerted effort, human research on the neural systems involved in social and emotional behavior has been slow to develop. This has not been due to a lack of early interest in these questions, however, either from social psychologists or from neuroscientists. As is recognized increasingly today (e.g., Heatherton, 2004), social psychologists early on recognized the importance of understanding the brain bases of social behavior. In one of the first social psychology textbooks, Floyd Allport (1924) wrote:

> The chief contributions of the cortex to social behavior may be summarized as follows: It underlies all solutions of human problems, which are also social problems, and makes possible their preservation in language, customs, institutions, and inventions. It enables each new generation to profit by the experience of others in learning this transmitted lore of civilization. It establishes habits of response in the individual for social as well as for individual ends, inhibiting and modifying primitive self-seeking reflexes into activities which adjust the individual to the social as well as to the non-social environment. Socialized behavior is thus the supreme achievement of the cortex. (p. 31)

Similar early emphasis can be found in one of the most famous neuropsychological cases of all time, which concerned disruptions of socioemotional behavior. In the late 1800s the "mysterious" case of Phineas Gage was well documented and generated great interest (Goldenberg, 2004; Macmillan, 2000). After damage to his orbitofrontal cortex in a freak railroad construction accident, Gage was described as being "no longer Gage." Gage had intact cognitive faculties but apparently diminished ability to conform to social norms (making lewd comments, inappropriate jokes, displaying inappropriate affect, etc.).

Despite this early interest, human research on the social or emotional brain was largely absent until the 1980s. The reasons for this dry spell are likely fourfold. First, it was during the first half of the 20th century that radical behaviorism was the dominant force in psychology. Because behaviorism was decidedly and antagonistically nonmentalistic, and social and emotional behaviors have a strong experiential component, the study of such behaviors was left out of the research mix.[1] Second, as described earlier, socioemotional behaviors often have been conceived as more primitive and animalistic than are our so-called higher cognitive faculties. In a sense, affect was noise in the cognitive signal, and the effects of affect were to be eliminated. Thus, when the yoke of behaviorism was cast aside and the cognitive revolution reintroduced mentalistic concepts to psychology, emotion again was left out of the cognitive science research mix (Gardner, 1985). Third, both in behaviorism and in cognitive science (as well as their descendants—behavioral neuroscience and cognitive neuroscience) there has been an emphasis on identifying species-general principles that govern behavior. This emphasis on the general leaves out social and emotional factors that vary by individuals and by contexts. Fourth, and last, psychologists and neuroscientists simply lacked the tools to easily and precisely study the brain bases of socioemotional phenomena in humans. Animal researchers could stimulate or ablate brain systems, but human researchers were left to the study the consequences of uncommon brain-damaging accidents of nature (such as stroke).

An early challenge to this status quo came from social psychology in the 1980s, when the use of peripheral psychophysiological measures to index autonomic nervous system (ANS) activity seemed to promise a means for studying the linkage between psychological and biological mechanisms governing social behavior. Unfortunately, such measures turned out to have only limited value for this purpose because (1) they do not directly measure the operation of the brain systems that implement psychological processes and (2) the measures themselves often show little differentiation across qualitatively different task contexts. As a consequence, correlations often are weak between ANS measures and either self-report or performance measures of behavior (Cacioppo, Berntson, Larsen, Poehlmann, & Ito, 2000), which renders these measures suitable for studying the *physiological consequences* of particular types of emotion or thought but less well-suited for drawing inferences about *information-processing mechanisms* (Blascovich, Mendes, Tomaka, Salomon, & Seery, 2003; Tomaka, Blascovich, Kibler, & Ernst, 1997; Wright & Kirby, 2003).

Be that as it may, interest in human neuropsychological research on the brain bases of socioemotional behavior was growing slowly, and appeared on multiple fronts in the 1980s. Examples include, but are not limited to, research on the involvement of the right hemisphere in nonliteral aspects of language, such as humor and metaphor (Brownell, Simpson, Bihrle, Potter, & Gardner, 1990; Kaplan, Brownell, Jacobs, & Gardner, 1990; Winner, Brownell, Happe, Blum, & Pincus, 1998); studies of the psychological mechanisms underlying face perception and their breakdown in prosopagnosia (Ellis, 1992; Farah, 1990; Young & Ellis, 1989); descriptions of Capgras syndrome, which involves delusions that loved ones have been replaced by exact replicas (Ellis & Lewis, 2001); demonstrations that amnesics who lack explicit memory for melodies or encounters with people nonetheless can acquire preferences for them (Johnson, Kim,

& Risse, 1985); conceptually sophisticated psychophysiological work demonstrating distinct patterns for appraisals of threat versus challenge (Blascovich et al., 1992; Tomaka et al., 1997); scalp electrophysiological studies identifying cortical correlates of attitudes and evaluations (Cacioppo, Crites, Gardner, & Berntson, 1994; Crites, Cacioppo, Gardner, & Berntson, 1995); and a resurgence of interest in the effects on decision making and social behavior of orbitofrontal lesions like those suffered by Phineas Gage (Bechara, Damasio, & Damasio, 2000; Beer, Heerey, Keltner, Scabini, & Knight, 2003; Damasio, 1994).

This work set the stage for increased availability and common usage of functional imaging techniques such as positron emotion tomography in the mid-1980s, and functional MRI in the early 1990s, which enabled researchers to study the cortical and subcortical brain bases of phenomena in healthy normal individuals. The first topics to be studied using functional imaging were classic cognitive psychological phenomena involving language, attention, memory, and vision. This was due in large part to the fact that many of the best cognitive psychologists quickly became cognitive neuroscientists, and imaging work on their topics of interest has dominated cognitive neuroscience since its inception. But in the late 1990s, something changed and a new field emerged that was devoted specifically to the use of neuroscience methods to study the brain bases of socioemotional phenomena.

From Zeitgeist to Distinct Identity

What was it that changed? The preceding review points to the development of a Zeitgeist with three crucial elements. First, salient animal (e.g., work of LeDoux and Panksepp) and human (e.g., work of Damasio) studies of social and emotional behavior had achieved a great deal of notoriety, in part because they represented modern approaches to classic problems in both biological and social science that were discussed earlier. Second, functional imaging had become highly accessible in many research institutions, and high-profile imaging publications regularly received a great deal of attention. For researchers across many disciplines, these two factors made salient the questions and methodologies that when combined later would form the basis of social cognitive neuroscience.

Of course, as described previously, researchers have been using neuroscience methods to study questions about socioemotional phenomena for quite a long time. But researchers had not yet realized that the seemingly disparate strands of research listed earlier could be woven into a coherent whole. The third element of the Zeitgeist helped spark this realization. This element was a research climate very favorable to interdisciplinary research in which the past two decades had seen numerous new terms coined to describe distinct interdisciplinary fields. For example, the term "social cognition" came into common usage in the early 1980s to refer to the use of cognitive psychological theories and methods to study phenomena typically of interest to social psychologists. Then in the late 1980s, the term "cognitive neurosci-

ence" was coined to refer to the use of neuroscience methods to study the brain bases of phenomena typically studied by cognitive psychologists. In the early 1990s, the term "social neuroscience" was coined to refer quite broadly to any research that linked the biological and social levels of analysis. This move broadened the use of an earlier term, "social psychophysiology," which had been used to describe the initially promising but ultimately limited movement in social psychology (described earlier) toward using peripheral autonomic measures as indices of underlying psychological processes. And finally, in the 1990s, the term "affective neuroscience" gave a name to the growing area of research (also described earlier) aimed at discovering the affective/emotional functions of specific brain systems.

In this context, social psychologists and cognitive neuroscientists in a number of locations began to use the term "social cognitive neuroscience" to refer to the use of cognitive neuroscience methods to study socioemotional phenomena. The first papers using the term described SCN as a marriage between social cognition on the one hand and cognitive neuroscience on the other (Lieberman, 2000; Ochsner & Lieberman, 2001; Ochsner & Schacter, 2000). Two motivations prompted the use of this term. First, it was thought to provide an accurate label for a new kind of interdisciplinary research that capitalized on what its parent disciplines have in common, at the same time making good use of their unique strengths. Both social cognition and cognitive neuroscience are concerned with information-processing mechanisms: whereas social cognition links the study of particular kinds of intra- and interpersonal experiences and behaviors to information-processing models of psychological mechanisms, cognitive neuroscience links these models to their neural substrates using neuropsychological, electrophysiological, and functional imaging methodologies. SCN puts it all together. The second motivation was pragmatic. It was hoped that the term "social cognitive neuroscience" might be intuitively appealing to both social cognition and cognitive neuroscience researchers who would see the name of their field in the new term and might therefore be encouraged to participate in it. Despite these principled hopes, however, in actual practice the nature of a field is defined by those who work within it. And as usage of the term "SCN" began to grow, important questions arose about the boundaries of the field.

Staking a Claim to a Research Domain

Questions about the domain and scope of a new research domain are common and important to address during its formative years. In the case of SCN, at least two important questions concerning its scope and boundaries need to be addressed.

The first question is simply whether it is useful to try to define a distinct new area of research. Or, in other words: With all those other interdisciplinary fields and subfields already out there, why coin a term for a new one? The answer, of course, depends on whether the new field is truly distinct, and whether the new term proves useful for

guiding, promoting, and drawing new researchers into conducting a specific and potentially new kind of research. In this regard, it is useful to consider SCN's relationship to its closest neighbors: *social neuroscience* (SN)*, affective neuroscience* (AN), and *cognitive neuroscience* (CN)*. Each of these terms and the fields they define have been around for a decade or more.

In the case of SN, although the term originally was intended to be quite broad, within psychology, "SN" initially was used to describe human studies that linked social variables to psychophysiological, endocrine, and immunological measures (Cacioppo, 1994). Animal researchers also began using the term "SN" to describe their research linking neuroendocrine and subcortical brain systems to affiliate and bonding behaviors (Insel & Fernald, 2004). In this context SCN was a newer term that appealed to social cognition and cognitive neuroscience researchers who did not identify themselves with the types of research SN had been used to describe previously. Similarly, the term "affective neuroscience" had been used most often by animal and clinical researchers studying the cortical and subcortical bases of so-called basic emotions and their role in affective disorders (Davidson, Jackson, & Kalin, 2000; Panksepp, 1998). Researchers interested in SCN also were interested in affect but construed more broadly the range of affect-related phenomena they wished to address. For SCN, this range included phenomena not typically of interest to affective neuroscientists such as attitudes, stereotyping, person perception, self-reflection, and decision making. An interest in such topics also differentiates SCN from CN, whose domain is typically conceived as the study of so-called basic mental abilities, such as memory and attention, that may be deployed in any number of social or nonsocial contexts. Thus, the term "SCN" appealed to researchers who (1) were interested in using cognitive neuroscience methods to study a wide array of socio-emotional phenomena, (2) wanted to use this combined methodology to elucidate the information processing level of analysis, and (3) did not identify with the types of research questions and content areas previously associated with related fields, such as SN, AN, and CN.

That being said, the kinds of research to which a given term refers are somewhat fluid, and certainly evolve over time. For example, some researchers use the terms "SN" and "SCN" interchangeably, whereas others see them as distinct but interrelated. Perhaps the most useful way to think about this issue is in terms of a part–whole relationship. As originally intended, SN can be used broadly to describe many types of research that link social phenomena to their biological substrates described at any one of many levels of analysis, ranging from the cortical region to the neurotransmitter system. By contrast, SCN refers to an important subset of this larger domain, where researchers specifically integrate social cognitive and cognitive neuroscientific methods (see Figure 3.6, and the section "Mapping a Road Toward the Future").

This brings us to the second question facing an emerging field of research: What are its boundaries? Or in the case of SCN, what is *social* about SCN?[2] A partial answer to this question was provided by examining historical boundaries between disciplines that help define the relationship of SCN to its neighbors. For the rest of the answer one must understand that what is *social* about SCN is determined in large part by the proclivities of researchers who call themselves *social cognitive neuroscientists*.

Primarily two types of researchers have rallied around the SCN flag. Many are cognitive neuroscientists who bring with them numerous habits and assumptions about the way in which any type of phenomenon should be studied using neuroscience methodologies. As discussed later, this has led them to favor the use of memory, perception, and attention paradigms to study neural responses to visual perceptual stimuli that have social signal value (such as faces). For these researchers, what is *social* about SCN is that the purview of cognitive neuroscience has been broadened to include the processing of "basic" social stimuli.

The other main group drawn to SCN are social cognition researchers who also bring with them some important assumptions. In particular, they are interested in studying a much wider range of phenomena. Indeed, social psychology's purview includes the study of a wide variety of interpersonal phenomena, ranging from nonverbal perception to persuasion, as well as many intrapersonal phenomena, such as self-perception and self-regulation. For a social cognition researcher, what is *social* about SCN is that involves unpacking what is special about the way people—with all their motivations, goals, and contexts—process stimuli, and what happens when the stimuli are themselves social. As is discussed in the section, "Principles Governing the Practice of SCN," incorporates both of these perspectives in its core principles concerning the types of *contexts* and *content* with which the field is concerned.

Following the Parent's Lead: Taking One Step Down to Take Many Steps Forward

SCN is in the interesting position of viewing itself either as *social cognition* plus *neuroscience* methods or as *cognitive neuroscience* plus *social* content. However one views it, the new addition can be seen as broadening its scope, explanatory power, and conceptual breadth beyond that of its parent discipline. The addition of a new level of analysis to an existing area of research is old hat for social cognition and cognitive neuroscience, for similar transitions were responsible for the inception of each of these parent disciplines.

In the case of social psychology, a shift down one level of analysis from the social to the information-processing level marked the birth of social cognition. This shift has been credited as providing an answer to the, "crisis in social psychology" that happened in the late 1970s (Taylor, 1998). At that time social psychology lacked a unifying conceptual framework to describe the similarities and differences between different phenomena. Researchers working on seemingly similar topics came up with their own individualized lists of factors that predicted long lists of dependent variables. The information-processing language of cognitive psychology offered a way out: by

appealing to concepts such as automatic and controlled processing, accessibility and spreading activation, selective attention, and schemas and scripts, social psychologists could start providing theoretical explanations that described the processes linking these lists together, which gave their theories greater coherence and staying power.

The case of cognitive neuroscience is quite parallel: Its birth was marked by a shift down one level of analysis from the information-processing level to the level of neural substrates. This move was prompted by a number of factors, not the least of which was a desire to use new methodologies to obtain new kinds of data that can help constrain information-processing models of cognitive phenomena (Ochsner & Kosslyn, 1999; Posner & DiGirolamo, 2000). As has been described in greater detail elsewhere, neuroscience has been used to provide converging evidence concerning the existence of multiple memory systems, the nature of mental representations underlying visual mental imagery, and the fractionation of attention into multiple interacting subsystems (e.g., Kosslyn, Ganis, & Thompson, 2001; Posner & Petersen, 1990; Schacter, 1997). For cognitive psychologists, the power of neuroscience methods is that patterns of brain activations or neuropsychological deficits can be used to draw inferences about the number and nature of underlying psychological mechanisms (Kosslyn, 1999; Ochsner & Lieberman, 2001).

By taking a step down, social psychology became social cognition,[3] and cognitive psychology became cognitive neuroscience. Thereafter, each field took many conceptual and empirical steps forward. SCN's emergence can be construed as either other a step down for social cognition or a step up for cognitive neuroscience. Either way, SCN is following in its parent's footsteps.

From Conception to Coherence: Milestones on the Road to Maturity

Once the term "SCN" began being used and gained currency in the research world, investigators scattered across numerous disciplines began to feel that they might share an identity. One of the key events in the crystallization of a singular identity for SCN was the first stand-alone meeting dedicated to the topic held in April 2001 at UCLA. This 2½-day meeting was organized not just by social psychologists and cognitive neuroscientists, but also by developmental psychologists, anthropologists, and political scientists. The meeting included attendees from all these disciplines and more, ranging from health psychology to behavioral neuroscience. The makeup of the organizers and attendees of this meeting is significant because it signaled that from the get-go, SCN offered a banner under which scientists interested in studying socioemotional phenomena at multiple levels of analysis could rally and find like-minded individuals whose work would be very relevant to their own.

In this regard, the role of developmental psychology in the growth of SCN is particularly important. Developmental psychologists had used the term "theory of mind" to describe the social and emotional deficits suffered by children with autism. Such children do not understand that other humans are agentic beings guided by internal mental states that describe goals, feelings, wants, and desires. Rather, they perceive other humans to be "sacks of flesh" that move unpredictably (Baron-Cohen, 1995). Psychologists studying autism had already been developing models of the disorder that cut across the social, information-processing, and neural levels of analysis. This multilevel approach was exemplified by the 1995 book *Mindblindness*, by Simon Baron-Cohen, which presented an empirical and theoretical account of autism that interpreted behavioral experiments in terms of hypothetical neural substrates. This book can be seen as one of the earliest examples of a social cognitive neuroscience analysis of a phenomenon, even though it predated the coalescence of the field. As described below, from the outset one of the strongest research programs within SCN concerned the neural bases of the social cognitive processes that support theory of mind and related abilities.

Since the UCLA conference, there have been numerous markers of growth in SCN research. Small private conferences dedicated solely to SCN work have been held at institutions such as Dartmouth, the University of Chicago, and Princeton. On the national level, starting in 2004 SCN preconferences were held prior to the annual meetings of the Society for Personality and Social Psychology and the Cognitive Neuroscience Society. The first jobs specifically advertising for positions with a focus on SCN were listed for Dartmouth in 2000 and Columbia in 2002. By 2006, postings for social psychology jobs with an SCN focus had become common. Undergraduate and graduate courses in SCN and related topics mushroomed, with growth in graduate programs offering training in SCN keeping pace. SCN's growth also has been apparent in the numerous special issues devoted to the topic that appeared in both psychology and neuroscience journals, including *Neuropsychologia*, *Journal of Personality and Social Psychology*, *Political Psychology*, *Journal of Cognitive Neuroscience*, *Neuroimage*, and *Cognitive Brain Research*.

But perhaps the most important developmental milestone for SCN has been the availability of funding from national agencies. In 1999 and 2000 the National Science Foundation (NSF) awarded Small Grants for Emerging Research (SGER, or "sugar" grants) to numerous researchers seeking to establish SCN research programs on numerous topics, ranging from stereotyping and person perception to self reflection and emotion regulation. These grants were awarded at the discretion of the director of behavioral science at NSF, Steven Breckler, who sought to provide seed money that would enable researchers to acquire pilot data for future grant applications. Then in 2001 the National Institute of Mental Health issued a Request for Applications (RFA) in social neuroscience, which provided the first opportunity for SCN researchers to apply for funding to a program specifically designed to meet the needs of interdisciplinary work linking social behavior to its neural bases. By 2005, other agencies, such as the National Institute on Drug Abuse and the National Institute on Aging, had issued similar RFAs.

The importance of funding for launching a new field cannot be underestimated. As an illustration of this point, consider the rapid growth of cognitive neuroscience in the early 1990s. Throughout the 1990s the private McDonnell-Pew Foundation provided substantial grants to researchers seeking to develop CN research programs, to train postdoctoral fellows, and to hold conferences. Other private foundations also provided money for small meetings that helped establish core groups of scientists whose work would exemplify the CN approach (M. S. Gazzaniga, personal communication). Although other factors played important roles, including a summer training institute at Dartmouth as well as an annual meeting and society, the availability of money, and the vote of confidence it implies, is essential for the development of any field. In this regard, SCN has been recognized as a distinct field by federal funding agencies. In the final section of this chapter, we revisit the topic of funding in the context of translational research that connects basic findings in SCN to clinical disorders characterized by socioemotional deficits.

PRINCIPLES GOVERNING THE PRACTICE OF SOCIAL COGNITIVE NEUROSCIENCE

In an American twist on the sentiments Ebbinghaus expressed earlier, Yale psychologist Neil Miller once quipped that "In most disciplines the scientists of today stand on the shoulders of the great scientists that have come before them. In Psychology, we step on their face" (S. Kosslyn, personal communication). The observation that psychologists don't just forget the past but actively may try to erase it may be an academic reflection of the market-driven mentality of Western culture. In the capitalist marketplace businesses compete for consumer dollars by marketing products as if no similar products ever had been offered before. Cars, cameras, and cookies are all the newest, most unique, and most satisfying. To the extent that product placements appeal to history, it is to emphasize that a particular product is the newest exemplar of a long line of products that always have been the most unique and most satisfying.

Miller is suggesting that psychologists are no different. Psychologists are essentially academic business-people hocking their theories and results in the marketplace of ideas. The consequence is that researchers often present their work in an historical vacuum that emphasizes their unique contributions at the expense of relating it to prior work.[4] Importantly, the tendency to ignore research peers is present not just at the level of the individual scientist but at the level of the scientific discipline as well. It is easy for researchers in either the traditionally "hard," biological and physical sciences or the traditionally "soft," social sciences, to believe that their cross-disciplinary colleagues can—and perhaps should—be ignored. Whether it is because their colleagues across the research fence are perceived to ask fundamentally different types of questions, to use fundamentally different kinds of methods, or to offer fundamentally uninteresting answers,

it is clear that many biological and social scientists do not buy what their colleagues have to offer.

This all-too-human tendency to value one's kin, one's comrades, and one's research culture over those of others is as much a danger for SCN as it is for any discipline. The costs of such disciplinary myopia could be especially acute, however, for SCN. Because the field requires incorporation of the methods and theories of different disciplines, researchers who "go it alone" risk making conceptual and methodological mistakes both naive and serious. As illustrated in this section, whereas in *principle* SCN work prioritizes interdisciplinary collaboration, integrative methodology, and multilevel theory, in *practice* this does not always turn out to be the case. This section highlights core principles that govern the psychology–neuroscience partnership that lies at the heart of SCN by illustrating the partnership with examples of problems that may arise if it is not honored. These examples are then used to distill four core principles for SCN.

Specifying the Goals of SCN Research

There are two types of goals that motivate SCN research in particular, and more generally, any research seeking to link psychological and neural levels of analysis (Ochsner & Lieberman, 2001; Sarter, Berntson, & Cacioppo, 1996). The first goal is sometimes referred to as brain mapping, which means conducting experiments that link the involvement of specific brain regions to specific types of behavior and experience. The emphasis here is on drawing *functional inferences* about brain systems by carefully manipulating task demands and observing corresponded changes in the recruitment of brain regions. Research conducted in this mode is necessary to draw *functional inference* about the processes associated with specific brain systems. Drawing *functional inferences* has been the primary goal guiding CN and AN research, which has produced detailed models of the neural systems involved in both high- and low-level visual cognition, implicit and explicit memory, visual mental imagery, fear conditioning, and numerous other phenomena (see Gazzaniga, 1995, 2000, 2004, for reviews).

These models of brain function provide the foundation for work guided by the second goal of SCN research, which is to use information about brain function to draw inferences about the psychological processes underlying a particular phenomena. The emphasis here is on drawing *psychological inferences* about the processes underlying a given behavior or experience by using the activation of particular brain systems as markers for the occurrence of particular kinds of psychological processes. The strength of these *psychological inferences* depends on the reliability with which particular functions can be ascribed to particular brain systems. For example, in the case of some psychological processes that have received a great deal of empirical attention, such as the encoding and retrieval of explicit memories, the reliability of these inferences is fairly strong: One can be reasonably certain that, for example, activation of the hippocampus reflects recruitment of a process used to encode configurations of activated perceptual inputs and stored representations that

together comprise an explicitly addressable memory for a life episode (Brewer, Zhao, Desmond, Glover, & Gabrieli, 1998; Davachi, Mitchell, & Wagner, 2003; Schacter, Alpert, Savage, Rauch, & Albert, 1996). By contrast, the neural bases of many emotional and social cognitive processes of particular interest to SCN have just begun to be investigated. This means that one must be careful when drawing psychological inferences based on patterns of brain activity whose association with specific brain regions has yet to be solidified.

The reciprocal interplay of these two goals in guiding research design and inference is illustrated in Figure 3.2. In a sense, every experiment is serving both of these goals by (1) providing additional information about psychological processes that elicit activation in particular regions of the brain and (2) requiring that we place these results in the context of previous research to draw inferences about the psychological processes that observed activations represent. Decades of neuropsychological and neurological study combined with 15–20 years of functional imaging research has provided a reasonable set of methodological tools and theoretical models for understanding the function of brain systems implicated in memory, attention, language, and other "classically cognitive" processes (Gazzaniga, 1995, 2000, 2004). Work on core self-referential, social cognitive, and emotional processes builds on this foundation.

In Practice, How Are These Goals Achieved?

Whichever goal guides a specific experiment, one must be careful that (1) the experiment is designed to maximize the potential for drawing the strongest inferences possible about either brain function, psychological processes, or both; (2) one appropriately interprets the meaning of one's results in the context of other studies. As is argued below, the probability that these two constraints are satisfied may vary as a function of whether one approaches SCN research as an extension of one's existing field (i.e., adding neuroscience data to social psychology or social phenomena to cognitive neuroscience) or whether one treats SCN as a true interdisciplinary partnership that draws on the theories and methods of both fields simultaneously.

Potential Pitfalls of Market Expansion

The former approach is analogous to market expansion in business: Just as a corporation might decide to expand from supplying automobile engines to making the entire automobile, social psychologists and cognitive neuroscientists might decide to expand their domain of inquiry to include the neural or social levels of analysis. As discussed in the first section of this chapter, the development of SCN can be described as involving exactly this type of market expansion on the part of SCN's parent disciplines. However, for this expansion to be successful, one must acquire the expertise necessary to succeed in the new market. An engine maker turned automobile manufacturer would surely fail if it did not incorporate principles of ergonomics when designing a car interior, principles of materials science when selecting the rubber for tires, and so on. In the context of SCN, a failure to acquire either the necessary neuroscience or social psychological expertise can result in experiments that either draw improper functional inferences, that lack an organizing meta-theory, or both.

Psychological Inference

Infer operation of psychological process from patterns of brain activation

Brain System

Psychological Process

Functional Inference

Infer psychological function of brain system from covariance with behavior and experience

FIGURE 3.2. SCN seeks to draw two types of inferences concerning the relationship between psychological and brain processes. The first are functional inferences about patterns of experience and behavior to the operation of specific brain systems. The second are psychological inferences concerning the mental processes underlying a given experience behavior. In the case of functional imaging experiments, drawing these inferences depends on being able to reliably associate specific functions with specific brain systems based on prior research. For detail and explanation, see the section "Specifying the Goals of SCN Research."

THE FAULTS AND FOIBLES OF FUNCTIONAL INFERENCE

To illustrate one important danger of market expansion without acquiring proper expertise, consider the case of a social psychologist who wishes to use functional imaging to deepen her understanding of the way in which we make predictions about our emotional states. This kind of prediction is known as an *affective forecast*, and behavioral studies have suggested that there are numerous ways in which we overpredict the duration of our negative emotions and underestimate our ability to cope with adversity (Gilbert & Wilson, 2000). Let us imagine that this researcher would like to use functional magnetic resonance imaging (fMRI) to draw inferences about the psychological processes supporting affective forecasts about the near and far future. Her hypothesis is that judgments about the near future might evoke strong emotional responses whereas judgments about the far future might be made in a cold, abstract and propositional fashion (Eyal, Liberman, Trope, & Walther, 2004; Trope & Liberman,

2003). To test this hypothesis she records brain activity while participants make judgments about how they would feel about a hypothetical event (e.g., winning the lottery) if it took place in the near future (tomorrow) as compared to the far future (in a year). She knows that analysis of imaging data is similar to analysis of the behavioral data in that it involves contrasts of values on dependent measures in two conditions of interest. Thus, to identify brain regions more strongly associated with near forecasts, she subtracts activation on *far* trials from activation on *near* trials. To identify regions associated with far forecasts, she does the reverse, subtracting activation on *near* trials from activation on *far* trials. As illustrated in all four panels of Figure 3.3, the *near > far* contrast reveals greater activation in a region of medial prefrontal cortex (MPFC) identified by the crosshatched square.

What inference can she draw about the relationship of MPFC activation to her initial hypothesis? To address this question, she turns to the imaging literature on emotion and finds 48 different studies that show activation in MPFC when participants are perceiving, remembering, or experiencing emotion. As can be seen in Figure 3.3A–3.3D, the region identified in her *near > far* forecasts contrast lies in the middle of these emotion-related activations. She concludes that her initial hypothesis is supported—that near forecasts are more emotional than far forecasts—and proceeds to write up her results and

sends them to a well-known cognitive neuroscience journal for publication.

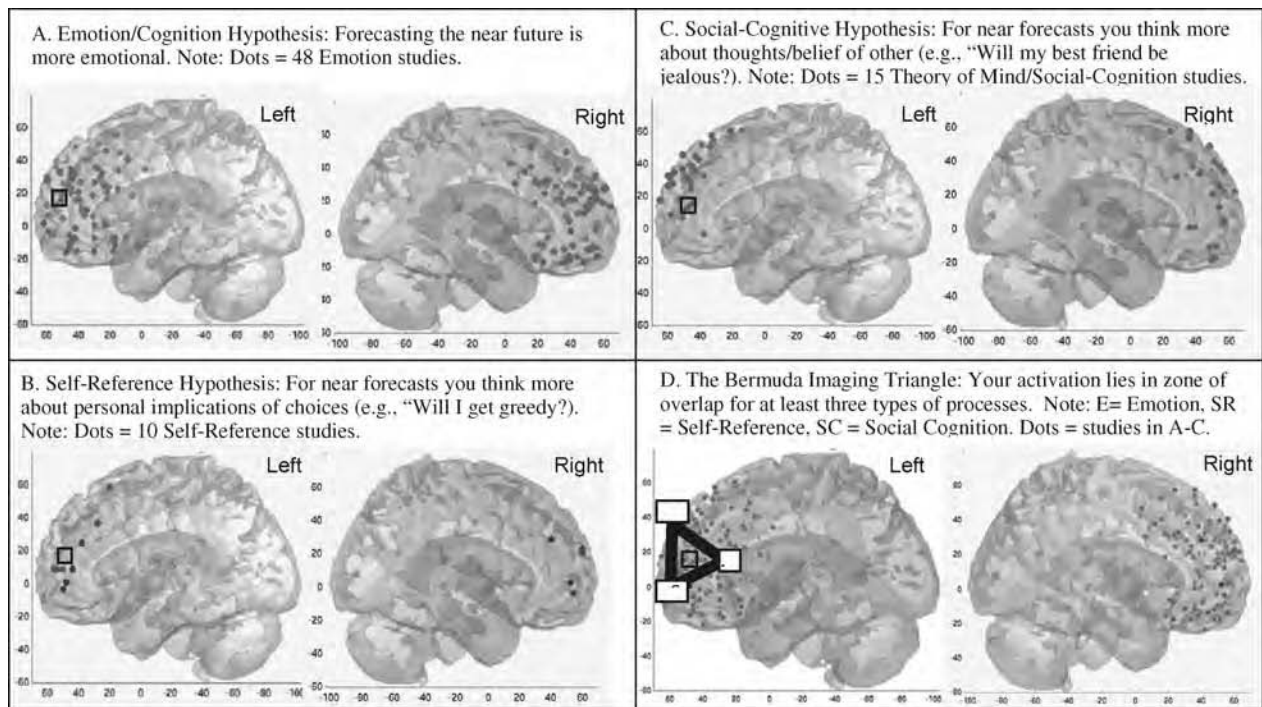
What might her reviewers say about this paper? Imagine that the paper receives three reviews. Reviewer A is an affective neuroscience researcher whose work has suggested that emotion activates MPFC (see Figure 3.3A). Reviewer A therefore writes a positive review suggesting that this is an innovative application of imaging research to address social psychological questions. Reviewer B, however, does not write a positive review. Reviewer B is a cognitive neuroscience researcher who has found that self-referential judgments activate MPFC (see Figure 3.3B), and Reviewer B suggests that the experiment has failed to rule out an alternate hypothesis: when making *near* forecasts participants might be more likely to think about the personal implications of their choices (e.g., If I win the lottery, will I get greedy? Will it change me?). Reviewer B reasons that engagement of self-reflective judgments recruits MPFC and could be the reason the social psychologist observed MPFC activation in her experiment. Reviewer C also writes a negative review. Reviewer C is a cognitive neuroscience researcher who has found that theory-of-mind tasks activate MPFC (see Figure 3.3C), and C suggests that the experiment has failed to rule out another alternate hypothesis: When making *near* forecasts individuals are more likely to think about the thoughts, beliefs, and feelings of other people (e.g., If I


FIGURE 3.3. A diagrammatic illustration of the difficulty of inferring the operation of specific psychological processes given the one has observed activation in a specific brain region, such as medial prefrontal cortex (MPFC). Activation for a hypothetical affective forecasting task is illustrated by the crosshatched square superimposed over the left MPFC. Across panels A–C, MPFC activation is superimposed on images showing activation associated with emotion (A), self-referential judgments (B), and social cognitive attributions (C). For detail and explanation, see the section "The Faults and Foibles of Functional Inference" for details.

win the lottery, will my best friend be jealous? What will my wife think? Will my coworkers think I'm cool?). Reviewer C reasons that engagement of social-cognitive judgments recruit MPFC and could be the reason the social psychologist observed MPFC activation in her experiment.

At this point, the poor social psychologist might feel that she has been caught in what could be called the *Bermuda Imaging Triangle* (Figure 3.3D) from which her paper cannot escape. Because her focus of activation lies in a zone of overlap for studies that involve three (or more) putatively different types of psychological processes, it is difficult to draw post hoc inferences about what her pattern of activation means. As a consequence, the social psychologist could be perceived as naive by neuroscientists, her paper could be rejected, and she may feel confused and lose confidence that imaging can prove useful as a tool in her research program. An alternative, but in certain ways equally unfortunate, review outcome would be for her paper to receive only positive reviews from researchers that are favorable to her initial hypothesis (like Reviewer A). In this case, publication of her paper could be greeted by skepticism and disdain by neuroscience colleagues who study self-referential processing and social cognition who might perceive her as naive for thinking MPFC was only involved in emotion. Either way—in the review process or when the paper reaches the literature—evaluation of her work might suffer because she has not yet grasped the relevant neuroscience literature and thereby taken into account alternative explanations for the phenomenon question.

Given the multiple functions that could be associated with MPFC, what can the social psychologist infer about the meaning of MPFC activation in her study? And how can these inferences help her achieve a more positive publication result? At least three factors will determine the strength of her inferences. First and foremost, as is the case for all forms of psychological experiment, the design of her study is critical in determining what psychological inferences she can draw about the meaning of her observed brain activations. For example, she would be on firmer footing in making the claim that participants were more emotional for *near* than for *far* forecasts if her experiment had included a self-report or autonomic measure that indicated this was the case. In general, one must always include behavioral measures in experiments that index the psychological constructs in question. As described in the next section, many early imaging experiments on emotion failed to do this and as a consequence, are ambiguous with respect to why particular patterns of activation were observed.

Second, as highlighted by Figure 3.3, the extent to which converging evidence from other domains of research implicate clear functions for a given region will also constrain the inferences one might draw. In the case of MPFC, one might question whether the overlap of MPFC regions involved in emotion, self-reference, and theory of mind is more apparent than it is real. Cross-study comparisons of brain activation foci are clouded by various factors that could lead to apparently similar or dissimilar patterns of activation, including: individual dif-ferences in functional brain anatomy, differences in methodology and operationalization of psychological constructs, and the facts that different researchers spatially normalize and analyze their data in different ways. This makes it is difficult to say whether two studies with apparently similar locations of MPFC activation (or activation of any other brain region) truly are recruiting identical regions.

One way to address this question is by designing studies that include conditions that allow one to test alternative accounts of the processes underlying the phenomenon question. In the forecasting study, the social psychologist either could have included separate additional tasks that involve self-reference or theory of mind or could have included conditions in her forecasting task that vary the extent to which one is engaged in self-referential or theory-of-mind processing. If greater MPFC activation was found for judgments that elicit stronger emotion, are more self-referential, and involve judging others' mental states, then the social psychologist could infer that a computation common to all these judgments has been recruited. By contrast, if all three types of judgment recruited distinct regions of MPFC— and *near* forecasts are associated with just one of them— then the social psychologist could more clearly infer that one type of process was involved.

Third, leverage for drawing psychological inferences about patterns of brain activation can be gained by performing meta-analyses that identify patterns of association that are reliable across large numbers of studies. Meta-analyses for studies of emotion (Phan, Wager, Taylor, & Liberzon, 2002; Wager & Feldman Barrett, 2004; Wager, Phan, Liberzon, & Taylor, 2003) as well as various higher cognitive processes (e.g., working memory and attention switching (Wager, Jonides, & Reading, 2004; Wager & Smith, 2003) have begun to identify patterns of activation that can be associated reliably with specific types of stimuli (e.g., memories or images), emotional states (e.g., sadness vs. anger), and individual differences (e.g., gender). The promise of meta-analyses is that they may one day be able to provide probabilities that activations observed in any specific region reflect different types of psychological processes (T. Wager, personal communication, January 2005). MPFC, for example, may turn out to consist of multiple overlapping subregions and, depending on where one's observed activation falls, could be associated with self reflection with a high probability (0.7), emotion with a moderate probability (.4), and theory-of-mind attributions with a low probability (.1). Of course, meta-analyses are only as good as the studies they comprise, which should be designed to test specific hypotheses about the phenomenon in question. These hypotheses can be informed by prior results, by meta-analyses, or, as discussed in the following section, by metatheoretical perspectives that motivate experimental designs.

METATHEORETICAL MISSES, MISSTEPS, AND MISTAKES

The social psychologist of the preceding section was described as somewhat naive about neuroscience data and

theory concerning MPFC function. More broadly, she could be described as being naive about the metatheoretical perspective that guides cognitive neuroscience research. A metatheory describes the relationship between dependent and independent variables at a level of abstraction removed from the particulars of a given phenomenon, and can be said to coherently describe core elements of theories within a field.

The metatheory guiding cognitive neuroscience research was first described by the late vision scientist David Marr (1982). Marr described three levels of analysis at which a given behavior or experience could be explained. At the highest *computational* level one provides a precise description of the phenomena to be explained. Marr termed this the "computational level" because it provides a description of the computational output to be produced by mechanisms described at lower levels of analysis. At the middle *algorithmic* level one provides a description of the information-processing mechanisms that give rise to the phenomena described at the computational level. At the lowest *implementation* level one provides a description of the neural hardware that instantiates information processing mechanisms described at the algorithmic level. Marr believed that these levels were independent, positing the functionalist view that any computation could be produced by numerous algorithms, each of which could be implemented in any type of hardware. Cognitive neuroscience, however, treats the levels as interdependent and interacting, because it recognizes that (1) not all algorithms can be implemented in all hardware (see example of mathematical operations permitted by Roman vs. Arabic numerals from Kosslyn & Maljkovic, 1990), and (2) although there may be numerous ways in which a given computational output could be produced by different algorithms, cognitive neuroscience is concerned with the ones that the human brain actually implements. The goal of cognitive neuroscience research is to construct a *theory of a functional architecture* that describes a phenomenon at these three levels of analysis (Ochsner & Kosslyn, 1999). This metatheoretical perspective finds expression in theories of memory, mental imagery, language, attention, motor control, and various other phenomena (for reviews, see Gazzaniga, 1995, 2000, 2004).

Our social psychologist's lesson in market expansion is that knowledge about the brain systems that could be involved in the processes under investigation is necessary at the outset. This would allow her to formulate a priori hypotheses about the brain regions that could be involved in affective forecasting, which would comprise the social psychologist's first-pass theory of the functional architecture underlying forecasts (Ochsner & Kosslyn, 1999). This theory should include a description of the specific kinds of forecasts under investigation, the psychological processes that are engaged for each type of forecast, and the hypothetical neural substrates for each type of psychological process. The psychological processes and neural systems could include those implicated in emotion as well as other types of processes, such as self-reflection or theory of mind. This theory then could be used to design appropriate control conditions for her

experiment that could rule out alternative hypotheses about the mechanisms underlying forecasting. If these criteria are met, she will be in a much stronger position to infer that predicted patterns of brain activation (if observed) support her hypotheses about the processes underlying *near* as opposed to *far* affective forecasts.

Although our examples thus far have focused on what a social psychologist might not know about cognitive neuroscience research, it is no less important for cognitive neuroscientists interested in SCN to recognize their own potential for naiveté about the metatheory guiding social psychological experimentation. Indeed, because cognitive neuroscientists thus far comprise the largest number of scientists interested in SCN, it is perhaps more important that they become aware of the metatheoretical stance taken by many social psychologists. Although aspects of this metatheory have been described in many ways, a consensual account would include the interaction of two elements: (1) a person, with all of his or her dispositions, chronically accessible mental constructs, concerns, temperaments, moods, and so on; and (2) a situation, which may include other individuals and their thoughts and feelings, and various cues that set goals or are the triggers for specific behaviors, including prescriptions for socially normative behaviors, the desire to make a good impression, and so on. This *person × situation* interaction posits that a person's behavior at any given moment in time is a product of the interaction between who that person is and what behaviors are available, permissible, and possible in a given context (Ross & Nisbett, 1991). Critically, it implies that the meaning we ascribe to a stimulus is not inherent in the stimulus itself but, rather, is a flexible product of our interpretation or *construal* of its meaning according to our current goals, which in turn may be a function of the current context. Individuals often fail to realize that their judgments, impressions, emotions, memories, and experiences are the product of *construals*, which can explain the numerous self-serving and self-enhancing biases the people exhibit (Robins & Beer, 2001; Taylor, Kemeny, Reed, Bower, & Gruenewald, 2000). This view has been described as *naive realism*, a term that captures the implicit assumption that one's perceptions reflect a realistic picture of the world that accurately and directly conveys its true nature (Robinson, Keltner, Ward, & Ross, 1995; Ross & Ward, 1996). This metatheoretical perspective finds expression in theories of personality, attribution, self-awareness, stereotyping, impression formation, and various other phenomena (Higgins, 1997; Mendoza-Denton, Ayduk, Mischel, Shoda, & Testa, 2001; Mischel & Shoda, 1995; Mischel, Shoda, & Mendoza-Denton, 2002; Ross & Nisbett, 1991).

Lack of awareness of this metatheoretical perspective could lead a cognitive neuroscientist interested in SCN to miss the richness of socioemotional phenomena that is captured by the person × situation interaction. To illustrate this possibility, consider early cognitive neuroscience studies of emotion. Most of these studies examined either uninstructed perception, recognition/identification, or memory for stimuli with ostensible emotional value. The most commonly used stimuli were facial ex-

pressions of emotion, followed by photographs of real-world scenes that elicited different types of emotional responses, emotionally evocative film clips, emotion-laden autobiographical memories, and auditory (e.g., screams and music), tactile (e.g., feather or shock), olfactory (e.g., sour or sweet odors), or gustatory (e.g., chocolate) sensory stimuli that elicited pleasant or unpleasant feelings. Meta-analyses of these studies have revealed that emotion-related activations do not array themselves simply as a function of modality of input, type of task, or type of "basic" emotion involved (Feldman Barrett, Ochsner, & Gross, in press; Phan et al., 2002; Wager et al., 2003).

Why the inconsistent results? From the perspective of a social psychologist, these studies treated emotion as a stimulus property like shape, size, or color rather than a context-dependent *appraisal* process that interprets the emotional value the stimulus in the context of an individual's current goals, wants, and needs (Figure 3.4) (Ochsner & Feldman Barrett, 2001; Ochsner & Gross, 2004; Scherer, Schorr, & Johnstone, 2001). As a consequence, these studies fail to manipulate the way in which individuals construed, or *appraised*, the meaning of stimuli, which leaves participants free to appraise stimuli in numerous different ways. Classic studies in social psychology, including the seminal work of Schacter and Singer and Lazarus, have shown that how we cognitively appraise the meaning of an event may determine how we respond emotionally to it (Lazarus, 1991; Schachter & Singer, 1962), including the regulation of emotion via deliberate or spontaneous appraisal of emotional stimuli as neutral (Erber, 1996). In part, lack of control over appraisal seems to have been a holdover from animal models of emotion that were derived from studies employing stimuli with primary reinforcing properties, such as pleasant tastes or electric shocks. Some cognitive neuroscientists have suggested that human emotions are essentially responses to linked with differing degrees of complexity to reinforcers of this type (Rolls, 1999). While it is true that emotions are adaptive responses to situations of relevance to current goals, and that some may involve evolutionarily conserved responses to reinforcing

stimuli, from a social psychological perspective human emotions may be elicited by both stimulus–response (S-R) and schematic mental representations; many involve experiential, behavioral, and autonomic components; and may involve various types of cognitive processing (for examples, see Scherer et al., 2001). The failure to appreciate this perspective also led to the failure of many studies to provide independent behavioral confirmation that emotional responses were, in fact, elicited. In the absence of independent behavioral verification that emotions were elicited—in the form of self-reports of experience, indices of autonomic arousal, or evidence of emotional behaviors such as facial expression—it is difficult to determine why or why not activation in a given brain structure has occurred.

The theory motivating most of these studies was that stimuli with emotional properties should activate classically "limbic," lower-order emotion-processing structures such as the amygdala but should not activate classically higher-order cognitive structures such as prefrontal cortex. Although some studies were consistent with this simple hypothesis (e.g., Buchel, Morris, Dolan, & Friston, 1998; Fredrikson et al., 1998; Irwin et al., 1996; LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998; Lane et al., 1997; Morris, Ohman, & Dolan, 1999; Shin et al., 1997; Zald, Lee, Fluegel, & Pardo, 1998), numerous other studies were not. Some observed activation in prefrontal cortex but not the amygdala (e.g., Canli, Desmond, Zhao, Glover, & Gabrieli, 1998; Delgado, Nystrom, Fissell, Noll, & Fiez, 2000; Kesler-West et al., 2001; Mayberg et al., 1999; Phillips et al., 1998; Taylor et al., 1998), whereas others observed activation in both structures (e.g., Buchel, Dolan, Armony, & Friston, 1999; Crosson et al., 1999; Damasio et al., 2000; Phillips et al., 1997). From the emotion-as-stimulus-property perspective, these results were difficult to explain and seldom received specific commentary. By contrast, from the emotion-as-appraisal perspective, these results can be seen as the product of a relative reliance on top-down cognitive appraisal processes as compared to bottom-up stimulus-driven appraisal processes (see Figure 3.4 and Feldman Barrett

Social Psychology	+	Cognitive Neuroscience	=	Social Cognitive Neuroscience
• Emotion as appraisal process dependent on context, needs, and goals		• Emotion as perception of stimulus property like shape, size, color		• Emotion as interaction of bottom-up (stimulus-driven) and top-down (goal-driven) appraisals, influenced by context
• Examine when, why, how appraisals produce particular emotions		• Find brain bases of recognition, memory, or attention to		• Examine brain bases of interactions between bottom-up and top-down appraisal processes

FIGURE 3.4. Diagram illustrating the differing approaches to explaining (middle row) and studying (bottom row) emotion for social psychology, cognitive neuroscience, and social cognitive science. For detail and explanation, see the section "Metatheoretical Misses, Missteps, and Mistakes."

et al., in press). The cognitive neuroscientist's lesson in market expansion is that the activations observed in different brain structures is not just a function of stimulus content but also a function of context and construal as well. As described earlier, current SCN experiments are investigating the conditions in which specific types of top-down or bottom-up appraisals lead to different types of emotional responses (see also Figure 3.4).

The Metatheory of SCN: Four Core Principles

The metatheory of SCN can be described as a combination of the metatheories guiding cognitive neuroscience and social psychology. SCN aims to describe behavior at three levels of analysis (see Figure 3.1 and Ochsner & Lieberman, 2001). The first is described as the *social* level, which includes a description of the phenomena of interest in terms of the experience and behavior of a person in a given context, as she perceives and interacts with a social target. Importantly, that target could be the someone else, or it could be the perceiver herself, as she reflects on her own traits, states, and goals and attempts to understand and make use of them. The second is the *cognitive* level, which includes a description—in information-processing terms—of the psychological processes that give rise to the experience or behavior of interest. The use of the term "cognitive" here is a holdover from the parent disciplines of social cognition and cognitive neuroscience and is not meant to imply a specific type of processing mechanism that is *cognitive* as opposed to something else. Instead, "cognitive" is a placeholder term for the notion that various types of processes and representations comprise the functional mechanisms that give rise to social level phenomena. Whether we call those mechanisms *cognitive* or *affective* or *motivational* may differ depending on the social level phenomena we are trying to explain, The third is the *neural* level, which includes a description of the neural systems implicated in the psychological processes hypothesized to underlie the social level phenomenon. SCN research uncovers relationships between variables described at these three levels of analysis by conducting studies that provide information about the psychological processes associated with specific brain systems, or uses information about brain systems to inform theories of the psychological processes engaged in social behavior (see Figure 3.2).

At its core, this metatheoretical perspective rests on four principles (see Figure 3.5).

- *Converging evidence:* Data from multiple levels of analysis provides constraints on theory
- *Content:* Processing of and by people is special
- *Construal:* All stimuli are multiply construable
- *Context:* Individual (internal) and situational (external) factors influence how specific types of content are construed

FIGURE 3.5. A list of four principles that form the core of social cognitive neuroscience's meta theory. For detail and explanation, see section "The Metatheory of SCN: Four Core Principles."

Constraints and Convergence

The first principle is that multileveled theories of behavior must be constrained by data collected using multiple methods with variables described at the three levels of interest. The combination of multiple streams of data allows researchers to converge on theoretical explanations that are robust and flexible and are not tied to a single specific experimental methodology. This principle is part of the bedrock of cognitive neuroscience research (Ochsner & Kosslyn, 1999), which employs multiple types of neuroscience methods, including not just functional neuroimaging (which is the emphasis in this chapter) but analysis of behavioral deficits in neuropsychological populations, electrophysiology, and many other related techniques (for reviews, see Kosslyn, 1999). In an analogous fashion, this principle also is part of the bedrock of social psychological research that employs multiple types of behavioral methods to study phenomena of interest. These methods range from self-report to various *measures* of behavior that indirectly indicate operation of a particular psychological process (response times, recall or other memory measures, etc.) to psychophysiological methods indexing sympathetic and parasympathetic arousal, and more (for reviews, see Cacioppo, Tassinary, & Berntson, 2000; Gilbert, Fiske, & Lindzey, 1998). SCN incorporates all these methods (Cacioppo, Berntson, Taylor, & Schacter, 2002).

Content

The second principle is that SCN is concerned with special kinds of content, at all levels of analysis. At the social level the field is concerned with social content, which includes stimulus cues involved in interactions with people. These cues include nonverbal perceptual inputs such as faces, facial expressions, eyes, bodies, and biological motion but also include higher-level inputs such as spoken language, nonverbal behaviors, and other forms of social communication including the beliefs and attitudes expressed by others. As noted earlier, the person with whom we interact is in some cases ourself, as our own behaviors, beliefs, and feelings become the focus of self-awareness, perception, and judgment. At the cognitive level the information-processing mechanisms engaged when processing social cues may be tailored to processing social information. The mental representations supporting perception of social cues, and the processes engaged when making judgments about them, may be different than those involved in processing nonsocial stimuli such as inanimate objects. Furthermore, the processes engaged typically are *hot*, which means that they involve processes that interpret the *emotional significance* of social cues, that *motivate* us to perceive or judge ourselves and others in particular ways, and that *affectively* color our experience while doing so. Most every judgment—social or otherwise—carries with it an evaluative core (Osgood, 1976), which places motivational processes at the core of SCN. At the neural level, there may be specific systems supporting the representations and processes engaged when processing socioemotional con-

tents. A significant portion of current SCN work aims to understand whether the processes and neural systems engaged when processing social stimuli are similar to or different than those engaged when processing nonsocial stimuli (e.g., Mitchell, Heatherton, & Macrae, 2002; Mitchell, Macrae, & Banaji, 2004).

Construal

The third principle is that the meaning of any stimulus is a function of the way in which its meaning is construed. In other words, the impact of a stimulus is determined both by the bottom-up, stimulus-driven processing of its intrinsic perceptual properties (e.g., a pleasant or unpleasant smell or the depiction of a disgusting scene) as well as top-down, goal-driven processing that can control the way in which stimulus meaning is extracted (Feldman Barrett et al., in press). As described previously, the power of construal to determine the meaning of a stimulus is one of the bedrock elements of social psychology's metatheoretical perspective (Ross & Nisbett, 1991).

Context

The fourth principle derives from the fact that any given stimulus can be construed in many different ways, which has been termed "the multiple construal problem." Two kinds of context help determine the way in which perceivers solve the multiple construal problem by interpreting, for example, a stimulus person as a lawyer rather than a black man, or a comment as a joke rather than an insult. The first is an individual's *internal* context, which consists of his or her biological temperament, preexisting beliefs, attitudes, chronically accessible schemas, goals, memories, and biases (Kosslyn et al., 2002). The second is an individual's *external* context, which consists of various aspects of their current situational milieu. The external context can include situational cues that specify specific behavioral goals (e.g., to make a good impression or to determine if someone is deceiving you) and place constraints on normatively acceptable behavior (e.g., not cutting in line at the supermarket or not making lewd comments to a woman in a bar), by activating specific mental representations that comprise an individual's internal context (see Higgins, Chapter 19, this volume) for a detailed discussion of how person and situation factors influence activation of different types of knowledge, and in turn, construals).

A Metaperspective on SCN's Metatheory: Specificity versus Universality

If SCN's metatheory describes the kinds of theoretical accounts the field aims to develop, how specific should these theories be? Traditionally, a primary goal of much physical behavioral and biological science has been the derivation of species-general, universal laws that govern behavior irrespective of context, content, and construal. The search for such universal laws of behavior may represent an attempt to mimic the physical sciences, which aim to formulate "fundamental" laws of matter and energy that are widely applicable. The laws that govern behavioral and biological science may be fundamentally different, however (Kagan, 1998). Over the course of evolutionary time, natural selection exerts the greatest pressure for an organism to retain a heterogeneous set of mechanisms supporting behaviors appropriate for specific survival contexts that in turn depend on specific biological adaptations. The key is that behavioral and biological science fundamentally is about understanding the mechanisms that govern an interaction between an organism's biological endowment and its ecological environment (i.e., its *situation*). In keeping with this notion, SCN places relatively less emphasis on abstract universal principles and relatively greater emphasis on discovering contextually sensitive laws that govern human behavior. These laws specify underlying mechanisms at multiple levels of analysis. For example, following social cognitive models of dual processing, we might specify how and when automatic and controlled processes come into play as a function of situational factors such as motivational involvement and information-processing capacity, and following cognitive neuroscience models of control, we might specify the prefrontal dynamics underlying these processes.

THE FUTURE PROMISE OF SOCIAL COGNITIVE NEUROSCIENCE

This chapter began by drawing an analogy between personal and professional relationships on one hand and the nature of SCN on the other hand. From the personal perspective, social psychology and cognitive neuroscience can be seen as parent disciplines whose progeny has grown into an independent discipline. From the professional perspective, social psychology and cognitive neuroscience can be seen as business partners who need each other's expertise in order to expand their research market.

Which metaphor is correct? The answer is that metaphors are not mutually exclusive. Each one highlights different aspects of SCN that are important for understanding its development and its practice. Indeed, understanding the nature of any field presents its own multiple construal problem. In the case of SCN, the field can be construed as the offspring of successful parents with venerable research bloodlines, as an entrepreneurial startup with research potential, or a bit of both. The choice of construal may depend on the question one asks. If one wants to understand SCN's historical antecedents, the personal metaphor may be most useful. If one wants to understand what social psychologists and cognitive neuroscientists need to know about what the other discipline has to offer, the partnership perspective may be most useful.

Whichever metaphor guides one's construal of SCN, the question arises as to what the future may hold for the ongoing development of the field. Its rapid growth and the proliferation of conferences, publications, and funding opportunities suggests that SCN is not merely a flash in the pan. That being said, it is important to consider

what questions currently are central to SCN research and how current research may translate into promising directions for future work.

Predicting the Future: Three Examples from Current Research

An old aphorism states that past behavior is the best predictor of future behavior. This suggests that a good way of predicting what the future may hold for SCN is to consider the state of its current understanding of a few key questions. In this section, we illustrate the SCN approach with examples of current research that highlight the difference between approaching topics from an integrative SCN perspective as opposed to approaching them from a social psychological or cognitive neuroscience perspective alone.

Person Perception

"Person perception" is an umbrella term referring to the various ways in which we first perceive social cues, judge social targets, and subsequently form impressions of social actors. SCN research on person perception has followed two major threads. The first has been heavily influenced by the cognitive neuroscience emphasis on bottom-up, stimulus-driven processing of perceptual cues. Research following this thread has examined the neural systems responsive to face as compared to nonface objects, facial expressions of various kinds, facial features such as the direction of eye gaze, bodies as compared to other objects, and biological as compared to nonbiological motion (Allison et al., 2000; Puce & Perrett, 2003). Much of this work is concerned with the question of whether or not social cues enjoy privileged status in the brain. For example, one hotly contested debate asks whether faces possess unique features and are processed by a dedicated cortical module (the fusiform face area, or FFA) or whether faces are one example of a stimulus for which we have gained great expertise and are processed by cortical regions tuned to support recognition of any stimulus for which we are recognition experts (Gauthier, Curran, Curby, & Collins, 2003; Gauthier & Tarr, 1997; Gauthier et al., 2000; Grill-Spector, Knouf, & Kanwisher, 2004; Kanwisher, McDermott, & Chun, 1997; Kanwisher, Stanley, & Harris, 1999; Yovel & Kanwisher, 2004). It is noteworthy that traditional social psychological approaches to person perception take it for granted that social cues are recognized accurately and concern themselves with subsequent stages of judgment and impression formation. By contrast, SCN models unpack this initial step into a suite of neural systems dedicated for processing different types of social cues. In so doing, SCN models deepen the understanding of person perception offered by social psychological models that are concerned less with the question of how nonverbal cues are recognized.

The second thread in SCN research on person perception concerns the way in which we infer or understand the intentions of other individuals. This research thread also has been heavily influenced by the cognitive neuro-

science emphasis on stimulus-driven processing as exemplified by research on "mirror neurons" (Rizzolatti & Craighero, 2004), Mirror neurons were first described in primate studies of motor control. Some prefrontal cortical neurons would fire when a monkey would execute a hand motion and also would fire when a monkey would observe a different actor's hand executing the same action. Subsequent studies suggested that these neurons were sensitive to the goal of an action and not just its superficial gestural characteristics (Rizzolatti & Craighero, 2004). Human neuroimaging research picked up this thread by demonstrating common regions of primary motor, left inferior prefrontal, and parietal cortex that seem to be similarly responsive to the perception and execution of a motor action (Buccino, Lui, et al., 2004; Buccino, Vogt, et al., 2004; Decety, Chaminade, Grezes, & Meltzoff, 2002; Hari et al., 1998; Iacoboni et al., 1999; Ruby & Decety, 2001). Other studies have suggested that common neural systems may be involved when individuals perceive and pose facial expressions of emotion (Carr, Iacoboni, Dubeau, Mazziotta, & Lenzi, 2003) or both personally experience and watch others experiencing pain or disgust (Calder, Keane, Manes, Antoun, & Young, 2000; Jackson, Meltzoff, & Decety, 2005; Morrison, Lloyd, di Pellegrino, & Roberts, 2004; Singer et al., 2004; Wicker et al., 2003). These findings have led some to propose that "shared representations" underlying the perception and execution/experience of an action form the foundation of our ability to understand others' mental states (Gallese, Keysers, & Rizzolatti, 2004; Meltzoff & Decety, 2003). Thus, shared representations presumably provide an automatic internal simulation of what it would be like for the perceiver to perform an observed action and this simulation, or perception–action "resonance" enables the perceiver to understand what someone is doing and why.

There are three significant problems with this account. The first is that, to date, the activation of motor mirror neurons has never been shown to predict the ability to understand actions—whether social or nonsocial—of another individual in either a laboratory or a real-world context. Studies involving the experience and perception of pain have shown that common regions of activation covary with individual differences in empathic ability, but they have not yet demonstrated that the tendency to coactivate a given region in both perceptual and experiential contexts predicts the ability to accurately judge what another person is feeling or thinking. If the mirror neuron account was correct, such evidence should be found. The second problem is that the shared representations that have been identified to date are informationally sparse and are unlikely to support the inferences necessary to understand another person's intentions. Both developmental and social psychological models of intentional inference suggest that individuals draw on both semantic and episodic memories to help guide judgments about what a given individual is thinking or feeling in a given context, as well as higher-order capacities for reasoning and judgment. The shared motor and affect representations identified therefore are unlikely to contain this information. They might support vicarious

learning about the causes and consequences of particular actions, but they likely do not support understanding that a person is trying to deceive us, that he or she might have incorrect beliefs about what we believe, and so on. The third, and perhaps most significant, problem is that mirror neurons/shared representations theories of person perception really are not theories at all. They are descriptions of data and provide neither precise social-level descriptions of the full range of phenomena to be explained nor information-processing descriptions of the steps necessary to achieve specific kinds of interpersonal understanding. By contrast, social psychological models of person perception provide both kinds of descriptions, which enables them to explain the situational and motivational factors that determine when and how we are likely to imitate others (Chartrand & Bargh, 1999; van Baaren, Horgan, Chartrand, & Dijkmans, 2004; van Baaren, Maddux, Chartrand, de Bouter, & van Knippenberg, 2003) and more generally what determines whether we are accurate or inaccurate empathizers (Hodges & Wegner, 1997; Ickes, 1997) or social judges (Gilbert, 1998; Krueger, 2003). Our errors of person perception are particularly revealing because they lay bare the egocentric biases, heuristics, and implicit theories that guide our judgments of others (Epley, Savitsky, & Gilovich, 2002; Saxe, 2005; Wilson & Brekke, 1994). Mirror neuron accounts of social cognition do not speak to these errors.

Current SCN work is moving beyond simple shared-representation models of person perception toward linking the systems used to encode perceptual cues to those important for the high-level processes and memory representations used to draw social inferences (Gallagher & Frith, 2003; Lieberman, Gaunt, Gilbert, & Trope, 2002; Mason, Banfield, & Macrae, 2004; Ochsner et al., 2005) and is just beginning to understand how these representations may bias the person perception process (Mitchell, Macrae, & Banaji, 2005). Two of the strengths of this work are its strong foundation in developmental psychological models of intentional inference and its breakdown in autism (Frith, 2001; Frith & Frith, 2003; Saxe et al., 2004) and its potential to help fractionate the person perception process into component parts by identifying different common and distinct patterns of brain activation associated with different types of judgment (Kosslyn, 1999; Ochsner & Lieberman, 2001). Thus, imaging experiments may be able to identify systems involved in the dynamic interplay of bottom-up and top-down processes during person perception, as well as systems involved in biased as compared to accurate judgments.

Self-Perception

Another major theme of current SCN research concerns the neural correlates of self-perception. As was the case for research on person perception, work on self-perception has transitioned from being strongly influenced by the CN emphasis on perception and recognition to a broader emphasis influenced by social psychological models of self-knowledge.

An initial attempt to organize neuroscience research on self-perception suggested that right-hemisphere advantages for various self-related tasks supports the theory that the right hemisphere plays a special role in self-recognition (Keenan, Nelson, O'Connor, & Pascual-Leone, 2001). These tasks included recognizing photographs of the self as compared to others (Keenan, Freund, Hamilton, Ganis, & Pascual-Leone, 2000; Keenan et al., 1999), retrieving autobiographical memories (Tulving, Kapur, Craik, Moscovitch, & Houle, 1994), and maintaining a coherent map of the body and its location in space, which is commonly disrupted by right parietal lesions that produce deficits of body and spatial awareness (Ramachandran, 1995). The major problem with this view is that it lacks a coherent theory or metatheory to explain what it is that links all these behaviors together. In what sense is viewing a photograph of one's self as compared to a stranger a core social cognitive process that is critical for social functioning? In what sense does this have anything to do with perceiving one's personality attributes and one's qualities? How does retrieving an autobiographical memory or being unaware that one has a neuropsychological deficit involve processes similar to or different than those involved in recognizing yourself in a photo? What criteria determine whether a task does or does not involve these processes? These questions have not been addressed by this account.

A second line of research on self-perception has used functional imaging to study the neural correlates of the self-reference effect in memory (Symons & Johnson, 1997), which refers to an advantage in memory for trait words (e.g., friendly) encoded by judging how well each trait describes oneself as compared to encoding them by judging some other semantic or nonsemantic attribute (e.g., number of syllables). Linking words to the complex organizational structure of self-knowledge is thought to enhance memory to levels difficult to match without some other sufficiently organized and elaborate method of study (Symons & Johnson, 1997). Initial neuroimaging studies of this effect suggested a special role for MPFC in judging the relevance of trait words to the self as compared to judging their relevance to famous but not personally known individuals, such as President George W. Bush (Craik et al., 1999; Fossati et al., 2003; Kelley et al., 2002; Macrae, Moran, Heatherton, Banfield, & Kelley, 2004). Subsequent studies have suggested that MPFC activation may be elicited by various other kinds of self-referential judgments as well, including assessing one's emotional state (Ochsner, Knierim, et al., 2004), preferences (Zysset, Huber, Ferstl, & von Cramon, 2002; Zysset, Huber, Samson, Ferstl, & von Cramon, 2003), abilities (Johnson et al., 2002), and attitudes (Cunningham & Johnson, 2007). Furthermore, some studies have suggested that similar regions of MPFC are involved in judging one's own feelings or attributes and the feelings and attributes of others (Ochsner et al., 2005; Ochsner, Knierim, et al., 2004; Schmitz, Kawahara-Baccus, & Johnson, 2004). These findings suggest that the process of reflecting on what others think about us is very similar to

the process of thinking about ourselves directly, which bears on theories of the origin and nature of self-knowledge.

The fact that MPFC has been implicated in various types of self-perception, as well as mental state attribution more generally, is striking for least two reasons. The first is that it suggests that seemingly disparate social phenomena may share common underlying information processing and neural mechanisms. These data could not have been obtained using behavioral studies alone. This is important because social psychologists typically study some of these phenomena—such as attitudes and judgments of personality—independently from one another. The fact that they may share common neural mechanisms sheds light on their potential similarities in terms of common psychological processes that depend on those brain systems. The second reason was highlighted earlier, in the section "Principles Governing the Practice of SCN," which considered the difficulty of drawing specific inferences about the nature of these neural mechanisms given the fact that MPFC has been implicated in multiple different behaviors. An important direction for future research will be performing within-study comparisons contrasting different types of self-referential judgment as well as different types of judgments about the mental state of others. The goal is to determine the functional organization of MPFC, which could help clarify the similarities and dissimilarities on the different types of judgment associated with MPFC activation.

In this regard, it may be important to distinguish theoretically between different senses of self (cf. Gillihan & Farah, 2005), a topic that has been the focus of much social psychological research (Baumeister, 1998). One distinction that might be useful contrasts the first-person sense of ownership over one's actions and perceptions and the third-person sense of being the object of one's introspection. William James referred to these two senses of self as the *I* and the *Me* (James, 1890). The experience of the *I* is immediate and direct and accompanies both the stream of conscious sense of experiencing one's perceptions as well as the agentic sense of controlling one's behaviors. The experience of the *me* is metacognitive and indirect and accompanies the sense of reflecting on one's attributes, abilities, states, and body. It has been hypothesized that ventral portions of MPFC may be more strongly associated with the *I*, whereas dorsal portions of MPFC may be more strongly associated with the *me* (Ochsner & Gross, 2005). It remains for future work to test this hypothesis (for other potentially useful distinctions related to types of self-knowledge, see also (Higgins, 1996b; Lieberman, Jarcho, & Satpute, 2004).

Self-Control

The ability to control the content of one's thoughts, the nature of one's feelings, and the expression of one's actions is commonly referred to as self-regulation. In contrast to topics such as person perception and self-perception, this topic has seen perhaps the greatest amount of independent research from each of SCN's parent disciplines. Within CN, self-regulation first was studied under the rubric of executive function, which referred to a variety of abilities impaired by frontal lobe function, such as planning and problem solving, that were measured by neuropsychological task batteries. Global concepts of a central executive generated by this work have given way to focused models of specific forms of cognitive control, including working memory, selective attention, and response selection, all of which can be measured by sensitive speeded response-time tasks. Within self-perception, "self-regulation" has been an umbrella term referring to any number of different instances in which an individual needs to curb an impulse (e.g., to diet), alter an emotion or mood, or salve a blow to one's self-esteem or social relationships.

The key is that within both disciplines, the need to inhibit or transform prepotent responses has been a major focus of research. The long history of self-regulation research in both CN and self-perception has provided a firm foundation for interdisciplinary bridges to be built in the form of collaborative SCN research. This research has taken the form of using CN models of cognitive control and emotion to help elucidate the dynamics underlying various forms of control over person perception, affect, and emotion, traditionally of interest to social psychologists (Ochsner, in press; Ochsner & Gross, 2005).

For example, a number of studies have manipulated the level of attention paid to briefly presented faces that express emotion or are exemplars of racial ingroups or outgroups. These studies have tested the hypotheses that (1) emotionally relevant social stimuli should activate the amygdala, and (2) following the logic of behavioral experiments these responses could be considered automatic to the extent that they do not vary as a function of attention (Öhman, Flykt, & Lundqvist, 2000). In general, results have been mixed. Some studies have found results consistent with these hypotheses (Anderson, Christoff, Panitz, De Rosa, & Gabrieli, 2003; Öhman, 2002; Vuilleumier et al., 2002; Vuilleumier, Armony, Driver, & Dolan, 2001), whereas others have found that amygdala responses diminish as a function of attentional load (Pessoa, Kastner, & Ungerleider, 2002; Pessoa, McKenna, Gutierrez, & Ungerleider, 2002) or exposure (Hart et al., 2000).

Although there may be numerous reasons for these discrepant results, one possibility is salient in light of earlier discussion. Much CN research on emotion has treated it as a stimulus property, has lacked a meta-theoretical perspective, and as a consequence has failed to measure or manipulate the way in which participants appraise the meaning of stimuli with affective relevance. Thus, it is possible that qualitatively different processes—including those involved in cognitive control—become engaged when participants devote their full attention to the encoding of emotionally evocative stimuli as compared to when few attentional resources are available.

This possibility is supported by research suggesting that when attentional resources are available and directed toward individuating (Wheeler & Fiske, 2005) or thinking verbally (Hariri, Bookheimer, & Mazziotta,

2000; Hariri, Mattay, Tessitore, Fera, & Weinberger, 2003; Lieberman, Hariri, Jarcho, Eisenberger, & Bookheimer, 2005) about socioemotional stimuli, that amygdala responses may be reduced. In part, this may be due to heightened awareness of ambivalent feelings about target stimuli possible, which participants regulate by engaging control processes. Thus, faces that can be perceived as expressing either surprise or fear activate the amygdala when judged to express fear and ventral MPFC when judged to express surprise (Kim, Somerville, Johnstone, Alexander, & Whalen, 2003). Similarly, attitude targets that elicit both positive and negative evaluations—such as abortion or a black face for a white participant who professes no explicit prejudice but exhibits prejudice one implicit tasks—tend to activate dorsal anterior cingulate and right lateral prefrontal regions implicated in cognitive control (Amodio, Harmon-Jones, & Devine, 2003; Cunningham, Raye, & Johnson, 2004). It remains for future research, however, to identify the specific patterns of social cognitive appraisal that lead stimuli to be perceived in neutral as compared to affectively arousing terms.

Studies examining the use of cognition to regulate the experience of emotion have identified at least two different types of *re*appraisal that engage prefrontal and cingulate control systems to downregulate emotional appraisal systems such as the amygdala. One strategy involves becoming psychologically distant and detached while observing an emotionally charged photo or film, which has been shown in behavioral experiments to be effective for downregulating negative emotion (Gross, 1998). Imaging studies have shown that this strategy engages prefrontal systems to regulate activation of appraisal systems related to sadness (Levesque et al., 2003, 2004), sexual arousal (Beauregard, Levesque, & Bourgouin, 2001), or negative emotion more generally (Ochsner, Ray, et al., 2004; Phan et al., 2005). A second strategy involves "looking on the bright side," or, "finding the silver lining," in an aversive event by reframing its meaning in terms that neutralize or even positivize its emotional punch (Lazarus & Alfert, 1964). For example, one could imagine that a sick man depicted in a photograph has a hearty constitution, feels little pain, and soon will be well. This strategy also activates prefrontal and cingulate control systems to downregulate amygdala responses to aversive images (Ochsner, Bunge, Gross, & Gabrieli, 2002; Ochsner, Ray, et al., 2004).

The specific locations of control and appraisal-related activations have varied considerably across studies, however, and it will be necessary for future research to provide within-study comparisons of strategy and stimulus type to determine how and why specific kinds of regulation are associated with specific neural dynamics. One study has directly compared the *self-focused* and *situation-focused* strategies described earlier, and found that they differentially depend on medial and lateral prefrontal cortex, respectively (Ochsner, Ray, et al., 2004).

It also will be essential that future work examine the numerous other forms of self-regulation typically studied by social psychologists, which range from the control of eating to the recovery of self-esteem after a failure or rejection (Ayduk, Mischel, & Downey, 2002; Heatherton, Polivy, Herman, & Baumeister, 1993; Steele, Spencer, & Lynch, 1993). Such work could help determine whether regulatory responses to social threat depend on psychological and neural processes similar to or different than those used to regulate responses to physical threats, such as pain (Eisenberger & Lieberman, 2004), or responses to any emotion-eliciting discrepancy between desired and actual outcomes (Higgins, 1996a, 1999). The goal here is to identify and understand the dynamics of core systems important for control on the one hand and emotional appraisal on the other. As discussed below, such models could have important implications for the development and dysfunction of social and emotional abilities (Ochsner & Gross, 2005).

Mapping the Road Toward the Future

All forms of research are journeys of discovery. With any luck, the journey follows a road that does not endlessly wind back on itself but moves forward toward its ultimate goal. In the case of SCN, that goal involves building multilevel models of socioemotional phenomena. Thus far, this chapter has been concerned with building normative models that describe the behavior of physically and psychologically healthy adults. But this is only a first step. Once a normative adult model has been established, it can and should be extended in numerous directions. As considered in this section, models can be applied toward understanding new domains of research and can be extended to additional levels of analysis.

When contemplating any journey it is often useful to have a map. To guide our discussion of new directions for future SCN research, Figure 3.6 maps the relationships between SCN and a number of allied disciplines, all of which are concerned with understanding the relationships between psychological processes, neural systems, and/or clinical outcomes. Construing the term "social neuroscience" broadly to refer to any research that links social-level variables to biological variables (Cacioppo, 2002; Cacioppo et al., 2002), this map charts the relationships among various disciplines within *social neuroscience*. The point of this map is to help visualize points of potential connection between SCN and other disciplines that could be the focus of collaborative work.

New Domains of Research

SCN is more of an interdisciplinary approach to asking and answering questions about (both intra- and interpersonal) social phenomena than it is a field with crisply defined topical boundaries. Understood this way, the SCN approach could be used to profitably address questions of interest to a number of closely related sister disciplines, some of which are depicted in the lower left of Figure 3.6.

For example, affective neuroscience, which as described earlier has been concerned with mapping the brain correlates of a basic set of emotional responses, potentially could benefit from SCN's emphasis on construal and context. For SCN, emotional experiences are many
FIGURE 3.6. Diagrammatic map of the relationship between SCN and allied disciplines. The three large circles represent traditional disciplines in the social sciences, health sciences, and neural sciences. The concerns typically associated with each of these three major disciplinary categories are listed in the periphery. Interdisciplinary fields such as social cognitive neuroscience lie at the intersection of traditional disciplinary boundaries. Research that incorporates aspects of all three disciplinary categories would lie in the center of the figure, which is represented by the "translational triangle" designated with a capital *T*. Such *translational research* uses models of socioemotional behavior derived from basic science research with normative populations to address questions about the mechanisms underlying maladaptive mental and physical health outcomes. The map is intended to visualize the potential points of connection between SCN and other disciplines that could be the focus of collaborative work. For detail and explanation, see the section "Mapping the Road Toward the Future."

and varied and the product of cognitive construals or appraisals that may depend on a variety of neural systems. An important avenue for future research could be unpacking the ways in which different external situational and internal (states, goals, dispositions, etc.) contexts determine what type of emotional responses are generated (Feldman Barrett et al., in press; Ochsner & Feldman Barrett, 2001).

In like fashion, an SCN approach could benefit neuroscience research that recently has begun to emphasize the study of personality and individual differences (Hamann & Canli, 2004; Kosslyn et al., 2002). Although this research is explicitly focused on understanding the way in which internal contexts impact psychological and neural processes, it may benefit from SCN's additional emphasis on the way in which experience and learning impact the construal process as well. For example, apparent gender differences in neural responses to emotional stimuli could arise from ways in which cultural learning shapes the way men and women construe the meaning of emotional experiences (Wager & Ochsner, in press). These differences in construal may, of course, have neural correlates, but their origin may be attributable to the tuning of neural circuits via culture rather than innately specified genetic, endocrine, or other biological factors.

An SCN approach also could be used to help understand the development of and change in various social and emotional abilities across the lifespan. Cognitive neuroscience research has identified different developmental trajectories for systems related to cognition and emotion such that emotional appraisal systems such as

the amygdala reach adult size earlier in life than do prefrontal control systems, which undergo a rapid growth spurt between the ages of 8 and 12 and continue to structurally develop into one's late 20s (Diamond, 2002; Giedd, 2004; Luna & Sweeney, 2001; Luna et al., 2001). This differential sensitivity to aging continues into older adulthood, as age-related degeneration of the amygdala (and other structures related to emotion, like orbitofrontal cortex) is slow compared to degeneration observed in lateral prefrontal and cingulate systems related to cognitive control (DeCarli et al., 1994; Raz, Gunning-Dixon, Head, Dupuis, & Acker, 1998; Salat, Kaye, & Janowsky, 2001). Behavioral data suggest that working memory and attentional capacities wax and wane with the growth and degeneration of prefrontal and cingulate control systems (Grady, 2002; Klingberg, Forssberg, & Westerberg, 2002; Milham et al., 2002; Reuter-Lorenz et al., 2000; Thomas et al., 1999), but it is not yet known if social and emotional functions wax and wane with structural changes in a similar fashion. The implications of developmental trends for person perception, self-perception, and emotional self-regulatory abilities could be an important topic for future SCN research—as would the potential impact of cultural learning history and life-stage transitions on the development of these abilities as well (Higgins & Eccles-Parsons, 1983).

The emerging field of neuroeconomics might similarly benefit from an SCN approach. Neuroeconomics is concerned with understanding the neural correlates of social exchanges, decisions, judgments, and predictions that have varying degrees of utility, or value, to a person. SCN

could be instrumental in unpacking the concept of utility in terms of both the neural systems associated with subjective utility and systems associated with computing the objective value of a commodity. SCN models of self-perception and self-regulation could also inform the way in which decision makers regulate their affective responses to choice options and decision outcomes. For example, depending on whether one anticipates a positive or negative choice outcome (e.g., winning a bet), cognitive control processes could generate either anticipatory eagerness or regret. Depending on which outcome is actually experienced, control processes could help regulate disappointment, sadness, regret, or other negative emotions (Larsen, McGraw, Mellers, & Cacioppo, 2004). As described earlier, current SCN research is examining the neural systems implicated in emotion regulation, and the findings of these studies could be relevant here. Various studies of judgment and decision making activate prefrontal systems such as those used for emotion regulation (e.g., Bechara, Tranel, & Damasio, 2000; Rogers et al., 2004; Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003), but the relationship between the two is not yet clear. The key is that SCN incorporates social psychology's emphasis on context and construal and provides a direct link to a large body of social psychological research examining the way in which these factors influence judgment and choice.

Finally, an SCN approach also could inform other hybrid disciplines whose emergence may be on the horizon. For example, a recent special issue of the journal *Political Psychology* was devoted to describing the possibility that *political neuroscience* research could use neuroscience methods to study phenomena typically of interest to political scientists. An SCN approach to this endeavor could help specify the ways in which content, context, and construal are related to the neural systems underlying political attitudes, political decision making, and related phenomena (Lieberman, Schreiber, & Ochsner, 2003).

Translational Research

As normative SCN models of person perception, self-perception, self-regulation, and other abilities are solidified, they can be extended to help explain how their underlying mechanisms contribute to the maintenance of mental and physical well-being. Such *translational research* seeks to apply the methods and findings of basic science research to understanding the causes and consequences of both psychological and physical ailments. Translational SCN research would connect research located in the lower left of Figure 3.6 with traditionally biomedical and psychiatric research located in the upper right of Figure 3.6, thus occupying the intersection of the three primary domains of research depicted in this figure. This intersection zone is represented by the "translational triangle" in the center of the figure, designated with a capital *T*.

A prime candidate for translational SCN work might be unpacking the functional consequences of structural and functional abnormalities in emotional appraisal and cognitive control systems that have been identified in vir-

tually every major mood, anxiety, and thought disorder, including depression, anxiety, posttraumatic stress disorder, obsessive–compulsive disorder, and schizophrenia (Bremner, Vythilingam, Vermetten, Vaccarino, & Charney, 2004; Davidson, Pizzagalli, Nitschke, & Putnam, 2002; Heckers et al., 2004; Mayberg, 2003; Quintana, Wong, Ortiz-Portillo, Marder, & Mazziotta, 2004; Rauch, Savage, Alpert, Fischman, & Jenike, 1997; Tillfors et al., 2001). Despite the fact that many of the distressing symptoms accompanying these disorders are often social or emotional in nature, the majority of extant functional studies have measured brain activity while participants are either "at rest," in the scanner or performing a cognitive task. A clear avenue for future SCN research will be to translate its basic models of normative functioning to clarifying why and how clinical populations are anhedonic, asocial, highly anxious, or depressed or experience other forms of affective and social dysregulation.

Equally important will be translating SCN models of self-perception and self-regulation into an understanding of how they relate to physical health outcomes. Health psychological research has identified relationships between social variables—such as the experience of shame or loneliness or the size of one's social support network—to the occurrence of common colds, cardiovascular disease, and level of immune functioning more generally (Bandura, 2004; Cacioppo et al., 1998; Dickerson & Kemeny, 2004; Kemeny, 2003; Kiecolt-Glaser, Cacioppo, Malarkey, & Glaser, 1992; Taylor et al., 2000; Uchino, Cacioppo, Malarkey, Glaser, & Kiecolt-Glaser, 1995). Current models of these effects either connect social level descriptions of interpersonal and regulatory behavior to other social-level descriptions of physical symptoms or bridge many levels of analysis between high-level descriptions of social variables and very low-level descriptions of molecular markers. These models do not yet make clear, however, how social, cognitive, and neural-level variables interrelate to produce adaptive or maladaptive health outcomes. SCN can play an invaluable role in filling in the missing levels of analysis, linking social variables to psychological processes, psychological processes to neural systems, and neural systems to transmitters, hormones, and endocrine systems.

Learning the Language

This chapter began with an everyday real-world scenario—waiting in the supermarket checkout line—that provides a glimpse into the metaphors by which we live. As the tabloid headlines reveal, human endeavors are easily described and understood in terms of personal or professional relationships. Much of this chapter used these two metaphors as the starting point for describing the historical development of SCN and the core principles that govern its experimental practice.

The supermarket checkout line reveals another important facet of human psychology, however, namely, the importance of communicating in a common language. Take a moment to think about the supermarket checkout line. In doing so, the reader may have spontaneously gen-

erated visual mental images of the scene. It is quite likely that the magazine headlines viewed in the mind's eye were printed in one's native tongue. Now imagine instead that the magazine covers are printed in an unknown foreign language. In this case, although one may be able to glean from the glossy cover photos that the stories inside are about people, the essential meaning of the stories is lost.

For an interdisciplinary field such as SCN, the importance of communicating in a common language cannot be underestimated. As described earlier in this chapter, there is always a danger that researchers in one domain will not be interested in the research products of their colleagues in another domain. This disinterest stems in no small part from an inability to understand cross-disciplinary jargon. Social psychologists may not understand the language of cortical and subcortical systems or fMRI scanners, and neuroscientists may not understand the language of attitudes, attribution, and person × situation interactions. Luckily for SCN, most newcomers to this field already have in common the cognitive, information-processing component of SCN's multilevel research language. Language pitched at this level provides descriptions of the psychological processes that link social phenomena and neural systems. This language, with some variation, includes terminology and concepts such as automatic and controlled processing, storage and retrieval, and selective attention that are part of social psychology and cognitive neuroscience as well as behavioral economics, psychiatry, and related disciplines.

A simple analogy can be used to illustrate the importance of the information-processing metaphor for understanding the mechanisms of socioemotional behaviors and unlocking the functions of neural systems. In the early 1800s, scholars in many nations were working to understand the meaning of Egyptian hieroglyphics. Their work focused on a stone slab discovered in the town of Rashid (*Rosetta*) in 1799 by Napoleon's invading army. Known as the *Rosetta Stone*, this slab contained a text written in three different languages. As depicted in the left panel of Figure 3.7, the top of the stone was written in hieroglyphics, a 3,000-year-old pictographic language. The middle and bottom portions were written in Demotic and Greek, which were the languages of literate Egyptians (of the time) and the government, respectively. In 1822, French scholar Jean-Francois Champollion deduced that repeating combinations of characters in each of the three texts referred to the royal name Ptolemy, and from there, he was able to link Greek and Demotic characters spelling the name to their hieroglyphics counterparts (Andrews, 1985).

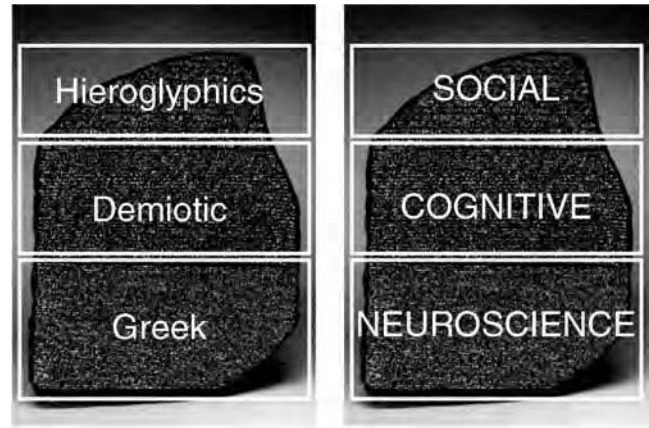
The problem of translating hieroglyphics into Greek is not unlike the problem of translating the language of neuroscience into social psychological terminology—or vice versa. For the decoders of the Rosetta Stone, Demotic, the everyday language of literate Egyptians, was the link between modern Greek and ancient Hieroglyphics. For social cognitive neuroscientists, the everyday language of information processing is the link between neuroscience and social psychology, as illustrated by the right panel of Figure 3.7.


FIGURE 3.7. The ancient Egyptian *Rosetta Stone* provides an analogy for understanding how one can learn to translate between the differing languages used by social, cognitive, and neuroscience researchers. The original Stone contained the same text written in three different languages: hieroglyphics, Demotic, and Greek. The relationship between Greek and Egyptian hieroglyphics was decided when it was realized that Demotic characters spelling the name of a Pharaoh could be linked to their Greek and hieroglyphic counterparts. For social cognitive neuroscientists, the everyday language of information processing, originally derived from cognitive psychology, may provide a similar means for translating between neuroscience and social psychology.

Closing Comment: The Value of SCN

In the long run, SCN will succeed only if social psychologists and cognitive neuroscientists alike perceive the value of its approach. Toward that end, it will be important to recognize that SCN can be more than a simple addition of neuroscience data to social psychology or a new focus on social phenomena for cognitive neuroscience. SCN asks questions and aims to construct theories similar to, but importantly different than, those formulated by either of its parent disciplines. In comparison to social psychology, SCN offers the opportunity of constraining psychological theorizing through the use of neuroscience data that can use patterns of brain data to identify common and distinct processing systems underlying various behaviors. In comparison to cognitive neuroscience, SCN offers the opportunity to understand how contexts impact the way in which socioemotional contents are construed, thereby providing invaluable data about the functions associated with specific brain systems. For its practitioners, SCN can be an emergent discipline greater than the sum of its parental investment.

NOTES

1. During this time period paradigms for studying various forms of learning were developed, and theories to describe the nature of the learning process were advanced, that did not make reference to mental states. Ironically, these paradigms are used today to study fear, reward, and their underlying mental processes.
2. It is notable that, historically, there also has been debate concerning what is "social" about social cognition. Some have defined the term as we define it here in the context of SCN, but importantly distinguish it from the social psychology of cognition, which is quite different. For discussion, see Higgins (2000).
3. It also could be argued that cognitive psychology to a "step up," to become social cognition (Higgins, 2000).
4. As has been noted in many circles, this may be attributable to an academic system that places emphasis on distinguishing the contribution of independent individuals, rather than teams or groups, in order for individuals to be granted tenure.

PART II
COGNITIVE SYSTEM

CHAPTER 4

Prediction

The Inside View

DAVID DUNNING

Friends may come and go, but there is one companion that never leaves a person's side. This companion is hardly the easiest of acquaintances, making a habit of mystery and suspense, cloaking moves in a constant uncertainty of what might happen next. In reaction, people spend a great deal of time, thought—and even money—to analyze this companion, to anticipate the twists and turns this friend might take. This work is never ending, and the companion's actions remain subject to unpredictability and surprise throughout a person's life.

This lifetime companion is the future, and a simple survey of everyday life reveals just how people spend a good deal of their hours thinking, talking, and calculating about what this friend—the future—might hold. This obsession arises in both personal and professional spheres. In their personal lives, people strive to anticipate what other people will do (e.g., *Will my boss give me a raise?*), what they themselves will do (i.e., *Will I make the high school basketball team?*), as well as what will happen in the world at large (e.g., *Will the rain hold off until the picnic?*). Trying to answer these questions, people may consult their friends, their elders, even a ouija board or astrological chart for some clue about how the future might behave.

This fixation on the future is equally apparent in people's professional lives. The prediction business is a $200 billion industry. There are at least 200,000 people licensed by the National Association of Security Dealers to estimate future stock prices and company earnings. Roughly $5 billion a year is devoted to forecasting the weather (Sherden, 1998). And these figures do not in-clude professions that have prediction as a core element in their activities, such as doctors providing prognoses of their patients' future health, personnel directors divining which job applicant will best fulfill job duties, and city planners calculating the environmental impact of new construction.

There is, however, a troubling truth about the task of prediction. In an observation that has been variously attributed to Nobel laureate Nils Bohr and to baseball great Yogi Berra, among others, prediction is hard, especially about the future. People strive effortlessly to anticipate the future, but their forecasts often tend to be far from perfect and sometimes prove dramatically wrong. People fail to hire the right person for job. They misestimate their chances of getting into the "right" law school. They find themselves working on projects far later than they anticipated working on them.

Even professionals whose careers depend on providing plausible projections meet with only modest success (Sherden, 1998). Despite the billions of dollars spent on weather prediction, meteorologists still accurately predict future weather only a few days into the future (Ahrens, 1991). Despite its obvious social consequences, forensic psychologists and psychiatrists predicting which criminals will prove dangerous again in the future achieve only meager achievement at the task, and they are often outperformed by simple mathematical formuli that can be quickly designed to do the same task (Dawes, 1979; Dawes, Faust, & Meehl, 1989; Meehl, 1954). And, despite a history of over 100 years, economists know for sure that the business cycle exists, but they cannot pre-

cisely project when the next boom or recession will be-
gin. As famous financial guru Warren Buffett put it, of-
ten the only apparent value of economic forecasting is to
make the fortunetellers look good.

This chapter focuses on the psychology of prediction
and outlines some of its principles. It describes how peo-
ple approach the important, ever-present, yet vexing task
of prediction, delineating the strategies that people
commonly pursue when they calculate what the future
holds for them as well as the usual outcome of those
predictions—that is, how accurate those predictions tend
to be.

In doing so, the chapter describes three different sets
of principles regarding the psychology of prediction.
First, the chapter enumerates *principles of outcome*, de-
scribing what patterns researchers typically find when
they explore the level of accuracy and bias in prediction.
Second, the chapter outlines *principles of process*, describ-
ing the psychological processes by which people reach
their predictions. Third, the chapter outlines *principles of
improvement*, describing alternative ways that people
could approach their predictions to ensure greater accu-
racy. Table 4.1 provides an outline the material con-
tained in this chapter, as well as a list of the types of prin-
ciples that are described and discussed in it.

In giving such an "inside" view to the psychology of
prediction, the chapter sets forth two assertions. The first
is that the real story of prediction is not how people go
about doing it but rather on what they *fail* to do but could
if they developed the habit; people could make more ac-
curate predictions if they paid more attention to crucial
information they potentially have at their disposal. The
second assertion is that prediction is an inherently diffi-

cult task. People very rarely have all the necessary infor-
mation at their disposal to make accurate forecasts. As a
consequence, people should not be expected to be over-
whelmingly accurate in the predictions they make—and
the meager success people achieve in personal and pro-
fessional realms should not be considered that much of a
surprise. After discussing these two assertions, I finish
the chapter by talking about additional steps, suggested
by recent research, that people can take to reach more ac-
curate forecasts of what future lays ahead of them.

PRINCIPLES OF OUTCOME: COMMON BIASES IN PREDICTION

Before discussing the strategies people follow in making
predictions, it is important to stipulate, with data, that
predictions tend to be far from perfect—and, thus, out-
line the principles of outcome that characterize typical
imperfections. History is replete with bad predictions. In
1895, Lord Kelvin pronounced that heavier-than-air fly-
ing machines were a physical impossibility. The Institute
for Boiler and Radiator Manufacturers in 1955 predicted
that U.S. homes would soon be heated and cooled by
their own household nuclear reactors; vacuum maker
Alex Lewyt that same year forecast that nuclear-powered
vacuum cleaners would be in the stores by 1965. Decca
Recording Company in 1962 rejected a contract with the
Beatles because it felt that guitar music was on the way
out (Kusterbeck, 2004).

Of course, not all predictions are bad ones. History is
also filled with accurate forecasts that could be just as eas-
ily recounted. Thus, beyond counting up the good pre-
dictions with the bad, is there any comprehensive way to
describe the worth or worthlessness of people's predic-
tions? Such a task is difficult, but the psychological litera-
ture provides clues about the systematic types of errors
that people make in their forecasts. In all, predictions
tend to be characterized by two general shortcomings,
which serve as two principles of outcome. The first prin-
ciple is that people tend to make predictions of the fu-
ture that are too optimistic. The second principle is that
people tend to be overly confident in their predictions,
overestimating the likelihood that those predictions will
prove right, whether those predictions point in an opti-
mistic or pessimistic direction.

Undue Optimism in Predictions

People tend to render predictions that are overly opti-
mistic in that the future they ultimately encounter of-
ten does not match the rosy outlook described in their
forecasts. Evidence for this first principle of outcome,
undue optimism, comes in two forms in the psycholog-
ical literature. First, when people make predictions,
they overpredict the occurrence of positive actions and
outcomes and underpredict negative ones. Second,
when people estimate how long it will take to com-
plete a task, they typically underestimate the amount
of time it will take.

TABLE 4.1. Outline of Principles of Prediction Discussed in This Chapter

Principles of outcome
  Undue optimism
    Overprediction of desirable events
    Planning fallacy
  Overconfidence

Principles of process
  Prediction as scenario-building process (adopting an "inside"
    approach)
  Incomplete scenario building
    Focusing on abstract and neglecting the concrete
    Focusing on central outcomes and neglecting alternatives
    Focusing on the optimistic and neglecting the pessimistic
    Focusing on distinctive features of events and neglecting
      shared ones (focalism)
    Focusing on the strength of evidence and neglecting its weight
  Limited utility of scenario building
    Unknown and unknowable situational details
    Inaccessibility of emotions and their impact

Principles of improvement
  Prediction as data-based process (adopting an "outside"
    approach)
  Cognitive repairs
  Aggregating predictions

Overprediction of Desirable Events

The best of all possible worlds tends to be the one that people believe will arrive in the future. For example, when people are asked to describe their past, they provide a portrait containing a mixture of positive and negative features. However, when they describe the future, the picture they paint tends to be uniformly positive (Ross & Newby-Clark, 1998).

One sees this rose-colored optimism in the predictions people make of their future behavior. People tend to overestimate the likelihood that they will buy a flower for charity, volunteer to work at an American Cancer Society fundraiser, vote in an upcoming election, volunteer to do a long and arduous experiment, and have a long-lasting romantic relationship (Epley & Dunning, 2000, 2004; Sherman, 1980). They overestimate how likely it is that they will challenge an aggressive opponent in a negotiation (Dieckmann, Tenbrusel, & Galinsky, 2003) and an employment interviewer who sexually harasses them (Woodzicka & LaFrance, 2001). College students overpredict their performance on their course examinations (Gilovich, Medvec, & Kerr, 1993). Women overpredict the effectiveness of the contraceptives they use, as well as whether they will use them in the month ahead (Hynie & Lydon, 1996).

One also sees this undue optimism revealed in people's actions. People spend significant amounts of money on home exercise equipment, yet a 1997 Sporting Goods Manufacturers Association survey found that the equipment was not regularly used in around a third of the relevant households. People buy memberships in health clubs—and then go so seldomly to the club that they would have been better off to have paid for each individual visit separately rather than for the rather expensive memberships (Della Vigna & Malmendier, 2002). People go on diets yet fail to keep the weight off. One typical reaction is to go on the diet again, causing a syndrome of yo-yo weight loss and gain that can be more injurious to health than just living with one's original weight (Polivy & Herman, 2002). Corporate CEOs announce mergers and then typically watch the stock price of their company and the one they want to acquire go *down*, not up, contrary to their optimistic assessment (Hayward & Hambrick, 1997).

The Planning Fallacy

People also display undue optimism when they specifically estimate how long it will take them to complete tasks or projects they are currently working on, a phenomenon known as the *planning fallacy* (Buehler, Griffin, & Ross, 1994). For example, taxpayers filing their returns typically predict that they will finish the forms 1 week sooner than they do in actuality—2 weeks sooner if they expect that they will receive a sizable refund (Buehler, Griffin, & MacDonald, 1997). College seniors completing a thesis "realistically" predict that they will complete their work 3 weeks sooner than they actually do—and even their "worst case" prediction tends to be 1 week too optimistic relative to the actual amount of time they take (Buehler et al., 1994).

The prevalence of the planning fallacy is not constrained to individuals making informal predictions in their personal life. Business predictions made by organizations tend to be characterized by the same bias. Research on "grand scale" projects, such as the Golden Gate Bridge, Erie Canal, and the Empire State Building, shows that these projects tend to take much longer to build and cost much more money than originally anticipated. Moreover, once built, the revenue stream these projects generate tends to come in much lower than initially estimated (Shapira & Berndt, 1997). In perhaps the most illustrative example, the Sydney Opera House in 1957 was predicted to open in 1963 at a cost of $7 million. It finally opened in 1973, in a scaled-down version, after $102 million had been spent (Buehler, Griffin, & Ross, 2002).

Overconfidence in Prediction

People also tend to imbue their predictions, whether optimistic or pessimistic, with too much confidence. As a long history of psychological research indicates, when people are asked to estimate how likely their predictions are to prove right, the likelihood they cite is too high relative to actual accuracy (for an informative review, see Lichtenstein, Fischhoff, & Phillips, 1982). For example, when an individual states that he or she is 80% certain to receive an "A" in a relevant course, the real likelihood that the student will receive that grade tends to be significantly lower. Indeed, even when people express 100% certainty in their predictions, they tend, depending on the circumstance, to be wrong roughly 20% of the time (Fischhoff, Slovic, & Lichtenstein, 1977; see also Dunning, Griffin, Milojkovic, & Ross, 1990; Vallone, Griffin, Lin, & Ross, 1990). This typical overconfidence serves as the second principle of outcome in the psychology of prediction.

Such overconfidence has been observed in a wide variety of contexts. Students predicting, for example, whether they will take part in the school play, change their career plans, question their decision to attend their college, take part in intramural sports, and change roommates tend to overestimate the accuracy of their predictions, on average, by 10 to 15 percentage points (Dunning & Story, 1991; Vallone et al., 1990). Professionals, too, make predictions with too much certainty. Several examples abound in the medical literature. Physicians diagnosing pneumonia dramatically overestimate the accuracy of their decisions (Christensen-Szalanski & Bushyhead, 1981). Surgical trainees do the same with their diagnoses of possible fractures after examining patient X-rays (Oksam, Kingma, & Klasen, 2000). Clinical psychologists overrate the accuracy of their diagnostic inferences after reading patient case materials (Oskamp, 1965). Similarly, professionals engaged in international security and politics (e.g., think-tank policy analysts and government intelligence analysts) overestimate how likely their predictions about world events will later prove accurate (Tetlock, 2002).

Why might prediction fall prey to these twin biases of undue optimism and unwarranted confidence? One answer to this question may lie in the strategy people adopt when they engage in the task of prediction. However, perhaps the better answer lies in what people *fail* to do when they follow that strategy.

PRINCIPLES OF PROCESS: I. THE SCENARIO-BASED NATURE OF PREDICTION

Prediction might be hard, but describing the basic strategy people use to reach predictions is somewhat easier. A good deal of evidence from cognitive and social psychology indicates that people estimate the likelihood of an event by constructing scenarios that would suggest it. To the extent that scenarios suggesting an event are simple, easy to construct, plausible, and numerous, people conclude that an event is more likely to happen (Atance & O'Neil, 2001; Dougherty, Gettys, & Ogden, 1999; Dougherty, Gettys, & Thomas, 1997; Kahneman & Lovallo, 1993; Kahneman & Tversky, 1982; Koehler, 1994; Koriat, Lichtenstein, & Fischhoff, 1980; Lagnado & Sloman, 2004; Mynatt, Doherty, & Dragan, 1993). In essence, the act of prediction is one of "mental simulation," that is, taking current conditions and building causal chains of events that would lead to the focal outcome in question. In the literature, this scenario-building strategy is referred to as the "inside approach," in that people set up a mental model of the relevant situation and explore its internal dynamics to see what outcomes are most plausibly suggested (Kahneman & Tversky, 1982; Lagnado & Sloman, 2004). In terms of a principle of process, this reliance on scenario building serves as an overarching principle in the psychology of prediction.

This inside, scenario-building view of prediction is evident in many corners of psychology. For example, in their discussion of the *representativeness heuristic*, Kahneman and Tversky (1973) suggested that people predict uncertain events by taking what they know of the world to see if it matches their model of some outcome in question. For example, if Donna loves books, speaks three languages, and shows little concern for money, one can easily spin a story that Donna will become a professor of comparative literature. Her talents and preferences squarely match the job profile of the typical comparative literature professor, and thus it is easy to simulate Donna favoring this career choice if she were exposed to it. The scenario needed to translate Donna's current characteristics to this future career choice involves neither too many steps nor ones that are implausible. In contrast, spinning scenarios in which Donna becomes an economist or a lawyer requires more numerous steps of uncertain plausibility, and thus these future career choices would seem less likely.

Asking people to describe their thoughts while they make predictions also reveals the storytelling approach people bring to the task. Dougherty and colleagues (1997) presented college students with vignettes and asked them to predict the most likely explanation for the final outcome. For example, students read about a firefighter who had died outside a building that was on fire and were asked to estimate the likelihood that he had died of smoke inhalation. Students were also asked explicitly to describe their thoughts as they reached their estimates. Students overwhelmingly thought in terms of scenarios, linking how the circumstances they read about would lead to smoke inhalation (e.g., the smoke was so thick he couldn't see) or would not (e.g., firefighters typically wear oxygen masks), and their likelihood estimates closely tracked how well their scenarios suggested smoke inhalation versus some alternative cause.

A scenario-building approach to prediction is also evident from Buehler and colleagues' (1994; see also Buehler & Griffin, 2003) work on the planning fallacy. In one study, Buehler and colleagues asked college students to think aloud that they predicted how long it would take them to complete a project they needed to get done for class. Students dwelled on mental simulations for getting the task done: A full 74% of thoughts focused on creating scenarios of how they would complete the task—either the plans they had for getting the task done or the obstacles that lay in their path. The bulk of the rest (15%) centered on specific deadlines they were laboring under, which also can be construed as a major ingredient in the scenarios they built to arrive at their estimates.

PRINCIPLES OF PROCESS: II. INCOMPLETE SCENARIO BUILDING

Running mental simulations to predict future events might be a more or less reasonable strategy, but it would be a more reasonable stratagem if people did not practice some unsound habits when constructing their simulations. People are not very thorough or exhaustive in the scenarios they build. Instead, when adopting an inside approach, they construct only partial scenarios of the future, systematically ignoring possibilities that they know, if pressed, are relevant. As such, an adequate discussion about the psychology of prediction must turn quickly from the tactics people follow in prediction to spend most of its time talking about what stratagems people eschew. Thus, paradoxically, although the first principle of process regarding prediction is that it is scenario based, the second overarching principle of prediction is that people hardly do a comprehensive job of building those scenarios. The real story of prediction must focus on what people ignore as they construct their forecasts.

In total, the psychological literature suggests five separate and systematic ways in which people's scenarios fail to be comprehensive representations of possible future events, serving as subprinciples under the overarching principle of incomplete scenario building. First, people often base their scenarios on only a few abstract, higher-order features of the events they strive to predict, particularly when those events are far off in the future. Second, they focus almost exclusively on the particular outcome their attention is drawn to, neglecting to simulate the likelihood that some other alternative outcome might

transpire. Third, they accentuate the positive too much in their scenarios while overlooking the negative. Fourth, when comparing the likelihood of one event to another, they focus too much on characteristics that differentiate the two events and too little on features the events have in common. Finally, when people collect information to build their scenarios, they often fail to take into account the reliability and validity of that information. All these habits lead to predictions that err systematically, as well as predictions that are held with too much confidence.

Focusing on the Abstract and Neglecting the Concrete

When simulating uncertain events, people do not construct an exhaustive set of concrete and detailed possibilities. Instead, they often stay at an abstract level, constructing only a partial simulation that dwells on a few central features of the relevant situation. This serves as the first subprinciple under the overarching principle of incomplete scenario building.

The fact that people fail to consider all possible concrete instantiations of an event has been shown by work on support theory (Rottenstreich & Tversky, 1997; Tversky & Koehler, 1994). For example, Tversky and Koehler asked some of their participants to predict the likelihood that someone had died of "natural causes" in the past year. The likelihood estimate participants gave was significantly smaller than the estimates given by another set of participants who were asked to estimate the likelihood of a number of concrete ways people can die of natural causes (e.g., cancer and heart disease). Similarly, participants asked to estimate the chance that someone died from homicide provided higher likelihood estimates when asked to consider separate sets of potential perpetrators (e.g., acquaintances and strangers) than when just considering the general category of homicide alone (Rottenstreich & Tversky, 1997).

Other work shows that overly simple scenarios that skate across details might underlie the planning fallacy. Kruger and Evans (2004) proposed that the planning fallacy arose because people fail to "unpack" the steps needed to complete complex tasks, such as holiday shopping, preparing food, getting ready for a date, or formatting a document. In their studies, they asked some of their participants to furnish more complete scenarios in which those participants detailed and considered all the concrete subtasks they would have to confront in order to finish a complex project. Relative to a control condition, participants who explicitly and deliberately enumerated all the relevant subtasks produced more pessimistic estimates of the time it would take to complete their overall tasks and in two experiments provided more accurate assessments.

Jorgensen (2004b) found a similar pattern when he examined software development teams estimating how much time it would take them to generate a new piece of software. Teams provided more accurate estimates when they pursued a bottom-up strategy, estimating how long it would take to complete each subtask and then simply summing the results to estimate the total amount of time to finish the development project. Teams provided more optimistic and less realistic estimates when they used a top-down strategy, focusing on the project as a whole.

This tendency to rely on simple, abstract, and stereotypical simulations is exacerbated to the extent that people consider events that dwell in the far off future. When focusing on distant events, people concentrate on a few general, higher-order, features of the situation, basing their simulation largely on schematic knowledge of the situation at hand. For example, if Archie asked Edith if she would like to take a vacation on Maui next summer, Edith might base her judgment on just a few general and schematic features that come to mind, such as warm weather, beaches, and comforting tropical breezes. What is left out of her simulation are lower-level, more concrete features of the situation, even though they obviously exist, such as the long plane flight to the island, the need to make hotel reservations, and whatever work might be left at the office while she is gone.

A good deal of recent research has shown that people tend to think of the distant future in terms of high-level features—building simple, abstract, and schematic scenarios—giving short shrift to lower-level features that may have a significant impact on their preferences, actions, and outcomes (Trope & Liberman, 2003; Vallacher & Wegner, 1987). People tend to think of more abstract features when they consider the distant future. For example, Liberman and Trope (1998) asked participants to describe what came to mind when they considered such actions as *locking a door* either in the distant future (e.g., next year) or some time more immediate (e.g., tomorrow). Participants tended to report more higher-ordered and abstract descriptions of the action when it took place in the distant future (e.g., *securing the house*) than when in took place more immediately (e.g., *putting the key in the lock*).

Other measures showed that people think more simply about events in the distant future than events that are almost upon them. When considering an event such as *moving out of an apartment* in the distant future, participants sorted objects associated with the event (e.g., computers, stereo, and clothes) into fewer groupings than they did when considering the event in a more immediate time frame (Liberman, Sagristano, & Trope, 2002). Still other measures show that people tend to think about future events stereotypically. Liberman et al. asked participants to list events that would constitute a "good" or "bad day," either 1 day or 1 year hence. The events listed for 1 year in the future tended to be less variable and more extreme, relative to those listed a day away. Similarly, in a different study, when participants were asked to describe how they would cope with daily events 1 year rather than 1 week into the future, participants described less variable coping strategies considering life 1 year ahead relative to 1 week ahead.

Basing predictions of the future on simple, abstract, and schematic simulations can produce errors, particularly mistakes about what one will prefer in the future. Liberman and Trope (1998), for example, asked college

students which of two class assignments they would like to complete in the future. One assignment had a desirable higher-order feature (its topic was romantic love) but an undesirable lower-order one (the paper to be read was not in the students' native language). The other assignment had an undesirable higher-order feature (its topic was the "attitude concept") but an attractive lower-order one (the paper to be read was in the student's native language). When the due date for the assignment lay 9 weeks in to the future, students preferred the assignment on the desirable topic. However, when the assignment was due within a week, students switched their preferences to the more mundane assignment that was easier to complete. Similar work has shown that when people consider gambling for money, their preferences in the distant future focus on the possible payoff of the gamble. However, as the time frame of those gambles approach, people give more weight to the concrete detail of whether the odds of winning are favorable (Sagristano, Trope, & Liberman, 2002).

People also show a tendency to lean on the simple and abstract when making predictions about other people in the distant future. When predicting another person's actions in the distant future rather than more immediately, people seek out more information about a person's global personality characteristics. People also predict that other people will act more consistently in the remote future than they will in the near future. They are also more likely to ignore important situational details when explaining another person's behavior in a distant time frame rather than explaining more immediate actions (Nussbaum, Trope, & Liberman, 2003).

Focusing on Central Outcomes and Neglecting Alternatives

In their simulations, people focus on the specific outcome in question and fail to pay equal attention to alternative ones. For example, if a student wonders whether she can get into Harvard Law School, she will likely focus on scenarios that would lead to her gaining admittance but fail to consider scenarios that would lead to her rejection. This focusing on central outcomes serves as the second subprinciple under the overarching principle of incomplete scenario building.

This neglect of alternatives has a long history in social psychology. For example, in their classic demonstration, Snyder and Swann (1978) showed that directing people to a focal outcome, such as asking participants whether another person was extroverted, prompted them to seek information that was consistent with that outcome over information that would be inconsistent, such as signs of whether the person was shy (for a review, see Snyder, 1992). As a consequence, the impressions people were left with were biased in the direction of the outcome considered.

In a similar vein, Dunning and Parpal (1989) asked students to consider whether purchasing prepared class notes would improve their course grades. Students stated that the notes would help quite a bit, unless their attention was focused on the alternative of not having the notes. When asked whether not having the notes would hurt their grade, students stated that the notes would not make much of a difference. Dunning and Parpal (see also Dunning & Madey, 1995) showed, with data, that students provided more muted predictions of the notes' impact because they were now simulating what they would do to compensate for their lack of notes. They could have simulated these compensatory efforts when asked the original question about whether the notes would help, but people tend to stay focused on simulating the event in question and neglect simulating the alternative.

Neglect of alternatives is also seen in research on support theory (Rottenstreich & Tversky, 1997; Tversky & Koehler, 1994). In one example, participants were asked to write down the last digit in their telephone number (from 0 to 9) and then to estimate the number of couples in the United States who had that number of children. Estimates for each number of children were then added together, and the resulting sum was 199%, suggesting that subjects had focused on scenarios that would produce the specific number of children they had been asked about but not about alternative numbers of children (Tverksy & Koehler, 1994, Study 2).

Other data more specifically showed that participants failed to consider concrete alternatives. Redelmeier, Koehler, Liberman, and Tversky (1995) gave doctors a detailed case study in which a woman complained of intense abdominal pain. They were then asked to judge the probability that the woman suffered from gastroenteritis, ectopic pregnancy, or some other malady. Doctors on average stated that there was a 50% chance that she suffered from some other malady. However, in a separate condition, when they were reminded of two other concrete diagnoses that lay in the "some other malady" category, their estimates rose to 69%.

This neglect of alternatives has been linked directly to overconfidence. Koriat, Lichtenstein, and Fischhoff (1980) asked college students to answer trivia questions and then to estimate the likelihood, for each answer they gave, that they had been right. They were also asked to provide any reasons suggesting their answer was right and any suggesting they were wrong. The confidence people expressed in their answers was more highly related to how many reasons participants cited supporting their answers than it was to the number of reasons contradicting their answers—suggesting that people were focusing on simulating why their answers were right rather than wrong. Of key importance, when students in a separate study were asked explicitly to write down reasons why an alternative answer might be correct, they were significantly less overconfident in the answers they gave. When students were explicitly asked to provide reasons supporting their answer, there was no change in their confidence levels, presumably because thinking of supportive reasons was a cognitive activity they were already spontaneously engaged in.

Neglect of alternatives may also explain why people tend to be too optimistic in their predictions. Positive events tend to be the focal event in people's predictions.

Predicting such events, they may concentrate on the forces that would produce these positive outcomes. If, instead, people were compelled to simulate the production of more negative alternatives, the predictions they make may become more pessimistic but also realistic. Evidence for this speculation comes from Hoch (1985), who asked students finishing business school to predict whether they would obtain high-salary jobs upon graduation. Students were unduly optimistic about their job prospects unless they were first asked explicitly to write down reasons why they might fail to achieve a lucrative job offer. In contrast, students asked to write down reasons why they would achieve a high-paying job were no different in their confidence level relative to a control condition. Again, this lack of an effect presumably was due to the fact that participants in the control condition had focused on these supportive reasons—but not contrary ones—without any prompting.

Alternative neglect may also explain why people express too much confidence in their judgments and predictions, whether those assessments are optimistic or pessimistic in nature. When college students were given case materials about hypothetical hospital patients who could be suffering from one of two diseases and symptom information about one of the diseases, their confidence increased or decreased depending on whether the symptoms were consistent with the disease. However, when given symptom information about the alternative disease the patient might be suffering, their confidence about the focal disease did not change (McKenzie, 1997; for similar results, see Arkes, Christensen, Lai, & Blumer, 1987; Koehler, 1994).

Focusing on the Optimistic and Neglecting the Pessimistic

In their scenarios, people also concentrate on the optimistic, whereas they underweight or simply disregard the pessimistic. This focusing on the optimistic serves as the third subprinciple of prediction under the overarching principle of incomplete scenario building. The planning fallacy arises, in part, because people generate upbeat scenarios about how they are going to complete future tasks. Newby-Clark, Ross, Buehler, Koehler, and Griffin (2000) asked college students to estimate how quickly they would complete a class assignment that was due within the next 3 weeks. The students were also asked to generate a realistic scenario for completion, a best-case scenario, and a worst-case one—estimating when they would complete the assignment under each scenario. The estimate based on the realistic scenario lay much closer to the one associated with the best case than it was the estimate related to the worst-case scenario. Estimates based on the realistic scenario also correlated much more highly with best-case scenario estimates than they were with worst-case ones. This relative neglect of the worst-case scenario arose even though participants were quite comfortable giving these pessimistic scenarios weight when predicting the completion times of others.

This predilection for accentuating the optimistic appears to be greater when predicting events falling in the distant future rather than the immediate. Eyal, Liberman, Trope, and Walther (2004) asked college students to discuss various changes in the ways final exams could be given in their class (e.g., changing to an honor system). If asked to discuss these changes 3 months before the final exam was to take place, students tended to dwell on positive reasons for the change rather than on reasons against the changes. However, this tendency reversed if asked 2 weeks before exams were scheduled; students focused less on the *pro* and more on the *con* of changing exam procedures.

People's goals also slide from the positive to the negative as events draw near. Pennington and Roese (2003) asked college students about their goals for an upcoming exam. When the exam lay 2 weeks ahead, participants were focused on optimistic goals, such as getting a high score, improving their grade-point average, and showing off their strengths. However, on the day of the exam, students were much more focused not on attaining the positive but on avoiding the negative, such as disappointing themselves and damaging their academic transcript.

A reliance on optimistic scenarios that dissipate over time might explain one commonly observed pattern of overconfidence that similarly evaporates as an event draws near. Gilovich and colleagues (1993) asked college students how well they were going to do on a college exam. On the first day of the semester, students on average thought they would perform at the 82nd percentile of the course—a result that obviously speaks of too much optimism. However, on the day of the exam itself, students more cautiously reported, on average, that they would perform at the 67th percentile. Again, this average estimate was too optimistic, but at least it was closer to an appropriate answer (which would be an average response centered on the 50th percentile).

Further data show that this temporal pattern in confidence estimates comes from the different types of simulations people perform for distant events relative to more immediate ones. Students in a follow-up study were asked to consider different experimental tasks they might be asked to complete. Some of the students were told that they were going to perform those tasks almost immediately, whereas others were told it would be a few weeks before they were brought back to the laboratory to confront the tasks. Students were then asked to rate how well they thought they would do in each task, as well as the factors that would promote or inhibit their performance. Students considering tasks far in the future concentrated on reasons why they expected superior rather than inferior performance. Students in the immediate condition were more mixed in the reasons they cited—causing them to be less certain about whether they would perform well (Gilovich et al., 1993, Study 4). Other data confirmed this pattern of mental simulation. People dwell on the positive when thinking about performances in the distant future but become more mixed when the time of that performance draws near. Indeed, forcing participants considering a distant event to think about it

negatively causes them to lower their confidence significantly (Sanna, 1999; Sanna & Meier, 2000).

Focusing on Distinctive Features of Events and Neglecting Shared Ones

In their scenarios, people also focus too narrowly on building a model of the central outcome in question, ignoring the impact that life in general will have. For example, suppose Larry was asked how quickly he would get his holiday shopping done this winter. To answer this question, Larry is likely to think about how he would go about shopping. He would think about whom he would have to buy gifts for, what types of gifts he would have to get, and what stores he would likely have to visit.

All these details are central to the focal outcome of *getting shopping done*, but they are not the exclusive set of details that matter. Many events that, on the face of it, have nothing to do with shopping might have everything to do with the length of time it takes Larry to get it done. Larry might catch the flu. His car might break down. He might have a big project to get done at the office before the end of the year. None of these events is central to holiday shopping. Rather, they are central to everyday life and would be shared across *any* type of outcome that Larry might be asked to predict, such as whether he would get his taxes done, be able to take that long vacation, or finish painting the house. These background circumstances are potentially important in determining when Larry would finish any major project he might consider, not just one coming around the holidays.

In short, people build simulations that are too narrowly focused on the events they are specifically asked about and fail to build a simulation factoring in how the background *sturm und drang* of everyday living, shared across numerous circumstances, might promote or hinder the outcome in question. That is, they simulate the event but forget that it may be crucial to also simulate "life." This habit has been referred to as *focalism* (Wilson, Wheatley, Meyers, & Gilbert, 2000) or the *focusing illusion* (Schkade & Kahneman, 1998). Focalism serves as the fourth subprinciple under the overarching principle of incomplete scenario building.

The impact of focalism has been most directly shown in predictions people make about their emotional reactions to future life events. Wilson and colleagues (2000) asked college students how much joy they would feel if their college football team won or how much despair they would feel if their college team lost. Their estimates tended to be too extreme. On average, students did not feel as happy as they predicted after a win, nor did they feel as distraught as they expected after a defeat.

Wilson and colleagues (2000) proposed that people mispredict these future feelings because of focalism. Students in their study concentrated too narrowly on the central event of the team's fate and failed to consider how the background of everyday life would tend to add its own little joys and frustrations into the mix, tempering the impact that the football team's fortunes might have on the student's mood. To test this notion, Wilson and colleagues asked roughly half of their respondents to write down the types of activities they would engage in during the few days after a football game. Reminded of all these other quotidian events, respondents provided much more muted predictions about how the football team's fortunes would affect their mood, relative to a control condition. Indeed, the predictions of this "defocused" group proved quite accurate, relative to the more extreme—and erroneous—predictions made by the control group.

Focalism in prediction has been shown in many variants. People simulate the impact of an event for them personally but often fail to take into account that the event might have an equivalent impact on other people. For example, when students are told that 10 points might be added to everyone's test grade in a course whose grades are "curved," they report being quite happy about the prospect. Of course, if everyone's grade is being raised in a course using curved grade guidelines, then the increase has no impact on anyone's grade. Students, however, tend not to recognize this fact, focusing too much on how the 10 points will increase their own grade but failing to "simulate" that this event will have an equal impact on everyone else (Windshitl, Kruger, & Simms, 2003; see also Moore & Kim, 2003).

Similarly, students playing poker bet more after they are told that there will now be a number of "wild cards" in the deck. In a sense, students now act as if their chance of winning has increased—but, of course, it has not. Everyone sitting at a table, on average, is helped to the same degree by the presence of wild cards. People, however, tend to miss this fact, simulating how the wild cards might help them personally gain better hands but neglecting to simulate the "background," that is, how the wild cards will help everyone else as well (Windshitl et al., 2003).

Focalism also arises when people explicitly compare two events against each other, leading to mispredictions. When comparing two events, people focus disproportionately on situational features that distinguish those events, thus giving those distinctive features great weight in any future prediction—often, too much weight. For example, U.S. respondents tend to believe that people living in California are happier and more satisfied with life than people living in the Midwest. Comparing the two locales, it is easy to spot the basis for this prediction: California, for example, has terrific year-round weather. The Midwest does not. If good weather is one component to happiness, then California easily beats the Midwest on this score.

However, basing a prediction of happiness predominantly on weather is focusing too much on what distinguishes California from the midsection of the United States. There are many other factors—common to both locations—that influence well-being much more than the weather, such as one's health, social relations, and traffic on the way to work, among many other variables (Diener & Seligman, 2004). Neglecting these shared variables in a prediction about California leads to a prediction that is too extreme (Schkade & Kahneman, 1998). In a similar vein, college students comparing different dormitories overweight the distinctive features of those dorms, such

as their location, in their predictions of satisfaction, whereas they underweight the impact of features that tend not to distinguish dorms, such as social life (Dunn, Wilson, & Gilbert, 2003).

Focusing on the Strength of Evidence and Neglecting Its Weight

In their scenario building, people also neglect one important aspect of the evidence they survey. They collate evidence in favor of a prediction (and, on occasion, evidence against that prediction) and then examine how well that evidence suggests that prediction. However, they often fail to ask how reliable or valid the evidence before them is. For example, if Harry is politically liberal, loves books, and is not concerned about money, it is easy to predict that he is more likely to be a humanities than an economic major, presuming for the moment that those characteristics and preferences do, in fact, predict preferences in college major. However, what if those pieces of evidence are unreliable, changeable, or outright wrong? Perhaps it is not true that Harry is politically liberal. Perhaps he loved one book this week but will rarely pick up another book again. In short, if the evidence on which people base their predictions is unreliable or mistaken, their predictions will be wrong no matter how valid their prediction model is.

A growing body of evidence shows that people place too much emphasis on the *strength* of evidence, that is, how much the evidence suggests one outcome over another, but not enough emphasis on the *weight* they should place on that evidence, that is, the extent to which the evidence is likely to be valid or reliable. This is akin to judging that a young scholar will be a successful one because of a strong letter of recommendation written by a mentor (strength), without calculating whether the letter writer tends to be a credible judge of another person's potential. This issue goes to the weight one should place on the evidence cited in the letter (Griffin & Tversky, 1992). This emphasis on strength and neglect of weight serves as the fifth subprinciple under the overarching principle of incomplete scenario building.

The following example, modeled after Griffin and Tversky (1992), illustrates one way in which people pay too much attention to the strength but not to the weight of evidence. Suppose one possessed a coin that, if flipped, would have a slight tendency (say, 60%) to come up either heads or tails. However, which way the bias goes is unknown. Now suppose the coin is flipped three times and comes up heads all three times. This is evidence that is strong on strength (i.e., all flips point to heads) but low on weight (i.e., there are only three pieces of evidence). In situations such as these, people are roughly 85% confident that that coin is biased toward heads, although the actual likelihood of bias, based on a Bayesian analysis, is that the coin is only 77% likely to be heads biased. In this case, overemphasizing strength and underemphasizing weight leads to a prediction that is overconfident.

Now, consider a second case in which the coin is flipped seventeen times and comes up heads 11 times.

This is a circumstance that possesses low strength, in that the coin turns up heads only around 67% of the time, but high weight, in that the result is based on a total of 17 flips. In circumstances such as these, people tend to be roughly 65% certain that the coin is heads biased, but the actual likelihood via a Bayesian analysis is 88%. The advantage for heads in this case may be slight, but it is based on a relatively large number of flips, and thus the advantage is more likely to represent the coin's true bias. However, if people focus primarily on the strength (e.g., the extremity) of the evidence but not on the weight they should give it, they may end up not confident enough in their prediction that the coin is biased toward heads.

Other work shows the same sort of prediction biases. When strength of evidence is high but the weight given to it should be low, people tend to be overconfident. When the strength of evidence is low but the weight it should be given is high, people tend to be underconfident. College students and business managers, for example, showed this pattern when trying to ascertain whether a piece of market prediction software is accurate or biased (Jiang, Muhanna, & Pick, 1996). In a similar vein, MBA students trading securities in an experimental market also relied too much on the strength of evidence of whether a security was a good one and too little about whether the evidence they were using was reliable. As a consequence, market prices for securities tended to be too high when those prices were propped up by unreliable information that was, nonetheless, extreme. Traders spent too much money for such securities—and too little for securities that had less strong evidence in their favor but evidence that should have been given great weight (Nelson, Bloomfield, Hales, & Libby, 2001). Traders selling high-strength/low-weight securities, or buying low-strength/high-weight securities, tended to profit much more handsomely than peers doing the opposite.

Summary

In sum, one major difficulty people have in their predictions is that their scenario-building efforts tend to be incomplete. They tend to stay at a higher-level, abstract level in their simulations and fail to simulate important concrete details, particularly when making predictions about distant events. They concentrate on focal outcomes and fail to build full simulations about alternative ones. They simulate optimistic scenarios but then dismiss pessimistic ones. They suffer from focalism in all its variants, tending to simulate the influence of central events without considering the impact of normal, everyday background events. Finally, people respond more to strength of evidence in their simulations while neglecting the weight they should assign to those events.

All these habits explain why prediction tends to be imperfect. If people do not simulate all the facets of the future that are relevant, they will be left with an incomplete and flawed understanding of what the future might hold. That said, incomplete scenario building may not be the primary reason why people's predictions tend to be biased or wrong.

PRINCIPLES OF PROCESS: III. THE LIMITED UTILITY OF SCENARIO BUILDING

The primary reason why people's predictions might be imperfect is that it is impossible to build comprehensive and accurate scenarios of what the future holds. Although the strategy of scenario building may often lead to predictions that are adequate and accurate, it suffers from severe limits to its utility. Scenario building, to put it bluntly, might be somewhat of a fool's errand. It may mislead because people often are just not in a position to simulate all the possible scenarios that may unfold in the future. They simply do not have all the information they need to assess the plausibility and likelihood of future events, and this observation serves as a second overarching principle in process regarding the task of prediction. Two strands of research demonstrate how people cannot be expected to anticipate the future because they do not possess, nor can be expected to possess, all the information they need to do so. One strand focuses on the power of situational details that are often unknowable. The second has to do with how well people predict the impact of emotion on their behavior.

Unknown and Unknowable Situational Details

A central insight developed from decades of social psychological research is that how an event unfolds depends heavily on the exact details and features of that situation. Social psychology is filled with examples of people's behaviors being significantly influenced by small changes in situational circumstances (Ross & Nisbett, 1991). For example, whether someone offers to help someone else in need depends on any number of seemingly small or transient factors that are just not knowable until the moment the situation arises, such as how much time people have on their hands to help (Darley & Batson, 1973), how attractive that other person is (Benson, Karabenick, & Lerner, 1976), how many other people are around (Latane & Darley, 1969), and what mood the person is in (Isen, Clark, & Schwartz, 1976). The problem for anyone making a prediction about whether someone will help in any particular situation is that which of these small details will obtain are just unknowable until the relevant moment arises, and so any scenario an individual might build to predict it will be imperfect, at best. This observation about the unknowability of situational details serves as a first subprinciple under the overarching principle that people often cannot expect to have complete knowledge about future circumstances.

People fail to recognize this fact as they make their predictions. They commonly build only a single scenario, assuming that this scenario contains all the complete information necessary to make a prediction (Dougherty et al., 1997; Klauer, Musch, & Naumer, 2000). Or, if they do consider multiple scenarios, they then dismiss all the scenarios they have built except for the one or the few they consider especially likely (Dougherty et al., 1997). In following this strategy, they fail to consider two important facts. The first is that whichever scenario or scenarios they are considering need not be the one that will actually arise in the future—and that they should consider as many alternative scenarios as they can plausibly generate. The second is that generating as many alternative scenarios as possible is, in the end, a doomed enterprise. If people try to conjure as many scenarios as possible, they will never know with certainty if they have generated all the ones they should. Given this, they should just concede the fact that they do not know how the situation should turn out, and so they should just go ahead and generate a prediction but be hesitant in the confidence they assign to it (Griffin & Ross, 1991).

Griffin, Dunning, and Ross (1990) demonstrated that people predicate their predictions on somewhat specific scenarios that they assume are complete and true. Griffin and colleagues asked participants to make predictions about future events, such as how much they would stay on the phone if called by a survey taker. Participants provided an estimate and then placed an upper and lower bound around that estimate so that they were 50% sure that the actual value would be inside those bounds (and feel 50% certain that the actual value would lie outside those bounds). Participants were then introduced to one of four different experimental conditions. In the control condition, participants were simply asked to reconsider their predictions and to provide once again a best guess, an upper bound, and a lower bound. Not surprisingly, predictions tended not to change. Participants expressed roughly the same level of confidence as in their first prediction, in that the upper and lower bounds they placed around their estimates were only 5% tighter.

In a second condition, participants were asked to describe the features of the situation as they had imagined them before reconsidering their predictions. Participants tended to describe only one scenario, provide roughly the same predictions again, with upper and lower bounds that expanded by only 3%. In a third condition, participants were also asked to describe the details of the scenario and then to assume that those details were *exactly* how the situation would develop. Participants again mostly reiterated their previous predictions and held roughly the same confidence in them, constricting the upper and lower bounds by only 3%.

Taken together, the responses of participants in these three conditions suggest that those in the control condition were already doing what participants in the second and third condition were asked to do explicitly. Participants in the control condition, before making a prediction, were constructing a scenario and then assuming its completeness and truthfulness. By doing so, they revealed little awareness that the future might unfold in very different ways. As a consequence, the upper and lower bounds they placed around their predictions—representing the degree of uncertainty they expressed over their predictions—stayed roughly the same. What participants seemed not to do spontaneously was to consider multiple scenarios, or to recognize that the specific way the future would develop was unknowable and so they should be relatively uncertain about any prediction they made.

Bolstering this analysis were participants' responses in a fourth condition in which they were explicitly asked to

consider alternative scenarios and reminded, in reality, that they did not know how the future would unfold. Put through this exercise, participants expanded their upper and lower bounds by 38%—expressing much less certainty about the predictions they provided. A follow-up study replicated this result: Participants expressed more uncertainty in their predictions after furnishing two scenarios of the future situation surrounding a prediction. To the extent that those two situations differed in their detail and the prediction they suggested, participants expressed more uncertainty about what would take place (Griffin et al., 1990, Study 3).

Inaccessibility of Emotions and Their Impact

Other features of future situations also appear to be unavailable to individuals as they build their prediction scenarios. People are obviously emotional beings. Each month, many individuals pass through episodes of happiness, sadness, boredom, fear, surprise, anxiety, and elation, just to name a few of the emotional states people may find themselves in. Despite lifetimes of experience with the impact of emotion on their thoughts and actions, people do not demonstrate an adequate ability to anticipate how similar emotional states will influence them in the future. People mispredict the intensity of their emotional reactions to future events, as well as the duration of those emotions. They also fail to anticipate how emotionally arousing situations will influence their behaviors and preferences. In essence, if not in the relevant emotional state at the time they make their prediction, people fail in their attempts to simulate how that emotion will influence their reactions to events. Without these accurate simulations, the scenarios on which they base their predictions tend to be mistaken. This observation serves as a second subprinciple under the overarching theme that people often cannot expect to have complete knowledge about future circumstances.

Overestimating Impact of Events on Emotion

The first type of error that people make is that they overestimate the impact of events on their emotional states, in terms of both intensity and duration (Wilson & Gilbert, 2003). Regarding intensity, people believe that just missing their subway train will produce ample levels of regret, but this is not actually the case (Gilbert, Morewedge, Risen, & Wilson, 2004). People believe that Christmas will give them much more joy than they actually experience. Students at the moment they receive an exam grade that is worse than they expected experience fewer negative emotions than they predicted they would a few weeks before; students getting a higher grade than they expected do not feel as elated as they thought they would (Buehler & McFarland, 2001).

People also overestimate how long the emotional impact of an event will last. Young assistant professors overestimate how long their happiness will be damaged by being denied tenure. Voters overestimate how long they will be happy if their gubernatorial or presidential candidate wins or how sorrowful they will be if their candidate loses. Young lovers overpredict how long their well-being will be injured by a romantic breakup (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998). Sports fans overestimate how long their mood will be influenced by wins or losses of a favorite team (Wilson et al., 2000). Health clinic patients overestimate how long they will be distressed if told they are HIV positive, as well as how long they will feel relieved if told they are HIV negative (Sieff, Dawes, & Loewenstein, 1999).

People overestimate the impact of emotions for many reasons (Wilson & Gilbert, 2003), but one particular aspect of emotions that people seem unable to simulate is how such emotions spur them to action. Emotions energize people, and negative emotions energize specific efforts to dispel those emotions. After failure or disappointment, people are quite skilled at finding ways to rationalize the experience away (Dunning, 2001; Kunda, 1990). However, in the scenarios that people build about the future, they seem not to recognize that a negative event will invigorate these rationalization efforts.

For example, Gilbert and colleagues (1998) interviewed college students putatively for a very lucrative short-term job. For some of the students, the decision about whether they were suitable for the job was made by a single, perhaps idiosyncratic, MBA student. For others, the decision was made collectively by a panel of MBA students. Students asked hypothetically about how they would react to being rejected for the job thought they would feel relatively bad regardless of whether the individual or the panel rejected them. However, those actually rejected by the panel felt significantly worse than those rejected by the lone individual. Presumably, students found it easier to rationalize away the judgment of the single individual than that of the panel, but students making predictions about how they would react did not demonstrate any insight into this possibility.

Further research shows that people fail to recognize how negative events spur efforts toward rationalization that ameliorate negative emotional states (see Gilbert & Ebert, 2002), leading them to reach decisions that potentially could cause them to be less happy in the long run. For example, students facing potential rejection for a date by a person of the opposite sex opt to take higher doses of a drug aimed at alleviating psychic pain. However, the pain they anticipate is often dispelled effectively by a level of rationalizing expertise that people appear not to know they have (Wilson, Wheatley, Kurtz, Dunn, & Gilbert, 2004).

Underestimating Impact of Emotions on Action

The inability to recognize how emotion activates rationalization stands as a special case of a more general misunderstanding about emotion. In their simulations of future events, people fail to grasp how much emotions will alter what they pay attention to in a situation and what behaviors they will display and preferences they will express. That is, people may overestimate the intensity and duration of emotions they will feel, but they underestimate just how much that emotion, even somewhat less-

ened, will still have a significant impact on thought and behavior.

Emotions have been shown to have a significant impact on what people pay attention to in the landscape of a situation in front of them. Emotional arousal causes people to pay more attention to stimuli in the environment that are evaluatively valenced (Halberstadt & Niedenthal, 1997; Niedenthal, Halberstadt, & Innes-Ker, 1999), or to any stimuli that might explain the emotion they are feeling (Dutton & Aron, 1974; Valins, 1966). Emotion also predisposes people to reach different assumptions about the meaning of events, such as whether they are in control of them (Lerner & Keltner, 2001).

Thus, in one emotional state, people may view a situation differently from the way they would in a different emotional state—and people appear capable of understanding only imperfectly how their thoughts and actions might change when going from one state to the next. Instead, when they make a prediction, they appear to predicate their predication on the way they view a situation currently, even when they know "intellectually" that their emotional state may be different in a future circumstance. They fail to correct for changes in emotional state, instead projecting their current view of a situation onto the future one in question. For example, Van Boven and Loewenstein (2003) approached people either just before or just after they had worked out in a gym, asking them how much they would be bothered by thirst if they took a hike in the mountains. Respondents reported that they would be more bothered by thirst if they had just finished their workout (and likely to be thirsty themselves) than if they had yet to start. In essence, people had projected their current evaluation of a thirst-quenching drink onto a very different situation.

Other researchers have shown that people, in one emotional state, fail to adequately simulate how their preferences would be different in a dissimilar emotional state. Read and van Leeuwen (1998) approached office workers just after lunch with a promise to return 1 week later with a free snack, either again just after lunch or instead late in the afternoon. Respondents were asked which snack they preferred, a candy bar or a piece of fruit. Respondents realized that they would be hungrier if the experimenters returned late in the afternoon and so were more likely to choose the candy bar over the fruit if the experimenter said he or she would return at 4:00 P.M.

However, respondents' current state of being full from a recent lunch introduced some bias into their decisions. Relative to a group approached with the same proposition at 4:00 P.M., respondents choosing just after lunch were significantly more likely to choose the fruit over the candy bar, regardless of when the experimenters promised to return. Current hunger states had been projected into future hunger states—even when respondents knew at some intellectual level that their state of hunger would probably be different. This tendency has been demonstrated elsewhere and is exacerbated if people are not given time to think through their preferences (Gilbert, Gill, & Wilson, 2002).

Other research has shown how people inadequately anticipate how emotions change the landscape of thought and action. In one such study, roughly half of the college students in a large lecture class were asked, hypothetically, whether they would volunteer to go up to the front of the class to dance to a classic funk tune for $5. Most of the students said they would not, but on average said they would do it if they were paid roughly $21. However, a hypothetical decision to dance in front of hundreds of people is not very anxiety inducing. Being asked for real is—but respondents could not simulate how the emotion of potential embarrassment would change their perception of the situation and influence their decisions to volunteer. When the other half of college students in the room were given an actual opportunity to dance in front of the class for $5, only 8% did so. On average, respondents in this group said they would need to be paid $53 to dance (Van Boven, Loewenstein, & Dunning, 2004; Van Boven, Loewenstein, Welch, & Dunning, 2004).

Summary

Recent research on the psychology of prediction suggests that prediction would be difficult—and predictions open to error—even if people built more complete and thoughtful scenarios about how the future might unfold. People simply do not have access to all the information they need to produce perfect predictions. They often do not know, nor cannot hope to know, all the important situational details they need to know to furnish accurate predictions. In addition, they do not have cognitive access to how emotional layers to situations will influence their thoughts, preferences, and actions. As a consequence, they tend to predict that they will behave in the future the way they prefer to behave now, not able to anticipate how emotions change the landscape of what people think about and how they react to emotion-laden situations.

AFTERTHOUGHTS: REVERSALS TOWARD PESSIMISM AND UNDERCONFIDENCE

Up to this point, this chapter has reviewed work on the two general tendencies researchers tend to see in prediction—undue optimism and overconfidence. However, the astute reader of behavioral and cognitive sciences knows that tendencies are just that—what people tend to do and not what they always do. These inclinations toward optimism and overconfidence may be common, but they are hardly universal. At times, people show the reverse, being too pessimistic or too underconfident in their predictions.

What can be said about these reversals of these general tendencies? To date in the literature, much less has been said about undue pessimism and underconfidence relative to their more common counterparts. However, some fragments of themes have emerged to anticipate when people will be too glum or too unsure about what the future holds.

Undue Pessimism

One central principle guiding this chapter's treatment of prediction is that people often rely on a single scenario when they assess what the future might hold. Often, that scenario is a positive one, for people are awash in a sea of positive information or beliefs that they can use to build a prediction on (Matlin & Stang, 1978). That positive information might influence their guiding scenario by suggesting a tentative frame or hypothesis for the individual to start with. It is on this initial positive frame that people elaborate their predictive scenarios.

But what if the most prominent or bulk of information people had regarding a prediction suggests a negative frame? For example, if people were asked whether they would ever own a horse that won the Kentucky Derby, most would quickly assume that they would not—for the bulk of information they have accessible to them suggests a quick hypothesis that runs in a negative direction (e.g., I do not know enough to buy the right horse or have enough money to buy that horse with!).

One can conjecture that if people quickly come up with tentative hypotheses that are pessimistic, it would be a circumstance in which their predictions would tend to be *too* pessimistic—for many of the same psychological processes enumerated previously that support undue optimism could also just as equally support undue pessimism. For example, recall that people tend to suffer from focalism when predicting how they will perform relative to their peers in a competition—focusing on how some advantage will benefit them greatly even though the advantage is shared by all (Moore & Kim, 2003; Windshitl et al., 2003). This focusing on the self also occurs when people consider disadvantages, with people thinking that the disadvantage will hurt them disproportionately. For example, negotiators tend to think that time pressure and deadlines disadvantage them more than they do the people with whom they are negotiating, even though the same deadline exposes both sides to the same burdens and complications (Moore, 2004).

One can also see how many of the other processes discussed in this chapter can support pessimistic predictions if people's prediction scenarios take a negative turn. If people start from a negative frame—neglect alternative scenarios, focus on the abstract and neglect concrete details of future situations, forget about the mitigating nature of everyday life, fail to consider the weight they should assign to the evidence they have, and ignore the fact that they often just do not have access to how future circumstances will specifically unfold—they are likely to make predictions that are overly glum. The destination of a prediction may be a reversal of the general case, but the cognitive route to that destination may be paved in much the same way as are overly optimistic forecasts.

Underconfidence

Circumstances that lead to underconfidence are somewhat better delineated in the psychological literature. People tend to be overconfident, but if the prediction or task in front of them is quite easy, they seem not to be sensitive to that fact—thus imbuing their predictions with too little confidence, not too much (Gigerenzer, Hoffrage, & Kleinbolting, 1991; Lichtenstein & Fischhoff, 1977; Suantak, Bolger, & Ferrell, 1996). This underconfidence in the face of easy tasks has elicited much empirical and theoretical attention, and several explanations exist for it. Some explanations focus on statistical or artifactual accounts—for example, one can explain underconfidence for easy tasks by simply noting that it is difficult to be overconfident on a task one is getting right nearly all the time (see Juslin, Winman, & Olsson, 2000, for a review of statistical explanations for the hard–easy task effect on over- and underconfidence).

But, again, one can also imagine that the same psychological mechanisms that produce overconfidence in general also work to produce underconfidence when tasks are easy. For example, if people ignore the weight they should give to the evidence in front of them and, instead, concentrate solely on its strength, it would produce underconfidence when evidence is reliable and the weight that should be given to it is great (Griffin & Tversky, 1992).

The same goes for other indicators of accuracy. In adopting an inside view and focusing on scenario building, people tend to ignore past experience and the "outside" data that this experience provides. Sometimes that past experience suggests a decisive prediction; if an event has happened frequently in the past it should be confidently predicted to occur in the future. Thus, if one has bought at least one soda at some point in each week in the past, one should be confident that one will buy at least one in the week coming up. If one can never get one's coworker on the phone during lunchtime, one should confidently predict that calling that coworker at 12:15 P.M. will not work today. However, if people ignore such valuable data when making predictions, they will be underconfident in their predictions when those data clearly suggest a compelling conclusion (Dunning et al., 1990; Vallone et al., 1990). If they are overconfident when they go against decisive data, they may prove underconfident when their predictions are consistent with the data.

Individual Differences—And the Lessons They Suggest

There are also individual differences in the tendency to be optimistic. One particularly telling individual difference centers on *defensive pessimism* (Norem & Cantor, 1986). Defensive pessimists tend to be relatively anxious individuals who deal with the anxiety of upcoming challenges, such as a test in a college course, by setting low expectations about themselves and then running through all the various negative outcomes they might achieve. This strategy can be compared to that of *strategic optimists*, who deal with the same anxiety by making rosy forecasts of the future and then avoiding any contemplation of what might come next. Although defensive pessimists predict more doom and despair than do their more

optimistic counterparts, their level of actual achievement tends to be equivalent once the challenge arrives (for a review, see Norem & Chang, 2002).

However, beyond demonstrating that there are stable individual differences in optimism and pessimism, the literature on defensive pessimism suggests one potentially important facet of the psychology of prediction that, as of yet, has not perhaps been given the attention it richly deserves. So far in this chapter, I have discussed how people reach the predictions they make but have not discussed *why* people decide to make a prediction and choose the particular forecast they decide to endorse. The guiding assumption underlying this chapter is that people have one simple goal in making predictions—they wish to accurately anticipate the future and so their goal is to reach a prediction that will prove correct. People harbor just one motive—the one to be accurate—even if their cognitive habits often circumvent them from achieving that goal.

Tellingly, the habits of defensive pessimists, however, seem to be aimed at achieving a goal other than accuracy—that of reducing the level of anxiety they typically experience (Norem & Cantor, 1986). They predict doom and gloom not necessarily because they believe that is how the future will unfold; they predict doom and gloom because it makes them feel better. Similarly, strategic optimists predict rosy futures to achieve the same aim of reducing any apprehension and disquiet they may feel (Norem & Chang, 2002).

Given this reason, one may wonder what other motivations attach to the act of prediction that having little or nothing to do with the motivation to be accurate. As of yet, no exhaustive catalog of motivations exist, but other research findings affirm the notion that people make predictions for reasons that lie outside the goal of accuracy. For example, people tend to be less optimistic (and more realistic) in their predictions before they reach a final decision about how to act in a given situation. However, once they have committed to a course of action, they become more optimistic and sanguine in their predictions, especially concerning how their actions will lead to success (Gollwitzer & Kinney, 1989; Puca, 2004; Taylor & Gollwitzer, 1995).

This difference stands to reason if one presumes that the act of prediction is motivated by different goals before and after people have decided on a course of action. Before deciding, people are in a *deliberative mindset* in which they wish to accurately weigh which decision is the best to make. This goal pulls for realism and impartiality. However, after deciding, people are no longer interested in accuracy but are, instead, in an *implementational mindset* that aims at energizing themselves to succeed. In this situation, optimistic predictions are more motivating than realistic ones, and so people craft predictions that serve this goal toward fostering a happy outcome (Gollwitzer, 1990).

In sum, work on individual differences suggests that variations in goals might be the key factor that lead people to be overly optimistic versus pessimistic in the predictions they make. Such differences in goals may also influence whether people chronically appear to be over- or underconfident in their predictions—and recent research does suggest that people do differ reliably in the level of confidence they express about their predictions (West & Stanovich, 1997). However, to date, the relations among individual differences, goals, optimism, and confidence have yet to be exhaustively explored, and so remains a topic of tremendous potential for research.

PRINCIPLES OF IMPROVEMENT: ENHANCING PREDICTIVE ACCURACY

The preceding sections enumerate habits that typically lead people to make erroneous predictions, or at least predictions that are too optimistic and held with too much confidence. Given these problems, what is a person to do to improve his or her prediction-making ability? What habits should people adopt to form more perfect forecasts? What principles of improvement should they adopt?

The research literature contains many suggestions for improving predictive accuracy. First, one can construct a more comprehensive scenario-building analysis. Instead of focusing on optimistic scenarios, one should consciously set out to build pessimistic scenarios and then give them weight. Instead of focusing on circumstances that might produce a focal event (e.g., a company to succeed with its new product), one should also focus on conditions that might promote alternative outcomes (e.g., failing with the new product). Instead of succumbing to focalism, and just concentrating on features of situations that are relevant to an event, one could take deliberate pains to simulate how the normal hurly-burly of everyday life might affect one's feelings, preferences, and actions.

These steps may alleviate some predictive error and overconfidence. However, as some previously discussed material suggests, the details of the future are always going to be unknown and unknowable, leading any scenario-building strategy to be incomplete and, thus, imperfect. Given this, what is one to do?

Adopting the Outside View

The literature suggests that one primary way to improve predictive accuracy—that is, one principle of improvement—is to set aside scenario building and adopt a completely different strategy. Instead of taking the "inside view," focusing on the individual case to be predicted, analyzing its internal dynamics and assessing how certain outcomes are potentially caused, one should instead take an "outside view." Taking an outside view means recognizing that a particular situation is one example of a class of similar events and then surveying previous situations in this class to tally which outcomes have commonly followed (Kahneman & Lovallo, 1993; Kahneman & Tversky, 1982; Lagnado & Sloman, 2004; Lovallo & Kahneman, 2003). For example, an inside approach to predicting when one will finish one's tax returns is to enumerate the steps one has to take to com-

plete the task and to list the obstacles that might fall in one's way. This approach focuses on the internal dynamics of completing one's tax return and fails to reference similar situations and tasks in the past. Adopting an outside view pushes aside these efforts at mental simulation to instead collate data. One predicts when the tax return will be done by counting up when one has completed one's taxes in the past—or even by tallying when other people typically get their taxes done.

The extant literature suggests that people reach more accurate predictions when they pursue an outside approach to prediction rather than an inside one. This is akin to an experience related by Lovallo and Kahneman (2003), who described a group of education professionals working to revise a school system's curriculum. When each member of the group was asked to predict when the group would finish its work, the most pessimistic prediction was between 2 and 3 years. However, when group members were asked explicitly to adopt an outside view and to consider their experiences with similar groups in the past, one group member with extensive experience with curriculum revision conceded that similar groups took at least 7 years to complete their mandate, if they finished their task at all. Not surprisingly, this particular group finished its specific task 8 years later.

More formal research shows that people provide more accurate predictions when they adopt an outside view. For example, in a study on the planning fallacy, Buehler and colleagues (1994) asked college students to complete an hour-long computer tutorial program aimed at teaching them basic principles in psychology. When participants in a control condition were asked to predict when they would complete the tutorial, they tended to underestimate how much time it would take by over a day, and only 29% completed the tutorial by the date and time they predicted. However, when participants were asked to list when they had completed similar assignments in the past (and then reminded that past experiences are relevant to predicting current ones), they showed no tendency to underestimate the amount of time it would take them to finish the tutorial. Indeed, 60% of participants in this condition completed the assignment by the date and time they said they would.

Similar findings have been found in more real-world settings. Software developers provide more accurate estimates of when new software products will be completed if they can recall similar software projects from the past and use those past experiences in their estimates for calculating the time to complete current or future projects (Jorgensen, 2004a, 2004b). Ostrom and Shrauger (1986) found that college students who used "personal base rates," that is, they referred to the frequency with which they performed behaviors in the past, were more accurate in their predictions of future behavior (such as whether would fall in love or change their hairstyle), especially when they considered behaviors with extremely high or extremely low base rates.

Other data suggest that individuals achieve higher accuracy and avoid overconfidence when they use the behavior of other people as a guide to their own. College students make more accurate predictions about future behavior when they predict that they perform behaviors with high base rates than when they make predictions "going against" the base rate (Dunning & Story, 1991; Shrauger, Mariano, & Walter, 1998; Vallone et al., 1990). Curiously, although people appear to have accurate impressions of the base rates of behavior among their peers (Epley & Dunning, 2000, 2004; Nisbett & Kunda, 1985), they do not seem to give this knowledge much weight when they make predictions about individual people, whether it be themselves or a particular other person (Dunning et al., 1990; Epley & Dunning, 2000). As a consequence, they make erroneous predictions and suffer from overconfidence (Dunning et al., 1990; Vallone et al., 1990).

Cognitive Repairs

A second corrective habit is potentially not as radical. Instead of throwing away scenario-based predictions *in toto*, an alternative strategy would be to recognize that scenario-derived predictions carry some validity—they just have to be adjusted for any systematic error these predictions contain. For example, research on the planning fallacy shows that people systematically underestimate the amount of time it will take them to complete the projects they undertake, but people's predictions do contain information, and those predictions correlate significantly with their actual prediction times—with such correlations sometimes reaching as high as .75 (e.g., Buehler et al., 1994). That is, although people show a systematic bias in their estimates, their estimates do accurately discriminate between those who will take less time to complete a task and who will take more.

A similar pattern of error and accuracy arises for the prediction of socially desirable behavior. Overall, people significantly overpredict the likelihood that they will perform such desirable acts as voting in an election and maintaining their current romantic relationship. Despite this overall error, people's predictions carry some information: People who predict they will vote actually do so 75% of the time; those who predict that they will not, vote only 20% of the time. Once again, although people show *bias* overall in their predictions, in that they overpredict the likelihood of performing a desirable behavior, their predictions are not useless—in that their predictions exhibit *discrimination*. Their predictions can be used to discriminate who is the most likely to perform a behavior and who is not (Epley & Dunning, 2004).

The potentially useful principle of improvement to use in prediction would be to ask people for their predictions, which are likely to carry some discriminative information, and then to apply a *cognitive repair* to those predictions to remove the systematic bias that usually contaminates such predictions. One such cognitive repair would be to "dial down" the amount of optimism displayed in a prediction. If a person thinks she is 80% likely to vote, a cognitive repair would be to lower that likelihood to 70% or 60%. Such cognitive repairs are commonly practiced in the business world. For example,

Microsoft Corporation commonly asks its software developers to estimate how long it will take them to finish a new product and then takes that prediction and inflates it automatically by 30–50% if the product is a new operating system. This "repaired" or corrected prediction is the one the company uses in its planning. Similarly, structural engineers are typically asked to estimate how much concrete a structure will need to remain stable. That prediction is then taken and multiplied by a factor between 3 and 8 to guard against overconfidence (Heath, Larrick, & Klayman, 1998).

Aggregating Predictions

A good deal of psychological, economic, and sociological research also suggests that there is wisdom in numbers, in that an aggregated prediction from a group of individuals often outperforms the prediction of any individual. In 1924, Gordon asked 200 college students to rank-order the weights of several everyday objects. She then averaged the ranks given by the students and found that these average ranks predicted far better the weight of the objects than did the ranks given by the typical individual student. Indeed, the average rank given by the group outperformed the estimates of all but 5 of the 200 students in the study.

Since this classic study, research has discovered that aggregating people's judgments works as well for predictions of the future as it does for estimates of weight. Aggregated forecasts outperform individual ones, and often are almost as accurate if not as accurate as the best-performing individual group member (Clemens, 1989; Einhorn, Hogarth, & Klempner, 1977; Hill, 1982; Yaniv, 2004). This finding holds true in domains as diverse as mental health professionals predicting the outset of mental disease (Goldberg, 1965), economists forecasting turns in the economy (Zarnowitz, 1984), and business executives and sales managers predicting future advertising revenue (Ashton, 1986). Not many forecasts have to be aggregated to achieve the full benefit of averaging people's predictions together (Yaniv, 2004). For example, Libby and Blashfield (1978) discovered that the maximum benefit of aggregation was obtained by combining the forecasts of only 3 to 6 experts, although Hogarth (1978) suggested that up to 20 individuals should be consulted, especially if people differed in their estimates.

That, however, is not all. When individual group members are asked to indicate their confidence in their predictions, and these confidence estimates are aggregated, the level of confidence expressed at the aggregate level tends to match the level of accuracy achieved by the group quite well (Plous, 1995). That is, predictions at the aggregate level tend not to be overconfident—or at least not as overconfident as the predictions made by the individuals whose judgments are used to construct the aggregate. This serves as a third principle of improvement.

Aggregate predictions provide superior forecasts to individual predictions because of simple statistical verities. As discussed throughout this chapter, the predictions that individuals provide may be incompletely thought out and imperfectly rendered, but they do tend to bear some relationship, sometimes tenuous, to the truth. The rest of the prediction is made up of error caused by mistakes in analysis, incomplete or biased information, and important data that are simply unknowable. If a group of individuals tends to make predictions that cluster somewhat around the truth, those predictions will tend to diverge from each other and the truth because of forces that produce error. Aggregating those predictions will retain the part of the prediction that is related to the truth while getting rid of some of the individual errors, leading to a more accurate prediction (Einhorn et al., 1977). This analysis, however, depends on two assumptions. First, individual predictions must bear some relation to the truth. Second, the errors that people make must diverge from one another. If all individuals in a group make an error in the same direction (e.g., such as government officials overestimating the robustness of the economy), then the aggregate will retain this bias and fail to prove more accurate (Einhorn et al., 1977).

In sum, a long history of research suggests that the best way to improve one's predictions is to seek out the predictions of other people and aggregate them with one's own (Yaniv, 2004). This research, in addition, demonstrates the imprudence of two closely related strategies that would seem to be as good—if not better than—aggregating individual predictions.

First, if aggregate predictions merely match (or sometimes prove to be slightly worse than) the predictions of the best-performing individuals in a group, why not just identify those best performers and adopt whatever prediction they make? At first blush, this strategy would seem to be sound, but it is not for two reasons. First, people have a very difficult time discerning who among them are the best performers (Libby, Trotman, & Zimmer, 1987; Miner, 1984; Trotman, Yetton, & Zimmer, 1983; Yetton & Bottger, 1982). Second, the very nature of an aggregate prediction is that it gets rid of the error associated with individual predictions. Any individual predictor, even best performers, will be vulnerable to having a greater degree of error associated with his or her prediction. The very presence of that error puts best performers at risk for making predictions that, at times, are wrong. Because aggregate predictions remove, at least in part, that error, this risk is reduced.

The second imprudent strategy would be to bring group members together to hash out their predictions before aggregating them. Groups that interact with each other typically produce products that are not as good as those produced by "groups" formed by merely combining the efforts of individuals working separately (Diehl & Stroebe, 1987; Guzzo, 1986; Hill, 1982; Mullen, Johnson, & Salas, 1991). This is also true in the realm of forecasts. Plous (1995) asked groups of college students to estimate the answers to such questions as the year that Wolfgang Mozart died. Groups talking together produced worse estimates than those produced by averaging the individual estimates of people working independently.

Group interaction detracts from the benefits of aggregation because that interaction causes people to become

redundant with one another. Working separately and independently, each individual is likely to base his or her prediction on at least a slightly different set of information, background knowledge, beliefs, and theories. In this way, each individual brings something unique to the prediction process that, when aggregated with the unique insights of other individuals, may bring the group aggregate closer to reality. However, when people talk, they tend to dwell on the information and knowledge that they share and, thus, neglect perspectives that each uniquely brings to the task (Stasser & Titus, 1985, 1987), and that might pull the group's estimate closer to the truth. As a consequence, group interaction prompts group members to think of the prediction problem in the same way, and thus to become biased in their prediction in the same direction. Aggregation under this circumstance fails to cancel the bias that group members have acquired. As a consequence, group predictions fail to prove superior to individual predictions. This holds true even when groups adopt "best practices" that are often associated with good decision making, such as assigning one group member to play a devil's advocate to the rest of the group's thinking (Plous, 1995).

Group interaction, however, carries another deleterious consequence. Although interacting groups do not necessarily outperform individual judgments, groups that interact tend to reach more extreme and polarized judgments (Myers & Lamm, 1976), as well as judgments that are held with more confidence (Ono & Davis, 1988; Paulhus, Dzindolet, Poletes, & Camacho, 1993; Sniezek & Henry, 1989; Stephenson, Clark, & Wade, 1986), particularly when they reach wrong decisions (Punchohar & Fox, 2004). Interacting groups display more overconfidence than groups formed by aggregating estimates generated individually and then averaged together (Plous, 1995).

Economists have increasingly recognized the value of aggregating predictions to forecast future events better, but they have supplied their own twist. Across several different domains, economists have set up *prediction markets* (also known as *information markets* or *events futures*) in which participants buy and sell financial securities based on their expectations of future events. From the prices of securities traded, researchers derive the probability that the event will occur (Pennock, Lawrence, Giles, & Nielsen, 2000; Wolfers & Zitzewitz, 2004).

The most famous example of such a prediction market is the Iowa Electronic Market (IEM) in which participants trade, for example, securities based on their predictions of who will win presidential and congressional elections. For example, in 2000, the IEM offered a security that paid $1 if Al Gore won the popular vote in the presidential election. People could pay from $.00 to $1 for the security, with the price offered roughly translating to the probability that Al Gore would win the popular vote, if they were acting rationally. For example, if a person bid $.52 for the Al Gore security, that meant that he or she would "break even" in expected value if there were a 52% chance that Al Gore would win (Wolfers & Zitzewitz, 2004).

Many such prediction markets have proliferated in recent years. The Hollywood Stock Exchange offers securities used to predict the opening weekend box office of individual movies, as well as Oscar winners. The Foresight Exchange trades securities tied to possible scientific discoveries. Tradesports.com issues securities tied to the outcomes of sporting events, as well as world events (such as whether Saddam Hussein would still be in power as of September 30, 2003) (Pennock et al., 2000; Servan-Schreiber, Wolfers, Pennock, & Galebach, 2004; Wolfers & Zitzewitz, 2004). Companies have started to run internal prediction markets, forecasting, for example, which new drugs are likely to be successful and which software packages will be developed before the deadline (Wolfers & Zitzewitz, 2004).

According to the logic of prediction markets, the market price serves as an accurate and unbiased estimate of the likelihood of future events. This accuracy arises because the market price contains the sum total of individual estimates driven by all the information and background knowledge that traders bring to the market. In addition, markets should draw only those people who have some information and expertise. People who have little information on which to base a prediction should avoid the market. But more important, markets provide individuals with incentives for trying to get the prediction right. Those incentives might be financial, but at times they can simply be the incentives inspired by competitive spirit and a need to maintain reputation. Such incentives should prompt individuals to set aside personal biases and may even motivate people to research their predictions (Wolfers & Zitzewitz, 2004).

Prediction markets, when tested, do seem to have an enviable record of accuracy. For example, prediction markets tied to elections appear to predict the actual outcome more accurately than do opinion polls. For example, the IEM missed the final popular vote total of U.S. presidential elections from 1988 through 2000 by less than 1.5%, whereas the Gallup poll missed on average by 2.1%. Across 15 cases in which the IEM was pitted against the prediction derived from opinion polls, the market proved more accurate in nine of the cases (Berg, Forsythe, Nelson, & Rietz, in press). In a study of sporting events, a market involving nearly 3,000 National Football League fans, the price set by the market outperformed all but roughly a dozen of the market's individual participants, regardless of whether market participants traded securities involving real or play money (Servan-Schreiber et al., in press). The Hollywood Stock Exchange provides estimates of opening weekend box office receipts that tend to diverge from actual receipts by only 4% on average, a rate that equals the most well-known prediction models used by the film industry. When it comes to predicting who will win the Oscar, the Hollywood Exchange predicts better than panels of experts (Pennock et al., 2000).

To be sure, prediction markets do not rid predictions of all biases that people display in their forecasts. Such markets do not completely stop people from acting on optimistic premises. Political partisans, for example, still

favor their party in election markets (Forsythe, Reitz, & Ross, 1999). In addition, markets, like people, still tend to overestimate the likelihood of rare events (Wolfers & Zitzewitz, 2004). Markets also are not necessarily accurate when dealing with events for which there is little public information available (such as who will be elected as the next Pope) (Wolfers & Zitzewitz, 2004). But, as a general mechanism for aggregating individual knowledge from diverse perspectives into an aggregate estimate, prediction markets, as demonstrated by an impressive first-generation of research, have shown much promise. They may not provide perfect predictions, but the level of perfection found in their predictions far exceeds that of any alternative. Future research will have to be conducted to see if this initial promise continues to be revealed or whether this promise is bounded by circumstances that have yet to be identified.

CONCLUDING REMARKS

At the beginning of this chapter, I noted all the time, energy, and expense that people spent focusing on the future and trying to anticipate it. I then went on to chronicle how, despite the effort that people expend on prediction, the forecasts they provide tend to possess some systematic biases. People tend to be too optimistic, and they tend to express too much confidence in the predictions they provide.

The extant research suggests that these biases share a common source. People build mental scenarios of the future, simulating what events might arise in the future and then noting what outcomes those events might imply. The scenarios that people build, however, tend to be narrow and incomplete. They neglect pessimistic turns that the future might take. They give short shrift to scenarios that might imply alternative outcomes other than the one the individual focuses on.

More problematic, however, is the impossibility of anticipating all the situational features and forces that might influence behavior once that situation arrives. Human behavior depends importantly on situational details, but often those details are unknowable. Human behavior also depends on emotion, and an emerging body of evidence suggests that people do not adequately anticipate how emotion influences the preferences people form and the actions they take once emotion is aroused.

However, such a portrait of the human ability to render predictions would be unnecessarily bleak. People may provide imperfect predictions when they build scenarios and adopt an "inside view" to prediction, but they do have information available that would help to form more accurate predictions if they used it.

In essence, if people formed new habits when they approached predictions or decided to use a different strategy, they might have the wherewithal to enhance the accuracy of their predictions. One new strategy would be to adopt an "outside," more data-driven, approach to decision making—looking at similar situations that have happened in the past or to other people and using those ex-

periences as a basis for their predictions. People would also profit if they collated their predictions with those of other people. People may base their individual predictions on incomplete information and imperfect expertise, but pooling their flawed suspicions with those of others appears to aggregate valid suspicions while getting rid of erroneous ones. Psychologists have discovered this principle by pooling the estimates of their respondents. Economists have discovered this principle as well in their explorations of market behavior.

Given all this, it appears that the time is ripe for further research on the psychology of prediction. Past research has shown, in some detail, what people fail to do when they render predictions, and how those failures damage the accuracy of people's forecasts. The future could, instead, turn away from these failures to make proposals about what people could or should do—what habits they could adopt—to render more accurate predictions. Are there ways to improve on the outside approach to prediction? Are there times in which the inside view is superior to the outside approach? How should outside tactics be blended with inside information to take advantages of the merits of both? And what about aggregating predictions? Are there other more valuable ways to combine the predictions that different individuals make? Putting this all together, is there a recipe of "best practices" that would aid people to provide the most accurate forecasts possible?

There are many questions to answer, and it is difficult to predict what the answers of those questions would look like.

CHAPTER 5

Expectancy

Neal J. Roese
Jeffrey W. Sherman

Contemplating the future consequences of present actions has a proud lineage among us primates, and is one of the secrets of what is still, by and large, the stunningly successful story of humans on Earth.

—Carl Sagan (1997, p. 91)

Nearly every human society has reserved a special place for those denizens claiming the ability to predict the future. Prophets, astrologers, shamans, witch doctors, and scientists are but a few examples of the numerous occupations predicated on foretelling what has yet to occur. Wielding runes, charts, crystal balls, hallucinogens, or mathematics, practitioners of prophecy have achieved widely varying degrees of predictive success. Yet even a little success goes a long way, for enormous is the value of prophecy to any society or any individual. Prophecy brings power in its purest sense: power to acquire that which is most desirable and avoid that which is most repugnant, power to achieve victory and conquest, power to bypass famine and flood. Regardless of the scope of prediction, the essential value remains invariant: to predict the future is to navigate it more effectively.

"Expectancy" is a generic term referring to beliefs about the future. From short-term dinner plans for the weekend to long-range forecasts of financial investments, people think about the future and use such thoughts in ongoing judgment, reasoning, decision making, and behavior. Expectancy is a core construct of psychology, a signature building block of cognition that is at once common among animals yet also uniquely human. It is common in the sense that the brains of all ambulatory organisms have evolved to abstract and record survival-oriented patterns of information (food here, predators there) that may then guide subsequent behavior. Yet expectancy is also uniquely human in the sense that we alone seem to have the capacity to create detailed imaginings of future possibilities, to erect vivid simulations of

environments and situations that have never before existed, and to coordinate ongoing behavior, often involving many people, to actualize those possibilities through effort and invention. Expectancy is perhaps a special case of the more general mental time travel capability inherent in episodic memory, which Tulving (e.g., 2002) also has argued to be unique to human cognition.

Expectancies are beliefs about a future state of affairs, subjective estimates of the likelihood of future events ranging from merely possible to virtually certain. This definition is taken from the expectancy chapter that appeared in the first volume of this handbook (Olson, Roese, & Zanna, 1996), and the review that follows is intended to build directly on that earlier chapter. The tone and argument of this chapter are similar and where conclusions remain the same, we restate them only briefly and refer back to the earlier chapter for elaboration. This chapter advances beyond the earlier one in three main ways. First, new insights into the tension between rigidity versus revision of mental representation, particularly in the face of disconfirming information, permit a more rigorous portrait of the expectancy construct. Second, the mushrooming literature on stereotyping (which may be defined partly in terms of expectancies for particular social groups) has yielded a variety of insights that must be integrated into a general overview of expectancy. Third and most centrally, this review is organized around a functional perspective rooted to principles of effective behavioral control, coordination, and automaticity. Expectancy is first and foremost an instantiation of those core cognitive mechanisms geared to action and survival.

The chapter is organized around the following sections. We first establish our theoretical framework by explaining the functional basis of expectancies. We then discuss determinants of expectancies, framed in terms of content-neutral parameters. The consequences of expectancies are then reviewed, structured by the central principle that behavior regulation is the primary function of expectancies, with cognitive and affective consequences operating in support of that primary function.

FUNCTION

The most general and basic function of expectancies is to guide effective behavior. Expectancies constitute information gleaned from past experience, but to be effective, they must be sufficiently lean to be deployed rapidly, particularly when processing resources are taxed. This section focuses first on how expectancies are used to regulate behavior, then on the efficiency of expectancy use.

Behavior Regulation

Expectancies are tools for survival. By anticipating future fortune or misfortune (i.e., by constructing a cognitive map that suggests and directs means of acquisition and avoidance), an organism is in a vastly better position subsequently to acquire and avoid successfully (Bandura, 1986; Higgins, 2000; Irwin, 1944; Rotter, 1954; Tolman, 1932). In short, to act effectively in the world is to draw on information gleaned from previous experience. The expectancy is where past and future meet to drive present behavior. This is the essence of the expectancy construct, a psychological mechanism that is first and foremost a tool for guiding behavior and, hence, ultimately a tool for survival.

Several core functions (or motives) have occupied center stage in recent social psychological theory, including needs for accuracy, control, improvement, affiliation, and affect regulation (e.g., Fiske, 2003; Sanna, 2000; Sedikides & Strube, 1997). Perhaps the most basic function underlying the majority of these conceptions is simply that of behavior control, the regulation of single and sequential actions to ensure survival. Effective management of ongoing behavior subsumes accuracy and control functions and may be put in the service of improvement and affiliation. Affect regulation (mood maintenance, mood improvement, self-enhancement, etc.) is a distinct function best explored separately, but we argue from the start that it is a secondary function of expectancies, largely subservient to the primary function of behavior control. But human beings do vastly more than merely survive; they plan marriages and careers, they move in and out of communities, and they spend an enormous amount of time attending to details both large and small to turn ideas into reality. Expectancy is not just a tool for survival but a necessity for modern living. For this reason, the functional basis of expectancy is best appreciated not at the level of discrete thoughts but at the level of complex thought systems.

Take the example of a roadtrip, say, driving from Chicago to Memphis. Such a journey over hundreds of miles requires not just an expectancy ("I'll be there on Sunday") but a system of expectancies, consisting of at least four different kinds of anticipatory cognitions: (1) a *superordinate goal* (i.e., the destination, Memphis, the ultimate endpoint that gives coherence to the other expectancy components), (2) *plans* (i.e., a set of subordinate goals specifying particular actions that must be implemented to reach the superordinate goal, such as routine car maintenance, buying gas, and making arrangements for an overnight stay midway), (3) *semantic expectancies* (i.e., derived from semantic memory, these form an interlocking web of implicit background assumptions, ranging, for example, from traffic laws, the map layout of interstate freeways, and the location of fast-food outlets), and (4) *episodic expectancies* (derived from similar past experiences stored in episodic memory, such as the last roadtrip down the I-57 highway or the degree of congestion during the last holiday long weekend). Successful goal completion rests on this interlocking set of multiple expectancies.

Regulatory feedback loops are a defining feature of goals (Austin & Vancouver, 1996), and indeed they pervade an expectancy system simultaneously and at multiple levels. A negative feedback loop is one in which the current state is compared to an ideal or expected state, with discrepancies between the two directly eliciting control changes designed to reduce the discrepancy. Returning to the roadtrip example, at the very lowest level, that of the briefest time duration and most subordinate of goals, sits a feedback loop for the mere act of driving. Yet driving is a behavior of tremendous complexity partly obscured by its automaticity. Driving requires continuous online monitoring of visual signals indicating position on the road, proprioceptive feedback revealing motion and acceleration, and symbolic information conveyed by signaling devices such as speedometers and signposts. This information is compared to expectancies, in the form of desired position or speed, and deviations between the desired state and the actual state require rapid correction using pedals and steering wheel. Absence of such correction (e.g., when sleeping at the wheel) is disastrous. This short-term, low-level feedback loop is but one example; yet the same conceptual operation, widely known as a TOTE unit (see Miller, Galanter, & Pribram, 1960), occurs over longer time periods and for larger goals. People compare their current marriages, careers, and other long-running experiences against expectancies taking the form of dreams, ideals, or obligations to others; they note discrepancies; and they engage subsequently in behavior aimed at correcting or reducing those discrepancies (Carver & Scheier, 1998; Higgins, 1987; Markus & Nurius, 1986).

The concept of a negative feedback regulatory loop emphasizes the twin aspects of stability and change with regard to both the incoming current state information and its behavioral response. Current-state information that is similar to the expected state embodies a situation that is normal and requires no change in behavior; state

information that is suddenly dissimilar creates a situation that is abnormal and does require change in behavior. In normal situations, then, expectancies serve to furnish background assumptions, and here their influence is silently implicit. In abnormal situations, however, expectancies become a jarring reminder of how things "ought to have been," defining in precise terms the ways in which the current situation has deviated, and thereby suggesting (or activating) information relevant to behavioral correction (Roese, 2001). Activation of cognitive efforts to better understand what amounts to a failure of prediction is the immediate result, but so too is activation from memory of information semantically related to the newly changed situation, information that creates new expectancies but also suggests new compensatory or corrective behaviors. In a subsequent section, we return to the enormous body of evidence that details what happens when expectancies are confirmed (normal situation) or disconfirmed (abnormal situation).

Behavior control therefore requires continuous online processing in the form of continuous comparison, or pattern matching, between the current state and the expected state. Very likely in parallel to this comparative process is the conceptually similar online comparison between the current state and recent past state. *Processing fluency* is a construct that captures the moment-by-moment degree of deviation detected in such comparisons, with high fluency characterizing the smooth flow of incoming state information that matches closely either the expected state or past state templates (e.g., Benjamin & Bjork, 1996; Jacoby & Dallas, 1981; Johnston & Hawley, 1994; Whittlesea & Williams, 2001). Processing dysfluency characterizes the detection of a mismatch and is the functional equivalent of an alarm system (Lieberman, Gaunt, Gilbert, & Trope, 2002). The perception of fluency and dysfluency may be explicit ("Why did she turn right with her left turn signal blinking?") or subtle and implicit (a momentary stutter in the ongoing processing of visual information that may not be consciously experienced, but may trigger resolution processes). Here there is an exciting new connection of cognitive function to structure with the identification of the anterior cingulate as the probable brain site at which this online monitoring of processing fluency occurs (Botvinick, Braver, Barch, Carter, & Cohen, 2001; Lieberman et al., 2002). Activity in the anterior cingulate indeed corresponds to rapid shifts in emotion, including pain and anxiety, and also attendant behavioral correction. Crucially, anterior cingulate activity is heightened when expectancies are disconfirmed (Carter et al., 1998). Also implicated in detection of expectation disconfirmation is the orbitofrontal cortex, a region with direct neuronal connections to the anterior cingulate (Berns, McClure, Pagnoni, & Montague, 2001; Camille et al., 2004; Thorpe, Rolls, & Maddison, 1983). From this vantage point, the key mechanistic underpinning of expectancy confirmation and disconfirmation is, respectively, activation of similar versus dissimilar information from memory and fluent versus dysfluent processing.

We argue that most expectancies are accurate. Those expectancies based on semantic memory (i.e., based on slowly learned, general world knowledge) are largely accurate, mostly implicit, and utterly essential to effective behavior. Past research on expectancies in particular, but also knowledge activation in general, however, has tended to overlook semantic knowledge in favor of those expectancies rooted to episodic memory (i.e., based on rapidly learned specific instances), which are more often explicit and perhaps more prone to bias. To be sure, expectancies can produce judgmental error, but they do so only rarely against a backdrop of magnificent, silent, and often unappreciated success at overall behavior control.

Efficiency

For expectancies to function well, however, they must deliver information not only accurately but also efficiently. Expectancies that cannot be applied quickly and easily will be of little use in situations requiring swift decisions and nimble action. Indeed, such situations heighten the value of applying expectancies to guide behavior. With insufficient time to comprehend a situation in terms of its unique array of specifics, the ability to bring past experience to bear can be a lifesaver. Empirical evidence from multiple domains supports the idea that expectancies are especially likely to be relied on under trying circumstances. For example, people rely to a greater extent on expectancies relevant to persuasion (e.g., expert opinions are valid) and intergroup behavior (e.g., skinheads are unfriendly) when processing capacity is constrained (for reviews, see Petty & Wegener, 1998; Sherman, Macrae, & Bodenhausen, 2000). More broadly, there is considerable evidence that human judgment and behavior proceeds via *bounded rationality* and that relatively simple rules (a kind of expectancy) are relied on to provide relatively accurate information in a very efficient way (e.g., Gigerenzer, Todd, & ABC Research Group, 1999; Kahneman & Tversky, 1973; Simon, 1956). The efficiency with which expectancies may be applied is affected by a number of important properties and is reflected in the ways that expectancies influence the ongoing encoding of expectancy-relevsant information.

Summary

Expectancies are mental constructions used to guide and regulate behavior. As such, they are best conceptualized as tools for survival. Expectancies guide behavior with great efficiency, meaning that they provide useful information rapidly and with little demand on processing resources. These main ideas are refined further in the next section.

DETERMINANTS AND PARAMETERS

Expectancies vary along several dimensions, or parameters, and the particular envelope of variation along all these parameters for any one expectancy goes a long way toward characterizing its determinants and conse-

quences. Using a parametric approach to categorizing expectancies was a central feature of the earlier chapter (Olson et al., 1996), and it may be contrasted to a typological approach that defines discrete subtypes of expectancies. Miceli and Castelfranchi (2002) used this latter approach, distinguishing between, for example, forecasts (predictions of events believed to be likely), hopes (future events that are thought to be desirable though not necessarily likely), and hope-casts (a predicted future event that is desirable, likely, and which therefore ought to occur). These authors also used mirror-image terms for negatively valenced events (fears and fear-casts). But because of its content-neutral usefulness in encapsulating numerous judgment domains, we retain the parametric approach employed by Olson et al., modifying it slightly to reflect new theoretical insights to have appeared in the intervening years. Five parameters are discussed: likelihood, confidence, abstractness, accessibility, and explicitness.

Likelihood

Perhaps the most basic way of describing an expectancy is in terms of likelihood of occurrence. An expectancy describes an event that may or may not occur with some degree of probability, often conveniently expressed using a scale ranging from 0 to 100% (or 0 to 1). Thus, some expectancies refer to events believed to be low in likelihood ("Dave's attempt to quit smoking has about a 10% chance of success"; "This policeman is unlikely to be friendly"), moderate in likelihood ("Boeing has a 50% chance of meeting its quarterly earnings target"; "Bill is neither particularly introverted or extraverted"), or high ("I am 90% certain that I will eat grilled fish on Saturday"; "All professors are absent-minded"). Olson and colleagues (1996) used the term "subjective expectancy" to denote such variable likelihood beliefs. The extremity of subjective expectancies critically influences the manner and extent to which those expectancies guide behavior and cognition and may be confirmed or disconfirmed by experience.

The determinants of expectancy likelihood reflect the more general input sources for all beliefs, namely, information derived from past experience, social learning, the popular media, and the like. Mood has been shown to influence likelihood estimates, such that positive and negative moods increase perceived likelihoods of positive and negative events (Johnson & Tversky, 1983), but this effect appears to derive largely from the informational cues inherent in particular affective states (DeSteno, Petty, Wegener, & Rucker, 2000). Importantly, when existing expectancies are confirmed, their subjective likelihood may increase. For example, previous success on a particular task increases expected likelihood of future success (Feather, 1966; Feather & Saville, 1967).

People make inferences and attributions that mediate between the input of information and the output of expectancies. For example, consensus information increases entity attributions (Kelley, 1967), which may be taken to reflect belief in an external, objective reality. In this way, consensus information makes expectancies

seem more factual, a process that likely contributes to the conversion of initially subjective expectancies into factual ones ("Everyone agrees so it must be true"). Also, when attributions reflect a belief in stability rather than instability (Weiner, 1985), the resulting expectancy is higher in likelihood ("Chuck failed the exam because of weak ability, which is a stable disposition; I expect Chuck will fail the next exam too"). Importantly, this attribution mechanism underlies the *theory of hopelessness depression*, which suggests that when self-attributions for negative events are stable and global, expectations for the future become chronically bleak, resulting in depressive symptoms (cf. Abela & Seligman, 2000; Abramson, Metalsky, & Alloy, 1989). These are just a few examples of the many ways that interpretive cognitive mechanisms shape the perceived likelihood of future events.

Confidence

Any belief may be held with varying degrees of certainty or confidence. It is important to emphasize that confidence is orthogonal to likelihood. That is, high confidence is not the same thing as a belief in the high likelihood of occurrence. Take the flip of a fair coin. The likelihood of the coin landing with heads up is 50%, and knowing that the coin is fair, an observer would expect this likelihood with extremely high certainty. Both low- and high-probability events may be expected with both high or low confidence ("Jack is very confident that his chances of winning the spelling bee are about 20%"; "Analysts are only somewhat confident of the projected 95% success rate of the new missile system"). Confidence and likelihood are sometimes conflated in studies of expectancy, but we hope future researchers more clearly distinguish between them.

The determinants of expectancy confidence overlap partly with those that influence likelihood. For example, information derived from experience and communication with others can dictate to a large extent the confidence with which the individual expects a particular outcome. Direct personal experience tends to have a greater impact on confidence than indirect experience conveyed by others, as indicated by research on attitudes (Fazio & Zanna, 1981). In either case, increases in experience in a domain increase both the confidence with which expectancies are held and the likelihood that they are abstract. Thus, because abstract expectancies are typically based on a greater sample of experience than episodic expectancies, abstractions are held with greater confidence. Attributions and other interpretive cognitions influence confidence as well as perceived likelihood. Finally, past confirmation of expectancies also increases confidence (see Olson et al., 1996, for further discussion of these points).

Another determinant of expectancy confidence is the interconnection between the expectancy and other beliefs. The greater the degree of interconnection among semantically related beliefs, the greater the confidence with which such beliefs are held. In research on the *hindsight bias* (Hawkins & Hastie, 1990; Roese, 2004), it has been shown that people have difficulty disregarding the

information contained in an outcome in trying to recall their earlier expectancies for that outcome (e.g., after observers learned that the outcome of O. J. Simpson's notorious 1995 murder trial was acquittal, they misrecalled their earlier predictions for acquittal as being higher than they actually were; Bryant & Brockway, 1997). In other words, integration of new information into existing knowledge structures enhances confidence with which particular elements of the knowledge structure are held to be true, and this effect is very nearly the same in both retrospective and prospective judgments (Fischhoff, 1976; Gilovich, Kerr, & Medvec, 1993; Koriat, Lichtenstein, & Fischhoff, 1980). Thus, when people make predictions, they tend to bring to mind attendant information that is consistent with the prediction, which directly fuels overconfidence; manipulations that encourage consideration of alternative future outcomes mitigate that overconfidence (Dougherty, Gettys, & Thomas, 1997; Dunning, Griffin, Milojkovic, & Ross, 1990; Griffin, Dunning, & Ross, 1990; Hirt & Markman, 1995). Like skyscrapers, beliefs structured on interconnected scaffolding stand confidently taller.

This principle of belief interconnection underlies several more specific determinants of both expectancy likelihood and confidence. When people engage in vivid imagination, or *mental simulation*, of particular future event sequences, they subsequently believe the event to be more likely and are more confident of this belief (e.g., Anderson, 1983; Kahneman & Tversky, 1982; Koehler, 1991). Similar effects occur when people are asked to provide explanations (Ross, Lepper, Strack, & Steinmetz, 1977; Sherman, Skov, Hervitz, & Stock, 1981; Wilson & LaFleur, 1995) as to why a particular event might occur in the future. Furthermore, individual differences have also been explored; for example, people higher in need for closure tend to be more confident about future prospects (Hirt, Kardes, & Markman, 2004; Kruglanski & Webster, 1996).

Abstractness

The parameter of abstractness contains enormous implications for the functional basis of expectancies, particularly in terms of efficiency, depth, and temporal dependence. Abstractness refers to the variation between concrete and specific representations (as instantiated by episodic memory) and abstract generalizations that summarize experience across multiple events, people, and contexts over time (as exemplified by semantic memory).

Semantic Expectancies Are Efficient

Semantic expectancies may be used more efficiently than episodic ones. Semantic expectancies are preexisting knowledge structures that are extracted from ongoing experience, stored in memory, and retrieved when needed. By contrast, episodic expectancies must be formulated on the spot before they can be applied. Although both processes (retrieval vs. formulation) may occur automatically (e.g., Hintzman, 1986; Smith & Zarate, 1992), there nevertheless remains a clear difference

in that semantic expectancies deliver accurate, generalizable knowledge relatively more rapidly and with smaller demands on available resources.

The advantage in efficiency of semantic over episodic expectancies is especially evident when individuals encounter novel circumstances (McClelland, McNaughton, & O'Reilly, 1995; Nosofsky, Palmeri, & McKinley, 1994; Sherry & Schacter, 1987). In such cases, ad hoc expectancy generation runs into several problems. First, the levels of temporal, spatial, and contextual details preserved in episodic memories may inhibit the application of such knowledge to novel situations that do not possess those same features. To quickly extract generalities from multiple concrete episodes in an ad hoc fashion is a challenge (e.g., DeLosh, Busemeyer, & McDaniel, 1997). Second, the predictive validity of such expectancies depends on the number and breadth of experiences on which they are based: The larger the sample size, the greater the validity (e.g., McClelland et al., 1995). Third, it is simply more efficient to extract and store generalities in an ongoing fashion than it is to recalculate them every time they are needed by retrieving and summarizing a subset of episodes (Bruner, Goodnow, & Austin, 1956; Hamilton & Mackie, 1990; Klein, Cosmides, Tooby, & Chance, 2002; Nosofsky et al., 1994). Indeed, research demonstrates that the retrieval and application of specific episodes is more easily disrupted than is application of abstract knowledge (e.g., Johnson, Hashtroudi, & Lindsay, 1993; Rothbart, Fulero, Jensen, Howard, & Birrell, 1978; Sherman & Bessenoff, 1999; Tulving, 1983). Thus, extracting and storing abstract features of experience for subsequent use are more efficient ways to turn the past into functionally accurate expectancies than are retrieving and summarizing a large number of relevant episodes in an ad hoc fashion.

Episodic Expectancies Provide Depth

It is also important for effective behavior control to retain and develop domain- and context-specific information that may provide more situationally accurate expectancies than is possible via abstract knowledge. For example, though from past experience we might expect that dogs in our neighborhood are friendly and harmless, it would be important to know that the Rottweiler named Spike who lives around the corner is aggressive and dangerous. Recent evidence points further to the functional interplay between semantic and episodic knowledge. First, specific episodes may be retained and associated with a relevant semantic expectancy, so that when the latter is activated, so too are specific exceptions to the general rule embodied in that semantic expectancy (Bartlett, 1932; Graesser, Gordon, & Sawyer, 1979; Klein et al., 2002; Nosofsky et al., 1994). Some have argued that the main evolutionary purpose of episodic memory is to store instances that violate general expectancies about the world (e.g., McClelland et al., 1995; Schank, 1982; Sherry & Schacter, 1987).

Very likely is a developmental sequence through which people construct a full complement of expectancies that maximize their ability to go beyond the specifics of past

experiences to predict novel situations, at the same time maximizing the specificity, applicability, and accuracy of those expectancies. Initially, expectancies are based on particular episodes, but as experience accumulates, individuals extract semantic expectancies that summarize events across stimuli, time, and situations. Sometimes, however, expectancies become overly general and yield inaccuracies. When confronted with these inaccuracies, expectancies are refined, and more subordinate, narrowly defined expectancies are developed. We learn that not all dogs, roads, or skinheads are the same, and we develop expectancy subcategories. As discussed in detail in a subsequent section, subcategorization is often a direct result of expectancy disconfirmation. In short, expectancies are initially narrow and specific, then become broader and more general, and finally settle at midlevels that balance breadth with depth.

Abstractness Is Temporally Dependent

Expectancies become more abstract the further into the future the individual looks. Events that are imminent, by contrast, are conceptualized more in terms of concrete details. Under the rubric of *construal-level theory* (Trope & Liberman, 2003), recent research shows that in expectancies focusing on the distant future, people use fewer categorical distinctions and are more likely to rely on cognitive simplifications such as the correspondence bias, as compared to expectancies focusing on temporally nearer events. Abstractness as described within construal-level theory can help to explain other kinds of temporal shifts (e.g., those involving value and motivation).

People place greater value on objects or events that are temporally close than far in the future (Loewenstein, 1987; Loewenstein & Prelec, 1993). Given a choice, people prefer rewards that are available in the short term over those available in the long, even if getting something sooner means trading off a bit in value, a piece of human nature that any lender, creditor, or loan shark can readily confirm. Several reasons for this temporal discounting have been suggested, including factors centering on the affective versus cognitive basis of expectancies (i.e., affective expectancies show greater temporal dependence than cognitively rooted expectancies; e.g., Loewenstein, Weber, Hsee, & Welch, 2001; Metcalfe & Mischel, 1999) and on the magnitude of expected value (i.e., smaller values show greater temporal shifts than larger values; e.g., Chapman, 1996; Thaler, 1981).

Motivation also varies with temporal distance. Using the framework of *regulatory focus theory* (Higgins, 1997), Pennington and Roese (2003) showed that goals emphasizing promotion focus (i.e., those aimed acquisition, accomplishment, and improvement to the status quo) tend to aim further into the future, whereas prevention goals (i.e., those emphasizing caution, security, and preservation of the status quo) target the more immediate future. Moreover, people tend to "brace for the worst" by pondering greater potentials for mishap when events loom temporally close than far (Sanna, 1999; Shepperd, Findley-Klein, Kwavnick, Walker, & Perez, 2000). Curi-

ously, it may seem that the temporal dependence of value and motivation are contradictory: A person wants something better in the short term but is motivated to achieve something better in the long term. This contradiction, however, is illusory and disappears when firm definitions of value and motivation are enforced. People may find a thing more desirable now than later, yet they may nevertheless expect to attain even more desirable things in the more distant future. This basic principle is well exploited by creditors who offer "pay no interest for a year" deals. Consumers are unwilling to wait to save money for desired products and so pay interest to get the products today yet are curiously overconfident of their ability to pay off high-interest loans in the more distant future, apparently failing to recognize that neither their income nor their spending habits are likely to change that much.

As suggested already, the increasing abstractness with which increasingly distant future events are construed may be the underlying determinant of both shifts in value and motivation. The concrete tangibility, or "bird in the hand" aspect of temporally near events, may in and of itself confer value, while the abstract generality of temporally distant events may in and of itself invite broader, more maximal promotion goals aimed at comprehensive improvement of life circumstance. Temporal-construal theory points to this integration, and new research in the near (rather than distant) future will likely tackle it more directly.

Accessibility

Accessibility reflects the ease with which the expectancy is brought to conscious attention. As with other forms of knowledge, accessibility reflects the likelihood with which knowledge will be applied to subsequent judgment. Expectancies may be highly accessible because of frequency or recency of prior activation from memory (Higgins, 1996). Moreover, the experience of accessibility itself may feed into judgments: Expectancies may be optimistic, for example, not only as a function of the accessibility of positively valenced information but also as a function of the inference that positive information feels easy to bring to mind (Sanna & Schwarz, 2004).

Whether an expectancy is confirmed or disconfirmed is an important determinant of expectancy accessibility. When an outcome confirms an expectancy, only the merest gist of information regarding the outcome is abstracted and stored in memory, and the expectancy itself remains relatively inaccessible. By contrast, the very occurrence of expectancy disconfirmation makes the expectancy more accessible and instigates sense-making activity aimed at explaining the discrepancy between what is and what was expected. The cascade of cognitive processes stemming from expectancy disconfirmation are considered in detail in a subsequent section, but here we pause to mention two different processes that may result in the *apparent* increase in expectancy accessibility as a function of the experience of surprise. The first process involves, as we have mentioned, the heightened accessibility of a preexisting expectancy. For example, if an of-

fice coworker is seen wearing no clothing, the surprise serves to make accessible an implicit semantic expectancy regarding normal business attire. A second process, suggested by *norm theory* (Kahneman & Miller, 1986), is the absence of a preexisting expectancy. A feeling of surprise may nevertheless result if the outcome evokes the online construction of a new standard of comparison (or norm), assembled via the rapid integration of relevant exemplars, which is then contrasted to the outcome in question. Although this sort of *postcomputed* judgment process produces effects that mimic the effects of *a priori* expectancies, relatively little research has explored either deeper processing differences or the different circumstances in which these two processes arise (see McGill, 1993; Medvec, Madey, & Gilovich, 1995, for exceptions).

Explicitness

Expectancies also differ in the extent to which they are explicit (able to be consciously reported) versus implicit (unconsciously held). At the most basic level, an expectancy may be little more than an association between a concept and an attribute. Such associations are often held without any conscious awareness of their existence (e.g., Greenwald & Banaji, 1995). However, many complex expectancies, such as those that regulate driving a car, dining at a restaurant, or conversing with a friend, are also held at an implicit level. Indeed, the vast majority of the expectancies that guide our behavior are likely doing so without our awareness (Bargh & Ferguson, 2000; Nisbett & Wilson, 1977). The expectancy that can be reported explicitly and accurately is the exception, and expectancies likely only become explicit either when we are asked directly by others to articulate them or when we explicitly formulate them in our own minds when striving toward goals.

This is not meant to suggest that people cannot verbalize many expectancies when directly questioned about them. However, these verbalizations may be linked tenuously, at best, to the nature of the underlying patterns of covariation among attributes and concepts represented in memory systems. Though explicitly considered and reported expectancies are surely influenced by underlying patterns of association, they also are influenced by many other factors, including a host of self-promoting and self-presentational concerns that may distort or conceal the accurate expression of expectancy. Sometimes, as in the case of racial stereotypes, people are unwilling to express their true beliefs, even if they are aware of their nature. In many other circumstances, people are simply unable to introspect and identify the expectations that guide their perceptions, judgments, and behavior. The so-called unwilling and unable problem is longstanding in research on attitudes (Eagly & Chaiken, 1993), and has, over the years, led to a proliferation of measurement techniques designed to circumvent people's reluctance and inability to respond accurately, from the so-called bogus pipeline technique of the 1970s (reviewed in Roese & Jamieson, 1993) to the more recent explosion of indirect

measures, of which one was termed (with tongue in cheek) a "bona fide pipeline" (Fazio, Jackson, Dunton, & Williams, 1995; see Fazio & Olson, 2003, for review of indirect measures).[1]

One important consequence of the development of indirect measures is that it is now possible to measure and observe the correspondence between implicitly held and explicitly reported expectancies. In particular, interesting problems arise when the content of these expectancies are at odds with one another. What does it mean when such a conflict exists? What are the implications for judgment and behavior?

Most frequently, such dissociations have been treated as evidence that people may retain and store both implicit and explicit expectations of the same entity or outcome (e.g., Wilson, Lindsay, & Schooler, 2000). In the stereotyping literature, such dissociations are often described as reflecting the existence of separate implicit versus explicit stereotypes. The idea is that multiple representations of the same object or event exist in memory simultaneously in different memory systems.

An alternative view, and the one we endorse here, is that these dissociations reflect differences in the processes required and permitted by the direct and indirect measurement tasks, rather than differences in underlying representations (e.g., Conrey, Sherman, Gawronski, Hugenberg, & Groom, 2005; Fazio & Olson, 2003; Roediger, 1990). That is, responses on different measurement tasks are just that: responses to tasks, rather than direct reflections of underlying representations. There is no isomorphism between task response and underlying representation. In this view, an important distinction between direct and indirect measures is the extent to which they permit conscious intentions and motivations to influence responses. Whereas indirect measures minimize these processes (though they do not eliminate them; e.g., Conrey et al., in press), direct measures do not. Direct, explicit measures demand subjective judgments that are influenced not only by the underlying systems of associations in memory but also by factors such as people's metatheories about what they believe, beliefs about what they would like to believe or should believe, and beliefs about what other people would like them to believe. Thus, in this view, dissociations between direct and indirect measures often reflect "downstream" processes that occur as an underlying, association-based "signal" is transformed into an explicit response, rather than reflecting true differences in the underlying expectancy "signal."

By no means do we intend to suggest that explicitly reported expectancies are meaningless or unimportant. Many important expectancies may be ill formed or may not exist at all until they are constructed and/or made explicit ("Where do you think this relationship is going?"; "What kind of wedding should we have?"; "How many children should we have?"). Moreover, regardless of their relation to implicit expectancies, the act of making an expectancy explicit undoubtedly has important consequences (e.g., making explicit the expectation that a relationship will lead to marriage). For example, explicitly

stating an expectancy increases the extent to which that expectancy guides subsequent thought and behavior (e.g., Kiesler, 1971; Rusbult, Martz, & Agnew, 1998). Finally, the overwhelming focus on implicit and explicit beliefs that are socially sensitive, such as those surrounding intergroup attitudes, has likely exaggerated the extent to which implicitly held and explicitly reported expectancies are dissociated. Rather little research of this sort has been conducted on other kinds of expectancies, a shortcoming we hope future research is able to address.

Ultimately, the most important question when considering implicit and explicit expectancies is to what extent does each actually predict behavior? So far the tentative answer is: It depends. Obviously, when there is no discrepancy between implicit and explicit expectancies, the two should influence behavior in similar ways. However, when the two are at odds, the key moderator appears to be the manner in which behavior is measured. Just as direct measures of belief permit greater influence of intent and motivation, so too do direct measures of behavior. Thus, it is not surprising that explicit measures (e.g., of racial attitudes and stereotypes) do a better job predicting explicit behaviors (e.g., verbal responses to white and black confederates, explicit evaluations of the confederates, racially relevant jury decisions, and judgments of the legitimacy of the Rodney King verdict) than do implicit measures of those beliefs (e.g., Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Fazio et al., 1995). When conscious intent is permitted influence, it similarly influences expressions of belief and related expressions of behavior. Obversely, measures of behavior that minimize the role of conscious intent (e.g., eye contact and other nonverbal behaviors) are better predicted by indirect measures of belief that also minimize such factors than by explicit measures (e.g., Dovidio et al., 1997; Fazio et al., 1995). Thus, the most valuable measure of expectancy depends on exactly what it is that a researcher wishes to predict from it.

Summary

This section reviewed five parameters that may be used to characterize expectancies: likelihood, confidence, abstractness, accessibility, explicitness. Also discussed were the various influences on these parameters. Together, these parameters capture deeper commonalities in expectancies that differ widely in overt content. The principles by which expectancies guide effective behavior are reviewed in the next section.

BEHAVIORAL CONSEQUENCES

The primary function of expectancies is to guide behavior successfully and effectively. Expectancies do so by informing cognition. In this section we outline how expectancies facilitate successful behavior, then turn in the subsequent section to the more detailed topic of cognitive consequences.

Semantic Expectancies Provide General Guides for Behavior

The most basic function of expectancies is that they establish a set of broadly generic roadmaps for ongoing behavior. Semantic expectancies are those that are abstract and typically implicit. Buying food, navigating about town, getting work done, and enjoying leisure activities on the weekend all rest on vast networks of generic knowledge that comprises semantic memory. Novel situations are dealt with effectively by reliance on assumptions drawn from generic schematic knowledge.

Expectancies for Success Facilitate Success

Although there are numerous qualifications and caveats, it may generally be concluded that belief in future success facilitates future success (Lewin, Dembo, Festinger, & Sears, 1944; Oettingen & Mayer, 2002; Vroom, 1964). Moreover, commitment to a goal and course of action also facilitates performance (Locke, Shaw, Saari, & Latham, 1981; Mitchell, 1974). Expectancies for success produce effects on behavior by way of increases in confidence (Feather, 1966) and task persistence (e.g., Battle, 1965; Carver, Blaney, & Scheier, 1979). In this way, minor setbacks do little to interfere with the broader optimism that keeps the individual on track toward goal completion. There are two main mechanisms by which expectancy effects on performance occur. First, optimism in the sense of expectations of both personal efficacy (ability to succeed) as well as outcome success produces positive affect, which has a general motivating effect that energizes ongoing action (e.g., Bandura & Locke, 2003; Erez & Isen, 2002). Second, elaboration of specific plans fosters implementation intentions that guide ongoing action (e.g., Brandstätter, Lengfelder, & Gollwitzer, 2001; Gollwitzer, 1999; Pham & Taylor, 1999).

These optimism effects perhaps represent the default, but certainly not the only way expectancies influence goal-related behaviors. Drawing again on the regulatory focus theory (Higgins, 1997), the aforementioned effects center on promotion motivation, which involves focus on the attainment of desired future outcomes. Keeping one's "eye on the ball," so to speak, facilitates the eagerness that sustains pursuit of desired outcomes. But people may also strive toward prevention goals, which involve preserving the status quo by keeping at bay those outcomes that are not desired. Under this different motivational orientation, vigilance and defensive pessimism (i.e., focusing on undesirable future possibilities) facilitate success at keeping current circumstances from getting worse (McMullen & Markman, 2000; Norem & Cantor, 1986; Norem & Illingsworth, 1993; Showers, 1992).

On average, however, expectancies for personally relevant outcomes tend to be optimistically biased. True, people can be optimistic about their ability to engineer future success in both promotion and prevention, yet the former is more clearly aligned to the construct of optimism than the latter (Grant & Higgins, 2003). In a subse-

quent section, we note how optimism produces positive affect and hence may be used strategically for affect regulation. In the present context, it seems that a biased construal of reality that "spins" the future more positively than is objectively warranted might be behaviorally advantageous, as it may facilitate performance through either of the two mechanisms named above. But does such bias have drawbacks?

Optimistic Bias Shifts as a Function of Commitment to a Course of Action

As numerous authors have debated, there is a tension between the costs and benefits of bias versus accuracy, for inaccurate forecasts may impede successful action (e.g., Baumeister, 1998; McNulty & Karney, 2004). More generally, blind optimism in the face of obvious setbacks would seem to preclude efforts at remediation. However, it appears that optimistic bias is contingent upon the stage of progress toward goal completion. That is, before a course of action has been committed to, individuals are relatively unbiased, which is useful in facilitating accuracy-motivated assessment of available options. But once commitment to a course of action has occurred, optimism increases, which may then work to facilitate ongoing performance in the manner described above (Gollwitzer & Kinney, 1989; Taylor & Gollwitzer, 1995).

Anticipation of Setbacks Facilitates Corrective Action

In the pioneering early years of manned space flight, NASA engineers anticipated and mapped out in detail numerous failure scenarios (engine failure, navigation failure, explosive decompression, etc.), planned responses for each such scenario, then practiced these responses in dress rehearsals called mission simulations. People do pretty much the same thing. They anticipate possible problems and proactively plan solutions (Aspinwall & Taylor, 1997; Sanna, 2000). Research on anticipatory regret has revealed that people routinely take into consideration the consequences of potential future decisions and actions, then decide and act to avoid future regret (Zeelenberg, 1999). Much research in this tradition has emphasized the potential for bias: For example, individuals sometimes select objectively worse outcomes to bypass the potential for future regret (Zeelenberg, Beattie, van der Pligt, & de Vries, 1996) and they tend to mispredict the amount of regret that is actually felt (Crawford, McConnell, Lewis, & Sherman, 2002; Gilbert, Morewedge, Risen, & Wilson, 2004). As noted earlier, a prevention focus (whether defined as a momentary state or chronic individual difference) that evokes vigilant action can be effective particularly under those circumstances in which obstacles are many (Norem & Cantor, 1986; Showers, 1992). At a more basic level, this research collectively underscores the ability of individuals to create detailed simulations of potential future problems for the specific purpose of guiding proactive avoidance behavior. In short, there is functional value to worrying.

Expectancies Can Be Self-Fulfilling

As the previously noted principles show, expectancies can create their own reality. Such effects may enhance performance and improve the individual's life circumstances, but they may also constitute counterproductive bias. A widely studied example has been variously termed "self-fulfilling prophecy" and "behavioral confirmation." One of the simplest examples is the self-erasing effect of predictive error (Sherman, 1980). When individuals make explicit predictions for their own future performance, the act of explicit expectancy formation renders consistent information more accessible from memory, making this information more likely to guide subsequent behavior and thus creating a push toward behavioral consistency. With behaviors shifting to confirm prior expectancies, predictive "errors" may become less apparent over time.

The self-fulfilling prophecy centers on the effect of expectancies on interpersonal behavior, particularly when the perceiver's impressions or stereotypes suggest expectancies about a target person with whom the perceiver is interacting. Such expectancies guide the perceiver's behavior during interactions with target individuals, with the resulting expectancy-consistent behavior serving to elicit further expectancy-consistent behavior on the part of the target individual. Early research focused in particular on how the expectancies of teachers might influence the achievement behavior of students (Jussim, 1986; Jussim & Harber, 2005; Rosenthal & Jacobson, 1968), but subsequent research has revealed the generality of such effects, for example, in expectancies centering on relationship partners (Downey, Freitas, Michaelis, & Khouri, 1998; McNulty & Karney, 2002), gender stereotypes (Eagly, Wood, & Diekman, 2000; Snyder, Tanke, & Berscheid, 1977), and racial stereotypes (Word, Zanna, & Cooper, 1974). Such effects occur automatically, typically without awareness on the part of either the perceiver (Chen & Bargh, 1997) or the target (Vorauer & Miller, 1997). Yet even so, such effects tend to be relatively weak, when viewed against the backdrop of the general accuracy of expectancies (Jussim & Harber, 2005).

Self-fulfilling expectancy effects tend to be reduced by heightened accuracy motivation and by explicit awareness of the expectancy (Miller & Turnbull, 1986). A general principle extending to any assimilative priming effect is that such effects diminish when the perceiver becomes aware of the prime (Lombardi, Higgins, & Bargh, 1987; Strack, Schwarz, Bless, Kübler, & Wänke, 1993). Moreover, awareness on the part of the target individual, especially when he or she does not like the implications of the expectancy (as in the case of recognition of being unfairly stereotyped), can create what amounts to contrast effects, in that the target may deliberately behave in a manner that contradicts the expectancy to emphasize individuality or autonomy (Brehm, 1966; Neuberg, 1989). Given that these latter effects are motivated, they tend to occur when the expectancy is negative but not when it is positive.

Placebo effects are another example of the self-fulfilling nature of expectancies. A placebo effect occurs when a medical treatment (e.g., a pill) produces a physical impact not by way of any physical effect (e.g., the pill contains no active drug) but rather by way of the perceiver's belief in the efficacy of the treatment (i.e., an expectation of health improvement). In short, people may sometimes be fooled into wellness. Although debate about underlying mechanism continues (e.g., Stewart-Williams & Podd, 2004), the generality of the placebo effect as medical fact and its basis in expectancy is well established (Ross & Olson, 1981) and was reviewed in detail in the previous version of this chapter (Olson et al., 1996).

Summary

This section formed the conceptual heart of this chapter, in that our main argument is that expectancies work principally to guide effective behavior. Expectancies for success facilitate success, but they are especially likely to fuel behavioral progress once the individual has committed to a course of action. Individuals routinely anticipate future difficulty and proactively avoid it. These examples of expectancies working to create their own reality may also be problematic, as when self-fulfilling prophecies serve to perpetuate inaccurate and unfair prejudices. Through all of the aforementioned effects, expectancies exert effects on behavior as mediated by a variety of further cognitive processes, which are utterly critical for continued effectiveness of behavior in light of changing circumstances and learning.

COGNITIVE CONSEQUENCES

The cognitive consequences of expectancies have dominated past research, particularly with regard to their role in attention, encoding, representation, and memory. At a basic level, expectancies guide processing in a manner that is self-perpetuating. Once useful expectancies have developed, our cognitive system is rather conservative about altering or replacing them. Clearly, it would be dysfunctional to abandon effective knowledge too easily. Yet it would also be dysfunctional if expectancies were so stubborn to the facts as to be unrevisable in the face of contradiction (Piaget, 1952). As several theorists have noted, a cognitive system that is either too flexible or too stable would be at an evolutionary disadvantage (e.g., Johnston & Hawley, 1994; Sherry & Schacter, 1987; Tulving, Markowitsch, Kapur, Habib, & Houle, 1994). Thus, despite the generally conservative nature of expectancies, specialized processes exist to maintain vigilance for inaccuracy, to facilitate the encoding of unexpected events, to enhance the integration of those events into expectancies, and to improve memory for the events.

Expectancies are functional because they help to maximize the ratio of useful information gained for effort expended (e.g., Sherman, 2001; Sherman, Lee, Bessenoff, & Frost, 1998). This principle accounts for many of the specific ways in which expectancies influence attention, encoding, representation, and memory, particularly when processing resources are constrained. As resource-conserving devices, it is in these difficult conditions that the functional advantages of expectancies are most acute, and that expectancies are most likely to guide information processing. At the highest level of analysis, the cognitive consequences of expectancies are secondary and subservient to the primary function of behavior regulation. Expectancies are retained, discarded, or tweaked specifically to furnish more useful information to guide ongoing behavior. The cognitive processes surrounding expectancies, and in particular reactions to their confirmation or disconfirmation, represent tools for survival.

Expectancy Confirmation and Disconfirmation

Cognitive consequences hinge critically on whether incoming information confirms or disconfirms an expectancy. The majority of research on the cognitive consequences of expectancies has focused on differences in how expectancy-consistent versus expectancy-inconsistent information is processed. The experience of expectancy confirmation may be seen as the cognitive equivalent of the seafaring condition of "situation normal," meaning that all is well, no new crew action is required, and the currently operative behavior (speed, direction, degree of readiness) is satisfactory. For goal expectancies, situation normal corresponds to a regulatory loop in which current versus ideal conditions approximate, hence corrective action is presently unnecessary.

By contrast, a disconfirmed expectancy is the equivalent of "all hands on deck," meaning that the current situation represents the potential for danger and thus demands at the very least (1) heightened vigilance, but perhaps also (2) corrective action. Expectancies that are disconfirmed may also represent (3) inaccuracy, thus demanding some sort of conceptual repair work to restore or improve accuracy. These three aspects, vigilance, problem-solving, and belief repair, constitute the three primary imperatives of disconfirmed expectancies.

Thus, the functional significance of expectancy-consistent versus expectancy-inconsistent information is quite different. These functional considerations as well as the need for efficient processing largely determine the manner in which expected and unexpected information is attended to, encoded, represented, and remembered. We describe these processes in order of psychological events from initial seeking of and exposure to information, through encoding, representation, and memory.

Information Seeking

Expectancies influence the types of information perceivers seek in the environment. Often expectancies are essentially hypotheses about the world, and individuals seek information to test their validity. This occurs primarily for subjective rather than factual expectancies (which tend to be taken for granted). Far from being evenhanded, however, diverse research indicates a ten-

dency to seek out information that confirms rather than disconfirms the expectancy (Klayman & Ha, 1987; Lord, Ross, & Lepper, 1979; Skov & Sherman, 1986). Indeed, this bias extends perhaps also to the manner in which scientists test theories (MacCoun, 1998). A more detailed discussion of this pattern appeared in the Olson and colleagues (1996) chapter.

Processing Fluency

Exposure to expected or unexpected information influences implicit psychological responses within milliseconds. Several theories have converged on the idea that online processing—attention to and awareness of current experience—involves continuous pattern matching between the incoming sensory stream and semantically related information in memory (e.g., Lieberman et al., 2002; Srull & Wyer, 1989; Whittlesea, 1997). Processing fluency describes the extent to which this pattern matching flows smoothly or is interrupted by mismatches (i.e., expectancy disconfirmations) (e.g., Benjamin & Bjork, 1996; Johnston & Hawley, 1994; Whittlesea & Williams, 2001). The subjective experience of dysfluency (i.e., surprise) may embody mismatches involving perceptual (What should it look like?) or conceptual (What does it mean?) features (Jacoby & Dallas, 1981; Roediger, 1990; Whittlesea & LeBoe, 2003). In sum, expected stimuli produce subjective feelings of fluency and comfort, whereas unexpected stimuli produce feelings of dysfluency and surprise.

Processing fluency represents the first stage at which the cognitive system registers a confirmed or disconfirmed expectancy. The implicit perception of dysfluency is the starting point for the cascade of cognitive consequences that come next.

Attention

Though people may not actively seek out unexpected information, when exposed to it, they will generally attend carefully—more carefully than to expected information. The processing dysfluency that results from expectancy disconfirmation may act as a functional imperative to attend. Research indeed shows that attention is rapidly and automatically directed toward stimuli that are in some way surprising (e.g., Barthalow, Fabiani, Gratton, & Bettencourt, 2001). Interestingly, this principle forms the basis of the enormously successful *violation-of-expectation paradigm*, which has been used to reveal age of onset of particular representational categories in infants (Baillargeon, 2004). Indexed by visual gaze duration, infants who attend longer to an object or event are presumed to have been surprised and hence interested, thus revealing that their brain had in some way represented an expectancy regarding that object or event (Baillargeon, Spelke, & Wasserman, 1985; Wang, Baillargeon, & Brueckner, 2004; Wilcox, Nadel, & Rosser, 1996). This method has revealed that infants as young as 2½ months of age understand that their physical world consists of objects having continuity (i.e., they exist continuously in space and time) and solidity (i.e., two objects cannot occupy the same space at the same time) (Baillargeon, 2004; Spelke, Breinlinger, Macomber, & Jacobson, 1992).

An important moderator of these effects is the availability of processing resources. Under cognitive load, the tendency to attend more carefully to unexpected than expected information is enhanced. Indeed, in these conditions, attention actually shifts from expected and toward unexpected information in the visual field (Sherman et al., 1998). Differences in the conceptual fluency of expected and unexpected information may contribute to this effect. Because expected information is easily assimilated to existing knowledge and is therefore easily comprehended, little attention is required during encoding. The fit between the information and existing knowledge may be briefly noted, with attention then redirected to more novel and potentially important information in the environment. This attention shift is more likely to occur when capacity is depleted because it is under those conditions that the cognitive system is most pressed for efficiency. Such a process embodies both the stability (via conceptual fluency and pattern matching) and plasticity (by directing attention toward unexpected information) of expectancies.

Individual motivational differences also moderate these effects. People who are motivated to see group stereotypes as malleable (i.e., "incremental theorists") are especially likely to shift attention from stereotype-consistent and toward stereotype-inconsistent information when they were under cognitive load (Plaks, Stroessner, Dweck, & Sherman, 2001). In addition, prejudiced people who also are prevention oriented are more likely to attend to stereotype-violating information (Förster, Higgins, & Strack, 2000; Förster, Higgins, & Werth, 2004).

Interpretation

The most readily visible cognitive consequence of expectancies is their influence on how individuals see and understand the world around them. This influence comes in two forms. First, expectancies may act as heuristics in providing direct input into judgments. Generally speaking, a heuristic is a quick and resource-frugal judgment that is accurate often but not always. The use of expectancies as heuristics has been demonstrated in many domains of psychology. For example, in persuasion research, expectancies about source expertise (experts are to be trusted) often influence persuasion to a greater extent than systematic reasoning about the strengths and weaknesses of given arguments (e.g., Petty & Wegener, 1998). In stereotyping research, stereotypes are often relied on to make judgments about others to the exclusion of individual behaviors (e.g., Sherman et al., 2000). In both cases, the expectancies are particularly likely to drive judgments when people either are unmotivated to process carefully or are unable to do so (e.g., if they are under cognitive load).

The second way that expectancies influence an individual's understanding of the world is through their influence on interpretation. The idea that people see what

they expect to see, or interpret events and objects in a manner that assimilates experience to the expectancy, pervades numerous theoretical constructs in psychology, including notions of coding system, frame, schema, script, and stereotype. Much early research showed how concepts, inferences, or category labels influence subsequent interpretation (Bruner, 1957; Bruner et al., 1956; Darley & Gross, 1983; Hastorf & Cantril, 1954; Higgins, 1996; Kelly, 1955; Vallone, Ross, & Lepper, 1985; Wilson, Lisle, Kraft, & Wetzel, 1989); more recent research has shown similar effects with complex goal-oriented expectancies (Kawada, Oettingen, Gollwitzer, & Bargh, 2004) and in active seeking of self-verifying information (Swann, Stein-Seroussi, & Giesler, 1992). In general, this expectancy-assimilation effect is stronger to the extent that the expectancy is stronger and the stimuli more ambiguous (e.g., Alba & Hasher, 1983; Budescu, Kuhn, Kramer, & Johnson, 2002; Swann & Ely, 1984; Trope, 1986; Tuckey & Brewer, 2003).

Conceptual versus Perceptual Encoding

Information that fits expectancies is more easily understood. One consequence of this comprehension advantage, however, is that people do not attend carefully to expected information (e.g., von Hippel, Jonides, Hilton, & Narayan, 1993). A related consequence is that people do not encode the perceptual details (e.g., physical features) of expected information carefully. Rather, the basic conceptual gist of such information is extracted, but little else. In contrast, though unexpected information is often poorly comprehended, it is attended to carefully, and the physical details are encoded well (Sherman, Lee, et al., 1998). As with attention, the perceptual encoding advantage for incongruent information is greater when resources are low, again attesting to the flexible efficiency of expectancy use (e.g., Sherman, Conrey, & Groom, 2004). The careful encoding of the details of incongruent information is another means by which the cognitive system preserves plasticity in the face of expectancy confirmation. Retaining these details helps individuals reconstruct the facts surrounding unexpected events at a later time, when new information and greater resources may be available to help make sense of them. Indeed, differences in the conceptual and perceptual encoding of expected and unexpected events have significant influences on the manner in which these stimuli are represented in memory and subsequently remembered. These issues are addressed in detail below.

Coping with Disconfirmation

Disconfirmed expectancies are at root discrepancies between cognition and reality. They embody failures of prediction and thus constitute inaccuracy within the individual's cognitive model of reality. Such a failure may or may not demand a conceptual fix, but to ascertain which, effort is directed at investigating the nature and source of the failure and correcting it. Summarized next are those higher-order consequences of disconfirmed expectancies that are aimed at cognitive repair.

Disconfirmed Expectancies Evoke Processing That Is Resource Demanding

Whereas confirmed expectancies result in relatively automatic processing, disconfirmed expectancies recruit processing that is more effortful (Bargh & Thein, 1985; Stern, Marrs, Millar, & Cole, 1984; Wilson et al., 1989). Initial perceptual processing takes longer for unexpected than expected stimuli (Jentzsch & Sommer, 2002; Matt, Lethold, & Sommer, 1992). Overall, surprise demands deeper and more careful analysis of relevant information, aimed at explaining and understanding the predictive failure. This core principle linking expectancy disconfirmation to systematic processing echoes through several theories, for example, those aimed at attitudes (Chaiken, Liberman, & Eagly, 1989) and linguistic interpretation (Burgoon, 1993).

Disconfirmed Expectancies Activate Sense Making

Explanation and attribution correspond to an attempt to make sense of an outcome. Because disconfirmed expectancies may constitute danger (as in the case of avalanches, attacking muggers, or outgroup mobs), cognitive effort designed to make sense of them is an essential ingredient for guiding subsequent behavior (e.g., fleeing, fighting, and negotiating).

Sense making involves retrieving information from memory that forms the basis for new explanations (Ahn, Novick, & Kim, 1995; Kelley, 1967), which aim to bridge the gap between prior understanding and current experience (Ahn et al., 2003). Three classes of sense-making activity all reveal evidence of activation by disconfirmed expectancy. *Causal attribution* involves the most basic process of identifying the cause of a particular outcome (John stepped on Susan's feet because he lacks coordination); *counterfactual thinking* involves the more elaboratively narrative articulation of how the outcome might have come about had the key causal condition(s) been different (John might have been a better dancer with more practice in high school); and *hindsight bias* involves the metaperception of confidence that the outcome in question was sensible and predictable (I just knew John would step on Susan's feet). Evidence is most voluminous in support of the activation of causal reasoning by expectancy disconfirmation (e.g., Hastie, 1984; Kanazawa, 1992; Wong & Weiner, 1981); similar evidence is nevertheless available for counterfactual thinking (Roese & Olson, 1997; Sanna & Turley, 1996) and hindsight bias (Roese, 2004; Schkade & Kilbourne, 1991).

Sense Making Results in One of Four Inferential Products

IGNORING

In this first case, the sense-making activity uncovers few insights and little new information in memory or is in some way truncated. The result is that no inferential product becomes available, and the discrepancy is essentially ignored. Examples include the cognitive dissonance theory concept of trivialization (e.g., Simon, Greenberg,

& Brehm, 1995) and the motivated shallow processing of self-threatening hypothetical behaviors (Sedikides & Green, 2000).

TAGGING

Though sometimes sense-making failures will be ignored, in other cases, they will be tagged for future examination and use. As noted already, even if unexpected information cannot be clearly explained, it may receive considerable attention, and the details of the event may be encoded carefully. This allows people to reaccess this information at a later time when comprehension may be more successful. Moreover, unexpected events may be "tagged" onto existing expectancies, so that when expectancies are activated, so too are individual exceptions to those expectancies (e.g., Klein et al., 2002; McClelland et al., 1995). This helps to constrain the reach of expectancies and maintain their plasticity.

BRIDGING

In this third case, the sense-making activity focuses on erecting a conceptual bridge between the expectancy and the disconfirming event, in effect explaining away the discrepancy. Importantly, bridging adds new inferential information while preserving the integrity of the underlying schematic understanding. According to *cognitive dissonance theory* (Festinger, 1957), for example, discrepancies between cognitions may be resolved by adding new cognitions. A particularly common way of bridging discrepancies is by elaborating an exception to a general rule in terms of a subtype category. For example, attributions for disconfirmed interpersonal expectancies tend to focus on external and unstable rather than internal and stable causes (Crocker, Hannah, & Weber, 1983; Feather, 1969; Kulik, 1983). In the context of stereotyping, an explanation for an unexpected group-member behavior may be accomplished by noting a subtype, or new subclass of the stereotype, in which the surprising act is explained in terms of an exception to the general rule embodied in the stereotype (Hewstone, Johnston, & Aird, 1992; Kunda & Oleson, 1995, 1997). These various sense-making efforts conspire to preserve the integrity of the extant expectancy in light of disconfirming evidence, but importantly, they also point to the progressive creation of successively more detailed, multifaceted, and flexible representations of the domain in question. Thus, original expectancies are maintained, but their generality of application is reduced. In short, this bridging principle is an indicator of the deeper, functional process by which schematic knowledge is elaborated in light of ongoing experience, thereby providing successively more effective guides for subsequent behavior. People learn from mistakes.

REVISING

In this fourth case, the discrepancy prompts a reassessment and revision to the original conceptual underpinnings of the expectancy. Unlike bridging, which preserves the integrity of the underlying schema, revising involves changes to the underlying schema at a foundational level. For example, if one goes to McDonald's with the expectation of dining on filet mignon, the magnitude of the error demands a reworking of the essential informational components of the expectancy, along with, perhaps, expansion of the knowledge base supporting it (elaboration of the categorical distinction between fast food and fine dining; gathering new insights from restaurant reviews, etc.). This process has been termed "conversion" in some writings (Hewstone et al., 1992; Piaget, 1952; Rothbart, 1981; Weber & Crocker, 1983), but our emphasis includes not only the dramatic shift in schematic valence denoted by conversion but also the valence-neutral expansion of schematic detail exemplified by the development of expertise (Tanaka & Taylor, 1991), sometimes referred to as *bookkeeping* (Rothbart, 1981).

Discrepancy Magnitude and Schema Complexity Determine the Inferential Products of Sense Making

Theorists have pointed to two main determinants of which type of inferential product tends to emerge from the sense-making activity evoked by a disconfirmed expectancy: the magnitude of the discrepancy between expectancy and outcome and the degree of complexity or sophistication of the underlying schematic basis of the expectancy. For the first determinant, discrepancy magnitude, small discrepancies will be more likely to be ignored than larger discrepancies. Large discrepancies typically result in subtyping processes, whereby separate, specialized subcategories are created to account for the discrepant stimuli or events. In contrast, moderate discrepancies tend to result in slow and steady expectancy revision (e.g., Rothbart & Lewis, 1988; Weber & Crocker, 1983).

Schema complexity, or the degree to which knowledge about the relevant domain is developed, also plays a role. With new schemas, as exemplified by low expertise (e.g., a novice squash player trying to grasp the intricacies of the game), initial attempts at reaching a coherent understanding result in an emphasis on confirmatory search and openness to divergent new information. In this case, the emphasis is on developing useful inferential tools rather than with testing the boundaries of those tools. Moreover, it is more difficult to note discrepancies from weak expectancies in the first place. With greater development of the underlying schema, discrepancies between expectancy and experience are more likely to be noticed and tend to be processed more deeply, resulting in bridging effects (cf. Srull, Lichtenstein, & Rothbart, 1985; Tanaka & Taylor, 1991). It is probably also the case that weak expectancies are more likely to involve revision, but as expertise, accuracy, and certainty grow, both disconfirmations as well as revisions become far less likely (Karniol, 2003). Those disconfirmations that do occur involve mainly bridging (subtyping, in particular).

Representation

Differences in the ways that expected and unexpected events are encoded affect the manner in which the information is subsequently represented in memory. Expectancy-congruent information is not attended to carefully and the details are not thoroughly encoded (e.g., Sherman, Lee, et al., 1998). Rather, the basic conceptual gist meaning is extracted via assimilation to prior expectancies, and little else is retained. Thus, expected events are likely to be retained primarily in abstract, semantic form. In contrast, unexpected events are attended to carefully and the details are more thoroughly encoded. In part, this is simple necessity in that such events cannot be well understood in light of existing knowledge. Accordingly, unexpected events are more likely stored as detailed, context-specific episodes (Sherman, Klein, Laskey, & Wyer, 1998).

Memory

Memory for expected versus unexpected stimuli differs in a number of respects. These differences result from the ways in which congruent and incongruent information is attended to, encoded, represented, and retrieved. The differences are moderated by several important variables.

Recall and Recognition

On measures of both free recall and recognition, memory is superior for unexpected than expected events (e.g., Alba & Hasher, 1983; Stangor & McMillan, 1992). Even when a congruent event can be remembered, its source may not be. For example, stereotypical behaviors are often falsely attributed to people who did not commit them (e.g., Mather, Johnson, & De Leonardis, 1999; Sherman & Bessenoff, 1999).

Such effects center mainly on encoding processes. As noted, incongruent events draw our attention, and because they challenge extant beliefs, individuals expend effort toward explaining them (e.g., *bridging*). This deeper, more elaborate encoding of incongruencies increases their memorability in a number of ways (e.g., Craik & Lockhart, 1972). First, the relatively greater amount of time perceivers spend considering these events in working memory increases their general accessibility (e.g., Higgins, 1996). Second, the attention and detail given to encoding the item-specific features of these events increases the likelihood that the features can be used subsequently as retrieval cues (e.g., Einstein & Hunt, 1980). Third, in trying to make sense of incongruent events, they become associated with other information in memory, creating a wider network of pathways through which they may be retrieved (e.g., Srull & Wyer, 1989). Fourth, the attention to detail and sense making associated with encoding unexpected events increases the likelihood that they will be stored episodically, with details intact (e.g., Klein et al., 2002; McClelland et al., 1995; Sherman, 2001). In contrast, congruent events receive relatively little attention and elaboration and are

likely to be represented abstractly, making it difficult to remember them accurately.

Response Bias, Search Strategies, and Familiarity Increase True and False Memory of Expected Information

Estimates of memory for expected events are often inflated by response biases to report congruent events. Thus, on a recognition test, for example, correct recognition of congruent items may be quite high. However, the high incidence of false alarms on these items indicates that performance is driven largely by a bias to respond positively, rather than by accurate memory. Because congruent items (including foils) fit well with general expectancies, perceivers set low thresholds for claiming their verity (e.g., Stangor & McMillan, 1992). These same biases also appear to account, in part, for stereotypical biases in source memory (Spaniol & Bayen, 2002). The implications for eyewitness testimony are significant.

False memories of expectancy-congruent events may also be based on a feeling of processing fluency associated with those events. Because they fit with expectancies, these events may feel familiar even if they did not actually occur. This familiarity may be misinterpreted as being due to prior exposure, rather than to expectancy fit, leading people to falsely judge typical events as likely to have occurred (e.g., Greenwald & Banaji, 1995; Sherman et al., 2004).

Both true and false memory for expected information is also facilitated by retrieval strategies that take advantage of our expectancies. Thus, even though congruent events may be poorly encoded, they may be remembered when people use their expectancies to generate events that may have occurred. Often, when people are asked to remember what happened, they may reframe the question to themselves as "What is likely to have happened?," leading to a hypothesis-confirming search for expectancy-congruent information (e.g., Hirt, 1990; Hirt, Erickson, & McDonald, 1993). This same process may lead to the construction of typical events that did not occur.

Moderators of Memory Effects

One important moderator of all the effects described earlier is expectancy strength. As expectancies become clearer, more coherent, or more focused, incongruent events are increasingly surprising, but by the same token congruent events are increasingly taken for granted (e.g., Srull et al., 1985). The associated increased disparity in the extent to which expected and unexpected events are attended to, encoded, and stored episodically affects memory for the events. Thus, the advantage in accurate memory for incongruent events increases with expectancy strength. So, too, do response biases, feelings of familiarity, and expectancy-driven search strategies increase for congruent events (e.g., Sherman & Frost, 2000; Sherman, Klein, et al., 1998).

A second moderator of memory effects is the level of processing capacity available during encoding. When under cognitive load, people tend to attend more care-

fully to and encode the details of incongruent than congruent information. Accordingly, the memory advantage for unexpected events is greater when capacity has been restricted during encoding (e.g., Sherman & Frost, 2000). At the same time, diminished capacity increases the extent to which people rely on guessing strategies, feelings of familiarity, and biased search strategies in remembering typical or expected events. The increased reliance on these factors may increase both true and false memories for congruent events.

Summary

This section summarized the numerous cognitive consequences of expectancies. We attempted to integrate the general offshoots of expectancies, such as biased hypothesis testing, the expectancy heuristic, and expectancy-assimilative interpretation effects, with the more specific offshoots of expectancy confirmation versus disconfirmation, including effects in processing fluency, attention, interpretation, encoding, sense making, representation, and memory. All these cognitive consequences are aimed at extracting useful information from experience for the specific purpose of guiding subsequent effective action.

AFFECTIVE CONSEQUENCES

Affective responses to expectancies may be viewed as regulatory signals regarding goal progress, with positive affect signaling sufficient and negative affect signaling insufficient progress (as indicated by smaller vs. larger discrepancies, respectively, between expected and current status within a regulatory feedback loop). As such, affect constitutes an informational signal intrinsic to behavior regulation (Schwarz, 1990). This section elaborates on this idea, but also touches on optimism as an instance of affect regulation, and on broader affective consequences that have received considerable research attention, including attitudes, aesthetics, humor, and depression.

Behavior-Oriented Affective Consequences

Negative Affect Fuels Behavior Change

The immediate default response to a disconfirmed expectancy is negative affect (Mandler, 1975; Olson et al., 1996). This primary affective consequence is best understood with regard to its implications for behavior regulation. Specifically, negative affect spurs greater behavioral effort aimed at problem solving (McDonald & Hirt, 1997; Schwarz, 1990; Taylor, 1991), as mediated by the cognitive consequences reviewed in the previous section. Studies of regret and disappointment have been particularly revealing as indications of how negative affect spurs alterations in behavior (Zeelenberg, 1999). This basic notion also extends through the *investment model* of interpersonal relationships, in which a relationship that is perceived to fall short of a generic expectation of relationship quality (termed a "comparison level") results in negative affect (disappointment) which in turn predicts relationship dissolution (Rusbult et al., 1998; Thibaut & Kelley, 1959).

Negative Affect Is the Default Response to Processing Fluency Disruption

On a more basic level, the disruption of processing fluency is experienced as affectively unpleasant (Reber, Winkielman, & Schwarz, 1998; Winkielman & Cacioppo, 2001). It must be emphasized that we are referring to the initial and default affective response to processing dysfluency; this affective response is by no means the only or the typical response. As detailed subsequently, inferential processing creates secondary affective responses, which may vary widely in valence as a function of the specific form of interpretational attribution (e.g., Whittlesea & Williams, 2001).

Expectancy Disconfirmation Shifts Evaluation via Contrast Effect

Reactions to success and failure hinge not only on the intrinsic quality of the outcome but also on how the outcome is framed by expectations. A negative outcome creates dissatisfaction when it is expected but is even more extremely dissatisfying when unexpected. By the same token, a positive outcome may taste sweet if expected but may be all the sweeter when it takes the perceiver by surprise.

The underlying mechanism for such effects is the perceptual contrast between the expectancy and outcome (Mellers, Schwartz, Ho, & Ritov, 1997; Roese, 1997). Specifically, an outcome that disconfirms an expectancy can be evaluated in part by comparison to the expected yet unattained outcome (i.e., a counterfactual comparison). The juxtaposition of an alternative that is either better (an upward counterfactual) or worse (a downward counterfactual) renders the evaluation of the factual outcome either more negative or more positive, respectively (Roese, 1994). By this analysis, the evaluative direction between the obtained outcome and its counterfactual alternative matters most in determining affect (Barthalow et al., 2002; Bettencourt, Dill, Greathouse, Charlton, & Mullhuland, 1997; Feather, 1969; Shepperd & McNulty, 2002). Hence, an unexpected failure evokes more negative affect than an expected failure by virtue of the contrast to an upward counterfactual (i.e., the expected, more positive outcome), and an unexpected success evokes more positive affect than an expected success because of the contrast to a downward counterfactual (i.e., the expected, less positive outcome). New evidence suggests a somewhat different interpretation, that both positive outcomes (that could have been better) and negative outcomes (that could have been worse) may be characterized not so much as contrast-effect shifted unitary affect experience but rather as an ambivalent experience of simultaneous mixed emotions (Larsen, McGraw, Mellers, & Cacioppo, 2004).

That expectancies shape evaluation is a rule of thumb assumed by many, as exemplified by the tactic of "lower-

ing the bar." For example, prior to the 2000 presidential election debates, candidate George W. Bush's handlers tried to "spin" low expectations for his performance, thereby ensuring that nearly any performance by Bush would exceed expectations and thus enhance voter satisfaction via a downward counterfactual comparisons ("He could have performed so much worse . . . "). Research indeed suggests that individuals sometimes strategically reduce expectancies of success (Shepperd et al., 2000; van Dijk, Zeelenberg, & van der Pligt, 2003). Corporate earnings statements have similarly been shown to be manipulated in such a way that they just barely exceed (but rarely just barely miss) earlier forecasts of performance, thereby ensuring that downward rather than upward counterfactuals are the most salient consequence (Burgstahler & Dichev, 1997).

Optimism and Affect Regulation

People are, on average, optimistic: When looking to their own future, they see more positives than negatives (Newby-Clark & Ross, 2003). In pondering future career moves, romantic encounters, financial deals, or vacations with family, people expect events to go well and dedicate relatively little thought to negative possibilities. Such optimism has been documented against several benchmarks, the most common of which is an interpersonally relative judgment in which individuals predict the likelihood of good and bad events befalling them compared to similar others. This form of judgment has often been called *unrealistic optimism* (Radcliffe & Klein, 2002; Weinstein, 1980; Weinstein & Klein, 1996). Another benchmark is the individual's current circumstance, and here again there is a general tendency to expect future improvement relative to current state; this judgment has been termed "upward temporal comparison" (Heckhausen & Krueger, 1993; McFarland & Alvaro, 2000; Wilson & Ross, 2001). Yet a third benchmark is actual outcomes, and again individuals tend to expect greater riches and rewards than objectively occur at a later time (Mitchell, Thompson, Peterson, & Cronk, 1997; Wirtz, Kruger, Scallon, & Diener, 2003). A variation of this observation has been termed the "planning fallacy": In judging the future accomplishment of personal or professional goals, projects, or assignments, people expect to complete more and in a briefer period of time than actually turns out to be the case (Buehler, Griffin, & Ross, 1994; Kruger & Evans, 2004; Newby-Clark, Ross, Boehler, Kohler, & Griffin, 2000). Although people are on average optimistic, variation across individuals (e.g., Norem & Cantor, 1986) and cultures certainly exists (e.g., Chang, Asakawa, & Sanna, 2001; Heine & Lehman, 1995), and one recent argument was that variability in optimism constitutes perhaps the most basic of personality factors (Haugen, Ommundsen, & Lund, 2004).

Why are people unrealistically optimistic? Several explanations have been offered, such as those rooted to an egocentric emphasis on self-relevant information (e.g., Karniol, 2003; Kruger & Burrus, 2004). But another ex-

planation running through several prominent theories is that optimistic expectancies produce positive affect, and therefore individuals are motivated to create them. According to this view, people are optimistic simply because it feels good to imagine a more positive future. Accordingly, people use optimistic expectancies for affect regulation; for example, optimism increases in a compensatory fashion in response to threat (McFarland & Alvaro, 2000). In the *theory of positive illusions* (Armor & Taylor, 1998; Taylor & Brown, 1988), unrealistic optimism was one of several self-aggrandizing cognitions that, as long as they remain moderate rather than extreme distortions of reality, serve to facilitate psychological well-being (Kaiser, Major, & McCoy, 2004; Scheier, Carver, & Bridges, 2001), aid in coping with misfortune (Aspinwall & Taylor, 1997), and even enhance physical health (Peterson & Bossio, 2001), as indexed, for example, by immune system functioning (Segerstrom, Taylor, Kemeny, & Fahey, 1998; Taylor, Lerner, Sherman, Sage, & McDowell, 2003). Benefits of optimism for productivity, persistence, and life satisfaction have also been observed (e.g., Gilham, 2000; Seligman, 1998). The ultimate negative expectancy is death, and according to *terror management theory* (Greenberg, Solomon, & Pyszczynski, 1997), recognition of one's own mortality unleashes a range of processes aimed at keeping this horrific expectancy cloaked in obscurity. The theory suggests that many beliefs and behaviors are aimed at providing distraction from mortality awareness; examples include religion, political ideology, nationalist or other ingroup identification, and even sexual ritual (e.g., Goldenberg, Pyszczynski, Johnson, Greenberg, & Solomon, 2000). All considered, the range of evidence to support the claim that optimism is motivated, or is sometimes recruited for affect regulation, is substantial. Contemporary theory moreover emphasizes the deep interplay (rather than opposition) between motivated and purely informationally based mechanisms (e.g., Kruglanski, 1996; Kunda, 1990).

Under the rubric of *affective forecasting*, the concept of *impact bias* has been used to describe people's tendency to exaggerate the emotional impact of future events (Wilson & Gilbert, 2003). In this literature, the focal judgment is magnitude of emotional consequence following a specified event, operationalized in terms of both intensity and duration of affective experience. Bias is defined in terms of a comparison between predicted and actual emotional experiences (Buehler & McFarland, 2001; Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998); for both positive and negative emotions, people expect greater emotional intensity and duration than actually transpires. At first glance, findings on affective forecasting with regard to negative emotions seem to contradict the standard optimism finding: Research on affective forecasting suggests that people exaggerate the emotional impact of negative future events, whereas research on unrealistic optimism indicates that people skew their future view in a positive direction. This contradiction may be explained by recognizing that these two literatures, in tapping separate judgments (emotional impact

and event likelihood, respectively) have differentially emphasized two sides of the same regulatory balancing act. When viewed together, impact and likelihood judgments are negatively correlated: The more emotionally consequential the event, the more unlikely individuals deem it to be (Blanton, Axsom, McLive, & Price, 2001). The most threatening expectancy would be one in which a possible negative event (losing a job, losing a spouse) is deemed both very impactful ("It would really wipe me out") and highly likely. Individuals forced to confront the prospect of a high-impact negative event may thus strategically reduce its perceived likelihood ("Sure that would be awful, but it'll never happen to me"). Similarly, if individuals realize that a negative event is likely, they may strategically reduce its perceived impact ("I know it might happen, but it won't be so bad"; Kay, Jimenez, & Jost, 2002). Such a balancing act between judged impact and likelihood is a further instantiation of the principle that individuals regulate expectancies to defend against affectively threatening inferences (Jemmott, Ditto, & Croyle, 1986).

To summarize, people are on average optimistic when they look to their own personal future, and this optimism brings about positive affective consequences, which in turn bring a variety of further beneficial consequences for health and performance.

Broader Affective Consequences

The previously noted principles center on the immediate emotional offshoots of expectancy confirmation and disconfirmation. In the following examples of attitudes, aesthetics, humor, and depression, the importance of the expectancy construct may be seen across a broader range of psychological effects.

Attitudes Reflect the Intersection of Expectancy and Value

Attitudes involve evaluations of people, objects, or issues, and a popular means of conceptualizing them involves the varying contributions of information, prior behavior, and affect (Breckler, 1984). The expectancy-value approach to attitudes (and judgment more generally) is that an attitude is the summation of a set of beliefs about the value of particular properties along with the expected likelihood that the attitude object contains those properties (Ajzen & Fishbein, 1980). A positive attitude toward an automobile built by Volkswagen, for example, would be the result of a set of value and expectancy beliefs regarding attributes such as price (low price expected with high certainty), quality (high reliability expected with moderate certainty), and driving experience (solid handling expected with some uncertainty). Although this perspective has proven useful, a recent controversy has centered on whether statistically inappropriate techniques have rendered many past findings ambiguous, and which techniques are best suited for new research (French & Hankins, 2003; Haddock & Zanna, 1998).

Aesthetic Appreciation Hinges on Moderate Expectancy Disconfirmation

Although critics will debate the merits of great versus mediocre art along innumerable dimensions, psychologists have long noted that aesthetic appreciation at its simplest level reflects moderate surprise. That is, new art is appreciated by most individuals when it involves a moderate, neither weak nor extreme, deviation from expectancies. As revealed in early psychophysical studies of taste, brightness, heat, and form, previous experience creates an adaptation level or habituation point, against which experiential discrepancies are perceived in affective terms (Haber, 1958; Helson, 1964). Later studies of aesthetic judgments of painting, music, and literature confirmed that very small deviations from past experience are perceived as boring; large deviations as unpleasantly bizarre, but moderate deviations as sweetly intriguing (Berlyne, 1974). Reber, Schwarz, and Winkielman (2004) argued processing fluency to be a key mechanism underlying the relation between expectancy and aesthetic appreciation. These authors proposed that the more fluently the perceiver can process an object, the more positive the resulting aesthetic response. Small deviations from expectancy may well be processed fluently, but perhaps so fluently as to barely register as interesting, blending instead into the perceptual background. Large deviations from expectancy, on the other hand, interrupt fluency by stimulating deeper cognitive processing aimed at explaining the discrepancy. Between these two extremes are intermediate deviations that stimulate simpler (and more successful) explanations that rapidly restore fluency to its prior, faster rate. In this regard, it is perhaps not so much greater fluency in an absolute sense that evokes aesthetic appreciation but, rather, the contrast effect resulting from a rapid shift from relatively low to high fluency that creates the subjective feeling of aesthetic pleasure (cf. Whittlesea & Williams, 2001).

Humor Derives from Resolution of Incongruity

The experience of humor may be taken as a special case of the more general principle guiding aesthetic appreciation covered in the previous section. Humor appears to be the product of a two-step process: a surprise based on some sort of incongruity (e.g., between a particular utterance and the expected word usage; between a "funny walk" vs. the typical way of walking), followed very rapidly by an inferential resolution that renders the incongruity nonthreatening (Suls, 1983; Wyer & Collins, 1992). As explored in greater detail in the precursor to this chapter (Olson et al., 1996), the greater the initial surprise and the more satisfyingly comprehensive the resolution, the bigger the laughs.

Depression Involves Hopelessness Expectancies

Depression is a mental disorder marked by extreme negative affect, demotivation, and behavior deficits. A signature symptom of major depression is global expectancies

of future negative events, especially events that are personally important to the individual, and has been specified in detail within the *hopelessness theory of depression* (Abramson et al., 1989). The correspondence between biased negative expectancies and behavioral dysfunction (e.g., job performance deficits and interference in interpersonal relationships) marked by depression stands in contrast to biased positive expectancies that facilitate the behavior among healthy individuals, thus further underscoring the functionality of expectancies modestly biased toward optimism (Taylor & Brown, 1988).

Summary

This section reviewed three main classes of affective consequences of expectancies, with a particular emphasis on consequences of expectancy disconfirmation. First, affective responses to expectancies were considered in terms of their role as regulatory signals regarding goal progress. Second, expectancies for personal events tend to be optimistic, which in turn brings about positive affective consequences. Third, broader affective consequences were also discussed, with a spotlight placed on attitudes, aesthetics, humor, and depression.

CONCLUSION

To predict the future is to navigate it more effectively. The psychological literature on the construct of expectancy is enormous, yet we argue that the numerous findings uncovered by this literature are most parsimoniously described with regard to behavior regulation, effective action, and survival. We distinguished between semantic and episodic expectancies, arguing that both facilitate performance but in different ways. Semantic expectancies are summaries of multiple prior experiences; they tend to be relatively abstract, implicit, and efficiently deployed. Most expectancies are of this semantic sort: They provide a wealth of general background knowledge and "common sense" that silently guide construal and behavior with efficient accuracy. Episodic expectancies are derived from memories of particular past instances; they tend to be relatively concrete and explicit and provide deeper, more specific information.

Whereas semantic expectancies provide implicit and mundane guidelines (a clear morning in July is likely to become a hot day, so dress lightly . . .), consciously held episodic expectancies may range from small to large plans, from tonight's dinner to next summer's wedding. Episodic expectancies for desired goals may not only guide behavior but also facilitate performance, either by energizing motivation via hopeful imagery or by making specific step-by-step behavioral requirements salient. Anticipation of problems and obstacles results in proactive avoidance behavior. Such examples of expectancies creating their own reality are deeply useful to human beings, yet the potential for mishap, as when negative and inaccurate stereotypes fuel self-fulfilling prophecies, springs from the same basic mechanisms.

The usefulness of an expectancy in guiding behavior depends on its accuracy; hence expectancies must be revisable in light of disconfirmation. At the same time, overly capricious sensitivity to nonrepresentative or nondiagnostic disconfirmation would impair rather than facilitate expectancy accuracy. Generally speaking, disconfirmed expectancies demand attention and require cognitive capacity to support efforts at explanation and understanding, the inferential products of which result in one of four consequences: ignoring the discrepancy, tagging the discrepancy, bridging the discrepancy with new insight, or revising the expectancy on a deeper level. Although we have argued that expectancies tend to be accurate overall, this assertion masks a complicated set of conceptual issues (Judd & Park, 1993; Kruglanski, 1989). These issues were explored in depth in the precursor chapter by Olson and colleagues (1996); that discussion still stands as an authoritative overview of this difficult subject.

Expectancy is one of the bedrock constructs in the field of psychology. Although numerous areas of psychology use the expectancy construct, from developmental to clinical psychology, from animal conditioning to cognitive psychology, this chapter emphasized the voluminous research deriving from social psychology. We have attempted to conceptualize the expectancy construct in terms of its functional basis in effective behavior control, positioning cognitive and affective consequences as secondary to and supportive of this main function. Yet as we write, social psychology is evolving rapidly to embrace new advances in brain imaging technology. With the emerging discipline of social cognitive neuroscience gaining momentum in pinpointing brain structure associated with specific cognitive function, we have constructed our review with an eye to providing a function-oriented roadmap for this new research. Indeed, we have noted one central and highly promising mapping of function to structure in the form of a processing dysfluency detector localized at the anterior cingulate. This is an exciting development, but merely the beginning of what promises to be a sharp expansion of our understanding of the deep relation between brain structure and cognitive function, an expansion we anticipate eagerly.

NOTE

1. The origin of the term "pipeline" can be traced to the seminal paper by Jones and Sigall (1971), in which they observed that psychologists have long fantasized "about discovering a direct pipeline to the soul (or some nearby location)" (p. 349).

The Principles of Social Judgment

Arie W. Kruglanski
David Sleeth-Keppler

The topic of social judgment has received considerable attention from researchers over the last several decades. To our knowledge, the first volume with the term "social judgment" in its title was the classic work by Muzafer Sherif and Carl Hovland (1961). Since then, a number of books (e.g., Eiser, 1990; Forgas, 1991; Forgas, Williams, & Von Hippel, 2003; Martin & Tesser, 1992; Nisbett & Ross, 1980; Wyer, 2004) and a much larger number of research articles (e.g., Beauregard & Dunning, 1998; Bodenhausen, Kramer, & Süsser, 1994; Dunning & Cohen, 1992; Fiedler, Armbruster, Nickel, Walther, & Asbeck, 1996; Gilovich, Medvec, & Savitsky, 2000; Innes-Ker & Niedenthal, 2002; Jackson, Sullivan, & Hodge, 1993; Lambert, 1995; Moskowitz & Roman, 1992; Mussweiler, 2003; Vallacher, Nowak, & Kaufman, 1994; Wegener & Petty, 1995) have referred to *social judgment* in their titles.

For the most part, these contributions have addressed a plethora of diverse phenomena and did not attempt to delineate an integrative theory of social judgment, or to articulate the general principles that govern the formation and/or change of social judgments (for exceptions, see Eiser, 1990; Wyer, 2004). Instead, each relevant article or volume addressed a specific category of judgmental contents (e.g., attitudes, attributions, stereotypes, numerical estimates, social comparison, and impression formation) and/or dwelt on a specific domain of variables affecting that phenomenon. For example, the volume by Forgas (1991) focused on the impact of *affective states* on social judgments, whereas Nisbett and Ross

(1980) examined mechanisms that may lead to *biased* judgments, and so on. The various contributions to the social judgment literature thus contributed empirical fragments to the complete "puzzle" without piecing them together for an overall perspective on the social judgment process.

Our aim in this chapter is twofold: (1) to provide a general overview of the topics (phenomena and mechanisms) that fit under the general umbrella of "social judgment," and (2) to provide an overall conceptual framework for organizing these topics and affording a set of principles governing the social judgment process. To that end, we explore commonalities between judgmental phenomena that have not been heretofore treated in similar terms, such as attitudes, stereotypes, attributions, heuristics, and biases, and cultural differences in judgment.

Our approach follows from our prior analyses of the epistemic process (see Chun & Kruglanski, 2006; Erb, Kruglanski, et al., 2003; Kruglanski, 1989, 2004; Kruglanski, Erb, Pierro, Mannetti, & Chun, in press; Kruglanski et al., 2005; Kruglanski & Thompson, 1999a, 1999b). In the pages that follow we first outline that process and the principles it suggests. We then apply these notions to heterogeneous judgmental phenomena and compare our framework to alternative conceptualizations, in particular to the various dual-process and dual-systems models of social judgment. Space considerations preclude a truly exhaustive review of the voluminous literature on social judgments. Ideally, however, we cover a

sufficient amount of diverse theoretical notions and research programs to illustrate the integrative potential of our approach.

THE PROCESS OF JUDGMENT FORMATION: THE "HOW" OF SOCIAL JUDGMENT

We are assuming that at a deep level all judgments, regardless of topic, are formed in the same way. Specifically

1. Judgments are derived from evidence in accordance with specific inference rules.
2. Such inferences may be consciously represented or carried out without conscious awareness.
3. They may be general or context specific.
4. They may be held commonly by group of people, or be unique to given individuals.
5. They may be rendered with ease and alacrity or via a tantalizingly laborious and time-consuming process.

Crucial to our overarching analysis of human judgment are several continuous parameters whose intersections may characterize different judgmental *contexts* and determine the impact of information on judgmental outcomes. Those parameters are described subsequently, after we have laid forth a few general assumptions.

The Concept of Evidence

As already noted, we are assuming that judgments are based on information the knower regards as pertinent "evidence." For instance, in forming an attitudinal judgment one might consider information about the positive and negative consequences mediated by an attitude object (Ajzen & Fishbein, 1980); these serve as evidence for the attitude object's goodness (or badness). Similarly, in forming a causal attribution, one may consider information about the covariation of an effect with an entity, and covariation (along with temporal precedence and contiguity) may serve as evidence for causality. In forming a personal impression of someone, one might treat as evidence that individual's category membership (e.g., her or his gender, profession, race, age, or religion), and the characteristics stereotypically attached to that category. In forming a forecast about one's affective reaction to a future event, one's evidence might be one's present feeling state plus one's subjective estimate of how long such feelings may endure (Gilbert, Gill, & Wilson, 2002; Wilson, Centerbar, Kermer, & Gilbert, 2005).

Some authors (in particular Lieberman, Gaunt, Gilbert, & Trope, 2002; Sloman, 1996; Smith & DeCoster, 2000; Strack & Deutsch, 2004) have argued recently that in addition to the rule-following process implicit in the notion of "evidence," individuals may also reach judgments via a more "automatic, associative" process. We discuss such processes at a later juncture and examine whether in fact they qualitatively differ from rule following, hence whether they constitute a valid alternative to the general inferential process we are postulating.

The Logical Structure of Reasoning from Evidence to a Conclusion

To function as evidence, information has to fit an inference rule of the "if X then Y" type (Erb, Kruglanski, et al., 2003; Kruglanski & Thompson, 1999a, 1999b; Pierro, Mannetti, Kruglanski, & Sleeth-Keppler, 2004). For example, information that an actor succeeded at a difficult cognitive task could serve as evidence that he or she is intelligent, given the prior assumption that "if someone succeeds at difficult cognitive tasks, he or she is intelligent." More formally speaking, the reasoning from evidence to conclusions is syllogistic. It involves a major premise, the "if X then Y" conditional rule mentioned earlier, and a minor premise that instantiates the antecedent term of the major premise (X) for a given entity (event, etc.) P. Specifically, such minor premise asserts that P is X, and hence that Y is to be expected. For instance, a person may subscribe to the stereotypic belief "if college professor then absent-minded." Upon encountering a person known to be a college professor (minor premise instantiating the antecedent term of the major premise), the knower would be subjectively justified in inferring that he or she must, therefore, be absent-minded.

Issues of Relativity or Invariance

In some cases, the major premises an individual subscribes to may appear to hold across contexts; in other cases they may be context-specific. For example, the statement "if mammal then nursed" applies to all mammals. On the other hand, the statement "if weighing over 7 lbs. then heavy" may be assumed to hold true in some contexts only, and not in others. For instance, a steak weighing 7 lbs. is heavy, but a bicycle weighing 7 lbs. is light. Similarly, a prison term of 7 years imposed by a given judge for a given crime may be judged as lenient in context A of other judges imposing considerably *longer* terms, and as harsh in context B of other judges imposing considerably *briefer* terms. In other words, one could adopt the premise "if 7 then lenient" in context A and "if 7 then harsh" in context B (Higgins & Stangor, 1988). As we shall see, major topics in the psychology of judgment (e.g., issues of assimilation and contrast, dispositional inferences, judgmental anchoring, and estimation tasks) are fundamentally related to the contextual dependence of pertinent inference rules to which individuals may subscribe.

Inferential and Enabling Factors in Judgment Formation

Inferential Factors

Persons may differ in the inference rules (major premises) to which they subscribe. Consequently, the very same information may lead them to different, and occasionally opposite, conclusions. For instance, one person may hold a stereotype whereby "all college professors are absent-minded," whereas another person may believe that "all college professors are well organized." These two individuals are, therefore, likely to form quite differ-

ent impressions (i.e., judgments) of a target person upon learning that he or she is a professor.

The derivation of conclusions from subjectively relevant evidence may appear to represent a highly "rational," deliberative, and conscious process. That is probably why authors have often juxtaposed rule following to automatic processes represented by the associationistic "route" to judgments (e.g., Conrey, Sherman, Gawronski, Hugenberg, & Groom, 2005; Sloman, 1996; Smith & DeCoster, 2000; Strack & Deutsch, 2004). Appearances can be misleading, however. Thus, some inferences may be routinized to the point of automaticity, and hence occur without much conscious awareness. For instance, Uleman's work on spontaneous trait inferences (Uleman, 1987, 1989; Uleman, Winborne, Winter, & Shechter, 1986) suggests that lawful (i.e., rule following) inferences presumably may occur without explicit inferential intentions, and without conscious awareness of performing an inference: The spontaneous trait inference that John is "clumsy" on basis of the information that "he stepped on Stephanie's foot while dancing" surely requires the inference rule "if stepping on a dancing partner's foot, then clumsy," or some variant thereof. A person who did not subscribe to that premise would not probably reach that conclusion. Unconscious inferences from mood states are treated in these terms by Schwarz and Clore's (1996) "mood as information" model.

As already implied, the major premise from which an individual draws her inferences need not be widely shared, or universally proclaimed as rational. For instance a premise whereby a rain dance by a shaman will engender rain (i.e., "if rain dance, then rain") might appear as "irrational" to sophisticated Westerners yet as quite valid to members of a tribe. Thus, the general mechanism of drawing conclusions from evidence is assumed to be the same irrespective of the apparent veridicality or "rationality" of one's premises to other persons (Cole & Scribner, 1974).

The foregoing analysis suggests that individuals' lay theories may determine what they regard as compelling evidence for a given judgment. Individuals who subscribe to an "entity" theory of intelligence (Dweck, 1999) may regard the observation that an individual failed an intelligence test as evidence for her or his low intelligence because of their assumptions that intelligence is an invariant personal trait tapped by intellectual tasks. By contrast, individuals subscribing to an "incremental" theory (Dweck, 1999), that is, ones who believe that intelligence is malleable, may view failure as irrelevant to an inference of intelligence.

Enabling Factors

TASK DEMANDS

Beyond inferential factors, such as the apparent relevance of evidence, judgment formation is affected by several enabling factors that do not typically enter into the judging individual's calculations. A major such factor is the cognitive demandingness of the information-processing task. This may be determined by the length and complexity of the information given, accessibility of major premises retrieved from memory (of the "if X then Y" type) and accessibility or saliency of information constituting the minor premises (X).

Accessibility of events from memory may affect judgments, without the judges' explicit awareness of it being so, and without such awareness entering into the judges' explicit inferential process. For instance, participants in a study by Lichtenstein, Slovic, Fischoff, Layman, and Combs (1978) estimated the relative frequencies of death from various causes without realizing that their personal experiences involving each class of lethal event (determining the events' accessibility) was correlated with their estimates. Accessibility of such personal experiences may have made their utilization *easy* in deriving an overall estimate of death causes. As shown subsequently, ease of applying an inference rule should play a particularly important role in judgments if one's processing resources were limited due to various motivational and cognitive factors.

MOTIVATION

Different motivational categories may determine (1) the extent of effort invested in information processing en route to judgment, and (2) the weights assigned to different informational items as a function of their desirability. The former effect has been classified in the category of nondirectional motivation and the latter in that of directional motivation (see Kruglanski, 1996, for a review).

Nondirectional exertion of effort is important in relation to task demands. In cases in which task demands are high (e.g., where the information was lengthy, complex or relatively inaccessible), considerable effort might be required for it to be properly utilized. For instance, with insufficient motivation and a demanding task, highly relevant information (e.g., high-quality arguments) might go underappreciated, whereas information of relatively low relevance (e.g., low-quality arguments) might be overappreciated (Petty, Wells, & Brock, 1976).

Differential weight given to informational items as function of their correspondence with a given "directional" motivation may result in bias such that the judgmental conclusions would be congruent with the individual's wishes and desires. For instance, an individual informed that coffee drinking is healthy or unhealthy may distort his or her memories of coffee-drinking instances (Kunda & Sanitioso, 1989) to reach a desirable conclusion that his or her coffee drinking habit is health preserving (see also Dunning, 1999; Kruglanski, 1999; Kunda & Sinclair, 1999).

The impact of a directional motivation may also depend on task demands. Where these are considerable, individuals' processing resources might be consumed by labors of decoding the information given, with less resources being left for suppression and/or alternative construals consistent with the directional motivation. Indirect evidence that processing "ease" facilitates motivational distortion comes from a number of sources. Festinger (1957), for example, argued that the *attitude change* occasioned by cognitive dissonance would take

place because it is an *easier* avenue of restoring consonance than is altering one's cognition about the dissonant behavior. Similarly, Wood, Kallgren, and Preisler (1985) found that participants with greater access to attitude-relevant information in memory, that is, participants for whom it should have been *easier* to generate motivationally congruent construals, generated more negative thoughts and were less persuaded by counterattitudinal, hence motivationally undesirable, messages than were less knowledgeable participants. Finally, Kunda (1990) as well as Hsee (1996) argued that motivational biases are more likely when implications of the information given are ambiguous versus clear-cut presumably because clear-cut implications are more *difficult* to distort. According to the present perspective, however, with sufficient motivational resources even information with relatively clear implications (i.e., clear to outside observers) might be distorted as illustrated—for example, by the occasional denials by widows and widowers of the death of their spouses (Stroebe, Hansson, Stroebe, & Schut, 2001), or the denials of terminally ill patients of their own impending death (Kübler-Ross, 1969).

COGNITIVE CAPACITY

The individual's cognitive capacity may play a similar role to nondirectional motivation in determining the extent of information processing en route to judgment. Thus, an individual whose cognitive capacity is taxed (e.g., by cognitive busyness or load) may be unable to thoroughly process and hence fully appreciate the relevance of the information given under high task demand conditions. Again, this may reduce the difference in impact of highly judgmentally relevant versus less judgmentally relevant information. In this vein, work by Petty and colleagues (1976) demonstrated that under distraction (vs. no distraction) conditions, individuals differentiated less between high- and low-quality arguments.

SEQUENCE AND CARRYOVER EFFECTS

Early information may bias the processing of subsequent information especially if the subsequent information is ambiguous. For instance, if the early information implied a given position, subsequent arguments may be interpreted in its light. Such early information may exist in the form of prior expectancies or attitudes to which the knower subscribes (Olson, Roese, & Zanna, 1996). In an early study demonstrating this effect, Lord, Ross, and Lepper (1979) found that participants differed in their perceived validity of research studies depending on the results' consistency with these persons' attitudes. Participants opposed to capital punishment regarded the methodology of studies supportive of capital punishment as inferior to the methodology of studies opposed to it. By contrast, participants in favor of capital punishment viewed studies supportive of capital punishment as methodologically superior.

In the realm of persuasion, biasing effects of heuristic cues on the processing of ambiguous message arguments were reported by Chaiken and Maheswaran (1994). Spe-cifically, under high-motivation conditions the same arguments attributed to a credible source were deemed of a better quality than when they were attributed to a noncredible source. Erb, Pierro, Mannetti, Spiegel, and Kruglanski (2003) showed further that early message arguments can bias the evaluation of subsequent message arguments, and also the subsequent perception of the communicator's expertise, determining their impact on the ultimate judgments.

This concludes our introductory analysis of judgmentally relevant factors. We now apply this framework to several classical issues in social judgment, beginning with the often-invoked notions of *assimilation* and *contrast*.

CLASSIC ISSUES IN SOCIAL JUDGMENT

Assimilation and Contrast

The concepts of *assimilation* and *contrast* were featured prominently in the early volume on social judgment by Sherif and Hovland (1961). These specific terms and the research paradigm from which they derived were heavily influenced by research in psychophysics. From this perspective, assimilation is said to occur when a stimulus is judged as closer to a standard (on some dimension, e.g., weight) than objectively warranted. Contrast, on the other hand, occurs when a stimulus is judged as more distant from a standard than objectively warranted. One may think about it in terms of the *range* of possible values introduced by the anchor. A heavy anchor, way above the stimulus series, creates a much larger range than a relatively light anchor close to the stimulus series. The wider the range the more its end points appear as different from one another. Such differentiation may be exaggerated resulting in contrast. For instance if the high end of the range is 200 grams then 5 grams appears *extremely different* from that value and the notion of "extreme difference" may lead to its *underestimation* leading to a judgment of say 3.5 grams. Assimilation on the other hand may lead to an exaggeration of similarity. Thus, if the difference between a stimulus and a standard was very slight (say, the standard was 5 grams and the stimulus was 4.5 grams) the difference might not be even discerned; the two stimuli may be perceived as "extremely similar," and the stimulus may be misjudged as even closer to the standard than actually is the case.

The same logic may apply to social judgments. A given stimulus, say, uttering a curse, would be seen as innocuous when the considered range of values included *genocide* and as much more hostile/aggressive when the range was much more restricted (e.g., with *shoving* as its high end). Occasionally opposite ends of a range can be activated or brought to mind by a primed social stimulus. Thus, Herr (1986) found opposite contrast effects through priming different person concepts: Priming the concept of Shirley Temple resulted in labeling a moderately hostile behavior as much more aggressive than priming the concept of Adolf Hitler. Presumably the Temple prime activated the low end of the aggressive range with regard to which the target stimulus (moder-

ately hostile behavior) was *contrasted* as aggressive. Similarly, the Hitler prime might have activated a high end of the aggressive range to which the target behavior was *contrasted* as nonaggressive.

It is instructive to consider the assimilation and contrast phenomena in terms of what a given stimulus, say, a given weight or a given behavior, *means* in a given context. The context, in other words, sets up an *inference rule* linking a given stimulus value with a given judgment. Consider contrast. In the context of highly aggressive behaviors a moderately aggressive behavior may be classified as mild in accordance with the inference rule "if mass murder is what *aggressive* means, then shoving is *mild.*" Similarly in the context of relatively unaggressive behaviors a moderately aggressive behavior may be classified as *very* aggressive according to a rule such as "if sulking is what *aggressive* means then shoving is *very aggressive.*" As noted earlier, these inferences could be mediated by the judgment that the stimulus and a comparison standard are *very different*, with the attached labels or numerical values (as in the case of weights) reflecting this notion of *difference*. Thus, if Gulliver's height is judged in the context of Lilliputs—his dissimilarity from them establishes him as a giant. If, however, it is judged in the context of Giants, his dissimilarity establishes him as a dwarf.

Whereas contrast is mediated by the perception of pronounced *dissimilarity* between a stimulus and a standard, assimilation is mediated by the perception of their *similarity* on some judgmental dimension. Such perceived similarity affords the inference of equivalence between the stimulus and the standard. If the category "adventurous," for instance, includes risky behavior, and if such category is activated, then any behavior with a risky component (say playing the stock market) may be considered an instance of the "adventurous" category (Higgins, Rholes, & Jones, 1977). The inference rule in such a case might be "if risky means adventurous, and if playing the stock market is risky then playing the stock market is adventurous." Thus, similarity between a stimulus and a category on a defining dimension may mediate assimilation in accordance with the general inference rule "if a stimulus is similar to a category on its defining property, then stimulus if a member of the category." This notion also underlies the classical representativeness heuristic discussed by Tversky and Kahneman (1974).

If assimilation and contrast effects are driven by exaggerations of perceived similarity and dissimilarity, it is possible that people whose cognitive style requires clear-cut distinctions (for instance, persons high on the need for closure dimension—Kruglanski, 2004; Kruglanski & Webster, 1996) would exhibit more pronounced assimilation and contrast effects. That is, they would judge relatively close stimuli as closer to each other, glossing over their possible differences, than people low on the need for closure and would judge relatively distant stimuli as more distant from each other, glossing over their possible similarities, than would the lows. These notions are akin to Sherif and Hovland's (1961) hypothesis that the strength of assimilation and contrast effects, expressed in polarized perception of others' attitudes, would be posi-

tively related to the judges' ego involvement in the issue. If one could assume that ego involvement determines commitment to one's position, and if commitment induces a desire for clarity and an intolerance of ambiguity, this could result in a polarization of one's assessment of other people's positions. Various studies have confirmed this proposition in the context of racial attitudes in the United States (see Eiser, 1990, for a review).

Needs for Specific Closures

Our analysis suggests that setting up an inference rule determining assimilation and contrast effects should be influenced by two processes: (1) identification of the standard and (2) assessment whether the judged stimulus is similar on a relevant dimension to (assimilation) or different from the standard (contrast). Among other factors, this may depend also on individuals' directional motivations, or needs for specific closure (Kruglanski, 1989, 2004). For example, a committed group member may be motivated to view the group norm as a standard, an aspiring worker may be motivated to view the boss' attitudes as a standard, and mediocre students may be motivated to view a failing grade as a standard (from which they may wish to differentiate themselves), and so on.

Given that a certain standard had been identified, individuals may be motivated to perceive themselves as close (i.e., similar) or as distant (i.e., different) from it. If the standard was positively valued (e.g., if it represented success, health, or happiness), one might be motivated to perceive oneself as similar to it (resulting in assimilation). If, however, the standard was negatively valued (representing failure, illness, or unhappiness), one might well wish to distance oneself from the standard (resulting in contrast). For instance, in Brewer's (1991) optimal distinctiveness model, individuals might wish to identify with others under some circumstances; such motivation could foster an exaggerated perception of similarity between themselves and the group standard. In other circumstances, however, they might wish to assert their uniqueness. This may lead to exaggerated perceptions of a difference, and hence to a contrast, between themselves and other people.

Inclusion and Exclusion Processes

The comparison standard may be placed within the category (or, within the stimulus series) or outside it. This may affect how the category as a whole is evaluated. Inclusion increases the perception of similarity between the category and the standard whereas exclusion increases the perception of dissimilarity. Bless and Schwarz (1998) had German participants consider Richard Von Weizsäcker (a highly respected German politician) either as president of the Republic (which excludes him from his party, Christian Democratic Union [CDU]) or as a member of the party (signifying inclusion). When he was included, an assimilation effect occurred and the CDU was evaluated more positively than in a control condition, whereas when he was excluded (i.e., placed outside the group) the CDU was evaluated more negatively than

in the control condition. A different party, the Social Democratic Party of Germany, was not affected by these manipulations.

Latitudes of Acceptance and Rejection

An intriguing concept introduced by Sherif and Hovland (1961) concerned the distinction between latitudes of *acceptance* and *rejection*. The latitude of acceptance denotes the range of attitudinal positions with which an individual *agrees*. These are typically clustered around the individual's own attitudinal position. The latitude of rejection is a range of positions with which the individual *disagrees*. These are typically clustered at some distance from the individual's own position. Sherif and Hovland (1961) hypothesized that the size of the latitudes of acceptance and rejection depends on the degree of one's ego involvement in the attitude at issue. When ego involvement is high, the latitude of acceptance narrows. In other words, the individual would agree with positions closely resembling her or his own, and disagree with other positions (see Hovland & Sherif, 1952).

As noted earlier, ego involvement may represent a motivationally based commitment to, or "freezing" on, one's position (Kruglanski, 2004; Kruglanski & Webster, 1996). This may induce a reluctance to change one's position in direction of other discrepant positions. In other words, the wider latitude of rejection evinced by ego-involved respondents might reflect a motivationally based refusal to move toward alternative positions.

But note also that ego involvement may reduce the latitude of noncommitment by interpreting items in this category as *supportive* of one's own position. This leads to the prediction that the relative size of the latitudes of acceptance and rejection might depend on the inclusion of ambiguous items (those defining the noncommitment category). The more such items are included, the greater should be the number of items in the latitude of acceptance category, hence the larger that particular category relative to the latitude of rejection. Similarly, the fewer such items the larger should be the latitude of rejection relative to that of acceptance.

In short, ego involvement may instigate both the freezing on one's own specific position, increasing the latitude of rejection, and the tendency to absorb ambiguous items (originally in the latitude of noncommitment) in one's latitude of acceptance, increasing the acceptance latitude through item distortion. Future research is needed to identify the moderator variables that might determine the relative strength of the "freezing" and distortion tendencies and, hence, the conditions under which ego involvement might lead to the narrowing or the widening of the latitudes of acceptance or rejection.

In summary, various findings in the assimilation and contrast literature may be interpreted in terms of the present conceptual analysis. Assimilation and contrast may depend on inference rules regarding the meaning attached to a given stimulus (e.g., a "shove") in a given context. This, in turn, should depend on this stimulus's similarity or dissimilarity to other stimuli whose mean-ings are known to the perceiver. Assimilation and contrast may also depend on participants' motivations, determining their tendency to stick to ("freeze upon") their positions, and determining their latitudes of acceptance and rejection.

Persuasion

Background Knowledge and Informational Impact

Background knowledge affects the degree to which an argument, delivered by some source, will be persuasive to individuals. For instance, a person who assumed (as part of her background knowledge) that military service is essential for an effective discharge of presidential duties will consider the information that a candidate served (or did not serve) in the military as relevant to whether he or she would be a good president. By contrast, a person who did not assume a relation between military service and presidential efficacy would not be affected much by information concerning a candidate's military service and would consider it irrelevant to the candidate's fitness for the job.

To be influential in persuasion settings, background knowledge need not be restricted to the *content* of presented arguments but may include assumptions related to the *context* in which they are presented to recipients. These may have to do, for instance, with expertise, or epistemic authority, of the communicator (Kruglanski et al., 2005), the degree of consensus about a given position, and so on (Chaiken, 1980). For instance, one's background knowledge may include the assumptions that "experts are correct," or "majorities can be trusted," lending persuasive power to information that a given communicator is an expert, or that a majority advocates a given position.

Background knowledge may have other effects as well. Thus, people with a great deal of such knowledge are likely to have well-formed and relatively fixed judgments and attitudes on the issues at hand. Such attitudes should allow them to make decisions quickly and effortlessly. For example, research by Fazio, Blascovich, and Driscoll (1992) as well as Blascovich and colleagues (1993) has shown that persons who rehearsed their attitudes toward sets of abstract paintings (vs. just focusing on the color of the paintings) showed less autonomic reactivity when requested to evaluate the paintings.

It appears then that possessing well-developed attitudes as part one's store of knowledge frees up cognitive resources for other tasks. On the other hand, having well-developed attitudes has a potential downside in effecting fixation and rigidity (Kruglanski, 2004). For example, individuals with highly (vs. less) accessible attitudes about an object appear to show greater difficulties in perceiving changes that it may undergo (Fazio, Ledbetter, & Towles-Schwen, 2000).

Relatedly, background knowledge may facilitate counterarguing against persuasive communications assaulting one's position, which may assist individuals in maintaining their original views. A recent meta-analytic review of the literature on forewarning found statistical support

for the notion (Wood & Quinn, 2003) that persons cognitively bolster their existing attitudes by recruiting available knowledge in support of their position.

Task Demands, Cognitive Capacity, and Processing Motivation

Information presented to recipients in a persuasive context may be easier or more difficult to process depending on the situation. For instance, the information may be lengthy or complex or fraught with irrelevant detail. All these may make it difficult to process. By contrast, if presented succinctly and pointedly information may be relatively easy to process. Furthermore, the inference rules that lend the information its relevance may be relatively inaccessible in memory, hence difficult to retrieve. Alternatively, they may be quite accessible and easy to retrieve (Higgins, 1996). If the information is difficult to process, discernment of its judgmental relevance may require considerable processing resources, consisting of cognitive capacity and processing motivation. Thus, if the judgmental task demands are high (the information is difficult to process, and/or pertinent inference rules are difficult to retrieve), persuasive impact of the information given will manifest itself to a greater extent under ample (vs. limited) processing motivation and cognitive capacity. Similarly, where cognitive capacity and motivation are limited, easy-to-process information would have a relatively greater persuasive impact than difficult-to-process information.

The aforementioned considerations are pertinent to our recent reinterpretation of evidence cited in support of the dual-process models of persuasion, the elaboration likelihood model (ELM) (see Petty & Cacioppo, 1986) and the heuristic systematic model (HSM) (Chaiken, Liberman, & Eagly, 1989; see, e.g., Erb, Kruglanski, et al., 2003; Kruglanski et al., 2006; Kruglanski & Thompson, 1999a, 1999b; Kruglanski, Thompson, & Spiegel, 1999). Basically, both dual-process models propose two qualitatively distinct ways of being persuaded. One is via the message arguments, the other by aspects of the context in which these arguments are embedded (e.g., characteristics of the communicator, one's mood, degree of consensus about the advocated position). Changing one's attitudes on basis of the message arguments has been referred to as persuasion by the central route (in the ELM) or via the systematic mode (in the HSM). Changing one's attitudes on basis of the contextual elements has been referred to as persuasion via the peripheral route (in the ELM) or via the heuristic mode (in the HSM). A great deal of empirical support for the dual-mode models of persuasion rested on evidence that contextual information is persuasive under different conditions than information contained in the message arguments: Contextual information was typically persuasive under conditions of low cognitive capacity and/or motivation, whereas message or issue information was typically persuasive under high capacity and motivation conditions.

Whereas these results appear consistent with the dual-mode view of persuasion, they are subjects to a general

alternative interpretation based on a possible confounding of task demands with informational type (Kruglanski & Thompson, 1999a, 1999b). In a typical (dual-mode) persuasion experiment, the peripheral or heuristic cues are presented up front, and the message arguments are presented subsequently. Moreover, the message arguments are typically lengthier and more complex than the (heuristic or peripheral) cues (see Kruglanski & Thompson, 1999b, for a review).

The foregoing features could have rendered the message arguments more difficult to process than the heuristic cues. That could be the reason why the cues typically exerted their persuasive effect under low processing motivation or cognitive capacity, whereas the message arguments typically did so under high motivation and capacity. Indeed, research by Kruglanski and his associates found in several studies that controlling for the difficulty of processing eliminates the previously found interactions between the type of information (peripheral/heuristic cues vs. message arguments) and processing resources as far as attitude change is concerned (Erb, Pierro, et al., 2003; Kruglanski & Thompson, 1999a, 1999b; Pierro et al., 2004; Pierro, Mannetti, Erb, Spiegel, & Kruglanski, 2005).

Subjective Relevance of Information: The "Override" Effect

A puzzling phenomenon in persuasion research has been that "peripheral" or "heuristic" cues, have appreciable impact on recipients' attitudes and opinions under limited (motivational or cognitive) processing resources (conditions of low "elaboration likelihood" in the ELM terminology), yet they typically fail to exert persuasive impact under ample processing resources, where the (subsequently presented) message arguments carry the persuasive brunt. One of the explanations for this effect was Petty's (1994) *cue-weighting* hypothesis whereby "when motivation and ability are high . . . the cues are in essence discounted as irrelevant at the time of attitude judgment" (p. 234). Indeed, in an analysis of the relevant research Pierro and colleagues (2004) discovered that (positive) cues are typically perceived by participants as less relevant to the attitudinal judgments than the (strong) message arguments used in that research. Based on this finding, Pierro and colleagues restated Petty's cue-weighting hypothesis in more general terms as a *relevance override* hypothesis whereby in a confrontation between a more subjectively relevant and a less subjectively relevant piece of information, *any* more relevant versus less relevant information (not necessarily message arguments vs. "cues"), the less relevant information would lose some of the persuasive impact it might otherwise exert.

Pierro and colleagues (2004) argued further that if the less relevant information came first and was followed by the more relevant information—the less relevant information should have greater impact under limited processing resources, and the more relevant information should have greater impact under ample processing resources, just as found in the preponderance of persua-

sion studies (see Kruglanski & Thompson, 1999a, 1999b, for reviews). If, however, the order was reversed and the more relevant information came first, it should have the greater impact irrespective of processing resources. Pierro and colleagues obtained strong support for the foregoing *relevance override* hypothesis across three different studies that differed in the type of information presented early ("cues" or "message arguments") and late ("cues" or "message arguments") in the sequence.

Taken as a body, the research to date suggests that the content or type of information (e.g., represented in the distinction between cues and message arguments) does not matter as far as persuasive impact is concerned. What matters are the judgmental parameter values (e.g., on subjective relevance, task demands, or presentation sequence parameters). When these are controlled for, prior pervasive *differences* between the peripheral or heuristic processing of "cues" and the central or systematic processing of issue- or message-related information disappear, questioning the need to regard the two modes of persuasion identified in the ELM or the HSM as *qualitatively distinct*.

Causal Attributions

Background Knowledge about the Meaning of Causality

Causal attribution requires that individuals use their background knowledge as to the nature of causality, namely, that it involves *temporal precedence* of the cause relative to the effect (see Kassin & Pryor, 1985, for a review), as well as *covariation* between the two (Hilton & Slugoski, 1986; Kelley, 1967, 1971; Kruglanski, 1989). Detection of temporal precedence of *X* with respect to *Y* and covariation between the two is evidence that *X* is cause of *Y*. So, for example, in Kelley's (1967) well-known scheme (the so-called Kelley's cube) an *entity attribution* is made if the effect covaried with a given entity but not with other entities (the distinctiveness criterion), and if it did not covary with persons (the consensus criterion), time, or modality (the consistency criterion), attesting that neither the specific person nor the time or the modality was a cause of the effect. Similarly, a *person attribution* would be made if the effect covaried with the person but not with time, modality, and entity (e.g., the individual was polite to all other individuals, at all times and in all situations).

Background knowledge, or the lay theories to which one happens to subscribe, may also determine what specific causal hypotheses are considered plausible in the first place. For instance, a person experiencing the symptoms of a common cold may generate the alternative hypotheses that this was caused by exposure to an inclement weather, an encounter with others suffering the same ailment, or insufficiently warm clothing, because this individual may have subscribed to lay theories causally linking these factors with the effect at hand. Individuals with different lay theories may generate different causal hypotheses to explain the same effect. In the realm of achievement motivation, for instance, individuals with an entity theory (Dweck, 1999) may account for failure on a task in terms of a lack of ability, whereas individuals with an incremental theory (Dweck, 1999) may account for it in terms of insufficient mastery.

Behavior Identifications versus Dispositional Attributions

The importance of background knowledge (about the concept of causality in general, and/or about specific "candidate causes") is not at all unique to causal attributions and is shared by all instances of judgment. A question whether this is actually so was raised in a set of intriguing papers by Yaacov Trope and his colleagues (Trope, 1986; Trope & Alfieri, 1997; Trope & Liberman, 1996). Trope (1986) proposed an influential dual-process model wherein the *contextual-constraint* information (i.e., whether powerful situational pressures existed impelling most people to enact the behavior under the circumstances) impacts judgments of behavior *identification* and *dispositional* attributions in qualitatively different ways.

Trope's (1986) analysis assumes a sequence of phases wherein behavior identification precedes dispositional attribution. It assumes further that at the behavior identification stage, the incorporation of contextual constraints is effortless, automatic, and independent of cognitive resources. By contrast, at the dispositional-inference stage the influence of context was assumed to be controlled, deliberative, and capacity demanding (Trope & Alfieri, 1997, p. 663).

In support of these notions, Trope and Alfieri (1997, experiment 1) found that assimilating a behavior to the context appears to constitute a resource-independent, effortless task that anyone can carry out, irrespective of cognitive capacity, whereas dispositional inference is effortful and resource-dependent and people can perform it only if endowed with adequate cognitive capacity.

But from a more general perspective, both behavior identification and dispositional attribution constitute judgments that differ in contents but presumably are governed by the same process. Behavior identification tasks turn on the question "*What is it?*" and How can it be classified? Dispositional attributions revolve about the different question of "*What caused it?*" According to our analysis, contextual information, to the extent that it is subjectively relevant, may constitute evidence relevant both to the behavioral identification and to the dispositional attribution judgments.

We assume as well that the more difficult the judgmental task, the more resources should be required to carry it out. In those terms, it is quite possible that Trope and Alfieri's (1997) findings pertain to a situation wherein, for some reason, using the contextual information to answer the *identification* question was relatively easy, and, hence, was unaffected by cognitive load, whereas using that same information to answer the dispositional-*inference* question was relatively difficult and hence sensitive to load.

That the dispositional inference question can be independent of load was demonstrated in a series of studies by Trope and Gaunt (2000). As Trope and Gaunt summarized it, "cognitive load eliminated discounting when situational [or contextual] information was low in salience,

low in accessibility, or low in specificity. However, when situational information was made more salient, accessible, or specific, it produced strong discounting effects even under cognitive load . . . " (p. 344). These results seem at odds with a dual-process model that portrays dispositional inferences (in counterdistinction to behavioral identifications) as *inherently* exigent of resources and, hence, sensitive to load.

Chun, Spiegel, and Kruglanski (2002) conducted three separate experiments investigating the parallel question, namely, that incorporating the context into *behavior identifications* would require resources if this was made sufficiently difficult. Consistent with this analysis, participants' perception of the ambiguous behavior was independent of cognitive load where the behavior identification task was made easy (by increasing the saliency of the behavioral or the contextual information), but it was significantly dependent on load where this task was difficult. From this perspective, it does not seem necessary to posit *qualitatively distinct* judgmental processes for the phases of behavior identification and dispositional inference. The extant evidence suggests that when the parameter of processing difficulty is controlled for the putative processing, differences between these phases disappear.

Correction Processes

Whereas nondirectional processing motivation (e.g., an involvement in an issue) may afford the discovery of an otherwise difficult to *discern* inference rule (e.g., embedded in a lengthy and complex message argument), directional motivation may affect individuals' *readiness* to use that rule. This issue has been addressed by research on correction processes in social cognition (Martin, 1986; Martin, Seta, & Crelia, 1990; Petty & Wegener, 1993; Wegener & Petty, 1995). Thus, Martin's (1986) set–reset model posits that assimilation of judgment to a prior context (such as a prime) is the default tendency for most people. For instance, if after being primed with the word "reckless" one finds out that "Donald shot the rapids in a kayak" one might apply the rule "If pursuing dangerous activities (such as rapid-shooting) then reckless" (representing assimilation). However, if the priming was particularly blatant and or if alternative information became available suggesting that a given bit of information was inappropriate and should not be used, people may suppress such information. The motivation to suppress the "illegitimate" information may fail in its quest if this required greater processing resources than the individual possessed or was ready to commit. In this vein, a study by Martin and colleagues (1990) showed that only people who were high but not those who were low in the need for cognition *contrasted* their impressions of a target person (along a dimension ranging from "stubborn" to "persistent") away from an implication of a prior prime.

Is assimilation invariably the default option? Petty and Wegener (1993) argued, alternatively, that this may depend on individuals' *metacognitive* inference rules about how their judgments are affected by prior information. Under some conditions, contrast rather than assimilation may be the default. Aware of this fact, individuals

motivated to correct for what they perceive as an illegitimate "contrast bias" may strive to eliminate it. In this vein, Petty and Wegener showed that under correction instructions, participants rated several target cities equally, regardless of whether they previously thought of a desirable vacation spot (i.e., Hawaii) or a more neutral spot (i.e., St. Louis). When no correction instructions were given, however, participants in the desirable location condition rated the targets as less desirable, compared to participants in the neutral city condition. These results suggest that assimilation can be the corrective strategy in situations in which the default bias seems to be to contrast an average target away from a desirable target. In other words, the rule "if Paris exemplifies a desirable vacation spot then Lawrence, Kansas is rather undesirable" was corrected for by participants who were specifically motivated to do so.

Wegener and Petty (1995) proposed, more generally, that people may hold either assimilative or contrasting inference rules (hence, that neither is necessarily the *default*). If motivated to correct they might do so by "bending over backwards" and executing contrasting or assimilative procedures depending on the perceived initial source of bias. In support of this hypothesis, Wegener and Petty found that if people held an assimilative theory they tended to use a contrasting correction strategy, following instructions to correct for the bias. However, people who initially subscribed to a contrast theory reacted with an assimilative correction strategy when instructed to avoid bias.

In summary, people may be aware of some of the inference rules that mediate their judgments. If led to believe that a given application of those rules is inappropriate and biased, and if motivated to correct for such a bias, they may either suppress the rules in question (Martin, 1986) or apply compensatory metacognitive rules (e.g., "If I overestimated the job satisfaction of someone in the Bahamas [because of contrasting or assimilative tendencies], I need to reduce my estimate.")

Heuristics and Biases

Base Rate Neglect and the "Representativeness" Heuristic

For several decades now, instigated by the seminal contributions of Amos Tversky and Daniel Kahneman (1974, Kahneman, 2003; Kahneman & Tversky, 1973), investigators of judgment and decision-making behavior have been exploring people's tendency to render judgments consistent with normative statistical models, versus relying on a variety of suboptimal shortcuts referred to as heuristics. A major appeal of this work was that it challenged the presumption of human rationality and questioned the rational-choice paradigm, popular in the various social sciences (Cohen, 1979, 1981; Hastie & Dawes, 2001; Scott, 2000). Whereas the normative statistical models (the Bayes theorem in particular) were seen to offer optimal algorithms for likelihood estimates from quantitative information, research has shown that people's actual behavior often strays from the dictates of

such models and seems governed by simplistic rules of thumb rather than more normatively appropriate statistical information.

Yet, if our analysis is correct, the claims that persons generally neglect normative statistical principles in favor of suboptimal heuristics have to be qualified by taking into account (1) people's background knowledge of statistical concepts, and their accessibility as well as (2) their background knowledge and accessibility of given heuristic rules. One way of doing so is to impart to individuals a rule, which some subsequent information might fit. In this manner, individuals who have been taught the rule may have it available in their mental repertory, while other individuals deprived of such training may not. Consistent with this notion, Ginossar and Trope (1980) found that people vary in their tendency to endorse the sampling rule linking base rates to likelihood estimates, and that the endorsers utilize the base rate to a greater extent than do the nonendorsers.

Other research (Nisbett, Fong, Lehman, & Cheng, 1987; Sedlmeier, 1999) has established that statistical reasoning can be taught and that it can result in the increased use of statistical information. Training effects were also invoked by Gigerenzer (1996; Gigerenzer & Hoffrage, 1995, 1999).

Furthermore, the perceived relevance of the individuating information can also be readily manipulated, for instance, by making it more or less fitting to a given stereotype. Ginossar and Trope (1987, Experiment 1), for example, found that when the individuating information was made relevant to the lawyer versus the engineer categories, it was used that way and the base rates were essentially ignored. However, when it was irrelevant it had no impact on judgments and the base rates were markedly utilized.

Beyond the availability of particular (individuating or statistical) rules that lend relevance to the information given, their utilization may depend on their accessibility. For instance, Sedlmeier and Gigerenzer (2001) showed drastic improvements in participants' ability to apply Bayesian inference rules, simply by reframing Bayesian conditional problems in terms of frequencies, a statistical notion more *accessible* to the average person than ratios (Sedlmeier & Gigerenzer, 2001). Erb, Kruglanski, and colleagues (2003) similarly indicated that making statistical constructs accessible through priming increases the use of base rates and reduces the reliance on stereotypical, "representativeness" information.

Processing Difficulty and Processing Resources

One might still wonder why relevant individuating information typically *overrides* the base rate information, even though the latter too is undeniably perceived as relevant and is generally used in the absence of relevant individuating information (Ginossar & Trope, 1987). In a recent paper, Chun and Kruglanski (2006) explored the possibility that this may be so in part because of a confounding in typical base rate neglect experiments between *type of information* (e.g., individuating vs. statistical) and its *processing difficulty*, recalling a similar confounding in per-

suasion studies (Erb, Kruglanski, et al., 2003; Kruglanski & Thompson, 1999a, 1999b; Pierro et al., 2005). In a typical "lawyer/engineer" study described in the literature (e.g., Kahneman & Tversky, 1973), the base rate information was presented via a single sentence appearing up front. The individuating (or representativeness) information usually followed and was conveyed via a relatively lengthy vignette. As a consequence, the base rate information may have been relatively easy to process, compared to the individuating information. If one assumes that participants in the typical base rate neglect studies had sufficiently high degrees of processing motivation and cognitive capacity, it is possible that they focused their processing efforts on the more complex individuating information and hence were able to appreciate its relevance to the judgment at hand. Furthermore, the focus on the later and more complex information may have reduced individuals' attention to the earlier information, resulting in its "neglect," just as in persuasion studies the early and easy-to-process "cue" information is typically neglected (under high motivation and capacity conditions) (e.g., Chaiken et al., 1989; Kruglanski & Thompson, 1999a, 1999b; Petty & Cacioppo, 1986).

But if processing difficulty (i.e., task demandingness) matters, we should be able to increase or decrease the use of statistical *or* individuating information, by appropriately varying its processing difficulty, and the participants' resources. Chun and Kruglanski (2006) found strong support for these notions across several experiments. For example, in their first experiment, these authors replicated the typical lawyer/engineer paradigm (Kahneman & Tversky, 1973) in one condition by presenting brief and upfront base rate information followed by lengthier individuating information. In a contrasting condition, these relations were *inversed* by presenting brief individuating information first followed by lengthier and more complex base rate information. As expected, the former condition replicated the typical finding of base rate neglect whereas the latter condition evinced significant base rate utilization. In a subsequent study (Chun & Kruglanski, 2006, study 2), imposition of cognitive load actually ironically increased the ("normative") use of base rate information when it was presented briefly and upfront; hence it was easy to deal with.

The considerable research accorded base rate neglect and other failures to use statistical information attest that these phenomena are nonunique and that they are governed by the same judgmental parameters that determine the utilization of any other information.

Other Judgmental Heuristics

AVAILABILITY

The availability heuristic pertains to judgments of frequency or likelihood of objects and events, in reference to reliance on the ease with which instances of such object or event categories come to mind (Kahneman & Tversky, 1973, 1982). Whereas *superficially* the availability heuristic may appear quite different from the representativeness heuristic—the two share a *deep* similarity in

that both refer to inferential rules, albeit of different contents. The representativeness heuristic refers to a rule whereby "if *X* (an object or an event) exhibits the defining properties of category *Y* (or is "similar" to the category) then it is member of that category." The availability heuristic refers to the metacognitive rule, "if an exemplar of a category comes to mind easily, there must be many instances of it" (Ruder & Bless, 2003, p. 21).

In recent years, the ease-of-retrieval interpretation of the availability heuristic was juxtaposed to the amount of instances (or content) interpretation. Thus, Schwarz and colleagues (1991) found that fewer versus more numerous instances of recalled instances of some trait (e.g., assertiveness) led to higher ratings on the corresponding trait (see also Schwarz, 1998; Wänke, Bless, & Biller, 1996). Nonetheless, the *amount* of instances (or content of the information) has also been found to mediate likelihood or frequency inferences. Thus, Rothman and Schwarz (1998) reported that individuals with low issue involvement relied on ease of retrieval whereas highly involved individuals relied on the content that came to mind (see also Aarts & Dijksterhuis, 1999). Assuming that the ease-of-retrieval rule is easier to apply than the content rule (that at the very least requires the operation of counting instances), these latter findings seem to constitute additional instances of the principle (illustrated in our earlier discussion of base rate utilization) that for it to be applied in judgment, the difficulty or demandingness of a rule must be matched by the individuals' processing resources.

Obviously, the ease-of-retrieval rule would not be used if the instantiating information about ease (the minor premise in the syllogism) was lacking. Thus, in research by Wänke and colleagues (1996) when yoked participants received a list of arguments generated by others, they were more influenced by the large (vs. the small) number of arguments, probably because the experience of ease was unavailable to them. Also, when the "ease rule" was rendered contextually inapplicable via a misattribution of difficulty to background music participants tended to use the "amount of instances" rule and to associate many (vs. few) instances with higher ratings on the focal trait (of assertiveness) (Schwarz et al., 1991).

Research by Fishbach, Igou, and Kruglanski (2005) suggested that participants are capable of using either the ease or the amount or the content rules and that they would use them when their corresponding instantiating information was rendered salient. These authors' research demonstrates that the ease-of-retrieval rule need not be easier to apply than the amount of instances or the content rules, suggesting that there is no universal connection between the tendency to apply the ease rule (or, for that matter, any other rule) and processing difficulty. For example, participants seem to be quite selective in their application of the ease-of-retrieval rule, and they realize that their own ease of retrieval is irrelevant to assessing another person's properties. Furthermore, when the ease-of-retrieval rule is made more accessible, participants rate themselves as more assertive in a fewer (vs.

more) recalled instances condition. However, when the amount-of-instances rule is made more accessible, participants rate themselves as more assertive in the more (vs. fewer) instances condition (Fishbach et al., 2005).

The foregoing research suggests that the availability heuristic pertains to inference rules (of either the ease or the amount variety) whose functioning and application are governed by similar principles (related to relation between the difficulty of accessing an inference rule and processing resources, perceived rule relevance to given judgments, etc.) as those underlying the use of other inference rules of different contents.

Anchoring Effects

One of the most interesting heuristics identified by Tversky and Kahneman (1974) is that of *anchoring* and *adjustment*. Empirically, this phenomenon is typically illustrated in a paradigm that includes two sequential questions. The first question requires participants to estimate whether a judgmental target, or target feature, is higher or lower than some numerical comparison standard, or anchor. This is referred to as the *comparative* question. The second question requires participants to provide an *absolute* estimate pertaining to the same judgmental target. In one of the most well-known studies employing the classic anchoring paradigm, Tversky and Kahneman's (1974) participants were first presented with a *comparative* question, which asked them to indicate whether the percentage of African nations in the United nations was higher or lower than 65% or 10%. Afterwards, participants were asked to provide an *absolute* estimate of the percentage of African nations in the United Nations. Despite the fact that the anchors were generated randomly (by spinning a wheel of fortune), results revealed that median estimates of the absolute percentage, 45% and 25%, respectively, clearly were impacted by those anchor values.

Recently, Strack and Mussweiler (1997) proposed that the anchoring effect may be explained in terms of a selective knowledge activation mechanism (SA), which assumes that judges, comparing a given target to an anchor value, may positively test the hypothesis that the target in question is identical to the anchor value, generating different contents of knowledge consistent with the magnitude implications of a given anchor (Chapman & Johnson, 1999; Klayman & Ha, 1987; Strack & Mussweiler, 1997). Anchoring effects essentially obtain, according to Strack and Mussweiler's (1997) model, because people tend to assimilate their final judgments to previously activated, anchor-biased target knowledge.

One of the implications of this model involves the degree to which the target knowledge, activated in response to the positive hypothesis-testing process, is deemed *relevant* to a subsequent absolute estimation task (see also Higgins, 1996; Martin & Achee, 1992; Wegener & Petty, 1995, 1997). The selective activation (SA) model posits that activated target knowledge has to be *applicable* to a subsequent absolute judgment and *representative* of the target of the absolute judgment (Strack & Mussweiler,

1997). Consistent with the notion that activation of specific target knowledge mediates anchoring, in one study (Strack & Mussweiler, 1997, experiment 1) an anchoring effect was only obtained in a standard anchoring condition in which the judgmental dimension in question (height of the Brandenburg Gate in Berlin) was held constant between the comparative and absolute judgments, whereas no anchoring effect was obtained in a condition involving a dimension change between the comparative and absolute judgments (from height to width of the gate), supporting the knowledge applicability constraint of the SA model (Strack & Mussweiler, 1997). Thus, the *subjective relevance* of the information generated during the comparative judgment task appears to affect the degree to which the anchoring effect obtains under conditions wherein the target of the absolute judgment differs from the target of the comparative judgment.

The hypothesis that people generate different contents of knowledge, or evidence, during the comparative phase, as a function of the anchor value considered during the comparison phase, is perhaps best supported by studies that show a reaction time advantage to anchor-consistent words in a lexical decision task (Mussweiler & Strack, 2000, study 1).

Despite the potential of the selective accessibility model to explain a wide range of anchoring effects, involving different targets and differentially extreme anchor values, there exists a class of anchoring phenomena, known as *basic anchoring effects* (Wilson, Houston, Etling, & Brekke, 1996), that are not easily explained by the semantic activation model. For example, anchoring effects appear to obtain under conditions in which the target of the initial comparison is completely unrelated to the target of the absolute judgment. In one study Wilson and colleagues (1996) asked one group of participants whether the number of nations in the United Nations was more than, less than, or equal to 1930 and another group whether the number of physicians in the local phonebook was more than, less than, or equal to 1930. In a subsequent absolute judgment task, all participants were asked to estimate the number of nations in the United Nations, showing anchoring effects with comparable effect sizes in both groups. As Wilson and colleagues have argued, anchoring effects can be explained by invoking a simple short-term memory representation of the numerical anchor itself. Because numerical values may be represented in short-term memory independent of the context in which they were initially encountered, anchors may influence a large variety of subsequent absolute judgments without the relevance constraints imposed by the selective accessibility model.

To unify the perspectives of semantic activation and basic numeric anchoring, Sleeth-Keppler (2004) recently proposed a simplified semantic activation model that has the potential to account for anchoring effects obtained under the classic paradigm as well as under conditions of changed judgmental targets. Unlike Strack and Mussweiler (1997), who include in their activation hypothesis primarily *target* semantics (e.g., selectively activated knowledge *about a given target*), Sleeth-Keppler has argued that the semantics generated during the comparative judgment task may consist of simple, semantic representations of the *numerical anchor value* itself (i.e., nontarget-specific information about quantity such as "large" or "small," "tall" or "short"). For example, in one study, testing this model, Sleeth-Keppler varied the target of the comparative judgment task in a between-subjects design, while holding the numerical anchor value constant. Thus, half of the participants were asked to indicate whether pop singer Britney Spears was older or younger than 45 years, whereas the other half was asked to indicate whether Hollywood actor Clint Eastwood was older or younger than 45 years. In the Britney Spears condition, participants were expected to be primed with the concept "old," because 45 years constituted a high standard for her age. However, in the Clint Eastwood condition, participants were expected to be primed with the concept "young," because 45 years represented a low standard for his age. After the comparative task, all participants were asked to rate the age of a third, unrelated target person (Senator Bennett, R-Utah). The results revealed higher estimates of the target's age in the Britney Spears compared to the Clint Eastwood condition. Furthermore, results from a lexical-decision task, which was conducted as part of the same study, showed a significant reaction-time advantage to target words related to the concept "old" in the Spears condition (compared to words related to the dimension "young"). This pattern of results was reversed in the Eastwood condition, where participants were faster at identifying "young" compared to "old" target words.

Note, that both Strack and Mussweiler's (1997) SA model and Sleeth-Keppler's (2004) general semantic model assume that manipulation of the anchor serves to generate information *relevant* to the judgmental task engaged in during the absolute phase of the procedure. Such information may activate matching aspects in the target, which then are used as evidence for the absolute judgment. For example, activation of the concept "old" by the comparative question may focus the individual's attention on corresponding features of the target (e.g., aspects of a person that signify old age). In turn, those activated features may serve as *evidence* that the target is in fact old. Alternatively, accessibility of the semantic term activated by the anchor may itself be taken as evidence that the target is characterizable by this term. Thus, if "old" comes to mind when thinking of a target person, this might suggest to one (i.e., be taken as "evidence," or intuitive hunch) that he or she in fact is old. In short, recent interpretations of the anchoring phenomenon suggests that it is mediated by inferences from evidence based on the appropriate "if–then" rules, just as are other judgments.

Finally, there is also evidence that when participants are motivated to engage in extensive informational search, and the relevant information is available in their environment, a high degree of accuracy motivation may lead these individuals to search for alternative evidence beyond that activated by the anchor, thus mitigating the anchoring effects (Kruglanski & Freund, 1983).

Additional Judgmental Domains

Social Comparison Processes

The present scope does not allow a detailed review of all additional domains of social judgment, but there are reasons to believe that the presently identified judgmental parameters play the same role in those other areas as well. Consider the well-tilled domain of social comparison processes. Recently Mussweiler (2003) provided an integrative review of this realm of phenomena, viewing social comparison as a special case of *hypothesis testing*. Obviously, such testing represents a "rule-based' process departing from the assumption that "if data D are observed, then hypothesis H is valid." What is special about social comparison is the comparative content of the hypotheses being tested. Thus, one may test the hypothesis that John has greater ability than Paul, or that Paul's age is less than John's. In cases discussed by Mussweiler persons are assumed to generate from memory data relevant to testing the various hypotheses of interest, though in other cases of social comparison data obtained from external sources, or by observation, may also be used. Individuals' cognitive capacity and (nondirectional and directional) motivation may play the same role in social comparisons as they play in other judgmental domains in determining the extent and thoroughness of information processing en route to judgment, as well as the amount of bias toward desirable (and away from undesirable) comparative conclusions (see Kruglanski & Mayseless, 1990, for a review).

Impression Formation

Impression formation has constituted a central domain of dual-process theorizing. Two influential models in this area have been those of Fiske and Neuberg (1990; Fiske, Lin, & Neuberg, 1999) and of Brewer (1988). Though these conceptualizations differ in important regards, they share several central features. Most important, they both distinguish between category-based and attribute-based processing and view them as *qualitatively different*. Category-based processing is assumed to be "top down" and attribute-based processing is assumed to be "bottom up" (Brewer, 1988, p. 4; Fiske & Neuberg, 1990, p. 60).

Both models also assume that impression formation follows a fixed order commencing with an automatic identification of the target in terms of some general categories. According to Fiske and Neuberg (1990), "the category label is more likely to be a social grouping (demographic category, role, job) than a single personality trait" (p. 10). Subsequently, if the incoming information and the knower's self-involvement warrant it, he or she may continue processing information and address individuating or personal-attribute information as well. In Brewer's (1988) model, for example, personalization requires a sufficient degree of self-involvement, which allows "attributes and behaviors . . . inconsistent with previously established expectancies (to) be processed extensively and incorporated into the person representation" (p. 23).

Fiske and Neuberg (1990) as well as Brewer (1988) are undeniably correct in pointing out that social category information may often appear highly relevant to various requisite judgments (e.g., the information that a target is a woman my seem relevant to the judgment of this person's submissiveness or nurturance by someone subscribing to a particular gender stereotype). But it is also true that such information might appear irrelevant to other judgments, to which individuating information may appear more relevant (e.g., the information that the target is a woman may appear irrelevant to a judgment of her wealth, whereas the information that her name happens to be Rockefeller may appear highly relevant to such judgment).The critical role of subjective relevance in this connection was noted by Medin (1988), who observed that "the response should depend on what information is *needed* and how well that information can be predicted from knowledge about who the person is, what groups they can be classified into, or what situation is instantiated" (p. 122, emphasis added). Earlier, the same point was implied by Bruner (1957) namely that "a primary determinant of category activation is the search requirements imposed by the perceiver's needs, objectives and task goals . . . " (cited in Brewer, 1988, p. 18).

Critics also questioned whether the terms "social category" and "personal attribute" may be meaningfully distinguished from each other as far as the judgmental process is concerned. In the statement "Judy is a nurse," the term "nurse" (i.e., a social category) can be readily considered one of Judy's attributes, as may the category "friendly person" in the statement "Judy is friendly." As Klatzky and Andersen (1988) noted, "Even individualized person concepts have associated attributes and . . . these attributes are themselves social categories" (p. 98). Medin (1988) expanded on this point to state that "if every person were treated as absolutely unique, than there would be no basis at all for generating expectations. This would be analogous to the situation of a physician being confronted with a totally new disease unlike any other . . . " (p. 122).

To summarize then, the information used on an encounter with a social stimulus may indeed represent a "social" *category* or a "trait/attribute" *category*, all depending on its subjective relevance ("search requirements," "task goals," or "informational needs") to the judgment at hand. As far as the judgmental process is concerned, "social categories," "traits," or "attributes" seem functionally equivalent in constituting *evidence* for requisite judgments. A detailed examination of dual-process models of impression formation in terms of the present judgmental parameters is given by Erb, Kruglanski, and colleagues (2003).

Dual-System Models of Social Judgment: Associative versus Rule-Following Accounts

Various dualistic social judgment models examined earlier revolved about *content differences* in inputs (to) or outputs from, the judgmental process. For instance, the ELM distinguished between the processing of *message*

arguments versus *peripheral cues* (Petty & Cacioppo, 1986) as inputs into attitude formation. Similarly, the HSM contrasted *message arguments* and *heuristic cues* as inputs. The work on biases and heuristics (Kahneman, 2003; Tversky & Kahneman, 1973) distinguished between the use of *statistical* (e.g., base rate) and *nonstatistical* (e.g., representativeness) inputs into likelihood estimates. Fiske and Neuberg (1990) as well as Brewer (1988) distinguished between inputs based on *categorical* and *individuating* information, and Trope's dual-process model of attributional inferences (Trope & Gaunt, 2000) distinguished between the judgmental *outcomes* of behavioral *identifications* versus dispositional *attributions*.

Sloman's Case for Two Systems of Reasoning

A different group of dualistic models distinguished between qualitatively distinct *systems* of reaching judgments. An early such model, described by Sloman (1996), distinguished between *associative* and *rule-based* systems of judgment. Sloman's primary attempt was to identify substantial criteria for building a case for the systemic-distinctiveness argument. For example, Sloman asked whether the speed with which a judgment is formed (e.g., in the context of engaging in simple vs. complex arithmetic problems) provides a demarcation for two systems of reasoning. But the *quickness* with which an answer comes to mind need not be compelling evidence for a qualitative difference in judgmental "systems." Instead, it could reflect the *difficulty* of the arithmetic task in the two instances. This may depend in part on the task itself, and in part on the degree to which it was routinized for a given individual (Schneider & Shiffrin, 1977). Thus, for a young child who is just learning to count, figuring out that 10 − 9 = 1 may be quite arduous and deliberative, whereas for a cashier who routinely sells a certain product for $27.35, figuring out the change for a $50 bill might be extremely rapid.

A second demarcation criterion, *awareness of the judgmental process*, was quickly discarded by Sloman (1996) himself. In his words, "Awareness provides only a fallible heuristic for identifying systems not a necessary or sufficient condition" (p. 6). For instance, "some reasoning is not obviously associative and yet apparently occurs without conscious awareness" (Nisbett & Wilson, 1977).

The S Criterion

Sloman (1996) finally settles on the one demarcation criterion that he viewed as satisfactory in warranting a qualitative distinction in process. This is his Criterion S (for simultaneity) described as follows: "A reasoning problem satisfies *Criterion S* if it causes people to simultaneously believe two contradictory responses" (p. 11). Because of the key importance that Sloman attaches to this particular criterion, it is well to submit it to a careful scrutiny. Take Sloman's own example, the statement that a "whale is a mammal" (p. 11). Whales are commonly perceived to resemble fish more than typical mammals like a cow or a horse. Thus, a knower may need to deal in this case with two contradictory

beliefs, one derived from the whale's outward similarity to fish and one derived from the "academic" knowledge that classifies whales as mammals.

Yet, it is quite possible that we may have here are two distinct *rules* yielding opposite conclusions. One rule is based on similarity, or the "representativeness" heuristic (and heuristics, after all, constitute rules *by definition*) (e.g., "if *X* looks like a fish, swims like a fish, and lives like a fish, *X* is a fish"). The other rule may be based on other criteria for classification in the mammal category (e.g., "breast feeding of offspring"), or, indeed the source *heuristic* "If a biology text claims *X* (e.g., that whales are mammals) then *X* is the case."

Perhaps the most striking of Sloman's (1996) examples concerns the Müller–Lyer illusion. Here, perception provides the answer that the lines are of unequal length, and a ruler furnishes an incompatible answer, that they are equally long. Once again, however, it is easy to understand this phenomenon in terms of two rules in which the individual happens to strongly believe, and that happen to yield disparate conclusions. One of these rules is that one's visual perceptions are valid ("if my eyes inform me that *X* then *X* it is"); the other, that application of a ruler yields valid answers.

Note that not every single person necessarily upholds both rules. For instance, individuals hampered by limited eyesight may probably harbor considerable doubt about the veracity of their perceptual experiences. Similarly, members of primitive cultures absent length measuring instruments may not trust the ruler much. Suppose, finally, that on two different occasions an individual measured the same line with different rulers, one of which was biased (e.g., having an inch represented by 3cm, rather than the normal 2.3cm). In one instance, the conclusion might be that the line's length is less than some *X*, and in the other instance, that it is more than *X*. Clearly then the use of the very same rule-based "reasoning system" (here application of a ruler) may lead to two contradictory conclusions, satisfying Sloman's Criterion S for systems distinctiveness.

In summary then, Sloman's (1996) criteria for a duality of the judgmental process seem readily explicable in terms of a single process determined by several quantitative parameters. Rapidity, lack of awareness, or automaticity more generally (cf. Bargh, 1996) may reflect degrees of routinization (hence processing difficulty) rather than a qualitative duality (as Sloman himself recognizes). And the Criterion S (of incompatible, strongly held beliefs) is compatible, in fact, with the notion that different rules (major premises) applied to the same evidence (minor premises) may yield completely different conclusions. None of this seems to warrant the assumption of a qualitative difference in the reasoning processes. That is not to say that associationistic processes do not exist but, rather, to question their qualitative distinction from rule-based processes. In fact, associations can be thought of as conditional rules of the "if *X* then *Y*" variety that may come to mind very rapidly and effortlessly because of their strength, that is, the degree to which the individual believes that *X* attests to *Y*, and their accessibility (Higgins, 1996).

Evidence from Conditioning Research

Conditioning phenomena (both classical and instrumental) are often viewed as the prototypes of associative learning. Yet, compelling evidence exists (Holyoak, Koh, & Nisbett, 1989; Rescorla, 1985; Rescorla & Holland, 1982; Rescorla & Wagner, 1972) that they are fundamentally rule based, in fact. Associative learning is assumed to constitute learning by *contiguity*, and *repeated pairing* of a conditioned stimulus (CS) and an unconditioned stimulus (US). Yet, evidence from the animal learning literature suggests that neither is necessary or sufficient for conditioning. That temporal contiguity is not necessary is attested by the fact that conditioning can occur when an interval of minutes or even hours elapses between the stimuli. Thus, if a rat ingested a novel substance and was made ill minutes or hours later, it will form a strong aversion to that substance (e.g., Garcia, McGowan, Ervin, & Koelling, 1968).

That pairing is not sufficient for conditioning has been further demonstrated (1) by Rescorla's (1968) results that if the probability of the reinforcer is the same in the absence of the CS as in its presence, no appreciable conditioning will take place, and (2) by conditioned inhibition effects whereby a higher-order stimulus (CS1) paired on some trials with another CS stimulus that on other trials was paired with some US (say, a shock) comes actually to inhibit the reaction associated with the US (e.g., crouching) even though a strict associationistic interpretation (of second-order conditioning) would suggest that this stimulus (i.e., the CS1) should evoke that very reaction. It thus appears that an animal, rather than responding mechanistically to contiguous pairings of stimuli over repeated occasions (representing the associationistic account) is attempting to learn environmental contingencies in which the occurrence of one event (e.g., shock) is conditional upon the occurrence of another (e.g., noise).

In the same vein, and based on their extensive review of pertinent conditioning studies, Holyoak and colleagues (1989) conclude that "representations of the environment take the form of . . . rules that compose mental models . . . the rat's knowledge about the relation between tones and shocks might be informally represented by a rule such as 'if a tone sounds in the chamber then a shock will occur, so stop other activities and crouch' " (p. 320).

The notion that "automatic" phenomena in the domain of (motor, or cognitive) skill acquisition involve a routinization of *if–then* sequences has been central to Anderson's (1983) adaptive control of thought model. Smith (1984, 1989; Smith & Branscombe, 1988; Smith, Branscombe, & Bormann, 1988) has extended this conception to the realm of social judgment. Specifically, Smith's research has demonstrated that social judgments represent a special case of procedural learning based on practice that strengthens the *if–then* components resulting in increased efficiency (or "automaticity). In summary, there are reasons to believe that the distinction between associative and rule-based processes, the former being "automatic" and the latter controlled or delibera-tive, confuses surface manifestations and deep structure, or as Bargh (1996) put it, constitutes a "false dichotomy" (p. 1706).

Reflexion versus Reflection

In a recent paper Lieberman and colleagues (2002) stated that "the idea that automatic processes are merely faster and quieter versions of controlled processes is theoretically parsimonious, intuitively compelling, and wrong" (p. 205). This conclusion is founded on the notion that different brain structures seem to be activated in automatic versus controlled behavior. More specifically, they propose that (what they refer to as) the X system, including the lateral temporal cortex, amygdala, and basal ganglia, is involved in automatic processing. By contrast, the C system, related to activity in anterior cingulate, prefrontal cortex, and hippocampus, seems activated when deliberative, or controlled processing takes place.

But the fact that different brain structures have been involved in instances of automatic versus controlled processing need not constitute compelling evidence that automatic and controlled processes are not "faster and quieter versions of controlled processes." The continuum from controlled to automatic processes is uncontroversial (Bargh, 1996; Schneider & Shiffrin, 1977), and the rule-like ("if–then") nature of "associationistic" as well as controlled inferences (Holyoak et al., 1989) has been generally recognized in the domain of classical conditioning. It is possible, for instance, that the different "brain systems" (i.e., X and C) simply respond to difficulty of processing such that beyond some threshold of difficulty, system X processing might not suffice and other brain structures (e.g., system C) need to kick in. This would be analogous to additional muscles, or stronger muscles, getting involved with increases in the weight that one tried to lift. Thus, involvement of different brain structures in the processing of more versus less practiced (and hence, efficient) *if–then* rules (Bargh, 1996) might merely signify the fact that the brain is responsive to *resource requirements* of information processing.

Lieberman and colleagues (2002) advanced an additional claim for their two anatomically distinct brain system. Namely, system X is assumed to process *identity information* (e.g., identification of a given behavior as member of a given category) whereas the C system is assumed to process causality information, and hence to be related to the behavior's causal origins. In other words, the X system is assumed to be involved both in the processing of identify information *and* in automatic processing. Similarly, the C system is assumed to be involved both in the processing of causality information and in controlled processing. All would be well if all identity processing was automatic, and all causality processing was controlled. There are reasons to believe, however, that this is not so. In work referred to earlier, Trope and Gaunt (2000), by making the causal attribution task easy, showed that it is insensitive to cognitive load, which would put it in the category of "automatic" processing (in terms of its efficiency).

On the other hand, Schneider and Shiffrin's (1977) classic task was one of identifying letters and digits in an array (representing an identity task par excellence), yet it took participants months to "automatize" it so that the speed of identification was not affected by the row length any more. Furthermore, in a study mentioned earlier, Chun and colleagues (2006) rendered the identification task "controlled" and hence resource dependent by decreasing the saliency of information pertinent to the "identity" inference. Thus, if system X is involved in automatic processing and not in controlled processing it could not be generally be involved in identity processing because, as we have seen, such processing can be "automatic" in some circumstances (in the efficiency sense) and "controlled" in other circumstances. Similarly, if system C is involved in controlled processing it could not be similarly involved in causal processing, which again could be "automatic" or "controlled." This reasoning leads to the conclusion that the dichotomy between the X and C systems does not offer strong evidence for a dual-process model of attributional inferences.

The Two Memory Systems Model

Smith and DeCoster (2000) proposed the existence of two qualitatively different memory systems: the slow learning and the fast learning systems. The slow learning system is assumed to be associative, and to learn general regularities slowly. The fast learning system is assumed to be rule based and to form representations of unique or novel events quickly. Presumably, the existence of this duality reflects the need to meet two conflicting demands: "One demand is to record information slowly and incrementally so that the total configuration in memory reflects a large sample of experiences. This is important so that general expectancies and long-term stable knowledge can be based on the average, typical properties of the environment. . . . A second demand is for rapid learning of new information so that a novel experience can be remembered after a single occurrence. After all, people can at least sometimes learn things by being told once" (Smith & DeCoster, 2000, p. 109).

Smith and DeCoster (2000) define rules as symbolically represented and structured by language and logic. "Symbolic rules may constitute a formal system such as the laws of arithmetic or of logical inference that is accepted by social consensus in a way that goes beyond its inherent persuasiveness for any given individual" (p. 114). Note that this definition is narrower than the general "if–then" conception of rules as contingencies (see, e.g., Anderson, 1983; Holyoak et al., 1989; Rescorla & Wagner, 1972; Tolman, 1932). There is nothing inherently wrong in defining rules the way Smith and DeCoster do, yet doing so has substantial implications. Thus, if to qualify as a rule a cognitive relation needs to be stated in symbolic terms, and be part of a formal system such as arithmetic or logic, then conditioning (of animal or human behavior) could not possibly be rule based contrary to recent agreements that *classical conditioning* is a form of signal or expectancy learning, involving "if–then" anticipations, generally viewed as "rules" (for re-

views, see Baeyens & De Houwer, 1995; De Houwer, Thomas, & Baeyens, 2001; Holyoak et al. 1989).

Furthermore, in Smith and DeCoster's (2000) framework, heuristics such as "expertise implies correctness" or "careful manner of dressing and persuasive argumentation are typical of lawyers" that may vary in their inherent persuasiveness to different individuals (Trope & Ginossar, 1988) could not qualify as rules even though they are pervasively defined as "rules of thumb" in the social judgment literature (Chaiken et al., 1989; Tversky & Kahneman, 1973).[1] To summarize then, the widely accepted definition of the rule concept in terms of its conditional, "if–then" structure is broader than Smith and DeCoster's definition that characterizes the rule concept in terms of its contents (symbolic, formal) as well as in the degree of social consensus it commands (see above).

Beyond definitional matters, the properties of rules proposed by Smith and DeCoster (2000) raise questions as to their generality. Thus, (symbolic) rules are assumed to be learned fast yet we know from experience how slow, difficult, and arduous can be the learning of statistical or logical rules (Evans, 1982; Kahneman, 2003; Tversky & Kahneman, 1973; Wason & Johnson-Laird, 1972). On the other hand, the learning of what Smith and DeCoster would define as "associations" could be exceedingly fast. Taste aversion is one striking instance of such rapid learning. Furthermore, evidence exists that evaluative conditioning (EC) can also occur in a minimal number of trials, even one (Baeyens, Crombez, Hendrickx, & Eelen, 1995; Martin & Levey, 1978, 1987, 1994; Stuart, Shimp, & Engle, 1987). Thus, apparently it is not necessary for associations to be built slowly over time, and/or for rules to be acquired very quickly.

According to Smith and DeCoster (2000):

> Rule based processing . . . tends to be analytic, rather than based on overall or global similarity, for example a symbolic rule may single out one or two specific features of an object to be used in categorization, based on conceptual knowledge of the category. In contrast, associative processing categorizes objects non analytically on the basis of their overall similarity to category prototypes or known exemplars. (p. 112)

The question, however, is whether phenomena such as classical conditioning, which have been typically regarded as quintessentially associative, actually are based on perceptions of *overall* similarity versus on specific features that seem to predict a given event (e.g., the onset of the US). In this vein, Holyoak and colleagues (1989) noted:

> Unless a feature is included in a candidate rule, nothing can be learned about its relation to other features or to appropriate behaviors. Moreover, a complex environment may contain many features, few of which are likely to be cues that would help form useful rules. For example, a rat may receive a shock while listening to an unfamiliar tone, scratching itself, looking left, and smelling food pellets. Intuitively, we might expect that the rule "if tone, then expect shock" will more likely be generated in this situation than the rule "If looking left, scratching, and smelling pellets, then shock" . . . unusual features of the environment are favored as candidates to build the conditions of new rules. (pp. 320–321)

In a similar vein, Murphy and Medin (1985) noted:

> A . . . major complication derives from the fact that no constraints have been provided on what is to count as a feature or property in analyses of similarity . . . any two entities can be arbitrarily similar or dissimilar by changing the criterion of what counts as a relevant attribute. Unless one can specify such criteria, then the claim that categorization is based on attribute matching is almost entirely vacuous. (p. 292).

The philosopher Nelson Goodman (1972) expressed this emphatically: "Similarity, ever ready to solve philosophical problems and overcome obstacles, is a pretender, an imposter, a quack. It has, indeed, its place and its uses, but is more often found where it does not belong, professing powers it does not possess" (p. 437).

Whereas Holyoak et al. (1989) emphasized that what determines the formation of associative rules is the principle of "unusualness" (i.e., salience) it is likely that other factors may also play a role. For instance, accessibility, which is different from salience (Higgins, 1996), may also determine the stimulus feature attended to and that one associates with another feature. Presumably then, if the construct "drink" was accessible in one's mind, one might more readily form an association between "drink" and "accident" if a person was seen to have a drink and subsequently be involved in an accident, compared to the case wherein "speed" was accessible in one's mind in which case an association between "speed" and "accident" might form more readily.

From the present perspective then, an association can be thought of as an expectancy, or as a conditional, "if–then," rule whereby given an antecedent term the consequent term may be expected. The contents of the consequent term may vary widely in the different rules. The kind of rules involved in conditioning phenomena are *predictive* in their content (Holyoak et al., 1989), for instance, an animal may learn to predict an important event such as the occurrence of a shock on the basis of a previously sounded tone. Thus, in conditioning studies the consequent of the conditional refers to a future occurrence of some event (e.g., the onset of the U.S.).

Other rules may have different consequent terms. Consider a semantic association between the terms "doctor" and "nurse." Clearly, encountering a doctor does not imply that a nurse will soon appear. The rule here is based on individuals' lay theories of what the "doctor" concept means, including, for example, the predicate "works with nurses" (representing the rule "if doctor then works with nurses"). In the same way that a tone may signal to an animal, and in this sense constitute evidence, that a shock will soon appear, knowledge that someone is a doctor may constitute evidence that this person works with nurses.

In summary, the distinction between slow associative learning and fast rule learning (Smith & DeCoster, 2000) is more complex than meets the eye. What has been traditionally viewed as associations can be learned relatively fast, whereas what has been characterized as rules may be acquired with difficulty and rather slowly. The notion that "associations" are learned on the basis of global simi-

larity and that "rules" are based on specific features too has been questioned (Holyoak et al., 1989; Murphy & Medin, 1985). Ultimately, associations can be thought of as "if–then" rules in which some term or category is conditionally linked with another. These arguments address the several dual systems models whose foundational assumption concerns the distinction between associative and rule-following (or propositional) processes (Gawronski & Bodenhausen, 2006; Sloman, 1996; Smith & DeCoster, 2000; Strack & Deutsch, 2004).

CONCLUDING COMMENTS

Vast Judgmental Diversity

The domain of social judgments is exceedingly diverse. First, judgments vary a great deal in terms of their contents: Causal attributions are judgments, but so are category assignments, stereotypical characterizations, behavioral identifications, likelihood estimates, personal impressions, attitudes, evaluations, and so on. Second, judgments vastly vary in speed and immediacy. Some are based on extended deliberations and a laborious examination of available evidence. Others have a "pop up" quality—they come to mind instantly, and they feel thoroughly natural, almost inevitable, under the circumstances. Judgments also may vary on the process-awareness dimension. In some cases (e.g., of attorneys in a court of law, or of academics arguing a point), the judgments rendered are exquisitely conscious and explicit. They often come in a written form wherein the details of the argumentation are fully transparent. In other cases, individuals may be hard pressed to explain what drove them to a given judgment, and their explanations might be wrong at that (Nisbett & Wilson, 1977; Wilson, Dunn, Kraft, & Lisle, 1989).

Small wonder then that a plethora of different models and theories were advanced to explain different judgmental phenomena. Some of these addressed specific content domains (e.g., models of stereotyping, of attribution, or of attitudes), others drew distinctions along the amount of processing continuum (Fiske & Neuberg, 1990; Petty & Cacioppo, 1986), yet others stressed the difference between "automatic" or "associative" and "deliberative" or "rule-following" ways of judging, including aspects of efficiency as well as awareness (Bargh, 1996; Devine, 1989). As a consequence of these various distinctions, the field of human judgment is highly fragmented these days, with different bodies of literature making little contact with each other, and the disparate research programs resembling those blind individuals in the adage, groping different parts of the same elephant.

But is there a deep-seated "elephant" behind the vast surface heterogeneity of judgmental phenomena, and how is it all put back together? (Anderson et al., 2004, p. 1036). It is in this vein that Newell (1990) argued for "the necessity of a theory that provides the total picture and explains the role of the parts and why they exist" (p. 18). In the present chapter we attempted to sketch an outline of such theory emphasizing the dimensional pa-

rameters along which different judgmental situations may vary.

The Principles of Social Judgment

Our conceptual framework affords the identification of several fundamental principles applicable to all of judgment. These are briefly elaborated below.

- *Principle 1*: *All judgments are rule based* (see also Anderson et al., 2004; Holyoak et al., 1989). This assertion is based on the notion that associations too are rule-like in the sense of denoting conditional "if–then" statements that may or may not be relevant to a judgmental question of interest. Nor is the concept of "pattern recognition" incompatible with rule-driven judgment, in the sense that a given stimulus pattern (e.g., of facial features, or of pathological symptoms) is assumed to warrant (or constitute a condition that justifies) a given judgment (e.g., that this face is Paul's, or that this patient has the flu) (for discussion, see Kruglanski, Erb, Pierro, Mannetti, & Chun, in press).
- *Principle 2*: *Judgmental task demands determine the amount of motivational and cognitive resources needed to appreciate the ("if–then") relevance of a given bit of information to a given judgment*. In some cases, the rule that lends the information its relevance may be highly accessible and, be activated immediately upon the individuals' encounter with the stimulus (Fazio, Sanbomatsu, Powell, & Kardes, 1986). In such circumstances the judgment (e.g., an evaluation) would be generated with considerable alacrity following the stimulus presentation. In other cases, the search for a relevant inference rule may be quite laborious. As a consequence, under limited attentional or motivational resources a less subjectively relevant, yet easier to access, rule may be utilized instead of a more relevant, yet more difficult to access, rule (Pierro et al., 2004).
- *Principle 3. The process of judgment formation is independent of the content of the inference rules being used*. Individuals may have at their disposal a wide variety of rules in different domains of interest. For instance, some of the rules may have to do with social stereotypes ("if X is member of category A, then X has properties a, b, c"), other rules may have to do with causal attributions (e.g., "If X preceded Y was contiguous to Y in time and space, and covaried with Y over time, then X is the cause of Y"), yet other rules may have to do with statistical inferences (e.g., "if X is chosen on the basis of its extreme standing in some distribution, then on a repeated observation X is likely to be less extreme"), and so on, yet the conditional ("if–then") structure is common to all inference rules, as is the relation between the difficulty of discerning or retrieving the rule (or task demandingness) and the role of individuals' cognitive and attentional resources in basing judgments on the information given. In other words, Principles 1 and 2 are assumed to apply across the multifarious content domains of judgment.
- *Principle 4*: *The rendition of all judgments is mediated by the same continuous parameters*, described earlier. Though the rendition of specific judgments may appear to differ

vastly from one instance of judgment to the next (some judgments may be rendered very fast, others rather slowly, some may be rendered spontaneously and/or unconsciously, others deliberately and in full awareness) the same general variables are involved in all instances of judgment formation. Thus, the speed of forming a judgment may depend on the degree to which the pertinent "if–then" rule has been routinized, In turn, the more routinized a rule is, the less conscious attention may be required for its application and as a consequence the less conscious an individual might be of its operation. From this perspective, judgmental speed and a lack of awareness do not necessarily indicate the operation of qualitatively different processes but may instead betoken routinization defining the level of task difficulty and the amount of resources necessary for appreciating the potential relevance of the information given to the requisite judgment.

NOTE

1. Indeed, Smith and DeCoster (2000) admonish Chaiken et al. (1989) for using the term "rules" in describing the heuristic processing system. According to their recommendation "if the representations used in heuristic processing were described as well learned associations rather than as rules, the distinction would be clearer" (p. 120).

Automatic Thought

SUSAN M. ANDERSEN
GORDON B. MOSKOWITZ
IRENE V. BLAIR
BRIAN A. NOSEK

Much of everyday life is guided by psychological processes that are unintended and unobservable. The nature of such processes has been the focus of experimental social psychology for well over two decades. Theories and methods capturing automatic aspects of human thought include those addressing trait concepts that guide person judgment and decisions, attitudes that guide evaluations, stereotypes and prejudice that guide intergroup interaction, significant others that guide interpersonal relations, and overall, motives and goal states that guide action. Controlled processes are now considered in terms of exactly how they direct, alter, bypass, or override automatic cognition. Indeed, controlled processes may become automatic with repetition. The curious interplay between automatic and controlled processes is thus one source of the widespread interest in automatic thought.

In this chapter, we consider what is known about automatic processes across differing research domains, and do so by focusing on each of four basic processes: the availability of social knowledge, the activation of this stored knowledge, its application to a new person or stimulus, and the question of whether and how it is self-regulated (Higgins, 1996a, 1996b). These processes involve varying degrees of automatic thought—collectively, they inform how social knowledge is used. The research domains through which we conceptualize the automaticity of each basic process cover much of social psychology. These include trait inferences, attitudes, stereotyping, significant personal relationships, and motives. Our goal in reviewing these research domains is to identify common themes and emergent trends that speak to these basic processes. We do not offer a comprehen-

sive review of each subfield but address pertinent work on which we may derive a metatheoretical characterization of automatic thought.

We begin with some brief definitions—the four components of automaticity, the four basic processes that comprise it, and the five research domains in which it is studied. We then present a characterization of five basic principles of automaticity that cut across these research domains and highlight questions and gaps in our knowledge that we have identified. These basic principles offer a framework for thinking about automatic thought and research that remains to be done. Following this presentation we briefly review the evidence across the four research domains to illustrate emergent themes by focusing on each process in turn (i.e., availability, activation, application, and regulation). Finally, we summarize with some concluding remarks.

DEFINITIONS

Automaticity: Four Components

Early conceptions of automaticity equated automatic processing with lack of conscious control (e.g., Hasher & Zacks, 1979; Hayes-Roth, 1977; Posner & Snyder, 1975; Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977). A process capable of running to completion without conscious monitoring was deemed automatic, even if initiated consciously. Given this definition, it is no surprise that automatic processes have often been equated with those that are *unconscious* and with methods that permit assessment of unconscious processing (e.g., subliminally

presented stimuli). If a person is unaware of a process, it occurred without conscious control. But automaticity can also be inferred when a process simply proceeds efficiently, or is involuntary, unstoppable, or unalterable even if conscious (Bargh, 1989, 1994). If initial stimuli are perceived consciously but a provoked process occurs outside awareness, or even despite attempts to prevent it, this is also automatic. Accordingly, automaticity is granted if the perceiver *lacks awareness* of the process, *does it with efficiency* (i.e., with minimal use of cognitive resources), has *no intention* to do it, or *cannot control* it. This approach frames automaticity as a continuous variable rather than as a discrete class of processes and as a matter of degree rather than kind. One or more aspects of automaticity may be in play in one circumstance but not in another, thus varying the form of automaticity (Bargh, 1994).

With the varieties of automaticity, interesting theoretical and social implications arise. Consider, for example, the implications of an attitude that influences judgment without one's awareness versus an attitude that has the same effect, *despite* one's awareness and attempts to avoid it. In practice, research tends not to delineate which type of automaticity is assumed or assessed, and few attempts are made to sort this out systematically. One consequence of this lack of specificity is the potential loss of information about how automatic processes operate in human judgment and behavior. Consistent with the literature, we nonetheless take an inclusive perspective on automaticity here, allowing that many procedures can be considered sufficient in demonstrating its presence. We hope that this inclusive approach will stimulate theoretical consideration of the nature of and variation in automaticity.

Four Basic Processes and How They Are Assessed

A useful and well-supported framework organizes psychologists' understanding of the automatic processes that guide the use of social knowledge (Higgins, 1996b; see also Higgins & King, 1981). First, social knowledge must be *available* in memory if it is to guide subsequent processing, and thus *availability* of social knowledge is a precursor to its use and understanding knowledge acquisition is thus relevant. Second, social knowledge must be accessible. *Accessibility* refers to a construct's readiness to be used, commonly defined as the degree to which it can be automatically *activated*. Third, accessible social knowledge may or may not be applied. *Applicability* refers to how well social knowledge matches attended-to features of a stimulus or situation. This match, or the usability of accessible social knowledge, determines in part whether or not the knowledge is applied. *Self-regulation* covers a heterogeneous set of processes that affect the accessibility and application of social knowledge such as inhibition, suppression, adjustment, or enhancement. Self-regulation can thus short-circuit activation at the outset, or redirect it once it has occurred, and can also prevent application or introduce a postapplication correction.

Given measurement challenges, there are often fuzzy boundaries between the processes of *accessibility* and *ap-*

plication. For example, a common method of assessing construct activation is one in which perceivers are exposed to a construct (e.g., hostile) as part of a perception task or comprehension task (as a prime), supposedly activating the construct. Activation is later assessed in a separate judgment task where impressions of a target are to be formed (e.g., hostile or not) based on a description of the target's (ambiguous) behavior (e.g., Srull & Wyer, 1979, 1980). In this method the automatic *application* of a construct is also serving as a proxy for automatic *activation* of the construct. The inference of automatic activation based on application is strengthened when it is clear that the individual is *unaware* of the activation and does not *intend* to apply such knowledge. For example, in Devine's (1989) classic study of automatic stereotypes, the activation of stereotypes was revealed through the judged aggressiveness of a target person following subliminal exposure to African American cues.

In distinguishing activation and application, the most direct measures of activation are those that are not necessarily "about" any particular target. Reaction time procedures, such as a lexical decision task, assess the comparative speed of judging whether or not a letter string is a word. When this judgment follows a prime in a priming task using a brief exposure of the prime stimulus, such as a Black or White face, the construct presented in the lexical decision task is primed/activated. Differential reaction times to different kinds of words, such as the word "good," as a function of the prime are thus taken as evidence of the automatic *activation* of evaluative knowledge in response to racial group members. These activation measures contrast with measures of application, which are quite directly "about" the stimulus cue (i.e., the person, group, concept, behavior in question), revealing the extent to which the social knowledge is (or is not) applied to the stimulus. This is termed "the aboutness principle" (Higgins, 1998) in which people seldom see an outcome or response as being "about" nothing (i.e., as "just occurring" at random). Increases in accessibility that are detected by the person (as a feeling of fluency) concern a particular concept and are seen as being "about" whatever target is salient in the context, and are thus applied to that target.

Beyond the conceptual relevance of these methods to the activation–application distinction, there is methodological promise in the realm of functional magnetic resonance imaging (fMRI) and event-related potentials (ERPs) for illuminating automatic processes through the linkage to related brain structures and to physiological responses. These methods offer the potential to observe brain activation prior to or in conjunction with these measures of mental processes that assess behavioral responses.

Differing Knowledge Representations across Five Research Domains

Bruner (1957) argued that categorization serves the function of prediction. Knowledge that an object is a diamond informs us that it will be shiny and hard. The mere presence of cues linked to a category facilitates the trig-

gering of that category, while the activation of the category heightens perception of category-relevant information (and even broadens the scope of what is seen as category relevant). This pragmatism/functionalism was embraced by social psychologists at the dawn of the cognitive revolution in the field (e.g., Higgins, Rholes, & Jones, 1977; Srull & Wyer, 1979), and it remains central to research on social cognition and automatic processing. Indeed, to study how a person will behave, think, and feel in the context of social forces requires the assumption that the person will categorize for the purpose of prediction. Is this new person a threat? Is the person friendly and likely to behave as such?

Consideration of linguistic noun and adjective categories clarifies Bruner's fundamental insight into the relationship between categorization and prediction. Noun categories label the person or category (jock, politician, professor, Hispanics), while adjective features are featural descriptions of the person (tall, old, brown haired, athletic, educated, aggressive, kind, adventurous). Social psychologists study noun categories to identify the adjective concepts linked to them and to predict when such adjectives will be automatically activated and applied to make behavioral predictions about category members (Wyer & Srull, 1986). "Proper noun" categories, such as one designated by a significant other's name, are also of interest for their relevance to understanding automaticity in the self and in significant relationships (e.g., Higgins & King, 1981).

This noun–adjective distinction is of some interest because it helps in conceptualizing the distinction between the study of stereotypes (typically labeled by nouns) and the study of trait-labeled categories in simple linguistic terms. Nouns are used to tell us what an object is as a whole, and who a person is as a whole, while adjectives are used to identify features (i.e., parts), for example, of a person presumed. And this is presumed by laypersons to be pertinent to predicting what a relevant person will do. The meaning of a trait adjective can also be modified quite automatically by an activated category (e.g., a stereotype), and a trait can also modify the meaning of a category because of relevant linkages in memory that become differentially activated (Kunda, Sinclair, & Griffin, 1997). The boundaries and mutual influence between the two linguistic categories highlights the dynamism of social information processing (Blair, 2002).[1]

The social psychology of automaticity exists in multiple literatures, herein considered as five central research domains, each concerned with a specific form of knowledge representation and how it is used in inference and prediction. We define each research domain below. Afterward, we present our understanding of the basic principles of automaticity and follow with an integrative review of the evidence in each domain that speaks to these basic principles and processes of automatic thought as we conceive them.

TRAIT CONCEPTS AND TRAIT INFERENCES

People are not merely interested in *who* a person is (noun categories) but also in *what* qualities the person possesses (adjective categories) that guide what he or she will do. Thus, with automatic categorization follows automatic inference. Predictions about others are based, in part, on inferences about their underlying dispositions—personality traits imputed to the person—which are assumed to influence actions (e.g., Gilbert, 1989; Jones, 1979; Ross, 1977; Uleman, Newman, & Moskowitz, 1996; see Heider, 1944).

At its inception, social cognition was strongly identified with research on the adjective constructs used in perceiving others (Higgins & King, 1981). This research was typically pursued using priming paradigms in which incidental exposure to cues signifying a particular trait were shown to influence later social judgments (e.g., Higgins et al., 1977). Investigations of spontaneous trait inferences have also assessed how behavior is classified spontaneously using trait language—with little conscious awareness or intent (Winter & Uleman, 1984; Uleman, Newman, & Moskowitz, 1996). This research is typically pursued using memory paradigms in which incidental recall for behavioral information is assessed as aided by supposedly inferred adjectives as memory cues. Such inferences presumably explain "why" the individual did the behavior, reflecting what is known as the fundamental attribution error (Ross, 1977).

This literature forms one of the oldest bases of research on the role of automatic processes in social information processing. To varying degrees, the other four research domains owe a debt to this work.

ATTITUDES AND EVALUATION

Research on automatic evaluation has been situated in the domain of attitudes and has offered powerful evidence for its pervasiveness in social perception. An attitude is defined most simply as the association between an object and an evaluation (Fazio, 1986). Applied to a person or group, an evaluation, such as the word "good" (or "bad") is an adjective. When an attitude object (or its symbolic equivalent) is perceived, the object–evaluation association arises easily, unintentionally, and even outside awareness. For example, in a priming paradigm, words designating attitude objects are presented just prior to target words that match the evaluation of the word (or not). With few exceptions, people are faster at judging the target words when they are congruent in evaluative tone with the prime words, implying that the evaluation associated with the primed word was automatically activated and facilitated processing of the subsequent word. More broadly, the automatic evaluation effect has been shown to occur regardless of whether or not the attitude is strong—as it occurs even for weak attitudes (Bargh, Chaiken, Govendor, & Pratto, 1992), as well as for novel objects (Duckworth, Bargh, Garcia, & Chaiken, 2002).

STEREOTYPES

Given that social cognition as a field began with work on adjective or trait concepts, it is noteworthy that there has also been a focal interest in noun-labeled categories that

classify types of persons (Wyer & Srull, 1986). Stereotyping can involve a whole range of noun-labeled categories ("geek," "goth," "rapper," "politician," "professor," "male"), nominalized adjectives ("Black," "elderly") or noun phrases (e.g., "fundamentalist Christian," "liberal elitist," "corporate mogul," and "kid from the projects") (Andersen, Klatzky, & Murray, 1990; see also Andersen & Klatzky, 1987).

A stereotype is defined in terms of the attributes associated with a social category (and such a category may be dissociable from its evaluation; Amodio & Devine, 2006). Research in this domain typically exposes participants to a social category cue and examines whether subsequent judgments are influenced by attributes associated with that category. Perceivers are typically not aware that the cue is affecting their responses, suggesting the automatic activation and application of the stereotype. In a paradigmatic study on automatic stereotyping, participants were subliminally exposed to words associated with African Americans (Devine, 1989), and they subsequently came to judge another person as more hostile (compared to participants in a control condition). If a stereotype is available in memory, relevant cues can activate it without need of awareness, intention, effort, or control.

SIGNIFICANT-OTHER AND RELATIONAL REPRESENTATIONS

One-of-a-kind representations of persons that are noun labeled are denoted by a name and thus "proper" nouns (Higgins & King, 1981). Exemplars designating a specific person (Smith & Zarate, 1992) are *N*-of-one representations, and have been shown to function much like other social knowledge in activation and use. Research involving such highly familiar and significant mental representations in the life of the perceiver has shown that they can act as a lens through which new others are perceived (e.g., Andersen & Cole, 1990; Andersen, Glassman, Chen, & Cole, 1995).

In this work, the degree of match between cues encountered about a new person and a significant-other representation activates the latter, which is then used to make sense of the new person (Chen, Andersen, & Hinkley, 1999). Of primary interest is the fact that people appear to be unaware of doing this (e.g., Andersen & Glassman, 1996). In addition, significant-other representations do not stand alone in memory as they are linked with the self and, once triggered, alter the self and self-regulation (Baldwin, 1992; Baldwin, Carrell, & Lopez, 1990; Chen, Fitzsimons, & Andersen, in press). Contextual variability is thus central to what is known about these representations and the relational self (Andersen & Chen, 2002), in parallel with other social-cognitive work on the self (Mischel & Shoda, 1995).

MOTIVES AND GOAL STATES

Motives and goal states involve ends to be attained and behaviors that can achieve these ends. Goals studied by social psychologists are often interpersonal and involve states that a person seeks to achieve, or in fact "features" the person hopes to attain, and are thus examined in

terms of adjectives. Adjectives such as *free*, *thin*, *smart*, *cool*, *great*, or *egalitarian* can reflect the goals one has. Goals need not be adjective categories, however, as the goal of writing five pages a day is not an adjective. Goals can be defined by the actions that achieve them, suggesting that they can be conceived as verbs too. They are thought to differ from other representations in how much they energize behavior (Aarts et al., 2005; Bargh, 1990; Carver & Scheier, 1981; Gollwitzer & Moskowitz, 1996; Kruglanski, 1996). Goal states can be conceived as mental representations in memory (Bargh, 1990), and typically research on this conception incidentally exposes participants to situational cues associated with goals and assessing relevant behavior (Bargh & Barndollar, 1996; Bargh & Chartrand, 1999; Bargh, Gollwitzer, Lee-Chai, Barndollar, & Trötschel, 2001; see also Aarts & Dijksterhuis, 2000). Planning in advance can also set the stage for automatic goal pursuit through implementation intentions (Gollwitzer, 1993, 1999), that is, by means of conscious commitment to a goal and the specification of *when*, *where*, and *how* one will respond to relevant situational cues. Implementation intentions promote goal attainment by removing the need for conscious reflection or thought of any kind at the moment of encountering the cues and initiating the action (e.g., Bayer, Moskowitz, & Gollwitzer, 2004 [as cited in Moskowitz, Li, & Kirk, 2004]; Brandstätter, Lengfelder, & Gollwitzer, 2001). In these ways, people regulate their behavior automatically to fulfill accessible goals (e.g., Bargh, 1990; Bargh et al., 2001).

WHAT WE KNOW AND WHAT WE DON'T KNOW: FIVE BASIC PRINCIPLES OF AUTOMATICITY

Automatic thought is best understood in terms of cognitive processes that transpire without effort, control, awareness, or intention (Bargh, 1989). The precise manifestations of these elements of automatic thought will depend in part on the social knowledge being used—and the research domains examined. Embracing the variability across these domains, however, enables consideration of emergent themes that span literatures and further illuminates a common core of the five basic principles of automatic processing.[2]

Automatic and Controlled Processes Are Not Discrete Opposites: Whither the Duel in Dual-Process Models?

In classic dual-process models of social cognition, automatic processes are assumed to occur first in the stream of information processing, and any altering of these processes to occur afterward, by overriding or correcting for the automatic process through a more controlled response (Chaiken & Trope, 1999). In automatic trait inference, an inference can be followed by correction, and if it is not, then correspondence bias (Gilbert, 1989) or priming effects (Thompson, Roman, Moskowitz, Chaiken, & Bargh, 1994) may emerge. When correction occurs, it is

often done inexactly, leading to contrast effects (Martin, Seta, & Crelia, 1990; Moskowitz & Skurnik, 1999; Strack & Hannover, 1996). In automatic stereotype activation too, relevant inferences can be followed by correction, and if not, stereotyping emerges (Devine, 1989). When correction occurs, stereotype control may emerge, but even this in itself can lead to stereotyping in rebound effects (Macrae, Bodenhausen, Milne, & Jetten, 1994; Monteith & Voils, 1998). In the attitude domain, correction can follow automatic belief in an assertion, and if it does not, an illusion of truth may emerge in which blatantly false information is believed to be true (Gilbert, Tafarodi, & Malone, 1993). Based on correction, information may correctly be identified as false. One may still be inaccurate by overcorrecting for this. Although there is no work we know of directly addressing correction or contrast effects in the study of significant-other representations, the consistency across other domains suggests that such effects would occur under the right conditions.

Dual-process models thus continue to capture a fundamental distinction in social cognition, but while they were once the reigning approach to studying automatic knowledge activation and use, they are now considered to be just one way that cognition is regulated. The simple temporal progression from automatic to controlled does not capture all that occurs. Contrast effects are often interpreted as deliberate attempts to correct for automatically activated constructs that are deemed to be biased. However, contrast can also occur automatically via simpler inhibitory and comparison processes, and some researchers have argued that they may occur exclusively automatically (Moskowitz & Skurnik, 1999; Stapel & Koomen, 2001b; Stapel, Koomen, & van der Pligt, 1997). Thus, evidence interpreted in terms of dual processing can at times be explained in simpler ways by considering the differing stimulus properties across the conditions of a study. One condition may simply activate different representations than another. Thus, differences across conditions might well be attributable to a change in the specific pattern of cues presented (an intricacy and multiplicity in cues that varies across the conditions). This suggests that different contexts may activate a different constellation of social knowledge and may do so automatically without dual processes.

Automatic Thought Is Context Dependent and Situation Specific: "It's the Context, Stupid"

That automatic thought is context dependent is better known than understood. A large body of work shows that subtle shifts in cues can substantially alter the automatic activation of social knowledge. If the situational specificity of thought is ignored, this central insight of social cognition is lost.

This is not to imply, of course, that baseline differences between people or between chronic tendencies to experience some social knowledge as more accessible than others, or particular self-regulatory patterns as more accessible, are unimportant. But even study of chronic differences in automatic processes between people requires examining variation in people's responses across different stimulus cues. Evidence shows that the if–then relation between individual and context is fundamental to automaticity, which has an intriguing parallel in social cognitive approaches to self and personality as well (Mischel & Shoda, 1995), suggesting that basic mechanisms of automatic thought are broadly relevant to understanding the person.

In short, the accessibility of available knowledge varies across contexts. Both chronic and transient sources of accessibility exist and play a role in increasing the relative accessibility of social knowledge with chronicity deriving from frequency of activation and transient accessibility deriving from recency (Higgins, 1996c). Knowledge that has been used frequently has a chronic readiness to be used (Bargh, 1999; Bargh & Thein, 1985; Higgins & King, 1981; Higgins, King, & Mavin, 1982), while transient accessibility arises based on triggering cues in the environment that temporarily increase social knowledge accessibility (Higgins et al., 1977; Srull & Wyer, 1979). Transient accessibility arises from a match between a cue to which one is exposed and an available representation when that cue is seen *before* a stimulus person is perceived (Higgins, 1989) or *while* the stimulus is perceived (Andersen et al., 1995). Context pulls from memory a representation and associated constructs, thus making the basic process of activation a shared venture between the representational system of the individual and the contextual cues that shape accessibility and retrieval. How this occurs remains under investigation.

Spreading activation models assume that knowledge is organized in memory through links or connections between isolated bits of information, or "nodes," in a network with the linkages reflecting the memory. When contextual cues trigger a memory, one or more nodes in the network are activated, and because these are linked through associations, spreading activation proceeds rapidly from one node to another as a function of the strength of association between the nodes. An act of kindness should thus facilitate the processing of associated concepts, with activation starting at the node directly triggered and traveling along whatever paths are present, flowing most easily and quickly along the paths that represent stronger associations. If the momentary accessibility of an available construct rises above threshold in any instance, the associated construct(s) will also be activated. This should occur automatically and thus quickly, "within 200 or 300 milliseconds [as] . . . [c]onscious processes take longer to develop—at least 500 or 600 milliseconds—and require considerable attentional resources" (Wegner & Bargh, 1998, p. 462).

Connectionist models, by contrast, tend to assume parallel distributed processing rather than activation that spreads serially across adjacent nodes (Rumelhart & McClelland, 1986). For example, Anderson's "ACT-R" model (Anderson, 1993) describes a systemwide set of associations that does not primarily emphasize nodes in a network organized as features and categories. Rather, it focuses on distributed activation that largely occurs all at once in parallel throughout the memory system (Kunda & Thagard, 1996; Smith, 1996), although concepts are still learned. To the degree that simultaneous activation

occurs, the dual-process models that dominated the 1980s and 1990s thus capture social cognition less well than competing models, about which we say more later.[3] For ease of discussion, we speak of categories and mental representations in this chapter, but we acknowledge that there is persistent debate about whether or not "representations" are in fact (entity-like) "things" in memory.

Indeed, regardless of the underlying structure and operation of the representational system, two basic principles emerge from this discussion. First, context provides a starting point for the rumblings of the representational system, determining the departure point from which some subset of available knowledge will be made relatively accessible. Second, because of the malleability of the process, the triggering and use of a concept alters the memory structure in a way consistent with the situational specificity. Thus, the construct triggered by and used in a specific context is altered accordingly in the process, such that whatever is stored is stored in modified form (see also Ross, 1989).

Intricacy in the Surround: Multiple Cues, Variable Representations

Cues are embedded in complex social contexts, which means there is rarely just one simple set of triggering cues that activate a representation without competition from others (Logan, 1989). Multiple knowledge categories often fit a given stimulus and context, and the final categorization may thus involve the concept that is retrieved most quickly (cf. Kunda & Thagard, 1996). This is why the strength of association between the stimulus and the relevant social knowledge, and also the relation between the stimulus and the social context, are so important. An Asian woman holding a pair of chopsticks elicits different associations than the same woman holding a makeup brush (Macrae, Bodenhausen, & Milne, 1995). The trait "aggressive" connotes one thing for an attorney in a courtroom, while this same trait connotes different associations for a "thug" in a back alley (Kunda et al., 1997). Numerous cues in the social context are processed simultaneously, thus constraining or enabling particular interpretations by inhibiting or facilitating concept activation.

Contexts Also Provoke Application Directly

Application occurs when knowledge is used to act on a goal or to draw inferences (Bruner, 1957; Higgins, 1989, 1996b; Higgins & King, 1981; Kunda & Sinclair, 1999; Kunda & Spencer, 2003). Although accessibility of social knowledge is a necessary condition for knowledge application, it is not sufficient. Delineating the conditions that lead to application has been a central concern to the field.

To a large degree, *applicability* of activated knowledge depends on social context. Knowledge that has been activated is more likely to be applied if it is *relevant*. When "aggression" is accessible, but seen as irrelevant to "Jane" due to gender stereotypes, it is not used in judgments of Jane (Banaji, Hardin, & Rothman, 1993). Similarly, when

people are able to identify why accessible information happens to be accessible, and it is also inapplicable, they may not use the accessible knowledge. This was demonstrated in a classic study showing that people offer more positive evaluations of their lives on sunny than on rainy days, but not when asked about the weather before making the global rating (see Schwarz & Clore, 1988).

Application also depends on the response. Activated racial bias may not be applied in explicit judgments of a group member but may alternatively be applied if assessed in nonverbal behavior (Amodio & Devine, 2006; Dovidio, Kawakami, & Gaertner, 2002; McConnell & Leibold, 2001). Activation of the elderly stereotype may speed the processing of stereotype-consistent versus stereotype-inconsistent information but simultaneously have a slowing effect on the respondent's behavior (Kawakami, Young, & Dovidio, 2002). The significance or "selection" of each response likely depends on the immediate context.

Another form of application that may be constrained by context is the misattribution people make about ease of processing, using it as information in their subsequent inferences. The ease with which information comes to mind influences various judgments (Schwarz et al., 1991; Schwarz & Clore, 1988) and inferences (Higgins & King, 1981; Tversky & Kahneman, 1973). People unconsciously misattribute perceptual fluency (induced by prior exposure) to how "famous" they think a stimulus person is (Jacoby, Kelley, Brown, & Jasechko, 1989) or to the confidence they have in their own beliefs, imputing more truth value to their own beliefs (Kelley & Lindsay, 1993; Skurnik, Moskowitz, & Johnson, 2006). Confidence in one's own thoughts increases with practice (Tormala, Petty, & Briñol, 2002), as does certainty in attitudes (Haddock, Rothman, Reber, & Schwarz, 1999) and even in negative expectancies about the future (Miranda & Andersen, 2005).

The relevance of contextual cues to stored social knowledge is likely to be calculated based on some kind of similarity metric (e.g., Tversky, 1977), reflecting how well the knowledge maps onto the stimulus (see Medin, Goldstone, & Gentner, 1993). This general principle may apply both to whether or not activation occurs and to whether or not such activated knowledge is applied.

Intentionality and Automaticity Are Not Opponent Processes: Don't Think, Regulate

People like to think of themselves as in control of their everyday actions. As such, the most intriguing questions about automaticity are those that concern the interaction of automaticity with intentional, controlled, effortful, and aware processing. What impact do the conscious processes that we treasure as essential to human nature actually have on thought and action? The accumulated evidence suggests a complicated interplay between automatic and controlled processes. As an example, while reading is automatic for literate adults, mundane behaviors such as picking up a book (or putting it down) are commonly subjected to intentional control. Likewise, even the dynamic process of physical balance or the

behavior of walking or of playing basketball reflect an interaction between automatic processes and volitional planning and execution. It is a dynamic interplay and is complex.

An especially complex issue is thus whether automatic thought can at times be considered intentional (Bargh & Gollwitzer, 1994). Automaticity is a heterogeneous construct that is inclusive of events with one or more of the four components of automaticity we have described—unintentionality, lack of awareness, uncontrollability, and efficiency in processing (Bargh, 1994). Because only one feature is necessary to assume automaticity, there is ample room for a wide variety of actions to be labeled "automatic" but to simultaneously possess one or more features of automaticity. Persons with obsessive–compulsive disorder may, for example, be perfectly aware of the thoughts relating to their obsessions or compulsions and yet still pursue them automatically because the operation of these acts is unintended and uncontrollable. Similarly, the notion of "intentional automaticity" occurs following practice and routinization of goals in recurring contexts. And, intended automaticity can occur when people establish an intention to pursue a goal when a particular situation occurs at a future time. The goal-relevant behavior can then be initiated automatically when relevant situational cues are encountered (Gollwitzer, 1999).

The interactive quality of automatic and controlled processes has shifted the understanding of self-regulation in social psychology. The answer to the question of whether or not self-regulation is conscious appears to be that "the field has evolved from a tentative answer of 'yes' to a firmer 'no' " (Vohs & Baumeister, 2004, p. 2). While dual-process models remain relevant to understanding the interplay between automatic activation and conscious intention to control the effects of that activation, it is clear that regulation also has automatic components. For example, self-regulation of stereotyping can involve deliberate corrective processes that overturn activated stereotypes (Fiske & Neuberg, 1990), or automatic processes that prevent the activation of stereotypes to begin with (for reviews, see Blair, 2001; Moskowitz, Li, & Kirk, 2004). Furthermore, there may be little use in discussing self-regulation as either automatic or controlled, because regulatory processes themselves may emerge from automatic processes (Dijksterhuis, 2005; Wegner, 2002).

Control in Self-Regulation

The preceding discussion does not dismiss the fact that intentions are of relevance for effective functioning and psychological health. What is it that predicts whether a person will formulate a behavioral intention that would be of value for him or her? How do automatic processes feed conscious intention? Evidence suggests that deliberating on and setting a goal is more effortful than implementing it once the goal has been set (Gollwitzer, 1999). People who have a goal that they want to accomplish over a period of time can automate that goal pursuit. For example, people who wish to avoid being prejudiced can develop a strategy that will automate nonprejudiced processes (Kawakami, Dovidio, Moll, Hermsen, & Russin, 2000). Those motivated to be egalitarian also appear to be sensitive to progress in reaching this goal, even experiencing guilt when faced with shortcomings in their own responses (Monteith, Ashburn-Nardo, Voils, & Czopp, 2002; Plant & Devine, 1998). And, when they are made aware of their shortcomings, they compensate for them automatically (Moskowitz et al., 2004). A possible explanation is that a feedback loop exists that sends implicit signals provoking the person to try to change course (see Carver & Scheier, 1981). However, if people are too conflicted to formulate an intention to do something (e.g., quit smoking), it will prevent establishing such a link between the goal and the relevant situations—accordingly, this intention will not be pursued in automatic behavior. Thus, when behavior change would be adaptive for a person, the question of how people formulate new, more adaptive goals that oppose habitual ones becomes important, as does the question of how the individual can become less conflicted enough to hold the new goals as focal, and this warrants further research attention.

This is still more complicated because conscious and effortful suppression quite often does not work, and instead backfires, as the classic studies asking individuals not to think of a white bear show in revealing rebound effects (Wegner, 1994). In these studies, people think more of a white bear than they otherwise would (for a different example, see Macrae, Bodenhausen, et al., 1994). Suppression of emotional expression also leads to more (not fewer) problematic consequences in physiological reactivity, again suggesting conscious efforts to regulate may not work. At this point, the evidence in social cognition greatly emphasizes the effectiveness of automatic self-regulation to the exclusion of effective conscious and effortful forms. Although the complex interplay between automatic and nonautomatic processes can introduce the homunculus problem of who is the controller and who the controlled (Ansfield & Wegner, 1996; Bargh, 1990; Wegner & Bargh, 1998), it remains important to better understand how and when mindfulness can be effective in self-regulation, a matter that is not yet well understood.

Automaticity at the Various Stages of Self-Regulation

Self-regulation is a process that guides both the activation and application of social knowledge. A formal analysis of regulation typically begins "by distinguishing two features of control—a *control action* (the influence) and a *control criterion* (the direction). Control involves acting upon something until a certain criterion is reached" (Wegner & Bargh, 1998, p. 450). The process involves (1) activation of relevant end states; (2) activation of beliefs about appropriate opportunities and means to successfully pursue these end states; (3) actions taken to remove whatever (negative) discrepancy exists between one's current standing and the desired state; and (4) monitoring of how close one is to attaining the end state (Carver & Scheier, 1999). Control theories in general can apply

to inanimate mechanisms such as thermometers, as well as to nonconscious biological homeostatic processes. Thus, these processes need not be accompanied by consciousness, nor do they need even to be specific to human thought.

The first steps of regulation are the activation and inhibition of goals, and these can both occur implicitly. Conceivably, other stages can as well. For example, monitoring processes that keep unwanted thoughts out of consciousness (Förster & Higgins, 2005; Wegner, 1994) and provide emotional feedback about goal pursuit or failure (Strauman & Higgins, 1987) can occur implicitly. Selective attention to goal-relevant stimuli and means (Moskowitz, 2002; Shah & Kruglanski, 2002), and then compensatory processes intended to bring one closer to desired end states (Moskowitz, 2001) are also implicit. Indeed, neural processes associated with such compensatory control are engaged within milliseconds of the activation of bias, well before conscious awareness that this might be needed is possible (Amodio et al., 2004). Such compensatory processes include inhibition of newly activated goals that are incompatible with a current goal that is already active (Fishbach, Friedman, & Kruglanski, 2003). Thus, the goal can be inhibited or its effects redirected so that the activated knowledge is not used (Kruglanski et al., 2002). Regulation is thus both "lateral"—with several competing constructs activated and "racing" to the top to influence perception (see Bodenhausen & Macrae, 1998; Kunda & Thagaard, 1996)—and "vertical" in that activation of an abstract goal may inhibit the activation of an incompatible, specific goal.

Changes in Knowledge Representation Based on Disuse

What happens to knowledge representations that were at one time habitual or automatic once they become regularly suppressed, replaced, or overridden by other responses? Do these knowledge representations decay with disuse, or do they simply become less accessible? While answers to such questions are far from clear in the literature, research on attitudes suggests that prior knowledge may well be retained when competing knowledge is formed. Some theories suggest that automatic evaluations are products of prior knowledge that are overridden by newer representations when self-regulation is successful (Wilson, Lindsay, & Schooler, 2000). Connectionist and learning theories do not conceive of new representations as replacing old ones that are then eliminated but, rather, see experience as continuously shaping the distributed representation system, allowing the possibility that "old" representations may be recovered quickly with reexposure because the neural network reflects the evolving course of the organism's entire learning history (McClelland & Rumelhart, 1985; Rescorla & Wagner, 1972). The social psychological understanding of the evolution of use and disuse of social knowledge may thus profit from insights stemming from classic and modern learning theories, and continuing research on such matters is of importance.

Automaticity Is Influenced by Practice and by What Social Knowledge Forms in Development

Although acquisition of automaticity is less commonly the focus of social psychological research, there is little doubt of its importance. We thus highlight this neglected aspect of automaticity as a needed area of research focus. This area of research may illuminate the processes underlying social concept formation and how the use of such concepts may become routinized.

Any representation that is available in memory can, in principle, be activated and used automatically. However, the existing literature suggests that the likelihood of such automization is moderated by multiple factors, most notably practice and repetition. Early work on automaticity drew from research on skill acquisition and equated automaticity with mental habits (Wegner & Bargh, 1998). From this perspective, mental tasks once performed with conscious direction can become habitual and autonomous with practice (Jastrow, 1906; Logan, 1988; Smith & DeCoster, 1999). Mental operations that once consumed attentional resources and were processed serially come to be processed efficiently in parallel (Shiffrin & Schneider, 1977). Rehearsal increases the efficiency of the mental operation, reflecting an elaboration of the related mental representation that can increasingly proceed efficiently and effortlessly (Logan, 1988). In other words, rehearsal is a mechanism for acquiring automaticity.

Automatic processing may also develop more indirectly by means of frequent and consistent environmental exposure to particular stimuli. Through this alternate route, people observe and store covariation information in their environment, and this process can be unintentional, effortless, unconscious, or uncontrollable (Devine, 1989; Smith & Decoster, 1999). In short, knowledge need not be consciously or effortfully learned and then routinized to be available for subsequent processing.

Practice and repetition concern the "quality" of the representation. Another factor for acquisition of automaticity is understanding the relevance of the social context. For example, the synapse model (Higgins & King, 1981) proposes that available knowledge will accumulate "charge" that rises above a variable threshold on the basis of contextual cues. Even so, there exists little research on this proposed process and on whether it is contextually cued or cued by internally generated thought, or both. In sum, this is a frontier for automaticity research that remains to be explored. How do cues to a construct actually trigger the construct in memory and raise its activation level? Does a basic process mediate between availability and activation?

More broadly, the availability of social knowledge is tied to socialization and development as they influence concept acquisition. Again, although the links between the automaticity literature and the developmental literature on concept acquisition are not often drawn and not well understood, their examination is likely to be important for a full understanding of automatic thought.

Automaticity on the Brain:
Process Meets Structure in Social Neuroscience

The rapid maturation of social neuroscience has benefited research on the automatic activation and use of social knowledge. For one, it provides converging evidence for fundamental findings from behavioral data, linking automatic processes to brain structures whose functions have been identified separately from years of neuroscience research. This contribution is not to be underestimated—as the successful convergence of disparate literatures provides mutual validation of constructs and principles derived from each. Identifying inconsistencies between literatures provides fertile ground for theoretical and methodological innovation.

Although some theorists suggest that this growing literature has yet to yield new principles of automaticity, it nonetheless holds promise for doing so, in the continuing challenge of bridging the gap between behavioral and neuroscience research on automatic thought. One of the best elaborated links between neuroscience and automaticity research is suggested by evidence that the amygdala, an area linked with emotional processing, is involved in automatic evaluation of social objects such as racial groups (Cunningham, Johnson, Gatenby, Gore, & Banaji, 2003; Cunningham, Nezlek, & Banaji, 2004; Phelps et al., 2000; see also Amodio, Harmon-Jones, & Devine, 2003). Indeed, evidence shows that the difference in amygdala activity in response to Black and White faces is correlated with behavioral indicators of automatic evaluation such as the Implicit Association Test and startle eye-blink (Phelps et al., 2000). Moreover, the dynamic interplay between automatic evaluation (e.g., via the amygdala) and self-regulatory processes via the prefrontal cortex (that modulates automatic responses) has also been shown (Amodio et al., 2004; Amodio, Kubota, Harmon-Jones, & Devine, in press; Cunningham et al., 2004; Lieberman, Hariri, Jarcho, Eisenberger, & Bookheimer, 2005). Demonstrating the societal relevance of this kind of research, arousal responses assessed by skin conductance based on fear conditioning to opposite-race (vs. same-race) faces, have recently been shown to extinguish significantly more slowly—among both African American and Caucasian participants, although the effect is moderated by whether or not one has had a cross-race dating relationship (Olsson, Ebert, Banaji, & Phelps, 2005). Taken together, these investigations show convergence across research domains examining automaticity and should thus spark further theoretical and empirical development.

Overall, converging evidence offers support for the five basic principles we have outlined here, that is, evidence that (1) automaticity and control are not discrete and opposing classes of processes; (2) contexts and situations are central to what mental representations are activated, applied, and how regulation is carried out; (3) regulation does not require the conscious will; (4) practice and repetition, habit formation, and developmental processes are central to the acquisition of concepts (to the availability and varying accessibility of social knowledge), and thus to the transition from conscious to automatic processing; and (5) automatic processes are reflected in recruitment of specific brain regions and functions. This evidence stems from a variety of research domains in social psychology, and we now turn to the evidence for these claims.

BASIC PROCESSES IN DETAIL: WHAT FIVE RESEARCH DOMAINS REVEAL ABOUT AUTOMATICITY

We organize our review the evidence for these basic principles of automaticity in terms of four basic processes—availability, accessibility, application, and self-regulation—and in turn address each process in terms of five different research domains in social psychology—that is, trait inferences, attitudes, stereotypes, goals, and relationships—by giving the most illustrative examples of the evidence.

Accessibility

Construct Accessibility Is Context Dependent: Contexts and Situations Shape Automatic Activation

SOCIAL CONSTRUCTS

Automatic accessibility accumulates and fades like a charge in an energy cell (Higgins, Bargh, & Lombardi, 1985; Higgins & King, 1981), and does so based on the concept's recency and frequency of use (Higgins et al., 1985; for reviews, see Bargh, 1996; Higgins, 1996b). Situational exposure to relevant cues influences recent and frequent concept use. Recent exposures temporarily increase activation potential. Frequent exposures influence the concept's chronic activation readiness (e.g., Bargh, Bond, Lombardi, & Tota, 1986; Bargh, Lombardi, & Higgins, 1988; Bargh & Pratto, 1986; Bargh & Thein, 1985; Higgins, King, & Mavin, 1982). Chronically accessible concepts have less impact on judgments initially compared with temporarily accessible concepts but more impact as time elapses (Higgins, et al., 1985). In particular, when the delay is brief (15 seconds), *recently* primed concepts guide judgments, but when the delay is extended (2 minutes), *frequently* primed concepts guide judgments. In short, the *decay function is not uniform* and is tied to how often a prime was seen and to how much time transpired since (Bargh et al., 1988). Chronicity and transient cuing appear to have an additive impact such that recent priming of a chronically accessible concept will result in high accessibility reflecting both its recency and its chronicity (Bargh et al., 1986).

The effects of recency and frequency on accessibility are not dependent on awareness of the exposures or knowledge of the relations between exposures and subsequent judgments. For example, subliminal exposure to cues increases their accessibility (Bargh & Pietromonaco, 1982). Individuals will apply such recently activated cues that were made accessible in one situation to another situation, without recognition that the prior exposure in-

fluenced subsequent judgments (indeed, without recognizing that the prior exposure occurred). Participants subliminally exposed to a list of words (one at a time) in which 80% reflected the trait "hostile" later judged a target person to be more hostile than controls (exposed to 20% or 0% hostility-relevant traits) (Bargh & Pietromonaco, 1982). Similar effects are observed among people known to have chronic levels of accessibility who judge a person (vis-à-vis the accessible dimension) in a way that assimilates the person to the accessible trait despite the perceiver lacking awareness that the trait is accessible or that the behavior judged is relevant to their chronic states (Higgins et al., 1985). In brief, both recent and frequent activation contribute to automaticity, when the construct is also relevant or applicable.

SPONTANEOUS TRAIT INFERENCES

People infer traits from behavior, even without realizing it (Moskowitz & Roman, 1992; Trope & Alfieri, 1997; Trope & Liberman, 1993; Winter & Uleman, 1984). This insight contradicts the initial assumption in social cognition that an explicit goal is needed to form an impression (Srull & Wyer, 1989). It also suggests a role for automaticity in the classic literature on correspondent inference (Jones & Davis, 1965; Ross, 1977).

Participants exposed to sentences describing behaviors that imply traits (e.g., "the librarian carries the old woman's groceries across the street") implicitly form trait inferences (e.g., "helpful"), as indicated in subsequent recall of the sentence when cued with the implied trait (Winter & Uleman, 1984). Activation of a trait category triggered by a behavior leads the trait to become associated with the behavior, facilitating joint retrieval in cued recall even though people are unaware of having made a trait inference. Implicit memory also arises in greater ease in learning lists of words including earlier inferred traits (Carlston & Skowronski, 1994). People also automatically attribute behavior to causes, whether physical events or previous behaviors (Hassin, Bargh, & Uleman, 2002). Automaticity in trait inference is revealed in reaction time paradigms where participants read a sentence and immediately after judge whether a word was present in the sentence. When the word was a trait implied in the sentence (vs. not implied) reaction times slowed and error rates were heightened, suggesting that the trait was spontaneously inferred during sentence comprehension thus leading to confusion regarding whether it was actually present (Uleman, Hon, Roman, & Moskowitz, 1996).

Implicit inferences enable rapid interpretation that probably sustains beliefs that the world is understandable and predictable (Anderson & Deuser, 1993; Bruner, 1957; Heider, 1958; Jones, 1979; Pittman & Heller, 1987). The automaticity of trait inference thus has functional value by making predictions of social behavior, something that the mind does effortlessly. If this were not an automatic process, then much of humans' deliberative resources would be spent categorizing, generalizing, and generating predictions about future social behavior, or else the social world would be continuously surprising and unpredictable.

AUTOMATIC EVALUATION

Object-evaluation associations, or attitudes, are readily activated automatically from memory (Fazio, Sanbonmatsu, Powell, & Kardes, 1986). Early work demonstrated that the brief presentation of a prime word (e.g., doctor) could facilitate (speed up) responses to a semantically related target word presented in sequence (e.g., nurse; Neely, 1977; Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977). Automatic evaluation effects are measured using a similar procedure in which an image or word denoting an attitude object is presented immediately prior to the presentation of a target adjective that must be judged as *good* or *bad*. When the time interval between the prime and target is relatively brief (e.g., 300 msec), evaluative judgments to the target word are faster to evaluatively congruent (vs. incongruent) target words. This effect illustrates the unintentional and uncontrollable aspects of automaticity. Because of the very short time between presentation of the prime and target, respondents have no opportunity to prevent evaluative activation of the prime or its influence on judgment of the target stimulus.

Automatic evaluation effects are robust and replicable across a wide variety of stimulus modalities and procedures, including subliminal presentation (Greenwald, Draine, & Abrams, 1996; Wittenbrink, Judd, & Park, 1997), familiar attitude objects (Bargh et al., 1992; Fazio et al., 1986), images (Fazio, Jackson, Dunton, & Williams, 1995), odors (Hermans, Baeyens, & Eelen, 1998), newly learned words (De Houwer, Baeyens, Vansteenwegen, & Eelen, 2000), and novel objects (Duckworth et al., 2002). Moreover, they occur not only when people make explicitly evaluative judgments (good–bad; Fazio et al., 1986) but also when they make nonevaluative judgments, such as a lexical decision task (word/nonword; Kemp-Wheeler & Hill, 1992; Wittenbrink et al., 1997), or simply pronouncing a target word (Bargh, Chaiken, Raymond, & Hymes, 1996; Glaser & Banaji, 1999). Current mood state appears to influence automatic evaluation too. Recent evidence reveals that robust priming effects that occur in positive mood states are reduced or eliminated in negative mood states. A prominent interpretation is that positive moods serve as a "go" signal that promotes finding connections between concepts, while negative moods serve as a "stop" signal indicating that something is not right, leading stimuli to be scrutinized individually (Storbeck & Clore, 2005).

A central debate in this literature was spawned by the question: Is automatic evaluation universal and unconditional (Bargh et al., 1992; Chaiken & Bargh, 1993), or does it occur *only* for strongly held attitudes (Fazio et al., 1986)? In priming paradigms, strength of association is taken as an indicator of the *degree* of accessibility. The fact that even novel stimuli (whether abstract art or novel words) elicit automatic evaluation (Duckworth et al.,

2002) suggests that the phenomenon is not restricted to preexisting and strongly held attitudes and that it can be evoked online. At the same time, the strength of the object-evaluation association moderates automatic evaluation (e.g., Roskos-Ewoldsen & Fazio, 1992), and "evidence suggests that attitude strength does play a moderating role in the activation of the attitude to the extent the object is being given conscious scrutiny (i.e., when it is the current focus of the person's goals); otherwise, any and all attitudes become activated automatically" (Wegner & Bargh, 1998, p. 469).

THE TRIGGERING OF STEREOTYPES

The accessibility of stereotypes is temporarily heightened by exposure to a category member (e.g., a Black face) or attributes of a stereotype (Bargh, 1999; Devine, 1989; Fiske & Neuberg, 1990), with even subliminal cues activating the stereotype (Bargh, Chen, & Burrows, 1996; Chen & Bargh, 1997). Automatic stereotype activation is assessed through outcomes such as response facilitation (Banaji & Hardin, 1996; Blair & Banaji, 1996; Macrae, Milne, & Bodenhausen, 1994; Moskowitz, Salomon, & Taylor, 2000; Wittenbrink et al., 1997), inhibition (Kawakami et al., 2000; Moskowitz, Gollwitzer, Wasel, & Schaal, 1999), word completion (Gilbert & Hixon, 1991; Spencer, Fein, Wolfe, Fong, & Dunn, 1998), and social judgment (Devine, 1989; Lepore & Brown, 1997). Automatic stereotype activation may be limited in time course, occurring as early as 500 msec (e.g., after seeing a Black face), but may not last long (not past 12 minutes, Kunda, Davies, Adams, & Spencer, 2002). It is also less likely among people low in prejudice (Kawakami et al., 2000; Wittenbrink et al., 1997) or those internally motivated to avoid it (Devine, Plant, Amodio, Harmon-Jones, & Vance, 2001; Moskowitz, Gollwitzer, et al., 1999).

ACTIVATING SIGNIFICANT OTHERS EVOKES INFERENCES, EVALUATION, AND EXPECTANCIES

Knowledge of significant others can be activated automatically (Andersen & Cole, 1990; Andersen et al., 1995; Baldwin, 1992; Fitzsimons & Bargh, 2003; Shah, 2003a, 2003b). In one example, when cues presented "about" a new person implicitly activate the significant-other representation (Andersen & Cole, 1990), participants come to infer that the new person has additional, unlearned features in common with their significant other. The accessibility of the associated significant other leads to an increased likelihood of falsely remembering features of their significant other as having been presented as descriptors of the new person (Andersen et al., 1995; Andersen & Baum, 1994; Andersen, Reznik, & Manzella, 1996; Baum & Andersen, 1999; Berk & Andersen, 2000; Glassman & Andersen, 1999a, 1999b; Hinkley & Andersen, 1996).[4] This effect can persist and even increase after a 1-week delay (Glassman & Andersen, 1999a) and is observed when the cues are presented outside awareness (Glassman & Andersen, 1999b). Significant-other representations are chronically accessible without priming (Andersen et al., 1995, study 1) and

are more accessible with even minimal triggering (Chen et al., 1999), with transient cuing and chronicity combining additively (Andersen et al., 1995; Baldwin et al., 1996). In this paradigm, automatic evaluation also occurs—with the favorability of the significant other automatically evoked in terms of what is applied to a new person who shares some features with the significant other (Andersen & Baum, 1994; Andersen et al., 1996; Berk & Andersen, 2000).

When a significant other's name or face is presented subliminally, followed by supraliminal Chinese ideographs, people evaluate these unfamiliar stimuli more positively than stimuli primed with a nonsignificant other (Banse, 1999). More positive affect is also evoked in participants' facial expressions while reading descriptions of a new person who resembles a positive (vs. a negative) significant other (Andersen et al., 1996)—and this occurs within a couple of seconds, implying intentionality may be unnecessary.

Representations of significant others are also of interest in research based on attachment theory focused on the role of caretaker responsiveness in development (Bowlby, 1969; Thompson, 1998). Attachment style can be evoked by subliminal cues related to a significant other (Mikulincer, Hirschberger, Nachmias, & Gillath, 2001), or involving the person's first name (Baldwin, Keelan, Fehr, Enns, Koh-Rangarajoo, 1996; Gillath et al., 2006), or consciously visualizing him or her (Mikulincer & Arad, 1999; Zayas & Shoda, 2005). Also, priming specific significant others can evoke distinct if–then expectancies related to attachment styles (Baldwin, Fehr, Keedian, Seidel, & Thomson, 1993). For example, securely attached participants responded faster than insecurely attached participants to positive outcome phrases (e.g., come through), while the opposite occurs when the phrase indicates a negative outcome (e.g., leave me). Likewise, automatic expectancies for social rejection, particularly by significant others, can exist on a chronic basis and be activated by contextual cues (Downey & Feldman, 1996), leading to a hypervigilance to threat cues.

TRIGGERING MOTIVES AND GOALS

Like other knowledge concepts, motives and goals can be activated automatically by cues in the environment (Bargh, 1990), and unlike semantic constructs, such as trait constructs, they are uniquely equipped to energize and guide behavior (Bargh et al., 2001). When activated by contextual cues, goal states evoke behavior (Aarts & Dijksterhuis, 2000; Bargh & Barndollar, 1996; Bargh & Chartrand, 1999). Triggering cues consist of any goal-relevant cues in the environment or in one's thoughts that evoke the desired end states (goals), which then evoke behavioral strategies for goal attainment (Bargh, 1990; Hommel, Muesseler, Aschersleben, & Prinz, 2001; Kornblum, Hasbroucq, & Osman, 1990; Kruglanski, 1996). When a goal is associated with a context, the context will then activate the goal and goal-relevant behavior automatically (Aarts & Dijksterhuis, 2003; Bargh & Gollwitzer, 1994). For example, viewing images of a li-

brary leads to faster lexical decision judgments for library-relevant goals and behaviors (e.g., to be quiet) relative to control words or nonwords, but only when participants expected to visit a library. Holding a goal in mind thus increases the accessibility of relevant behavioral norms.

Moreover, the activation of goal states and goal pursuit leads to positive affect once the goals are attained, and to tension when they are not (Aarts & Dijksterhuis, 2000; Carver & Scheier, 1998; Geen, 1995; Gollwitzer & Moskowitz, 1996). Goals thus function as other mental representations with specific activation consequences, and also as processes that operate on other mental representations, such as by introducing motivated shifts in automatic processing. What distinguishes goal priming from trait priming is that goals are not truly primed unless the affect associated with them is triggered (its incentive value, e.g., Custers & Aarts, 2005) and a tension state exists while the goal is unattained (Custers & Aarts, 2005; Moskowitz et al., 2004; Strahan, Spencer, & Zanna, 2002). For example, priming people with the goal of quenching their thirst activates the goal of drinking something (measured by selection of drinks in a later task), but only if the person is thirsty (Strahan et al., 2002). When initial tension is present, the prime triggers the goal. This does not imply that the goal must already be activated for automatic priming to occur. Rather, desiring an end state involves experiencing associated tension prior to goal satisfaction and is a precondition for nonconscious goal priming.

Goals are more pronounced among people who regard them as highly desirable (Aarts, Dijksterhuis, & DeVries, 2001; Aarts et al., 2005; Strahan et al., 2002), and the habitual pursuit of some goals over others leads them to become chronically accessible. Chronic goals have been widely shown to impact the way people process information. Some goals, such as to have control (Lefcourt, 1976; Pittman & D'Agostino, 1989; Pittman & Pittman, 1980; Rotter, 1966), to engage in cognitive activity (Cacioppo & Petty, 1982), to avoid uncertainty (Sorrentino & Short, 1986), and to have closure (Neuberg & Newsom, 1993), thus influence how information is perceived and categorized. In addition, a goal can be activated by contextually cuing a means to a goal. After subliminal priming with the means to achieving a goal, people respond more quickly to words reflecting behaviors that can achieve the goal than to control words—even when the task is irrelevant, such as deciding if a word is a trait or not (Shah & Kruglanski, 2003).

Complexity in Contextual Cues

In most circumstances, stimulus cues are complex, introducing a variety of possibilities for automatic categorization. The selection of cues for automatic activation is influenced by situational factors. For example, recent research made use of stimulus items that varied in evaluation (good or bad) and in semantic meaning (animal or religion) in a paradigm that pitted semantic priming against evaluative priming (Do animals prime other animals regardless of valence or do good words prime other

good words regardless of semantic category?) (Storbeck & Robinson, 2004). With four categories of primes and targets (good animals, bad animals, good religious terms, bad religious terms), the data showed little to no evaluative priming and substantial semantic priming. In other words, animals, good or bad, primed animals relative to religions; moreover, good animals did not prime good religions. At the same time, when the priming task involves stimuli from a single semantic category (animals) evaluative priming is observed, suggesting automatic evaluation may be conditional on the availability of obvious, alternative semantic features for categorization.

THE MULTIPLE CATEGORY PROBLEM AND CATEGORY SPECIFICITY

Group memberships are often activated automatically, influencing perceptions without intention or control, but if a stimulus belongs to multiple categories, what is automatically activated? The presence of multiple cues can be resolved by individuation, that is, by considering an individual's personal qualities, if one has the time and motivation (Fiske & Neuberg, 1990). However, one category is likely to become dominant in activation depending on the social context. In the competition to see which will be activated, some categories are automatically inhibited (while others remain active) due to inconsistencies among the categories and their fit with contextual cues (Bodenhausen & Macrae, 1998; Moskowitz et al., 2004; Sinclair & Kunda, 1999). An Asian female activates a different response after subliminal exposure to the prime "Asian" (vs. "female") (Macrae et al., 1995). In a lexical decision task following the "Asian" prime, response latencies show that Asian stereotypes are automatically activated while female stereotypes are inhibited, and vice versa following the "female" prime.

Exposure to a category label also activates multiple associated exemplars that have stereotype-relevant attributes (Rothbart, Sriram, & Davis-Stitt, 1996). Typical members of rival fraternities were more likely to be retrieved than atypical ones, which are inhibited. Automatic exemplar activation is thus relevant in stereotyping (Smith & Zarate, 1992; see also Andersen & Cole, 1990; Andersen & Glassman, 1996).

CONTEXTUAL SPECIFICITY AND THE MALLEABILITY OF AUTOMATIC EVALUATION, STEREOTYPES, AND GOALS

Accessible constructs are often assumed to be rooted in long-term experience and to be relatively insensitive to the situation (Bargh, 1997; Devine, 1989; Dovidio & Fazio, 1992). Over the last 10 years, a major shift has occurred with evidence indicating that activation depends on the social context. Automatic processes are responsive to immediate motives, goals, and contexts (Blair, 2002; Kunda & Sinclair, 1999; Kunda & Spencer, 2003; Kunda et al., 1997; Mitchell, Nosek, & Banaji, 2003; Moskowitz et al., 1999a).

Greater automatic negative evaluation of Black targets is evoked in a ghetto context (vs. in a religious context; Wittenbrink, Judd, & Park, 2001), for example, and a

weaker automatic negativity toward Blacks relative to Whites is observed immediately after exposure to admired African Americans and disliked Caucasians compared to a control condition (Dasgupta & Greenwald, 2001). Other research has shown that Black targets elicit more automatic negative evaluation than do Asian targets in a classroom but more automatic positive evaluation on a basketball court (Barden, Maddux, Petty, & Brewer, 2004). These effects suggest an interaction between group membership, social roles, and situations in determining automatic evaluation.

Simple manipulations such as having participants think about strong women (Blair, Ma, & Lenton, 2001) or provide information about well-known female leaders (Dasgupta & Asgari, 2004) can reduce automatic activation of gender stereotypes of women as weak rather than strong, as supporters rather than leaders. Moreover, evidence suggests that participants' belief that the world is dangerous is related to stronger automatic stereotypes associating African Americans with danger, but only when seated in a dark room (Schaller, Park, & Mueller, 2003).

Another component of social context is in the variety of cues that emanate from a single target. For example, a target's gaze direction influences the relevance of the target for the self. When a target person looks directly at the perceiver (vs. not) the target is more likely to be categorized (Macrae, Hood, Milne, Rowe, & Mason, 2002). Finally, context can present challenges that overburden the person, or processing tasks that usurp attentional or cognitive resources that would otherwise be required for stereotype activation (Gilbert & Hixon, 1991; Li & Moskowitz, 2005; Macrae, Bodenhausen, Schloerscheidt, & Milne, 1999).

Instead of emphasizing which cue (of multiple cues) is activated based on the context, research now emphasizes how multiple stereotypes and attributes may be activated simultaneously and automatically with each constraining the other's meaning and constructing a unique, emergent impression (Kunda & Thagard, 1996). This connectionist perspective is supported by computer simulations (Kunda & Thagard, 1996) and provides grounding for taking seriously the notion that automaticity is *truly* contextualized and does not just reflect which of a defined set of mental representations is activated (Mitchell et al., 2003).

GOAL ACTIVATION IS ALSO CONTEXTUALIZED IN SPECIFIC TERMS

Benign situations in which searching and exploring are permissible are known to trigger approach goals, whereas avoidance goals are associated with situations that are problematic and require rectifying action. Situations that call for specific types of motor actions can also determine whether approach or avoidance goals are activated. Contexts that involve tasks where one must contract flexor muscles trigger approach goals, whereas contexts that involve acting through the use of extensor muscles trigger avoidance goals (Friedman & Förster, 2000). Automaticity is shown by an inability to detect any

connection between the muscular activity and goal activation, as well as through the use of dependent variables that reflect automatic processing.

Observing another person in goal pursuit can also prime the goal in the perceiver if he or she values the goal (Aarts, Gollwitzer, & Hassin, 2004) in a kind of goal contagion where the other's goal is activated in one's own processing. This offers a naturalistic explanation for how goals are triggered automatically across various interpersonal situations—they are inferred from the behavior of others (see also discussion of such activation processes in trait inference by Moskowitz & Roman, 1992).

Furthermore, people with the goal of being egalitarian (and who strongly believe in this) reveal automatic activation of this construct when exposed to members of disadvantaged groups (Moskowitz et al., 2000). When such people are exposed to faces of Black men, the stereotype of African American men is inhibited and the goal of being egalitarian becomes more accessible (as measured in lexical decision judgments to goal-relevant vs. stereotype-relevant words; Moskowitz et al., 2000, 2004). Even strangers, then, can trigger goal concepts linked to specific actions. And if people have the goal of seeing the world as just (Lerner, 1980), this belief can be triggered by environmental cues that suggest injustice (Hafer, 2000).

INTENTIONALITY IN ACTIVATION AND LACK OF AWARENESS IN PROCESSING

Even when there are in fact intentions to judge or to evaluate, automatic effects of social knowledge are still observed. For example, despite the fact that respondents are intentionally evaluating novel targets, the unawareness component of automatic attitudes is shown in affect misattribution (Payne, Cheng, Govorun, & Stewart, 2005). That is, participants presented with a to-be-ignored prime (e.g., faces of Blacks or Whites) quickly followed by a novel pictograph to be rated for pleasantness exhibit an influence of these primes on their evaluations of novel pictographs. This suggests that people misattribute their affective reaction evoked by a prime to their evaluation of the novel object (Payne et al., 2005). Little awareness or control is involved, and warnings to discount the affective implications of the primes do not reduce the effect. In this case, intentions are directly opposite to the observed effects, which rely on lack of awareness and control.

By contrast, automaticity in goal activation may at times depend on having compatible intentions. Automatic goal triggering by a contextual cue is facilitated by the explicit intention to pursue the goal when the appropriate context occurs (Gollwitzer, 1999). Automatic goals enable behavior to be regulated automatically, and yet, it is the conscious valuing of the goal (of this desired end state) and having the intention to pursue it that enables automatic goal-directed behavior when relevant cues are encountered.

In other circumstances, goal activation parallels other social knowledge activation, showing that intentions are not necessary for goal activation. Once goal pursuit has

become routinized by being paired with specific contexts, the *explicit* intent to pursue the goal is no longer needed. The contextual cues alone can trigger the *implicit* intent to pursue the goal (Aarts & Dijksterhuis, 2000; Aarts et al., 2004; Bargh et al., 2001; Moskowitz et al., 2004; Shah & Kruglanski, 2002). Though needed initially, *explicit* intent recedes to the background as the affordance it established with the context takes hold.

Automatic Activation in Social Neuroscience as Triggered by Contextual Cues

Relevant neuroscience evidence on automatic evaluation concerns the amygdala—a small structure in the medial temporal lobe—which has been shown to be important for emotional learning (see LeDoux, 2000, for a review) and has been linked directly to fear conditioning in humans (Phelps et al., 2001). Amygdala activation is particularly pronounced in response to aversive cues. This work is informative about possible neurocortical underpinnings of automatic evaluation. Research shows that the amygdala is recruited in processing evaluative information, and that this occurs automatically and unconsciously (Morris, Ohman, & Dolan, 1998; Whalen et al., 1998). Research using fMRI reinforces the conclusion drawn from behavioral research that automatic evaluation occurs whether or not participants are intentionally evaluating stimuli (Bargh, Chaiken, et al., 1996). For example, participants rating famous names as *good* or *bad* (evaluative) or as *past* or *present* (nonevaluative) showed greater amygdala activity regardless of the task for the negative famous names (vs. positive famous names), suggesting immediate evaluation without intention (Cunningham et al., 2003).

To contrast automatic and controlled evaluative processing, the amygdala can be compared with the prefrontal cortex (PFC), a region thought to be involved in higher-order processes involving executive control and deliberative processing (Duncan & Owen, 2000; Stuss & Benson, 1984). In the study by Cunningham and colleagues (2003), activation of the ventrolateral PFC (but not the amygdala) was shown to be influenced by the evaluative ambivalence of target names, but only in the evaluation condition. This effect suggests that controlled, reflective processes via the PFC may be recruited to deal with attitudinally ambivalent cues when relevant to the response task. By contrast, automatic amygdala responsivity is relatively insensitive to the task demands. This neurological difference between automatic and controlled evaluative processes is thus consistent with social cognitive theories drawing this distinction (e.g., Cacioppo & Berntson, 2001; Greenwald & Banaji, 1995; Smith & DeCoster, 1999; Wilson et al., 2000).

The notion that amygdala activation may mediate automatic evaluation effects (Phelps et al., 2000) is also shown in greater amygdala activation in response to Black (vs. White) faces—as suggested by evidence that fMRI measures of amygdala activity to Black (vs. White) faces—is correlated with automatic racial attitudes tapped by the Implicit Association Test (IAT) and also by startle eye-blink to Black (vs. White) faces (Phelps et al.,

2000). This latter physiological measure is associated with threat, and thus is also correlated with the IAT assessing the automatic association of *good* and *bad* with *Blacks* and *Whites* (see Nosek, Greenwald, & Banaji, in press, for a review). Likewise, significantly greater amygdala activation was observed in response to subliminally presented Black (vs. White) faces (Cunningham et al., 2004) and startle–eyeblink responses revealed greater bias toward Black (vs. White) faces among individuals with less personal motivation to respond without prejudice (just 400 ms after a face was presented; Amodio et al., 2003). Together, this evidence supports the interpretation that evaluative processes are activated automatically (unconsciously and effortlessly) and consequently guide immediate responses to affectively charged information.

Recent evidence using ERPs of the brain has focused on the amplitude of the late positive potential (LPP), which is thought to measure categorization and which has shown differences when the target word and the context match in evaluation (Ito & Cacioppo, 2000; see also Crites, Cacioppo, Gardner, & Berntson, 1995). That is, even when participants are instructed to provide an overt response that is opposite to the evaluation of the stimulus (e.g., to say "positive" to a negative stimulus), or to perform a nonevaluative task (to make the choice "people" or "no people"; Ito & Cacioppo, 2000), there is a LPP difference when the evaluation of prime and target words match (vs. mismatch). This is the same context in which automatic evaluation without *awareness* or *intention* occurs (Bargh, Chaiken, et al., 1996).

Research using ERP and fMRI has also begun to chart the neural correlates of stereotype activation. ERPs have been examined in response to sentences that were stereotype congruent versus -incongruent, with regard to an antecedent noun and a reflexive pronoun (e.g., doctor, he, vs. doctor, she). Sentences that violate gender stereotypes produce a larger P600 response, compared to sentences that are stereotype congruent (Osterhout, Bersick, & McLaughlin, 1997). Similarly, both a later and larger P300 response to race stereotype-incongruent sentences emerges relative to congruent face-trait priming (Bartholow, Dickter, & Sestir, 2006). Importantly, this difference in the P300 is consistent with a response latency measure of stereotype activation from priming. Moreover, none of these purported indicators of stereotype activation (P600, P300, RT) is affected by alcohol intoxication, supporting their automaticity, whereas the ability to inhibit responses on stereotype-congruent trials was affected by alcohol consumption, and inhibition (vs. inability to inhibit) involved a stronger negative slow wave ERP response.

SIGNIFICANT-OTHER ACTIVATION

Neuroscience has also examined brain activity while people are exposed to pictures of human faces that are personally familiar. Exposure to a significant other's face versus one's own face leads to a markedly different pattern of brain activation as assessed by fMRI (Kircher et al., 2001) and distinct from that evoked by a

nonsignificant other face (Gobbini, Leibenluft, Santiago, & Haxby, 2004). A photograph of a close friend or family member leads to diminished right amygdala activation compared with one of a famous person or stranger, although a photo of one's own child evokes *stronger,* not weaker, amygdala activation, perhaps due to a vigilant protectiveness with one's own offspring (Leibenluft, Gobbini, Harrison, & Haxby, 2004). And, although familiarity (alone) also diminishes amygdala activation, this is less true for merely familiar than for significant-other faces (Gobbini et al., 2004); hence, the effect is not reducible to familiarity, although it varies depending on the exact nature of the relationship.

In sum, the evidence suggests that social neuroscience is contributing to our understanding of how automatic processes transpire.

Application

Contextual Triggering of Application

APPLICATION OF TRAIT CONCEPTS TO A TARGET PERSON

The more accessible a concept, the more likely that it will be applied to a potentially relevant, but ambiguous behavior (Bargh et al., 1986, 1988; Higgins et al., 1977, 1985; Srull & Wyer, 1979, 1980; for a review see Stapel & Koomen, 2001b). For example, subliminal priming of trait concepts increases temporary accessibility of the trait and, as a consequence, the trait shows an increased likelihood of being applied in making a trait inference about an ambiguous behavior (Bargh & Pietromonaco, 1982). Spontaneous trait inferences are also made based on observed behaviors and are applied to whoever is engaging in the behavior as if the trait is "about" the person (Carlston & Slowronski, 1994; Moskowitz, 1993; Todorov & Uleman, 2002). When a behavior implying a trait is paired with a face and with the instruction to remember it (Todorov & Uleman, 2002), exposure to the same face later paired with the implied trait that was *not* seen yields more false recognition of that trait, and a slower response to correctly say "no" to it having been presented. This shows that the trait becomes associated with the person (the face) in memory and is consistent with the two-stage inference and application model in which a target's behavior is first identified and then applied as an attribution to the target's stable qualities (Trope, 1986). It is equally possible, however, that there is simply one act of spontaneous trait inference activation that is always "about" the person, in which case activated trait concepts are simply applied to persons implicitly in judgment.

APPLICATION OF AUTOMATIC EVALUATION

The applicability of automatically activated attitudes has been defined by the *m*otivation and *o*pportunity as *de*terminants of attitude-to-behavior processes (MODE) model (Fazio, 1986), which predicts that accessible (stronger) attitudes are likely to be applied to judgments when perceivers have no motivation or opportunity to override it. Motivation and opportunity to override depend on numerous factors such as awareness of the evaluation, availability of cognitive resources to self-regulate, the intention to avoid the automatic response, and the controllability of the action. Most research on the application of automatic evaluation involves attitudes toward social groups and group members, especially in racial attitudes (i.e., prejudice).

Higher levels of automatic racial prejudice lead to lower-rated friendliness when interacting with a Black than a White person, as judged by both the target and by observers (Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Dovidio et al., 2002; Fazio et al., 1995; McConnell & Leibold, 2001; for similar effects for antifat attitudes, see Bessenhoff & Sherman, 2000). Higher levels of automatic preferences for Whites compared to Blacks are also associated with more blinking, less eye contact, less speaking time, less smiling, and more speech hesitations and speech errors (with a Black vs. a White interaction partner; Dovidio et al., 1997; McConnell & Leibold, 2001). The same behaviors are not predicted by explicit racial prejudice and, moreover, automatically activated attitudes do not predict behaviors that are more carefully controlled (Dovidio et al., 1997, 2002). A meta-analysis of predictive validity studies with the IAT suggests that automatic attitudes are better predictors, relative to related self-report measures, of behavior in socially sensitive attitude and stereotyping domains (Poehlman, Uhlmann, Greenwald, & Banaji, 2005). Finally, in a rare study involving minorities as participants, African American participants' automatic prejudice toward their ingroup predicted whether they explicitly preferred a White versus Black partner in an intellectually challenging task (Ashburn-Nardo, Knowles, & Monteith, 2003).

APPLICATION OF STEREOTYPES

One factor influencing the automatic application of stereotypes is the degree to which a target possesses features typical of a stereotyped group (Blair, Chapleau, & Judd, 2005; Blair, Judd, & Chapleau, 2004b; Blair, Judd, & Fallman, 2004a; Blair, Judd, Sadler, & Jenkins, 2002; Deaux & Lewis, 1984; Livingston & Brewer, 2002; Maddox & Gray, 2002; Sczesny & Kuhnen, 2004; Uhlmann, Dasgupta, Elgueta, Greenwald, & Swanson, 2002). People with more Afrocentric facial features (even if they are White) are judged as more likely to possess stereotypically African American traits than those with less Afrocentric facial features (Blair et al., 2002; Blair, Judd, & Chapleau, 2004; Blair, Judd, & Fallman, 2004). This differential application of stereotypes occurs without awareness and despite attempts to avoid it (Blair et al., 2002; Blair, Judd, & Fallman, 2004). Moreover, when in a categorization mindset, stimulus objects pertinent to categories will stand out and be given attention (Higgins, 1996b). A recent fMRI study (Wheeler & Fiske, 2005) showed enhanced amygdala activity among White subjects in response to Black (vs. White) faces when the task was to judge age, but not when it was to look for a dot on each face (or to judge whether the person liked a particular vegetable). The first task ostensibly encouraged social

categorization by age, enhancing the salience of the target's social category memberships (including race). The goals of a task thus shape which features are attended to and the apparent applicability of an activated category.

APPLICATION OF
SIGNIFICANT-OTHER REPRESENTATIONS

Significant-other representations are clearly activated and applied automatically, perhaps even more so than other forms of social knowledge, with effects on inferences and memory (Andersen & Cole, 1990; Andersen et al., 1995; Chen et al., 1999; Glassman & Andersen, 1999a). Also, facial affect arises relatively immediately that matches the overall valence of the significant other in response to the relevant stimulus cues (e.g., Andersen et al., 1996). Although it is not clear that this facial affect is "about" this new person, each stimulus cue that evokes this affect is presumed to be "about" the new person. Automatic expectancies of acceptance or rejection, and also relevant overt behaviors, are applied in the encounter as well (Berk & Andersen, 2000). Advanced priming can trigger application of significant-other representations, just as applicability-based cues in a person may do so (Andersen et al., 1995; see Chen & Andersen, 1999). Both forms of transient contextual cuing (incidental stimuli presented in advance, i.e., priming, and cues "about" the target presented when learning about the target) can provoke automatic application, as shown in relevant inferences and memory. When primed with a significant-other representation, people also respond faster in a lexical decision in which they first read an "If . . . " statement (e.g., "If I fail . . .) and then a "then . . . " statement (e.g., "then I will be rejected") if it is consistent with their significant-other relationship (Baldwin & Sinclair, 1996).

APPLICATION OF GOALS IN BEHAVIOR

Several goals have been shown to silently direct the extent to which stereotypes are applied, such as the need for structure (e.g., Kruglanski & Freund, 1983; Neuberg & Newsom, 1993), the need to repair self-esteem (e.g., Fein & Spencer, 1997; Spencer et al., 1998), and accuracy goals (e.g., Weary, Jacobson, & Edward, 2001). For example, when uncertainty beliefs are primed, people show no evidence of stereotyping, instead rating a member of a stereotyped group equally likely to be guilty of a stereotype-consistent crime as a member of a non-stereotyped group (Weary et al., 2001). Once any goal is activated, it may presumably provoke consistent behavior. As long as the new stimulus context or person presents an opportunity to act in a goal-directed fashion, the behavior will be applied regardless of the source of goal activation (Bargh & Chartrand, 1999; Lewin, 1936).

Implicit goal application is readily assessed through task interruption and spontaneous resumption (e.g., Wicklund & Gollwitzer, 1982; Zeigarnik, 1927). People primed with a high-performance goal (vs. not) often choose to continue a challenging word-formation task (e.g., constructing words using lettered tiles) when asked to choose whether or not to move on to a task involving humorous cartoons (Bargh et al., 2001). Goals can also be applied in one's own behavior by observing another person perform a similar behavior (goal contagion), as noted (Aarts et al., 2004). Participants who read a script describing another person acting in a self-serving way (with the goal to earn money) or in an egalitarian way (with the goal to help others) later adopted the same goal in their own behavior.

Intentionality and Automatic Goal Application

Can goal application be automatic if it is intended? Consciously deciding to pursue a goal in advance of doing so enables goal pursuit to occur outside awareness. Relevant cues in the environment will then activate the goal, triggering preexisting behavioral intentions that predict goal pursuit. Participants instructed to formulate a plan about how and when to collect a coupon from an on-campus office (an implementation intention vs. simply being given the goal), while pursuing a second, distracting goal of going elsewhere in the same building, picked up the coupon 80% of the time versus 50% if they had no implementation intention (controls) (Aarts, Dijksterhuis, & Midden, 1999) (i.e., they applied the goal in their behavior).

Implementation intentions heighten *efficiency* in initiating and continuing actions in both experimental tasks showing the efficiency under cognitive load and in naturally occurring cognitive load conditions (Brandstätter et al., 2001). When heroin addicts in withdrawal and recovered heroin addicts were asked to write a resume, those for whom the task specified where and when to do this were more likely to get it done—regardless of withdrawal/recovery status (Brandstätter et al., 2001). Goals are thus automatically applied to behavior efficiently, regardless of load, when behavioral intentions are activated.

GOAL-RELEVANT COGNITION

When goals are activated in a context, they can be applied by directing goal-relevant cognition (Chartrand & Bargh, 1996; Moskowitz, 2001). When explicitly asked to form an impression of a target person, people recall more about the person than when asked simply to remember the same information (Hamilton, Katz, & Leirer, 1980). For years, the explicitness of the instruction was assumed to be critical for engaging the impression formation goal and its impact on memory. But, indirect priming of impression formation (vs. memorization) goals elicits the same effect, and participants report no awareness of having had the goal in the first place, let alone of its impact on memory (Chartrand & Bargh, 1996). As another example, people asked to explicitly form an impression (vs. memorize) show recall that correlates more with schema-incongruent information (presented online) but judgments that correlate more with schema-congruent information (Hastie & Kumar, 1979). Subliminal priming of these goals has similar effects (Chartrand & Bargh, 1996), suggesting that goals can be

activated and applied automatically, without the person even being aware of pursuing them. As a final example, memory is often organized around broader life tasks relevant at the time information is acquired (e.g., Nidenthal, Cantor, & Kihlstrom, 1985; Woike, Lavezzary, & Barsky, 2001). Priming a goal can thus promote differences in memory organization and encoding (Woike et al., 2001) such that when one has the goal of agency (vs. communion) primed, there is increased memory for differentiation *when* the information is agentic but not when it is communal.

APPLYING GOALS TO AVOID UNDESIRED STATES

Cues in the environment can also suggest to-be-avoided states and evoke goals relevant to avoidance of such states. For example, the goal of avoiding death may lead to processes that buffer these concerns, even when death-related concepts are primed outside awareness (Arndt, Greenberg, Pyszczynski, & Solomon, 1997). Preexisting goals and behavioral intentions are thus applied and may even be provoked by cues that are antagonistic to the goal.

This effect is not limited to concerns about death. Both a temptation (delicious but fattening foods) and a focal goal (dieting) trigger the goal of being health conscious in eating behavior (Fishbach et al., 2003). That is, participants implicitly primed with food temptations by having been placed in a room with magazines and photographs depicting fattening food or implicitly primed with the goal of dieting both chose an apple as a gift versus a chocolate bar more than control participants. This reflects application of the goal regardless of whether it was the goal or the temptation that was primed. Similarly, when the goal of looking well groomed is primed, people apply the goal in action even if new contextual cues are inconsistent with this goal (dirty shoes). When the goal is accessible (vs. not), it facilitates response times to instrumental actions (e.g., polishing) (Custers, 2006).

Application by Means of Concurrent Activation of the Self or of One's Goals

Automatic stereotypes are also concurrently activated and applied to the self-concept in terms of self-evaluation. The strength of women's automatic gender–math stereotypes (math = male) and gender identities (female = me) predicts the strength of self-stereotyping or identification with math (math = me) (Nosek, Banaji, & Greenwald, 2002a) when these links exist in memory (Greenwald et al., 2002). Women who strongly and automatically identify with their gender and strongly and automatically stereotype math as male automatically apply math to the self less, that is, they readily process this association. Stereotypes and identity are thus interdependent in automatic activation and this occurs by means of concurrent activation.

Concurrent activation is also shown when a significant-other representation is activated and this activation spreads to the self, leading what is applied to the self to shift as well (Andersen & Chen, 2002). One's sense of self

at the moment becomes infused with the relevant relational self with this other (Hinkley & Andersen, 1996), including relevant shifts in self-evaluation.[5] When a new person resembles a significant other versus does not, people describe themselves in more self-with-significant-other terms (covarying out pretest scores), showing automatic application to the self (Andersen, Reznik, & Glassman, 2005).

Likewise, exposing graduate students to the disapproving face of their advisor outside awareness or, for Catholics, the face of the Pope (vs. an unfamiliar frowning face), leads to shifts in self-evaluation (Baldwin et al., 1990). Visualizing a significant other intentionally can also have a negative impact on self-evaluation if the relationship involves contingent acceptance based on success or failure (Baldwin & Holmes, 1987). Activating a significant-other representation leads to self-application of the *standards* that the significant other holds for the self (Reznik & Andersen, 2006; see Andersen & Chen, 2002), and to application of the *interpersonal role* with the significant other to new encounters (Baum & Andersen, 1999).

The latter effects both involve concurrent goal activation as well. Activating a significant-other representation, such as one's mother, activates the *goals* with this parent (such as the goal to be close, to help, or to achieve), which are then applied to immediate ratings, social interactions, or tasks (Andersen et al., 1996; Berk & Andersen, 2000; Fitzsimons & Bargh, 2003; Shah, 2003a, 2003b). For example, when primed with the name of their mother, participants show enhanced performance on an anagram task when their mother values achievement (Fitzsimons & Bargh, 2003).

Beyond goals per se, automatic evaluation is also applied to the self when attachment style with significant others is activated, as shown in a Stroop task—with anxious–ambivalent individuals responding most slowly for negative, self-relevant traits, while dismissive individuals were slowest for positive traits, and secure individuals slowest for all self-relevant traits (Mikulincer & Shaver, 2004). Moreover, individuals who anxiously expect rejection by others overreact to it with hostility and rage, applying such terms to the self (Downey & Feldman, 1996).

Inhibition of Application

INHIBITION BASED ON CONTRADICTORY INFORMATION

The reigning assumption in the early automaticity literature was that activation virtually always produces application, and application was thus a good proxy for activation. The current literature now draws a distinction between activation and application because of evidence suggesting that activated traits are not always applied (Bargh, 1989; Bargh, Chen, et al., 1996; Higgins, 1996b). A primed trait concept may not be applied to a behavior when it matches on evaluation but mismatches on applicability. Priming a "hostile" animal name, such as tiger or shark, activates the construct "hostile," but it is not applied to a target person (Stapel et al., 1997). Likewise,

when there is dissimilarity between two significant others and one is activated, the other may be inhibited, as not all significant-other representations are used simultaneously (Baldwin, 1992; Hinkley & Andersen, 1996) and attachment style varies by relationship (Baldwin et al., 1996; Pierce & Lydon, 2001). Sometimes, however, contradictions do not prevent application. When a new person with features of a significant other occupies a contradictory role, inferences may still derive from the significant-other representation (Baum & Andersen, 1999).

INHIBITION BASED ON INCOMPATIBLE GOALS

Inhibition can also occur in goal application, often assessed through task persistence. When a goal that is incompatible with an active goal is made accessible, some inhibition of the primary goal is observed. For example, subliminally priming an incompatible goal undermines performance and persistence on the focal goal, and this is moderated by the degree to which people perceive the goals as incompatible (Shah & Kruglanski, 2002). Perceptions of compatibility promote facilitation over inhibition. People effectively pursue an active focal goal by inhibiting incompatible concepts and goals (Moskowitz et al., 2004; Shah, Friedman, & Kruglanski, 2002). An activated stereotype is less likely to be applied when the focal goal to be egalitarian is also activated. Men with chronic egalitarian goals thus do not show facilitated lexical decision judgments to stereotypically female words (vs. control words) when primed with female faces, while men without this accessible focal goal do (Moskowitz, Gollwitzer, et al., 1999a).

People also shield goals from incompatible thoughts, even though adopting the goal of avoiding something (such as a temptation) through conscious suppression can lead to hyperactivation of to-be-avoided associations rather than to their inhibition (Wegner, 1994). That is, if the goal to suppress a particular response becomes associated with the to-be-suppressed item, the presence of the temptation can automatically trigger the focal goal of avoiding it (Shah et al., 2002). When goals are incompatible, they will have an inhibitory relation, so that priming one inhibits the other, and the greater commitment one has to the goal, the stronger the inhibition of alternative goals (Shah et al., 2002). Participants primed subliminally with a focal goal (from a list of three self-generated goals) responded more slowly in a task in which they were to decide whether or not a target word was an attribute of a nonfocal goal, with more inhibition of the alternative goal shown by those who were more committed to the goal (Shah et al., 2002).

Misattribution Based on Ease of Processing

In some instances, the ease with which information is processed also guides application. Some of the best evidence for the power of automatic stereotypes is the fact that stereotypes can work against attempts to be accurate and to not use stereotypes, as reflected in stereotype-consistent memory errors. Prior exposure to a name in-

creases its perceptual fluency, leading to misattributions of fame (Jacoby et al., 1989). Given the greater association of fame with males than with females, this "becoming-famous-overnight" effect occurs more for male names (vs. female names) (Banaji & Greenwald, 1995). In another paradigm, participants presented with several lists of words, including stereotypically male or female roles, showed more false recognition of other male roles in a later memory test—without awareness that the stereotypes influenced memory (Lenton, Blair, & Hastie, 2001; see also Macrae, Schloerscheidt, Bodenhausen, & Milne, 2002). Activated stereotypes also affect memory in that people tend to remember stereotype-consistent information better than inconsistent or neutral information (Fyock & Stangor, 1994). Indeed, practice in making a trait inference from a behavior leads this and other trait inferences to be made more efficiently, and this efficiency is misattributed to a positive evaluation of the behaviors (Smith, 1989). People are in fact more likely to infer that they favor a position when asked to list a few thoughts in support of it (vs. many) because it is easier to do so, and this ease is misattributed to a positive evaluation (Schwarz & Clore, 1988). This misattribution based on ease of processing reflects yet another means by which construct activation can lead to application.

Self-Regulation

Goals Shape Self-Regulatory Processes

Some goals have been suggested as core human motives, such as the goal to understand or comprehend, the goal to get along with others, to belong and affiliate with others, the goal to enhance self-esteem and feel positively about the self, and the goal to be accurate and have valid beliefs (Fiske, 2005; Moskowitz, 2005; Smith & Mackie, 2005; see also Andersen & Chen, 2002; Baumeister & Leary, 1995). These and other goals are central elements of self-regulation. For example, the goal to comprehend and also the goal to avoid bias shape the way stereotypes and traits are activated and applied in both judgment and behavior (for reviews, see Kunda & Spencer, 2003; Sinclair & Kunda, 1999; Spencer et al., 1998). These goals may contribute to the inhibition of knowledge activation or disrupt its application (e.g., Moskowitz, Gollwitzer, et al., 1999; Moskowitz et al., 2004). Emergent evidence suggests that self-regulatory processes can take place relatively unconsciously and effortlessly, and this tell us something about the complexity of "executive" operations.

As noted before, goals define end states and are associated with behaviors geared toward attaining them. Goal application can thus be used as a measure of self-regulation. For example, the degree to which one can complete a goal-relevant task while putting effort into a distracter task standing in the way of the goal reflects the automatic application of the goal in behavior (Aarts et al., 2004). Self-regulation occurs after goal priming as the incentive value of the goal becomes greater (Förster, 2005) and approach behavior ensues (Bargh et al., 2001; Förster, Higgins, & Idson, 1998).

THE GOAL OF COMPREHENSION

A fundamental motive in human psychological functioning is to seek comprehension, a degree of certainty in one's beliefs—that is, clear meaning and understanding (Heider, 1944). Although people do not always have an explicit intention (a conscious goal) to infer meaning, they make meaning all the time. Seeking comprehension is a distal goal that is fulfilled proximally with actions, such as making trait inferences about people, situations, and social objects (Uleman, Newman, et al., 1996). The automatic operation of motives or goals in trait inference involves self-regulation of trait activation and use. Once a trait is inferred based on an observed behavior in another person, the observation is meaningful.

The literatures on both attribution and accessibility have addressed such questions for decades. Our focus here is the automatic components of regulatory processes. For example, spontaneous trait inference, an automatic process of trait activation and application from observing another person's behavior, is moderated by a chronic need for structure. People with this activated goal show more spontaneous trait inferences, despite being neither aware of having the goal nor aware of forming the inference (Moskowitz, 1993). It is also moderated by chronic authoritarian goals (Uleman, Winborne, Winter, & Shechter, 1986).

Comprehension goals (the desire to understand) can inhibit stereotyping when a person feels that stereotyping would impede understanding. Priming these goals can thus lead people to be more attentive and careful in their judgments (Leyens, Yzerbyt, & Schadron, 1992; Macrae et al., 1995; Yzerbyt, Schadron, Leyens, & Rocher, 1994). On the other hand, comprehension goals can instead exacerbate stereotyping when it seems to the person that stereotyping might facilitate understanding (Kunda & Spencer, 2003; Pendry & Macrae, 1996; Stapel & Koomen, 2001a).

THE GOAL OF BEING ACCURATE AND AVOIDING BIAS

Research on the goal to avoid bias is most clearly seen in studies of stereotype application. Old assumptions about the nature of automatic stereotyping suggest that one cannot alter a stereotype's automatic activation, which led to early research on how one can regulate outputs from already activated stereotypes (Devine, 1989; Fazio, 1990; Fiske & Neuberg, 1990). Self-regulation can help people to avoid the effects of automatic stereotypes by suppressing biased impulses, attending to alternative sources of information (e.g., focusing on egalitarian responses), and attempting to correct for biased actions (see Devine & Monteith, 1999). These are output-control strategies and they have preconditions, such as awareness of the potential influence of the automatic stereotype, the knowledge that one was influenced and by how much, the motivation to avoid the influence, and the capability to implement an effective strategy to change the output (Moskowitz, Skurnik, & Galinsky, 1999; Wegener & Petty, 1997; Wilson & Brekke, 1994). This is asking a

lot, which explains one reason why stereotyping, prejudice, and discrimination are hard to eliminate, even among committed egalitarians.

Conscious attempts to suppress stereotypes can have unintended consequences, such as leading people who successfully suppress a stereotype to have a more accessible (automatic) stereotype later (Macrae, Bodenhausen, et al., 1994; see also Galinsky & Moskowitz, in press; Wegner & Erber, 1992). This backfiring of suppression occurs only for people highly motivated to avoid prejudice, showing that this paradoxical effect is moderated by motivation. In sum, automatic stereotyping involves failure to control biases that stereotypes introduce, despite one's best intentions (Monteith, 1993). While control of stereotype application can sometimes be demanding, conscious, and effortful, it can also occur automatically. Stereotypes may be automatically evoked, but motivation to avoid them may be as well, introducing the potential for automatic self-regulation.

Chronic egalitarians have a persistent goal to respond without stereotyping and prejudice (e.g., Plant & Devine, 1998). They readily detect information relevant to the goal of being egalitarian and inhibit incompatible responses (Moskowitz et al., 2004). Repeated attempts to suppress a stereotype are a form of practice that can lead to automatic inhibition with exposure to relevant stimuli (Bargh, 1990). Ultimately, the cues that activate the stereotype also activate the regulatory response by means of "spreading inhibition." Focusing attention on ignoring a stimulus (and its semantic associations) can lead to inhibition (Fox, 1995), termed "negative priming" (Tipper, 1985). In negative priming, spreading inhibition leads responses to "slow down" (vs. facilitation) when the relevant words are ones that are supposed to be ignored (Neill, Valdes, & Terry, 1995). Moreover, men with chronic egalitarian goals presented with pictures of women inhibit stereotypical thoughts automatically, whereas men with no such goals have more accessible stereotypical thoughts (Moskowitz, Gollwitzer, et al., 1999a). Chronic egalitarians also pronounce stereotypical words more slowly in response to female versus male pictures that were to be ignored, and thus seem to ignore stereotypical associations habitually. A female face triggers the goal and self-regulation, which then wards off the incompatible response, and this appears automatized. This and other research on racial attitudes and stereotypes shows that people with chronic goals to avoid bias develop automatic responses to stereotype-relevant stimuli that facilitate the avoidance of bias, such as the inhibition of stereotypes and the activation of goals, beliefs, and actions that oppose stereotyping (Amodio et al., 2004; Devine et al., 2001; Glaser, 2005; Moskowitz, Gollwitzer, et al., 1999; Moskowitz et al., 2000). This likely tells us something about the nature of control processes writ large. Goal activation can inhibit other relevant knowledge and goal activation and application and can do so automatically when rehearsed in advance.

A goal (such as to avoid prejudice) need not be chronic in order for implicit control (such as inhibition of stereotypes) to be produced. Indeed, even people without

chronic tendencies to be egalitarian can inhibit stereotype activation if sufficiently committed to the goal. This goal can be produced in the moment by giving people implementation intentions, say, to be egalitarian (to formulate specific plans regarding when and how they will be nonbiased) or by having people contemplate an instance in which they were prejudiced (failed to be egalitarian). Failure to attain the goal of being nonbiased is thought to lead to a state of "incompleteness" that accompanies failure in committed goal pursuit. This state triggers compensatory responses, including automatic processes that prepare the individual for goal-relevant behavior (Moskowitz, 2001, 2002). These compensatory processes include control over stereotype activation, inhibition of the stereotype (Moskowitz et al., 2004), and readiness to respond to goal-relevant cues.

One example of such readiness is the automatic process of selective attention whereby stimuli relevant to the goal of egalitarianism are attended to more quickly (relative to a condition involving no such incompleteness). This type of automatic attention effect has been shown in a computer task in which words relevant to egalitarianism are presented as distracters vis-à-vis a focal task (Moskowitz, 2002). When people are asked, as a focal task, to press a button indicating the direction that stimuli have moved on a computer screen (which move so quickly that they cannot be detected as words nor can their relevance be determined), their reaction times are slower if these distracter words are in fact relevant to egalitarianism. Only "incomplete" participants (those failing to reach the goal of being accurate and nonbiased) show this kind of distracted attention, thus illustrating attentional selectivity as a compensatory response to the goal state.

Beyond the control that individuals themselves exert over automatic stereotypes (or their outcomes), *social* regulation may also influence stereotypes and prejudice. Some people likely suppress stereotypes not because they do not believe in them but, rather, because of pressure from societal norms about what is considered appropriate (on internal and external motives, see Plant & Devine, 1998). Automatic stereotypes and prejudice are responsive both to motivation and to social context. Changes in context, whether instituted by the individuals, by others, or by settings, can alter both processes and outcomes (Blair, 2002). Exposure to minority leaders, and also to female scientists, can reduce automatic gender stereotypes and prejudice (Dasgupta & Asgari, 2004; Dasgupta & Greenwald, 2001; Richeson & Ambady, 2003). Increases in the numbers and visibility of such individuals may thus be able to reduce stereotyping and prejudice over time in society. Encouraging individuals to confront prejudices (e.g., diversity seminars) also appears to be associated with decreases in automatic stereotyping and prejudice (Rudman, Ashmore, & Gary, 2001), altering students' automatic associations and diminishing negative associations toward African Americans.

Indeed, simply making egalitarian norms salient can also impact automatic stereotypes (Sechrist & Stangor, 2001; Sinclair, Lowery, Hardin, Colangelo, 2005; Spencer, Fein, Zanna, & Olson, 2003). Lower levels of automatic race stereotypes arise when people are led to believe their stereotypes are "out of step" with those of their peers (Sechrist & Stangor, 2001). The expression of automatic stereotypes can even be completely eliminated (or reversed) when people are told that relative to their peers they score high on "contemporary racism" and low on "racial tolerance" as compared with scoring that way on nonracial dimensions (Spencer et al., 2003).

Automatic processes are thus more malleable than previously believed, and there are multiple influences on stereotypes that can succeed in changing their expression. For example, inducing people to focus attention on counterstereotypical associations can combat automatic stereotypes (Blair & Banaji, 1996). People led to expect counterstereotypical target associations (in stimuli to be encountered), rather than to expect stereotypical associations, produce significantly weaker automatic gender stereotypes. Counterstereotypical associations can also be formed through mental imagery (Blair et al., 2001). Spending 5 minutes creating a mental image of a strong (counterstereotypical) woman before completing a measure of automatic gender stereotypes leads to weaker automatic stereotypes (relative to creating a neutral image or no image or other controls, such as an image of a weak woman or a strong man, or while simply trying to suppress stereotypes). Counterstereotypical mental imagery also moderates automatic stereotyping on the IAT as well as on word detection sensitivity (d') on the go/no-go association task (Nosek & Banaji, 2001), and indeed on false alarms in a memory task based on a false memory induction.

In short, when people want to avoid bias, they may *try* to recognize when they have acted (or are about to act) in a way that falls short of their personal standards, in part because failing to do so would stimulate negative affect (guilt and disappointment; Devine, Monteith, Zuwerink, & Elliot, 1991; Monteith, 1993). Hence, cues for stereotyping come to be associated with aversive feelings anticipated based on regulatory failures (e.g., Monteith & Voils, 1998; Monteith, Voils, & Ashburn-Nardo, 2001; Monteith et al., 2002; Moskowitz, 2002; Moskowitz et al., 2004), such that cues of stereotyping are responded to as if they are *cues for control*, and they then provoke automatic self-regulation. This is unlikely to be something simply about stereotyping per se but, rather, is likely to tell us something about the nature of regulatory processes generally.

THE GOAL OF SELF-ENHANCING

People possess automatic positive self-views (Greenwald & Banaji; 1995; Hetts & Pelham, 2001), as shown in their preference for the numbers in their own birthday (Kitayama & Karasawa, 1997), for people who share their name or birthday (Finch & Cialdini, 1989; Jones, Pelham, Carvallo, & Mirenberg, 2004; Miller, Downs, & Prentice, 1998), and for the letters in their own name (DeHart, Pelham, & Murray, 2004; Koole, Dijksterhuis, & van

Knippenberg, 2001; Nuttin, 1985; Pelham, Mirenberg, & Jones, 2002).

One route to evoking self-enhancement goals is to threaten the self. Triggering negative stereotypes relevant to the self can thus provoke heightened ingroup favoritism and outgroup denigration, as a response to the threat to self-enhancement goals (Fein & Spencer, 1997; Sinclair & Kunda, 2000; Spencer et al., 1998). That is, people implicitly seek to restore feelings of self-worth. Automatic self-protective biases in response to threat are evoked in stereotyping because the threat provokes outgroup derogation in a compensatory fashion (Spencer et al., 1998). However, people who are motivated to see another person positively will also tend be more inclined to see the person as similar to the self (Sinclair & Kunda, 1999).

Self-enhancement emerges in compensatory responses evoked by failures or other threats to the self (Greenberg & Pyszczynski, 1985; Steele, 1988). For example, activation of a negative significant-other representation brings an influx of negative self-qualities into the working self-concept that activates a flood of self-enhancing qualities—that react against the negative relational self (Hinkley & Andersen, 1996; see Reznik & Andersen, 2004, for a related effect). Assessed by means of freely listed self-concept features, this effect is undergirded by automatic activation of the significant-other representation (Andersen et al., 2005).

Automatic self-regulation vis-à-vis significant others depends on the quality of the relationship (Chen et al., in press). People may respond to threat by automatically activating significant-other representations—an attachment figure—and may do so without awareness and in a compensatory fashion (Mikulincer, Gillath, & Shaver, 2002). When threat cues are presented subliminally, they may provoke thoughts of attachment figures, perhaps because thoughts of these others are comforting among securely attached individuals. People high in attachment anxiety are also prone to activation of attachment figures under threat, while those high in attachment avoidance show diminished accessibility (Mikulincer et al., 2002). Indeed, individuals who are anxiously attached respond to threat cues by pursuing closeness, and accentuating agreement with the other, while those who are avoidantly attached pursue self-reliance and emotional distance (Mikulincer, 1998; Mikulincer, Orbach, & Iavneli, 1998). To the extent that people are "good self-regulators" (i.e., good at delay of gratification), they also tend to have fewer negative interpersonal experiences, even when highly sensitive to rejection, and this may allow such people to function even more effectively than those low in rejection sensitivity (Ayduk et al., 2000). Such a process may begin effortfully (see Yovetich & Rusbult, 1994) but can presumably become automatic with practice.

Parents who perceive they have little power relative to their children respond to their child's behavior as if it is a threat—showing the activation of dominance ideation when under a cognitive load (Bugental, Lyon, Krantz, & Cortez, 1997). With sufficient cognitive capacity, such parents effortfully regulate their responses and can respond adaptively, but when distracted, they cannot, suggesting that their dominance ideation is automatic and their self-regulation is not.

THE GOAL OF GETTING ALONG

The goal of getting along with others, to make a good impression, and to fit in moderates stereotyping (Lowery, Hardin, & Sinclair, 2001; Richeson & Ambady, 2003; Sechrist & Stangor, 2001; Sinclair et al., 2005; see also Chen, Shechter, & Chaiken, 1996). People who believe they will evaluate a Black target versus interact with a Black partner of equal status show more automatic prejudice (Richeson & Ambady, 2003). Moreover, those believing they are in a subordinate role (vs. a superordinate one) produce the lowest levels of automatic prejudice. The other's status (i.e., authority role) outweighs race in the prejudice experienced. White individuals also show less automatic prejudice in the presence of a Black individual (rather than White) when this person is the experimenter (Lowery et al., 2001). This appears to arise due to the motivation to get along with and "tune in" to the experimenter's presumed beliefs. Social tuning can also reduce the expression of automatic prejudice even when an experimenter is White, is liked, and is presumed to hold egalitarian attitudes (Sinclair et al., 2005). Hence, social roles and perceptions of socially significant others' beliefs can also moderate automatic prejudice.

Protection of the other can also be evoked as self-regulation in the context of significant-other relationships. A positive relationship will lead people to treat negative aspects of their partner as virtues, with these flaws being seen as endearing, and this may contribute to relationship maintenance (Murray & Holmes, 1993). Negative cues about a new person who resembles a positive significant other (in transference) evoke a compensatory process in immediate facial affect, which becomes much more positive (but not in a control condition) (Andersen et al., 1996). In such a positive transference, more positive affect is expressed in momentary facial expressions in response to *negative features* than to comparable positive features "about" this new person, but this does not occur in the absence of transference, nor does it occur in negative transference. This highly positive response to negative cues also arises when the significant other is a parent, even if the parent was physically abusive (Berenson & Andersen, 2004), presumably protecting the valued relationship. More generally, people also show the same kind of name–letter effect for a significant other as they show for the self (DeHart et al., 2004). That is, people with high self-esteem show the effect both for romantic partners and for best friends, even when the relationship is troubled, while those low in self-esteem show it only when the relationship is going well.

Activation of a significant-other representation also indirectly activates goals that the significant other holds (Moretti & Higgins, 1999; Shah, 2003a), and these have a self-regulatory function (Baldwin et al., 1990). The goals *they* hold influence the individual's behavior (Andersen & Chen, 2002; Baldwin & Holmes, 1987; Shah, 2003a, 2003b), making him or her more inclined to achieve or to be helpful as the other prefers (Fitzsimons & Bargh,

2003; Shah, 2003a, 2003b). Evidence for such automatic self-regulation based on significant-other representations comes largely from priming studies presenting the name of a significant other outside conscious awareness (Shah, 2003a), which results in reports of greater commitment to the significant other's goals and more likeliness to behave in ways consistent with these goals.

Contrast Effects and Self-Regulation

DUAL-PROCESS MODELS

Most social psychological theory relevant to automatic processes postulates a distinction between automatic and controlled processes in which the latter modifies, inhibits, replaces, or enhances the former (Devine, 1989; Fazio, 1990; Fiske & Neuberg, 1990; Gilbert, 1999; Greenwald & Banaji, 1995; Smith & DeCoster, 1999; Strack & Deutsch, 2004; Thompson et al., 1994; Wegner & Bargh, 1998; Wilson et al., 2000).

Dual-process models (Chaiken & Trope 1999) assume, for example, that when a trait is automatically primed while one is inferring a trait from a behavior, correction may occur in an effortful manner. Correction was long considered essential in contrast effects (Martin, 1986), a process in which one adjusts an initial inference or judgment to satisfy a motive (e.g., to be unbiased). Correction models tend to assume that correction will not occur unless one is aware of a potentially biasing information source and has a theory about the direction of the bias, is also motivated to correct for it, and has the cognitive capacity to do so (Moskowitz, Skurnik, & Galinsky, 1999; Wegener, Dunn, & Tokusato, 2001). The response is then adjusted in a direction *opposite to* the perceived bias and in a magnitude commensurate with the bias's perceived magnitude. Contrast emerges from these regulatory steps when efforts to correct overshoot the mark—resulting in overcorrection (Martin, 1986; Martin et al., 1990; Moskowitz & Skurnik, 1999; Schwarz & Bless, 1992).

Using blatant priming, participants are more likely to see the connection between primes and the target judgments and this leads contrast effects to be shown (Lombardi, Higgins, & Bargh, 1987; Martin, 1986; Martin et al., 1990; Moskowitz & Roman, 1992; Moskowitz & Skurnik, 1999; Newman & Uleman, 1990; Strack, Schwarz, Bless, Kübler, & Wänke, 1993). Regulation in this process often involves subtracting the estimated bias contributed by the detected prime from judgments, which requires awareness of the prime. In such cases, initiation of correction is thus likely to be deliberate, even though the process may involve some automatic components. Often, when a contrast effect emerges in judgment following a blatant prime, people fail to report that the eliciting prime had any impact on the corrective judgment (e.g., Moskowitz & Skurnik, 1999), or that they had any explicit intention to correct (e.g., Wegener & Petty, 1995).

Deliberative corrective strategies depend on naive theories about what was influential and how it should be corrected. Even so, such theories can influence judgment without awareness (Anderson & Lindsay, 1998; Wegener, Petty, & Dunn, 1998). When people lack awareness that they implicitly used a theory in correction, they still show correction effects, such as by judging attractive vacation spots like the Bahamas against a high, abstract standard and Kansas City with a lower standard unless these places are compared directly (Wegener & Petty, 1995). When people are explicitly instructed not to be biased, they will rate Kansas City as much more desirable (compared with control participants), showing a different kind of correction and overcorrection with awareness (Wegener & Petty, 1995).

The latter is metacognitive in that it involves "thinking about thinking"—and is thus not fully implicit but involves judging whether one's own reaction is to be trusted, how one might adjust it, and how ongoing cognitive activity might have been influenced (Moskowitz, 2005; Skurnik, Schwarz, & Winkielman, 2000; Wegener et al., 1998). Such conscious processes are essential to our understanding of self-regulation and are not necessarily automatic. But although self-regulation is dictated by theories that implicitly influence judgments (and perhaps some consciousness), implicit processes are still integral. Indeed, explicit attitudes are intriguingly different from automatic ones in that people can alter explicit attitudes about groups when the attitude's basis is shown to be faulty but automatic prejudices remain largely unaffected (Gregg, Seibt, & Banaji, in press). Distinguishing automatic from nonautomatic self-regulation is thus critical.

STANDARD OF COMPARISON MODEL

Early work on contrast effects arose in the priming literature and showed that primed social knowledge that is moderate (i.e., not extreme) tends to produce judgments that assimilate a new stimulus to the prime, whereas primed categories that are extreme produce contrast (Herr, 1986). A standard-of-comparison model accounts for this by arguing that the triggered (primed) construct is used as a standard against which subsequent information is implicitly compared (Stapel & Koomen, 2001b). Ambiguous/vague behavior that is relevant to the prime and subsequently encountered is then assimilated to the primed construct given that the construct is moderate (Herr, 1986; Herr, Sherman, & Fazio, 1983; see Stapel, Koomen, & van der Pligt, 1996). The behavior is implicitly judged to be similar enough to the activated knowledge to fall within the range of acceptance. An extreme prime, by contrast, is dissimilar to whatever is judged next and thus this information/behavior is contrasted away from the primed construct to which it is implicitly compared. In this way, a contrast effect can arise as a form of automatic self-regulation as people pursue the goal of understanding new behavior. The comparison process is initiated and carried out without need of conscious monitoring or control (Moskowitz & Skurnik, 1999; Stapel & Koomen., 2001b), and even under cognitive load. As people pursue the distal goal of making meaning, using social comparison, and activated knowledge, they self-regulate based on standards or reference

points. In short, they appear to assume that moderate constructs (e.g., Bart Simpson), when primed, share features with a to-be-judged stimulus while extreme constructs (e.g., Hitler) do not. Donald may be hostile, but he is unlike Hitler.

INTERPRETATION VERSUS COMPARISON GOALS

The use of exemplars (Hitler and Bart Simpson) in describing the standard-of-comparison model is no accident. The standard-of-comparison model and correction models make opposite predictions about when contrast will occur. The former claims it occurs following extreme primes, while the latter claims it occurs following moderate primes (Moskowitz & Skurnik, 1999). However, research on the former tends to prime exemplars (nouns, often "proper" nouns) while the latter primes traits (adjectives). The two models describe different basic processes that produce contrast, each with a separate role for automaticity. Exemplar primes are used as standards of comparison that produce contrast through an automatic process of *comparison*, whereas trait primes serve as interpretive frames that produce contrast through conscious correction for perceived bias in judgment (with lack of awareness of the assumptions guiding the correction and perhaps of the fact (or degree) of the correction.

Given these distinct regulation processes, goal activation may play a central role in determining how activated constructs are used (Stapel & Koomen, 2001a). The goal to compare is likely to trigger standard-of-comparison-type processing (even when a trait is primed), while the goal to interpret is likely to trigger use of an interpretive frame (even though implicit, such as when a feeling of fluency is interpreted as being caused by a quality of the target). Research manipulating interpretive (vs. comparative) goals by means of instructions, followed by the activation of a relevant trait concept, results in different effects as a function of the goal (Stapel & Koomen, 2001a). With interpretation goals, activated concepts are used as interpretive frames resulting in assimilation. With comparison goals, contrast occurs. The primed concept thus serves as a standard. Interpretation and comparison are only a small subset of the goals people hold in social situations (e.g., see the discussion of cognitive dissonance below), but they are nonetheless quite important.

In summary, although some ways of conceptualizing self-regulation and self-control invoke explicit, conscious, or intentional processes, regulatory processes are not isomorphic with "conscious" control, because they can occur automatically (Custers, 2006; Fishbach et al., 2003; Förster & Higgins, 2005; Moskowitz, Skurnik, & Galinsky, 1999; Moskowitz et al., 2004; Shah & Kruglanski, 2002). In the attitude domain, even though automatic evaluation effects are facilitated by exposure to evaluatively congruent primes (Bargh et al., 1992; Fazio et al., 1986), this can be reversed when the primes are evaluatively extreme, and even when there is no intention to evaluate (Glaser & Banaji, 1999). One suggestion is that this contrast effect is evidence for regulatory processes that debias the effects of evaluatively extreme

primes, especially when subjects are motivated to respond accurately (Glaser & Banaji, 1999).

Most of these theories have been built on behavioral methods, and neurological investigations are also beginning to provide some converging evidence for the automatic- and controlled-processes distinction in evaluation. For example, a recent study presented Caucasian subjects with Black and White faces subliminally or supraliminally during event-related fMRI (Cunningham et al., 2004). For subliminal primes, the amygdala—a brain region associated with emotional processing of threat—was more active for Black versus White faces (see also Amodio et al., 2003). This supports prior research suggesting that automatic evaluation occurs and can do so without awareness of the eliciting stimulus. Furthermore, this difference in amygdala activation to subliminally primed faces was positively correlated with automatic evaluation on the IAT, $r (11) = .79$, $p < .01$. By comparison, when the faces were presented within conscious awareness (supraliminally), the difference in amygdala activation to Black versus White faces was significantly reduced, implying, perhaps, that other processes evoked by supraliminal presentation intervened in amygdala activation. Moreover, the difference in amygdala activation between the subliminal and supraliminal priming conditions was in fact correlated with activation of the dorsolateral PFC and the anterior cingulate, two areas of the brain associated with executive function and regulation (MacDonald, Cohen, Stenger, & Carter, 2000; Ochsner, Bunge, Gross, & Gabrieli, 2002). The latter finding thus lends some neurological support to the notion that automatic evaluation can be inhibited or suppressed by the introduction of controlled processing.

This hypothesis has also been tested directly by measuring ERPs among participants with strong automatic race-biased associations doing a task requiring the inhibition of racial biases (Amodio et al., 2004, in press). Higher levels of ACC activity, as indicated by the error-related negativity ERP component, predicted more controlled (i.e., less race-based) behavioral responses. Similarly, when individuals showing automatic racial bias engage in interracial interactions (Whites with Blacks), they self-regulate—and thus are slower afterward on a relevant Stroop color-naming task, suggesting resource depletion from that regulation (Richeson & Shelton, 2003). More to the point, those most impaired on the Stroop (who are also more implicitly biased) show more prefrontal activity (right dorsolateral PFC), as assessed by fMRI, when presented with Black faces, suggesting that such stimuli really evoke self-regulation, presumably due to social norms not to appear biased (Richeson et al., 2003).

Cognitive Dissonance and Self-Regulation

How do standards and expectancies salient at the time influence self-regulation? Cognitive dissonance is considered to be a negative drive state aroused when an individual perceives that he or she has more dissonant than

consonant cognitions about a particular entity. This aversive state motivates arousal reduction (Festinger, 1957), which can be accomplished through compensatory action (bringing behavior in line with cognition) or compensatory cognition (changing one's cognitions). The compensatory act alleviates the negative motivational state (Stone & Cooper, 2001). However, cognitions seen as dissonant in the context of one goal or standard may not seem dissonant in the context of another. Different types of behavioral discrepancies can trigger distinct motivational states within the rubric of dissonance (Stone & Cooper, 2001). Under some conditions, behavioral discrepancies trigger consistency-restoring responses—in upholding important attitudes (e.g., Harmon-Jones, Brehm, Greenberg, Simon, & Nelson, 1996). In other circumstances, dissonance motivates the reduction of aversive consequences of unwanted behavior, or the desire to affirm positive self-aspects, even those unrelated to the inconsistencies (e.g., Steele & Liu, 1983).

Evidence for automaticity in dissonance has emerged in that the various motivations that create dissonance—needs for psychological consistency, self-consistency, self-affirmation, reduction of aversive consequences—can be primed (Stone & Cooper, 2001). As an example, people high in self-esteem (vs. low) show more attitude change when implicitly primed with their *personal standards*. That is, they show more postdecision justification of a discrepant act. This dissonance reduction is evidence that dissonance motivation had been primed. By contrast, when implicitly primed with *normative standards* (e.g., "act as I should"), they show about the same level as do people low in self-esteem (Stone, 2001). Implicit priming in dissonance is also seen in priming dissonance reduction strategies as well as in priming arousal of dissonance motives. For example, dissonance reduction through use of self-resources for self-affirmation follows implicit priming of positive self-traits (e.g., I am creative) with behavior justification and counterattitudinal advocacy as the dependent variables (Stone & Cooper, 2003).

Dissonant cognitions can create tension, as can dissonance between a desired goal state and an actual goal state. Failure to attain a goal is thought to lead to a state of "incompleteness" that triggers compensatory responses, including automatic processes that prepare the individual for goal-relevant behavior. One such response to an incomplete goal is the automatic process of attentional selectivity to goal-relevant stimuli induced by failure in goal pursuit (Koole, Smeets, van Knippenberg, & Dijksterhuis, 1999). Having done poorly on a putative intelligence test involving unsolvable problems and thus failing at the self-image goal of being intelligent, participants first allowed to affirm an aspect of their self-image that was irrelevant to intelligence should presumably experience a buffer against the failure feedback. Indeed, a lexical decision task assessing implicit processes of facilitated attention to goal-relevant words showed that people who had not self-affirmed were faster to recognize words related to intelligence than those who had (or who received no failure feedback). Self-affirmation blocked selective attention, suggesting that attentional selectivity

repaired the tension associated with the failed goal pursuit. The mechanism underlying these effects is thought to be tension reduction. Unfulfilled goals evoke tension, which then evokes a drive to reduce. Such a reduction can be achieved by preparing to detect and pursue goal-relevant objects to compensate for the shortcoming by. Once the tension is repaired (as through affirmation), the process is shut down (e.g., Moskowitz et al., 2004).

Regulatory Focus and Self-Regulation

Once self-regulatory focus is activated, there is an automatic inclination to pursue goals, solve problems, and make decisions with this specific and distinct strategy. Regulation through approaching desired (ideal) states is *promotion focus*, while regulation through avoiding undesired states (which would result from behaviors one ought not to do) is *prevention focus* (Higgins, Roney, Crowe, & Hymes, 1994). The regulatory focus that becomes accessible during goal pursuit affects how goals are pursued. The same goal can be pursued through prevention or promotion, altering cognitions and behaviors (Förster et al., 1998; Förster, Higgins, & Strack, 2000; Friedman & Förster, 2001; Grant & Higgins, 2003; Higgins & Spiegel, 2004; Idson, Chen, Liberman, & Higgins, 2000; Shah & Higgins, 2001; Shah, Higgins, & Friedman, 1998).

A regulatory focus can be implicitly primed by leading people to think about achieving ideals or about preventing negative outcomes, while unaware of the influence that this framing has on their performance. People who are told they can earn extra money by performing at a certain level (inducing promotion focus) or can avoid losing money by such performance (inducing prevention) show regulatory focus effects (Förster et al., 1998). Asking people to solve the puzzle of finding a way for a rat to get out of a maze can also prime regulatory focus. The task is framed as a helping task implicitly when the route is to a piece of cheese versus the route to escape a hovering predator (Friedman & Förster, 2001). Behavioral measures of implicit promotion and prevention focus have also been associated with approach- versus avoidance-related patterns of neural activity, respectively (Amodio et al., 2004).

In this process, promotion focus induces a cognitive style characterized by "strategic eagerness" and prevention focus induces an inclination toward "strategic vigilance." People primed with a promotion focus generate more alternative hypotheses than those primed with prevention (Liberman, Molden, Idson, & Higgins, 2001)—when viewing ambiguous objects and asked to list as many identities for the objects as possible. Under promotion (vs. prevention), they are also faster in generating each hypothesis. After reading a scenario about someone performing helpful acts that could be situational or dispositional in cause, those in promotion focus show a positive association between these explanations, whereas those in prevention focus show a negative association, suggesting that promotion-primed participants are more open to alternative hypotheses about the causes of behavior.

The evidence reveals enhanced memory for stereotype-inconsistent information in promotion focus, especially when people are prejudiced because stereotype-inconsistent behavior then represents an even greater mismatch from expectations (Förster et al., 2000). Promotion focus should also be a riskier cognitive style and should lead to particularly speedy responses, whereas prevention focus should foster caution and accuracy. In promotion focus, people are in fact faster, especially when goal attainment is imminent, while in prevention focus there is more accuracy than speed (Förster, Higgins, & Bianco, 2003). Regulatory focus is also evoked when a new person with features of one's parent activates this parental representation and the parent's standards, which then guides self-regulation (Andersen & Chen, 2002; see also Shah, 2003b). The general point is that regulatory focus, when evoked, changes how contextual cues are processed and pursued.

In short, the influence of promotion and prevention orientations is automatic, as is the influence of the strategic inclinations with which they are linked, and each can activate the other. The orientations are broad and encompass many types of goals, including new, situated goals, and the inclinations general in that they can be realized with a variety of means, including new, situated means. The model thus extends beyond those targeting goal–means associations already established in memory (e.g., Bargh, 1997; Gollwitzer, 1999; Kruglanski et al., 2002), and once activated, these orientations implicitly influence processing.

Availability: Acquisition of Automaticity

Mechanisms of Acquisition in Automaticity

PRACTICE

The question of *how* automaticity is acquired is addressed by evidence showing that repetition of trait inferences leads to their automatization. For example, practice in inferring intelligence based on behaviors leads people to make such judgments more quickly and efficiently, and also to rate intelligent but unfriendly behaviors more positively (relative to practice in inferring friendliness) (Smith, 1989). This suggests that procedural efficiency may be misattributed to desirability (Smith, 1989; see also Monahan, Murphy, & Zajonc, 2000; Winkielman & Cacioppo, 2001). Research on spontaneous trait inferences has also shown that practice influences acquisition (Bassili, 1993; see Winter & Uleman, 1984).

In the literature on automatic evaluation, repetition is also influential. A prominent example is shown in the mere exposure effect (Zajonc, 1968). Repeated exposure to a stimulus object increases its ease of processing on subsequent presentations (Gordon & Holyoak, 1983). Such enhanced fluency is thought to produce a positive feeling of familiarity associated with the object, and the evaluation of novel stimulus objects can be acquired on this basis, even when the repetition is subliminal (Bornstein, 1989; Kunst-Wilson & Zajonc, 1980). Practice thus offers a means of automatic attitude acquisition. Practice in expressing attitudes can also lead to height-

ened attitude accessibility in terms of response latency and to greater attitudinal certainty (Holland, Verplanken, & van Knippenberg, 2003). Significant-other representations are also likely to be acquired in part based on repetition as people regularly interact with significant others, as the classic practice effect of consolidating memory and increasing positive evaluation (Chen & Andersen, 1999).

Acquisition of automatic self-regulation has also been shown based on practice in *not* resorting to the use of stereotypes. This can alter automatic responses. When people repeatedly practice negating stereotypes that they hold (e.g., about skinheads or racial groups), they show reduced stereotype activation. Using a priming-based Stroop task or a person categorization task shows diminished stereotype activation among those who practiced stereotype inhibition versus those who did not. Whereas this speaks more to diminished accessibility than to the altered availability of stereotypes in memory, it suggests that practice in negating stereotypes increases participants' proficiency in doing so, and this may occur by means of restructured associations in memory (i.e., the existence of incompatible associations) (Kawakami et al., 2000).

As with other social knowledge, research on goals suggests that routine pairings of goals with specific environments, and practice at pursuing a goal in a specific context, enable links to be forged in memory between goals and the environments in which they are pursued (Bargh, 1990; Bargh & Gollwitzer, 1994; Bargh et al., 2001). The goal is thus ultimately responsible for the repetition and for the habitual response (Aarts & Dijksterhuis, 2000). "Learned sequences of acts . . . become automatic responses to specific cues, and are functional in obtaining certain goals or end states" (Verplanken & Aarts, 1999, p. 104). Repetition increases efficiency in goal-related cognition until consciousness is unnecessary for goal pursuit (Bargh, 1990). The link between the relevant situation or cue and the goal becomes available in memory and can thus be activated and manifested in behavior (e.g., Aarts & Dijksterhuis, 2000, 2003).

CLASSICAL CONDITIONING

Attitudes can, of course, be classically conditioned as when unconditioned stimuli (e.g., positive or negative facial expression) are presented subliminally as primes (Krosnick, Betz, Jussim, Lynn, & Stephens, 1992) or as simultaneous stimuli (Olson & Fazio, 2001). Positive classical conditioning toward the self can be produced as well by repeatedly pairing smiling faces with self-relevant information in a computer game (Baccus, Baldwin, & Packer, 2004; *www.selfesteemgames.mcgill.ca*).

Acquisition of automatic attitudes can also involve physiological feedback. For example, exposure to novel stimuli while one's arm is flexed—as if pulling something toward the body—results in positive evaluations of those stimuli. Negative evaluations arise after exposure to items encountered when the arm is extended—as if pushing something away from the body (Cacioppo, Priester, & Berntson, 1993). These acts appear to operate as physi-

cal indicators of approach and avoidance and thus serve as information in acquiring evaluations of the stimuli. Moreover, recent research suggests that whether approach-and-avoidance motions lead to positive or negative evaluations is itself contextually situated, with approach enhancing positivity for positive things but not for negative, and vice versa for avoidance (Centerbar & Clore, 2006). Although not challenging the overall effect, this focuses again on context-based variability.

CONSTRUCTING LINKS TO THE SELF

Another mechanism of acquisition for automatic evaluation is based on group membership, such as that found in the minimal group paradigm (Tajfel, 1970; Tajfel, Billig, Bundy, & Flament, 1971). That is, liking for one's own group occurs even when the group and one's membership in it are random or fleeting (see also Ashburn-Nardo, Voils, & Monteith, 2001; see also Otten & Moskowitz, 2000; Otten & Wentura, 1999). Participants placed in a rather meaningless group that preferred the art of one painter (Quan) versus another (Xanthie) later showed an automatic preference for their own group compared with the other group, especially among those who were feeling angry (DeSteno, Dasgupta, Bartlett, & Cajdric, 2004). Automatic preferences can also develop even when people are not assigned to be a member of a particular group (Greenwald, Pickrell, & Farnham, 2002). People who are simply exposed to group members tend to like the group and identify with its members immediately and implicitly, as compared with an unknown group. Self-categorizing an object or group thus leads to some modicum of positive evaluation.

Early Acquisition of Concepts in Development

Humans expend considerable energy making sense of their environments, determining what particular social and nonsocial objects are, and ascertaining what qualities and functions those objects may have. Developmental research suggests that children infer stable traits in others by ages 9–10, whereas prior to that (e.g., ages 5–6) tend to rely on more basic evaluation (Alvarez, Ruble, & Bolger, 2001). At ages 9–10, trait concepts also mediate behavioral predictions in that children predict behavior in new situations to be consistent with prior behavior and relevant trait inferences, suggesting that the use of dispositional trait concepts emerges at this later moment in childhood (Rholes & Ruble, 1984). Children ages 9–10 even make spontaneous trait inferences to a greater extent than do adults (college students) (Bassili, 1993), suggesting the tendency to make automatic trait inferences may be acquired developmentally.

Developmental research also shows object-evaluation associations early in childhood, at least by ages 5–6 when they are clearly operative in judgments about others (Alvarez, Ruble, & Bolger, 2001; Ruble & Dweck, 1995). The evaluative component of categorization is well in place by ages 4–6 (Aboud, 1988), although children may not yet know stereotypes of various ethnic groups and may nonetheless show effects in evaluation. This is of in-

terest in part because stereotypes and attitudes can be automatized through direct and indirect socialization (Devine, 1989; Greenwald & Banaji, 1995; Smith & Decoster, 1999). Societal or cultural effects are suggested most clearly in the fact that societally disadvantaged groups show lower levels of automatic ingroup bias (and may even favor outgroups) on implicit bias measures and yet show high levels of explicit ingroup bias (Hummert, Garstka, OBrien, Greenwald, & Mellott, 2002; Lane, Mitchell, & Banaji, 2005; Livingston, 2002; Nosek, Banaji, & Greenwald, 2002a; Rudman, Feinberg, & Fairchild, 2002). Automatic stereotypes may thus be ingrained through socialization, even if the stereotypes contradict endorsed beliefs. Recent research shows that implicit and explicit attitudes have different developmental trajectories. Even young children (6-year-olds) acquire implicit racial attitudes, which remain strong in older children and adults (Baron & Banaji, 2005; Dunham, Baron, & Banaji, 2006), while explicit racial bias is less apparent in older children and often absent in adults (Baron & Banaji, 2006).

Group stereotypes and intergroup evaluations also arise in development as linked with the functional significance of the category (Bigler, 1995). Children 6–11 years of age randomly assigned to a condition in which gender has functional uses in their classroom (for 4 weeks; e.g., sex-segregated seating and bulletin boards) acquire pronounced occupational stereotypes defined by gender. Minimal group membership effects can also be produced at the same age if the classification is functional (Bigler, Jones, & Lobliner, 1997). Randomly assigning children of this age to a "red" or "blue" group used in class seating arrangements (vs. to no category or no functional category) leads to more intergroup bias after 4 weeks, even in the absence of any explicit evaluative differences. In addition, when one of the assigned groups is implicitly depicted as relatively low in status, the ingroup favoritism effect occurs for children in the high-status group but not in the low-status group (Bigler, Brown, & Markell, 2001). Categories with functional uses in one's environment become salient and are used repeatedly, suggesting a mechanism by which social categories become associated with beliefs and come to function automatically.

Given that stereotypes tend to be noun categories and traits attribute categories, it is of interest that noun categories are learned earlier in development than are adjective categories (Gelman & Markman, 1985; Gelman & Raman, 2003). Children as young as 2 label abstract objects with noun phrases and, by age 3, refer to attributes in a stimulus or context, such as an object's color. Certainly, children 3–4 years of age use category membership (noun labels) more than perceptual features (adjectives) in their inferences, suggesting that the noun–adjective distinction arises rather early as well, and far earlier than dispositional trait inferences (age 9; Alvarez et al., 2001). Indeed, the distinction between generic categories and exemplars (a specific object or person) also develops early and is in place by the age of 2 (Gelman & Raman, 2003). Early development of significant-other representations is supported too, unsurprisingly, in re-

search on face recognition showing that infants can readily distinguish familiar and unfamiliar faces in the first several weeks of life (Meltzoff & Moore, 1992; Pascalis, de Schonen, & Morton, 1994).

Significant others are present early in life and such representations are thus acquired early. Beginning with rudimentary caretaker representations acquired in infancy as working models (Thompson, 1998), socialization and development enrich what is represented, for example, among preschoolers (as assessed through mommy or daddy narratives; Oppenheim, Emde, & Warren, 1997; Toth, Cicchetti, Macfie, & Emde, 1997). Additional significant-other representations also form throughout childhood (Rudolph, Hammen, & Burge, 1995; Ryan, Stiller, & Lynche, 1994) and adulthood (Brennan & Morris, 1995; Collins & Read, 1994; Hazan & Shaver, 1994; Mikulincer, 1995; Simpson & Rholes, 1998), and their acquisition plays a profound role in the self-concept (Aron, Paris, & Aron, 1995; Baldwin, 1992; Higgins, 1989). Hence, these representations constitute a constrained class of concepts in how they are represented and in the processes by which they are formed. This makes creating actual (but temporary) significant-other "relationships" in laboratory settings almost impossible or at least a poor analog for how they function in real life, limiting the kinds of research that can be done on acquisition of such representations. Once specific significant-other representations develop, however, they can be generalized to other people (e.g., Andersen et al., 1996). Even in 8- to 12-year-olds, caretaker representations predict adjustment and in fact mediate peer rejection (Shields, Ryan, & Cicchetti, 2001), although it remains to be seen whether or not parental representations literally serve as the basis for subsequent significant-other representations or for generic person prototypes.

In sum, the acquisition of social knowledge and its development in children and adults is what determines availability and heightened accessibility based on context. Existing evidence in social cognition, however, has offered relatively few insights thus far about how learning occurs in associative memory. In behavioral neuroscience, learning can be studied at the level of the individual synapse. When stimulus meets response in reliable fashion, weighting processes occur and an association is learned. The ability for such reorganization of synaptic strengths to occur is what defines plasticity and accounts for learning (e.g., Bailey & Kandel, 1995). When an association between cue and response is automated, it is presumably because a stable change in the pattern of synaptic weights has occurred (i.e., plasticity). Hence, if one wants to know how information is made available (learned), it may be in part to this level of analysis that one must turn. Of course, the study of individual synapses is typically done in nonhuman organisms. At the level of "mind" studied in social psychology, the simple assumption is made that experience allows for learning and enables those formed associations to become more accessible if contextually cued. In neuroscience, long-term, stable changes in neural activity in response to experience are studied in humans and higher-order mammals

through cortical mapping (e.g., Kaas, 1995; Wiesel & Hubel, 1965) and practice (e.g., Pascual-Leone, Amedi, Fregni, & Merabet, 2005). It is our view that more research on such problems is needed in our field that spans multiple levels of analysis—from child development to practice effects as well as to classical conditioning and cortical mapping (and even synaptic mechanisms if ever feasible). More extensive research on how social knowledge becomes available is necessary if automatic thought is to be fully understood.

CLOSING REMARKS

In conclusion, what is known about automatic thought has continued to grow at a steady clip over the last decade. It is ever more clear that vast reaches of what is commonly considered *thought* may not be particularly conscious, effortful, intentional, or controllable. The basic processes by which automatic thought transpires (availability, accessibility, application, and self-regulation) are rather well understood, and yet numerous questions about them remain. When seen through the lens of the wide swathe of research literatures we address, which range from traits, stereotypes, and attitudes, to interpersonal relationships and to motives and goals, there are emergent themes that come to light that we conclude constitute the basic principles of automaticity. In particular, we argue that automaticity and control are not discrete, opposing processes; that contexts and situations, and all the complex cues therein, are crucial to what automatic thought then arises; that self-regulation occurs without need of conscious will; that social knowledge becomes available to the perceiver (is learned) through practice and repetition in conjunction with developmental processes and also synaptic mechanisms in the brain, thus enabling the shift from conscious to automatic thought; and that automatic processes occur concurrently with the recruitment of specific brain regions and functions. We believe these principles add texture and nuance to existing knowledge and prompt us to probe pressing questions on which the research has thus far been silent. Much is known, but much remains to be seen.

NOTES

1. It is worth mentioning that we conceive mental representations simply as collections of related knowledge in memory.
2. We recognize that this is a working list of principles, and like any such summary or list, it is imperfect and in progress as science is. Still, it reflects a reasonable approximation of what is now known in the field.
3. Both spreading activation and connectionist models involve the manner in which relevant cues shift activation.
4. This effect is not reducible to what occurs based on social categories because the effect that occurs for categories is less pronounced (Andersen & Cole, 1990; Chen et al., 1999), nor is it reducible to what is observed for a nonsignificant other (e.g., Andersen et al., 1995).
5. Baseline measures of overlap between the overall self-

concept and the self-with-the-other (and of self-evaluation reflected in these features) are assessed so that they can be controlled when assessing increases in this overlap score in the experiment and in associated self-evaluation.

CHAPTER 8

Information Ecology
and the Explanation
of Social Cognition and Behavior

KLAUS FIEDLER

To understand the structure of the human mind and the psychological processes within the individual, we first have to consider the texture and contents of the stimulus environment that impinges on the individual's mind. Some of the most influential theorists—Lewin (1951), Brunswik (1956), Simon (1956), and Gibson (1979)—have articulated this fundamental insight many decades ago. In current scientific psychology, these claims have been widely accepted and regularly cited. However, in reality the confession that ecology matters comes more like a truism that hardly needs to be substantiated than like a necessary ingredient for sound research and theorizing. No doubt, the ecological part in the inseparable interaction of the mind and the environment has been widely neglected. Half a century after Lewin, Simon, and Brunswik, and 25 years after Gibson, it must be admitted that there is little room for ecological concepts in contemporary social psychology. No major textbook or handbook so far has covered the topic of the present chapter, information ecology. When a textbook chapter is exceptionally devoted to the "environment," the term is meant in a different way, referring to stress, crowding, or environmentalist behavior rather than ecological constraints on information processing. The same negative conclusion—it should be added quickly—can be drawn for the entire discipline of scientific psychology as it has rapidly grown and flourished throughout the last five decades.

To be sure, there have always been notable exceptions to this negative appraisal, which are consensually cited as testimony for an ecological approach (Neisser, 1985; Zebrowitz-McArthur & Baron, 1983). However, these contributions, important and prominent as they do appear, can be characterized as unusual, alternative approaches that supplement the mainstream paradigms, rather than merging with cognitive theories to yield new models and research designs that take both parts into account, the mind and the environment. The current social psychology was hardly influenced by Simon's (1956) metaphor that mind and environment have to collaborate like the two blades of a pair of scissors, well adjusted to each other and equally important (Gigerenzer, 2004b). There is no conceptual role played by ecological variables in the most influential theories and paradigms, such as theories of implicit cognition and priming, social comparison, intergroup relations, stereotype threat, mortality salience, motivated processes, aggression, and prosocial behavior. One might conjecture that, as a matter of fact, theorists claim all the time that stimulus learning underlies implicit cognition, that aggression reflects the media environment, that stereotypes depend on culture, or that social cognition is domain specific. However, granting this truism that all behavior has its original learning input, which depends on historical, cultural, and contextual moderators, the leading theories no longer seem to require ecological variables, which are deferred to the background.

PREVIEW OF THE PRESENT CHAPTER

Given the wide neglect of the present chapter's topic, or the mere background role assigned to ecological factors, the format and organization of this chapter will slightly

deviate from a common handbook frame. Both the explicit, acknowledged role of information ecology in social psychology as well as its implicit, unrecognized role played "under different conceptual cover" are examined in the following sections:

- A brief historical overview of major conceptual origins of genuinely ecological ideas provides a starting point, along with a short discussion of how they map onto modern social and cognitive psychology.
- As the conceptual underpinnings required for ecological theories have not been developed to a similar degree as cognitive, motivational, or personality theories, considerable space is devoted to introducing such common ground.
- Drawing on this conceptual framework, a review of pertinent research covers both explicitly ecological research and implicit contributions traditionally treated under different cover.
- Particular attention is given to alternative explanations of well-established findings, which have to be revisited as ecological factors are taken into account.
- Quite uncommon for a handbook chapter, but appropriate to the present topic, the review of research is supplemented with previews of research that has not yet been done but that strongly suggests itself for future research.

MAJOR ORIGINS, IN HISTORICAL PERSPECTIVE

Shared Ecological Premises in Psychological Science

The conviction that human beings—like all living creatures—must reflect to some degree the social and physical environment in which they are embedded is uncontested. The whole behaviorist research program (Kimmel, 1970; Skinner, 1984) with its radical emphasis on environmental stimuli as determinants of behavior and its neglect of constructive, creative, self-generative cognitive processes within the organism's mind can be considered a historical antecedent of ecological theorizing. However, apart from the central role assigned to the stimulus, assumptions about the structure of the stimulus environment in the real world are virtually missing in prominent behaviorist models (cf. Rescorla & Wagner, 1972). Learning and conditioning have been explained in terms of organisms' performance rather than ecological constraints, such as the distribution of reinforcement schedules in different parts of the world, the problem of how to segment the world into discrete stimuli, the construction of complex compound stimuli, or the measurement of the adaptive value of learned responses.

Not too remote from behaviorism is the biological and ethological approach to behavioral science (Eibl-Eibesfeldt, 1975; Lorenz, 1978). Just as animal behavior is attuned to the restrictions of the environment and the filters of phylogenetic learning and evolution, human behavior may be understood in broad biological terms. From such a perspective, it seems clear that aggression relates to territories, that attraction is limited by incest

barriers preventing young animals from choosing their mating partners among close relatives, or that specific signals can strongly influence instinctive reactions. Although such insights have been adopted from ethology, they continue to exert little influence on modern social psychology. These notions are not central for current theories of aggression, attraction, or emotion, with very few exceptions (Bischof, 1972).

Similar points could be made for social psychology's interface with macrosociology, as exemplified in the notion of social–economical status (Bornstein & Bradley, 2003), or microsociology, as exemplified in symbolic interactionism (Goffman, 1990; Mead, 1934). Both perspectives highlight the truism that individuals are but small pieces in a larger whole of society and societal games. But although celebrated in their respective areas, both perspectives did not contribute much to the development of a comprehensive conceptual framework of ecological variables. To be sure, symbolic interactionism reappears in Snyder's (1984) influential work on social hypothesis testing, or in Schlenker (1985) work on self-presentation, but it had little systematic impact on methods, research designs, and the structure of modern theories.

Seminal Contributions to Ecological Theorizing

Aside from those general precursors in psychology and neighboring disciplines, the roots of ecological theorizing can be found in the seminal work of a few pioneer scholars. One of them, Kurt Lewin, became very prominent in social psychology and inspired many leading researchers and paradigms. Another pioneer, Egon Brunswik, remained a tragic figure. After committing suicide, he continued to be widely ignored in social psychology. He had a stronger influence, though, in some areas of decision making and personality assessment.

The dominant metaphor for Lewin's (1951) ecological approach was the notion of *field theory*, conceived quite analogous to magnetic, electrical, or gravity fields. Accordingly, behavior is not only a function of organismic factors but also of the surrounding environment. Social-impact theory (Latané, 1981; Latané & Wolf, 1981) provides a prototypical example of how the field metaphor influenced psychological theorizing. Just as the illumination of a given point in space is a joint function of the number, the distance, and the strength of surrounding lightbulbs, the social impact that impinges on an individual is conceived as a function of the number, the (social or physical) distance, and the power (status, attraction, amount of resources) of other people. Social-impact theory accounts for many empirical phenomena, such as diffusion of responsibility (Pruitt & Teger, 1969), or the relative influence of majorities versus minorities (Nowak, Szamrej, & Latané, 1990; Latané & Wolf, 1981; Wolf, 1987).

The leading metaphor in Brunswik's (1956) work is his *lens model*, which describes the process by which ecological entities that are not themselves amenable to direct perception (e.g., distance of a stimulus object) can be inferred from more proximal, observable cues (disparity of retina images, surface texture, lightness, echo, etc.).

These cues provide the lens, as it were, through which the organism perceives the environment. The "ecological validities," or diagnosticities, of individual cues are typically rather modest. No single cue is indispensable, but cue substitution is crucial for Brunswik's probabilistic functionalism; if some person has but one eye, the central disparity cue in depth perception is compensated by other cues. Nevertheless, through parallel processing of multiple cues, one can reach a remarkable degree of accuracy (Funder, 1995; Kenney, Horber, Kashy, & Chu, 1992), even in highly fallible, probabilistic environments.

Gibson's (1979) seminal work was originally confined to visual perception, where it is perfectly clear that stimulus attributes (e.g., color) have to fit the properties of receptor organs (sensitivity to specific wave length). However, Gibson's approach turned out to be applicable more broadly to the adaptive fit between organisms and their physical and social environment (Valenti, Hofstra, & Good, 1991; Zebrowitz, 2002).

CONCEPTUAL UNDERPINNINGS FOR COGNITIVE–ECOLOGICAL RESEARCH

No doubt, the famous ecologists introduced in this historical sketch testify to the existence of ecological perspectives. Yet, their systematic impact on current theories and research methods remained modest, as already noted. Indeed, the topic of the present chapter—the information ecology providing the input to all cognitive processes—is so uncommon that a conceptual framework has to be developed first, before pertinent research can be reviewed. The framework to be outlined in this section consists of three facets: (1) the distribution of stimulus information; (2) the topology of environments experienced from different perspectives; and (3) the constraints imposed on the sampling of environmental information. Within all three facets, or basic principles of the information environment, more fine-graded distinctions between important features of the information ecology can be drawn (cf. Table 8.1).

Distribution of Stimulus Information

Three aspects of the distribution of stimulus information are of principal importance for the cognitive–ecological interface, the *density* of information in different parts of the world, the *variance* of information, or change in density, and the *redundancy* structure of the available stimulus data. It has become common sense that social cognition is a function of what subset of information happens to be accessible in memory, but the more fundamental question of what information the stimulus ecology renders available is rarely considered in models of judgment, decision making, attribution, and behavior.

Although Internet and mass media render most sources of information available, the information to which a particular person is actually exposed is multiply restricted in terms of language, culture, highly selective mass-media coverage, education, specific music, food, advertising, sports news, and societal topics experienced from a particular political viewpoint. What renders this selectivity of environmental input important and influential is that strong cognitive and behavioral biases can arise in completely unbiased people, just because the input is biased. It is crucial to recognize that the samples of information to which individuals are exposed are virtually never random. On one hand, the individual receiver exerts a selective bias on the information input due to her location in time, space, and social context (e.g., the subculture of other undergraduates). On the other hand, the providers of information impose restrictions on the information conveyed. Thus, consumers are unlikely to learn about negative aspects of products, because producers won't reveal such data, the media won't be paid for such information, and rival producers will not dare to publish negative information about others' products for legal reasons.

Similarly, social interaction will show a positivity bias (Kanouse & Hansen, 1972; Parducci, 1968) in that interaction (discussion, exchange, negotiation, dating etc.) with others is likely to stop when it is unpleasant but likely to continue when it is pleasant (Denrell, 2005). The opposite can also be true, though, as expressed in Ditto,

TABLE 8.1. Conceptual Framework and Terminology Required to Delineate the Role of Information Ecology

Aspects of the distribution of stimulus information	Topologies creating asymmetries	Sampling strategies
Density of information about different categories	Self–other asymmetry	Natural (unconditional) random sampling
	Ingroup–outgroup relation	Output-bound sampling
Variability	Old–young asymmetry	Input-bound sampling
Redundancy	Principal-agent relation	Sampling by availability
	Distant versus close in time	Sampling by social rules
	Distant versus close in space	Emergent sampling in group interaction
	Distant versus close in culture	Self-generated sampling
	Status asymmetry	Sampling of aggregate versus individuating information
	Actor versus observer perspective	

Munro, Apanovitch, Scepansky, and Lockhart's (2003) evolutionary thesis that organisms may invest more in processing aversive than pleasant stimuli (Ditto, Scepansky, Munro, Apanovitch, & Lockhart, 1998). Other biases in the information supply are equally sensible: Simplifying and commonly shared information is more likely to be broadcast than complicated (though often more accurate) information. News that is consistent with prior knowledge will be encountered, and actively solicited, more often than expectancy-inconsistent information (Frey, 1986; Jonas, Schulz-Hardt, Frey, & Thelen, 2001). Or, shared information is more likely to be raised in group discussions than new, unshared knowledge (Stasser & Titus, 1985; Wittenbaum, Hubbell, & Zuckerman, 1999), even when the latter is more informative.

As a consequence of such pervasive biases in the information ecology, the resulting information input is constrained in three psychologically important respects: density, variability, and redundancy. All three aspects have a profound impact on environmental learning. *Density* refers to the frequency of pertinent observations, thus constraining the number of learning trials on a topic afforded by the environment. Of two equivalent stimulus objects (e.g., two consumer products of equally high quality), the one object with the higher frequency or density of exposure is likely to be preferred just because there are more opportunities to learn about this object's assets (Fiedler, 2000a; Fiedler, Walther, Freytag, & Plessner, 2002; Shavitt, Sanbonmatsu, Smittipatana, & Posavac 1999). Similarly, of two equally aversive stimuli, the one that is met with higher density is likely to be feared and avoided more, as we know from aversive-conditioning experiments, in which the strength of an escape or avoidance reaction increases with the number of trials.

To understand the impact of *variability*, the analogy to learning experiments is again helpful. Just as a partial reinforcement schedule, in which an unconditioned stimulus (US) does not occur on all trials, makes learning resistant to extinction, a stimulus that varies (in terms of presence, quality, and appearance) keeps the environmental learning process active and alerted. It is a well-established empirical fact (Kamin, 1968; Rescorla & Wagner, 1972) that learning decreases and ceases as a stimulus can be predicted with perfect certainty and loses all surprise value. Variability can also influence adaptive-behavior strategies. To keep within the consumer example, a variable market environment not only keeps the consumer alert but also prevents her from developing too rigid routines and facilitates her trying out different strategies, which is important for adaptive learning in changing environments.

Finally, the notion of *redundancy* refers to environmental correlations that hold between different stimulus aspects. Social individuals—like organisms in general—are highly sensitive to all kinds of stimulus redundancies that help them to detect regularities in the environment (Garner, 1974; Melara & Algom, 2003), such as contingencies between causes and effects, signals and dangerous events, or stimulus aspects that seem to go together, like price and quality of consumer products. In a complex ecology, redundancy facilitates discrimination (Eiser & Stroebe, 1972; Tajfel, 1957). Thus, having noted the (apparent) correlation between price and quality, the consumer can use price as a proxy for inferring the quality of products, which is not visible at first sight.

All three aspects of the distribution of environmental stimuli, their density, variability, and redundancy, can have a profound influence on learning and adaptation. All three aspects will thus play an important role in the interpretation of the empirical findings to be reviewed in the next section. At the conceptual level, the abstract notions of density, variability, and redundancy, which refer to environmental structures, are related to corresponding cognitive notions, just as in psychophysics sound pressure corresponds to loudness, or wave length to perceived colors. In the same vein, the notion of density is related to the more familiar subjective experience of (high base rate) expectation. Variability relates to uncertainty or risk experience, and ecological redundancy corresponds to perceived or learned contingencies. It is typical of an ecological approach to cognitive information processing that familiar cognitive variables have to be complemented with less familiar ecological variables.

Topology of Environments from Different Perspectives

The very location and movement of individuals and groups in the environment creates asymmetries and distinct topological relations, which are at the heart of many phenomena in social psychology. One particularly prominent topological feature of the information environment is the *self–other asymmetry*—one of the first distinctions acquired in infant learning. Similarly, the *ingroup–outgroup asymmetry* is central to the social psychology of stereotyping, discrimination, and intergroup relations (Pettigrew, 1986; Tajfel & Turner, 1986). The amount and structure of information that is available about one's ingroup (and self) differs markedly from the information one has about outgroups (others) in terms of all three aspects—density, variability, and redundancy. As a matter of rule, both the density and the variability of ingroup-related and self-related information are higher than for outgroup-related and other-related information, just because one is closer to the self and one's own group than to others and other groups. This asymmetry contributes to various phenomena, such as the self-serving bias (Pronin, Gilovich, & Ross, 2004; Zuckerman, 1979), the ingroup-serving bias (Brewer, 1979), the actor-observer bias in attribution (Jones & Nisbett, 1972; Watson, 1982), or the outgroup homogeneity effect (Judd & Park, 1988; Park & Rothbart, 1982). Assuming the same prevalence of desirable over undesirable behavior in an ingroup (self) and an outgroup (other), the unequal density will make the prevalent desirability more apparent for the ingroup—thus resulting in ingroup favoritism. Likewise, because of the relative paucity of outgroup

(other-related) information, its variability will not be as apparent as for the ingroup—thus producing the illusion of outgroup homogeneity (Judd & Park, 1988).

The asymmetry in redundancy is slightly more complicated. The correlational structure of traits attributed to an outgroup, or a distant group, tends to be simplified, suggesting a halo effect (strong correlations among traits sharing the same valence) and a low-dimensional factor pattern (Liberman, Sagristano, & Trope, 2002; Linville, Fischer, & Yoon, 1996). Nevertheless, more complex patterns of actually existing correlations may be more evident for an ingroup, due to richer input information (Fiedler, Kemmelmeier, & Freytag, 1999; Linville, Fischer, & Salovey, 1989). In any case, the asymmetries of judgments and attributions that inevitably arise between self and others, between ingroups and outgroups, or more generally between close and distant targets, cannot be explained in terms of biased cognitive and motivational processes alone. To understand the nature of these phenomena, the density, variability, and redundancy of the pertinent information has to be taken into account.

One particularly prominent consequence of the self–other asymmetry is the actor–observer effect (Jones & Nisbett, 1972; Malle & Knobe, 1997; Watson, 1982), that is, the tendency to attribute others' behavior to internal dispositions and personality factors but to attribute one's own behavior to external, situational circumstances. Although a number of different factors contribute to this bias, one major determinant lies in the respective information environments. The perceptual field of actors judging their own behavior is directed toward other people and the surrounding situation, whereas observers typically focus on the actor whose behavior they are to judge, as the vivid figure against the ground (Storms, 1973). Conversely, actors possess more background information about the history and the external stimuli and motives that have triggered their behavior than observers do.

Other, less prominent asymmetries can have similar effects. For instance, old people know more about being young than young people know about being old. Judgments and stereotypes of old versus young people are likely to be influenced by this asymmetry in the information ecology. Comparable to the *old–young asymmetry*, migrants (unlike immobile residents) are exposed to other people and cultures from more than one perspective, or androgynous people experience life from both masculine and feminine perspectives. A whole variety of asymmetries and topologies can be generated from the concept of *psychological distance*, as raised by Lewin (1951) and recently refined by Trope and Libermann (2003). In addition to the perspectival distance between self and others, ingroups and outgroups, familiar people and strangers, psychological distance can refer to space, past and future time, status and power, or affective involvement. Common to all these distance dimensions is that information input about remote targets differs systematically from information about close targets, for ecological reasons alone.

Sampling Constraints

Whereas the topological relations considered so far place hard constraints on the distribution (i.e., density, variability, and redundancy) of stimulus input, the remaining facet of the information ecology entails a number of soft constraints that are imposed on the sampling of information. The process of information sampling involves a genuine interaction between human beings (or, more generally, organisms) and their social and physical environment. This interaction is not fully determined by the structure of the external world alone but is to a large extent contingent upon the organisms' actively chosen standpoints, movements, strategies of information search, and the ways in which organisms shape their own environment. A considerable part of the information that impinges upon human's sensory system—through conversation, literature, mass media, internet, teaching, or advertising—is self-made, reflecting human products or artifacts.

Thus, the environment is not a purely independent variable that determines the organism conceived as a purely dependent variable. Rather, manifold sampling processes reflect a variety of intriguing ways in which systematic perspectives and biases arise from the manner in which people solicit information from environments that differ in density, variability, and correlational structure. Let the term "sampling" refer to such active information search, which always involves an interaction between the individual and the environment. For example, for a teacher to reach a fair evaluation of student achievement, it is important to collect a representative sample of all students' performance. However, real samples are hardly ever random. The density (i.e., number) and variety of observations (i.e., learning trials) the teacher gets about individual students depends on environmental constraints (presence vs. absenteeism of students, how often they participate and raise their hand, their sitting position and salience, etc.) as well as the teacher's own information search (i.e., selective attention to different students, her testing hypotheses about specific students, and her prejudice and prior beliefs). Redundancy can facilitate the teacher's complex memory task or exaggerate differences that in reality are not that clear-cut. For example, a stereotypical correlation such that girls raise their hand more often in language lessons whereas boys participate more in science may accentuate the impact of gender stereotypes on the teacher's grading decisions.

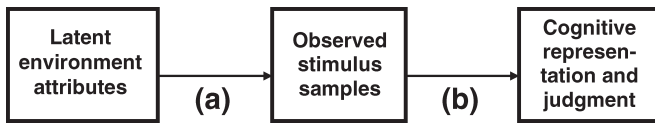
Sampling is a key concept to understanding the potential and the limits of human information processing. Figure 8.1 illustrates the role of sampling as a crucial interface between cognition and the environment. The *latent environment* on the left refers to the "actual" states of nature that are the focus of judgments and behavioral decisions. The quotation marks here suggest that the states of nature need not be "true" in a logical sense, or "real" in an ontological sense. There is wide agreement that a student's *body size* is a really existing attribute, less agreement as to whether his *math ability* is an objectively existing trait, and little agreement as to his *likability*. However,


FIGURE 8.1. Two-stage model of the cognitive representation of the environment: (a) translation of environment into stimulus samples; (b) cognitive assessment of characteristics in the stimulus sample.

all three attributes are estimated all the time, based on samples of observations, just as population parameters in statistics are estimated from sample statistics. By analogy, samples of infinite or very large size may be conceived as approximations of the "true" attributes in the latent environment. A student's "actual" ability in math can be understood as the proportion of correct responses given in an infinite sample of math tasks. Similarly, his "actual" likability can be defined through the overall consensus of all persons who interact with this student.

However the latent attributes are defined—physically, logically, or through social consensus—they are never amenable to direct perception or assessment. We have neither sense organs to directly perceive the actual values of environmental attributes, such as lethal risks, dangerousness of action, honesty of people, ability of students or applicants, or quality of products, nor access to infinite samples or entire populations of relevant observations. Virtually all cognitive assessment is contingent upon finite samples, which for the reasons depicted earlier are virtually never random. Samples reflect both the topological constraints of the environment (i.e., distance, asymmetries) and sampling strategies of the individual, resulting in overrepresentation of some features and underrepresentation of others. Moreover, samples are characterized by differences in grain size (Goldsmith, Koriat, & Weinberg-Eliezer, 2002), biases toward salient features (McArthur, 1981), and accentuation of redundant aspects (Tajfel, 1957).

In any case, the effective input to the organism's psychological processes is not the environment per se but finite, selective samples reflecting specific perspectives, topologies, and sampling strategies. Traditional research in psychology has been mainly concerned with the *utilization* of stimulus samples controlled by experimenters. Theories and explanations of psychological phenomena have mostly, if not almost exclusively, referred to that utilization process, that is, the manner in which organisms process and transform the given stimulus input, as function of goals, habits, mood states, capacity restrictions, and learned or inherited automatic reactions (Bargh, 1996). In contrast, the *generation* of the stimulus samples that trigger such organismic functions was considered only exceptionally in theoretical accounts of stereotyping (cf. Eagly, 1987; Kashima, 2000), intergroup relations (Linville et al., 1989), or group decision making (Mojzisch & Schulz-Hardt, 2005). One prominent goal of a genuinely cognitive–ecological approach to social psychology is to correct for this neglect and to revisit empiri-

cal research in terms of the constraints placed on cognitive processes by the environment.

REVIEW OF PERTINENT EMPIRICAL RESEARCH

Toward this goal, the first part of the review of pertinent research is devoted to alternative accounts of well-known empirical phenomena, which typically originate in cognitive research treating individuals as the unit of analysis. The next part is also concerned with traditional research topics but at levels higher than isolated individuals, such as groups and dyads. The third major part then addresses paradigms that are explicitly built on cognitive–environmental theories. The final part addresses some dynamic aspects of information environments that characterize modern societies.

Prominent Research Findings Revisited

Although little research was planned deliberately to test the impact of density, variability, and redundancy, numerous findings can be explained alternatively in terms of these aspects of the information ecology. The present subsection is devoted to such reinterpretations of well-established findings.

With regard to density, to start with, a basic law says that learning increases monotonically with the number of learning trials. Existing trends become more and more visible as the frequency or density of relevant observations increases. Prior to reporting relevant empirical data, I illustrate this basic principle with an example. In an operant-conditioning experiment, pigeons may learn to discriminate between two response options, A and B, producing reward on 75% versus 25% of the trials, respectively. Before the first learning trial, the pigeon has to start with equal expectations; pecking rates for the two response keys have to be 50% versus 50% (assuming no bias). As the number of trials increases, pigeons will learn gradually that A is superior to B, inducing a gradual shift toward the superior option, A, up to a point when the learning process is complete and the learning curve has reached an asymptote.

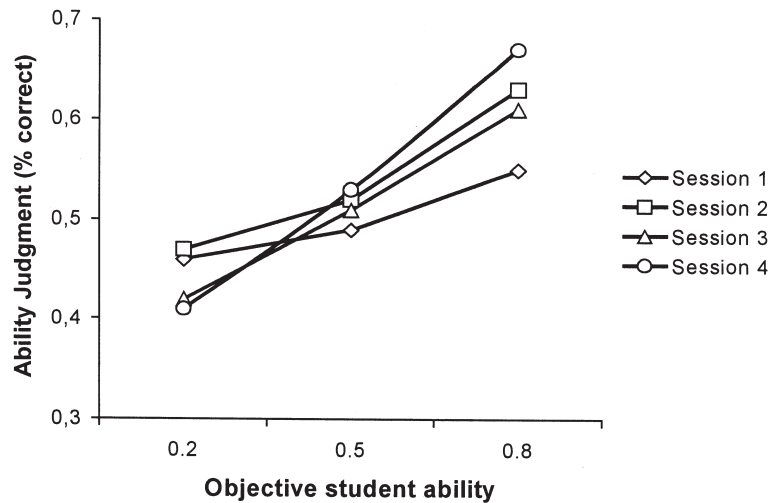
The same gradual curves characterize the learning process in complex human environments, as evident in the following data from a simulated classroom (Fiedler et al., 2002). Taking the role of a teacher, participants had to learn the rates of correct responses given by 16 students of a school class that was graphically represented on the computer screen. Each student's performance was controlled by a parameter specifying the probability of correct responses. Students' correctness parameter could vary from .2 to .5 to .8 (i.e., from 20% to 80% correct responses). At the end of each of eight lessons, teachers had to estimate all 16 students' correctness proportions. Figure 8.2 provides the resulting curves over four blocks of two lessons, averaging over all participants and students sharing the same performance parameters. As in the animal-learning sketch, learning to discriminate be-


FIGURE 8.2. The influence of increasing learning experience, across four sessions of a simulated-classroom experiment (Fiedler et al., 2002), on the ability to discriminate between high and low student ability. From sessions 1 to 4, judgments are becoming less regressive (i.e., closer to the diagonal indicating perfect discrimination).

tween superior and inferior students took time. From the first to the last block, the judges' ability to discriminate smart and poor students increased gradually, and the curves became less regressive. However, typical of a complex probabilistic ecology, learning was never complete; even after the last session the estimates of the correctness rates of smart versus poor students remained regressive. Such regressiveness is a central feature of all probabilistic environments (Fiedler, 1996; Nesselroade, Stigler, & Baltes, 1980; Sedlmeier, 1999).

As a matter of principle, an existing (probabilistic) trend in an environment becomes more and more visible as the density of observations increases. This principle is evident in many other findings. In the simulated classroom mentioned earlier, the student ratings could also be analyzed as a function of sample size, that is, whether few or many observations had been gathered about individual students' performance (i.e., whether the rate of observations about a student was above (large samples) versus below the median (small) of all students. When the density of observations was high, smart students were more likely to be recognized as smart and poor students were more likely to be recognized as poor than when the density was low.

More pronounced judgments with increasing sample size—when the trend to be captured is held constant—are also evident from an experiment by Shavitt and colleagues (1999). In two experimental conditions, the number of observations about a group was varied, presenting either 24 positive and 0 negative behaviors or 12 positive and 0 negative behaviors. Although the positivity rate was invariantly 100%, the density of observations varied and resulted in more positive impressions of the group when sample size was large rather than small—a normal reflection of the density principle. In general, the so-called density bias is a well-established, general finding in research on contingency assessment (Allan, 1993; Fiedler, 2000b). The same contingency (e.g., the difference in the occur-

rence rate of an effect given the presence minus the absence of a cause) appears stronger when the absolute occurrence rate (or density) is high rather than low.

Ingroup Favoritism

By the same token, the density principle offers an obvious alternative interpretation for naturally occurring differences in sample size. The ingroup–outgroup asymmetry affords a striking paradigm. The density of observations that are available about one's ingroup is generally higher than for the outgroup, for obvious reasons. As a consequence, any trend, or multiple trends, assumed to be equally prevalent in both groups should be more readily detected for the ingroup than for the outgroup. Granting that trends normally favor desirable, norm-conforming behavior rather than undesirable, norm-violent behavior (Kanouse & Hansen, 1972), the density principle alone affords a sufficient account of ingroup favoritism (Brewer, 1979; Tajfel & Turner, 1986). The higher density of ingroup than outgroup information implies that this common trend toward desirable behavior is more apparent for the ingroup. These differences can be predicted in the absence of any cognitive or affective processing bias. A simple, monotonically increasing learning function, which is sensitive to number of trials, is sufficient to predict an ingroup advantage. Self-evident as this consideration may appear, it is missing in traditional accounts of ingroup favoritism or its complement, outgroup derogation.

Self-Serving Bias

An analogous argument applies to the self-serving bias, the bias to perceive and judge oneself in more positive terms than others (Krueger & Gilovich, 2004; Kunda, 1990; Mullen & Riordan, 1988; Pronin et al., 2004; Wood, Michela, & Giordano, 2000). More observations

can be assumed to be available about oneself than about others. This difference in density alone implies that the prevalent trend toward positivity in social behavior should be more apparent for oneself than for others, regardless of whether a genuine self-serving processing bias or unequal processing of self-related versus other-related information may also contribute to the phenomenon. By the same token, it can be explained that when more negative behavior is available about oneself than about others, negative self-judgments can be exaggerated too (Blanton, Axsom, McClive, & Price, 2001; Kruger, 1999; Moore, in press; Ross & Sicoly, 1979), contrary to a self-serving bias.

Outgroup Homogeneity and Personal Distinctiveness

The same assumption—that is, higher density of self-related and ingroup-related information than other-related and outgroup-related information—can explain two other prominent findings, the so-called outgroup-homogeneity effect (Judd & Park, 1988; Linville et al., 1989; Mullen & Hu, 1989; Quattrone, 1986; Simon, 1992) and the need for personal distinctiveness (Brewer, 1993, 2003). The former finding says that outgroups are represented in a less differentiated, more simplified fashion than ingroups, whereas the latter finding means that people want to set their personal, distinct identity apart from other people of their own group as well as from other groups.

An obvious ecological account relies on the same simple notion as the aforementioned accounts of ingroup-serving and self-serving biases. If the natural asymmetry of stimulus input renders learning about the self and one's ingroup more complete than learning about others and outgroups, then this should affect the learning not only of singular predominant trends but also of multiple trends that can be found in a person or group. Thus, of many attributes A, B, C, . . . , X assumed to exist in either person or group, a higher subset is likely to be noticed—above some threshold—for the self than for others, and for ingroups than for outgroups. The resulting representation of the self and of one's ingroup should thus be more distinct and differentiated than representations of others and outgroups.

Thus, the density rule offers a parsimonious account of the two major empirical phenomena of intergroup research—ingroup-serving bias and outgroup homogeneity—and, at the same time, two major findings of the social psychology of the self—the self-serving bias and the need for self-distinctiveness. The rationale underlying this ecological account seems plausible and easy to understand, but direct empirical evidence is scarce. Most pertinent evidence comes from computer simulations that demonstrate that divergent ingroup and outgroup judgments can be expected to evolve if two groups differ in only one aspect, the number or density of observations. Such simulation models (Fiedler, Kemmelmeier, & Freytag, 1999; Linville et al., 1989) start from the assumption that two groups, an ingroup and an outgroup, are equally represented on some attribute dimension (e.g., the degree of extraversion, or honesty).

Samples of values are then drawn at random from this distribution, reflecting the scale value of group behaviors on the attribute dimension. The samples supposed to represent the ingroup are larger (e.g., 24) than the samples supposed to represent the outgroup (e.g., 12). To simulate memory loss or forgetting, part of the samples' attribute values are erased or obscured, and the scale values of the remaining sample values are then transformed to categories on some judgment scale. Because of the reduced variance of small samples, the simulated judgments of "outgroups" show less variation than "ingroup" judgments. Simulated outgroup judgments are also less differentiated in terms of the number of different attributes exceeding some threshold.

Such simulation findings are corroborated in experiments in which fictitious groups are described through large versus small samples of stimulus behaviors. Subsequent judgments of the smaller group turn out to show less variation and differentiation (Linville et al., 1989), and the correlation pattern for multiple attribute judgments is simpler than for the larger group (Linville et al., 1996).

Using synthetic ingroups and outgroups that only differ in sample size, as in all the experiments and simulation studies considered so far, has the advantage that the impact of a single factor can be isolated. The alternative research strategy—relying on naturally existing groups or persons—would inevitably confound the variable of interest (i.e., density) with many other aspects (e.g., liking, identification, and familiarity). Nevertheless, a few studies have found ways to deal with this problem. Sande, Goethals, and Radloff (1988) asked their participants to judge themselves as well as other people on various attribute dimensions, holding the self–other comparison constant and merely varying the format of judgment. In one condition, self and other ratings had to be given on bipolar scales, the poles of which represented antonyms on attribute dimensions (e.g., extravert vs. introvert). In another condition, separate unipolar ratings for both antonyms (e.g., one rating for extravert and one for introvert) of all dimensions were called for. Using this paradigm, other persons received more extreme ratings on bipolar scales—reflecting more simplified, one-sided representations—whereas the sum of both antonym ratings was more pronounced for the self—reflecting that both opposites characterized the self at the same time. An analogous set of findings, using the same method as Sande and colleagues, was obtained for ingroup versus outgroup ratings by Fiedler, Kemmelmeier, and Freytag (1999). Thus, with increasing density of information, group representations become more complicated and less simplified. Simon's (1992) finding that outgroup homogeneity is often reversed for minority groups is also consistent with the important role attributed to numerosity (i.e., density) as a crucial distinctive feature between ingroups and outgroups.

Mere Thinking

The same ecological principle can account for seemingly unrelated phenomena. For instance, the mere-thinking

effect (Tesser, 1978; Tesser & Leone, 1977), quite detached from self and intergroup research, can be understood as reflecting the same density principle. Merely asking participants to extend thinking about an attitude target can be shown to increase the extremity of attitude judgments, provided the participants' knowledge base is rich enough to support extended sampling of arguments in memory. Thus, men develop more extreme attitudes through continued thinking about sports, whereas women's attitudes get more extreme when they continue thinking about fashion (cf. Tesser & Leone, 1977). Simply increasing the number of thoughts can render an attitude more extreme (cf. Downing, Judd, & Brauer, 1992); no selective bias toward attitude-consistent thoughts is necessary.

Biases and Heuristics

A number of other biases in judgments and decision making, which have been traditionally attributed to biased heuristic processing in the judge's mind, can be explained alternatively just by considering the information environment. One striking example to start with is *unrealistic optimism* (Armor & Taylor, 2002; Weinstein, 1980). Most people consider themselves to be above average in terms of ability and below average in terms of risk. This phenomenon is usually treated like a prototype of a motivated, self-serving bias. However, the distribution of environmental data is not at all incompatible with the conclusion that most people are better than average. Consider, for example, the conviction that "I am less likely than the average person to be involved in a car accident." Indeed, the distribution of the number accidents per person is clearly right-skewed; there are many people who had no accident or only one or two, whereas an increasingly smaller number of people have records of three, four or more accidents. Given such a skewed distribution, the median is well below the mean, implying that a majority of people are indeed better than average (Gigerenzer & Fiedler, 2007).

This is not to say that skewed distributions can account for all manifestations of unrealistic optimism (Price, 2001) or that motivated processes such as wishful thinking cannot also contribute. However, the normal ecological input distribution alone is sufficient to predict an optimistic bias, in the absence of any cognitive or affective bias in the judge's mind. Moreover, the higher risk attributed to the average other than to the self can again reflect a density effect. As Price (2001) has shown thinking about the risk of the average other involves a larger sample of people and events than thinking about the single self. Accordingly, the bias disappears when risk judgments of several others are averaged rather than considering judgments of the average other.

The *overconfidence* bias figures prominently in textbooks and in many applied areas of judgment and decision making (Klayman, Soll, González-Vallejo, & Barlas, 1999; Lichtenstein, Fischhoff, & Phillips, 1982; Soll, 1996) and in metacognition research (Koriat, Lichtenstein, & Fischhoff, 1980). When judges are asked to indicate the subjective confidence (in percent) that their answers to knowledge questions are correct, they prove to be ill-calibrated. That is, their percentage estimates tend to be higher than the actual proportion of correct responses on such questions. Moreover, the discrepancy increases with the extremity of subjective confidence (Juslin, Winman, & Olsson, 2000).

Given the prominent status of the overconfidence effect, a major challenge arises from recent findings showing that the phenomenon largely disappears when the task ecology is taken into account. The typical strong overconfidence effect is for the most part confined to studies that use arbitrary samples of stimulus tasks, rather than representative samples. In such studies, researchers tend to select judgment tasks that intuitively promise to induce more confidence than is warranted, thus creating a task environment that yields the predicted overconfidence effect. In contrast, a minority of studies using representative samples of knowledge tasks from a clearly circumscribed domain (e.g., population size of all cities of a country) yield drastically reduced effects or even null findings (Gigerenzer, Hoffrage, & Kleinbölting, 1991). A recent meta-analysis of Juslin and colleagues (2000) testifies to the stability of this ecological influence on overconfidence. Moreover, research by Winman, Juslin, and Björkman (1998) shows that, like the overconfidence effect, the prominent *hindsight bias* (Fischhoff, 1975) can also be eliminated or even reversed through representative sampling of stimuli or tasks.

Such provocative discoveries highlight the failure of both researchers and participants to take the information ecology into account. Researchers have overlooked the impact of arbitrary task sampling on research findings (Wells & Windschitl, 1999), whereas participants exposed to selected tasks fail to recognize that the experimental task environment is more difficult than the learning environment in which their subjective confidence feeling was calibrated.

Similar findings have been obtained in the classic heuristics-and-biases research program (Gilovich, Griffin, & Kahneman, 2002; Kahneman, Slovic, & Tversky, 1982). Evidence on the availability heuristic (Tversky & Kahneman, 1973) also turned out to depend on researcher's intuitive generation of biased research environments. One of the most often cited findings—the overestimation of the frequency of words with the latter "k" in the first than the third position, supposed to reflect enhanced availability in memory—was shown by Sedlmeier, Hertwig, and Gigerenzer (1998) to hold only for the few letters that have been used intuitively in successful studies. For the rest of the alphabet, the phenomenon did not work. Although this demonstration need not undermine many other availability findings, it highlights the need to control for the stimulus ecology of psychological experiments.

Base-rate neglect (Bar-Hillel, 1990; Kahneman & Tversky, 1972), perhaps the most famous paradigm of the heuristics-and-biases program, refers to erroneous probability judgments of criterion events whose base rates differ from intuitive predictions. For example, the conditional probability that someone has HIV given a

positive test T_{HIV+} is drastically overestimated (Gigerenzer & Hoffrage, 1995; Swets, Dawes, & Monahan, 2000). As HIV is the cause most closely associated with T_{HIV+}, inferences from a positive T_{HIV+} result to HIV are readily made, neglecting the low base rate of HIV. Although—in the absence of further symptoms—the actual probability of the virus given a positive test, $p(HIV/T_{HIV+})$, is under 20% for the U.S. medical environment (cf. Swets et al., 2000), subjective estimates are extremely high, suggesting a strong base-rate fallacy.

This prominent bias is at least partly due to an information environment that invites output-bound judgment processes (Fiedler, Brinkmann, Betsch, & Wild, 2000). When judging $p(HIV/T_{HIV+})$, the logically appropriate reference set of all people having a positive test result T_{HIV+} is unknown. Available statistics and memory samples typically focus on the critical output events (e.g., the actual HIV cases), thereby inflating the likelihood of HIV cases in the effective judgment sample. When this ecological bias is eliminated (by inducing input-bound sampling with a focus on T_{HIV+} cases), the base-rate fallacy is greatly reduced (Fiedler et al., 2000; Gigerenzer & Hoffrage, 1995), as described in more detail in the section on biased hypothesis testing.

Dyads, Groups, and Distinct Social Topologies

The research revisited so far was not designed to study ecological influences. The general goal of the preceding section was to demonstrate that many well-known social cognition findings, obtained in intrapersonal task settings, can be explained in radically new ways as soon as the information environment is taken into account. The present section moves from single-person tasks to behaviors in dyads, small groups, or other settings that already constitute some interpersonal ecology. Nevertheless, the primary goal of these studies was still not environmental.

The explicit and implicit rules of social interaction among people in dyads and groups—as vividly described in early writings on symbolic interactionism (Goffman, 1990; Mead, 1934)—restrict and shape the social stimulus environment in distinct ways. What is likely to be said, written, and expressed; what behaviors are likely to be exhibited or hidden; and what information is sought or avoided depends on rules of conduct. Rather than revealing private motives and traits, people engage in self-presentation strategies and display rules, exaggerating normative constraints and reducing variability in the information ecology. The presence of an audience serves to reduce variability but to increase self-consistency (Duval & Wicklund, 1972; Schlenker, 1985) and thereby redundancy (i.e., correlations between different aspects of social behavior). Cooperation and social exchange rules oblige people to reciprocate actions shown by their interaction partners, thus imposing periodic distributive-justice rules on social interaction.

One particularly simple and straightforward assumption about the shaping of social input is as old as Thorndyke's (1916) law of effect (Nevin & Grace, 2000). Pleasant actions are more likely to be repeated and continued than unpleasant ones. Following this very simple

reinforcement law, it can be predicted that social interaction tends to be truncated when the input is negative in valence, whereas it tends to be continued as long as it is pleasant (Denrell, 2005). The resulting bias in the valence of social information input can account for a number of well-known phenomena. As already mentioned, the density distribution of stimulus behaviors is normally skewed toward more positive, desirable behaviors, which are the norm. Negative, undesirable behavior, which is the exception, is likely to be truncated and unlikely to be corrected resulting in more enduring negative than positive attitudes.

The same avoidance of unpleasant, conflict-prone experience characterizes *communication ecologies*, as evident in cognitive tuning (Zajonc, 1960). When communicating a message to somebody who is known to like (dislike) the message target, communicators tend to frame the message in positive (negative) ways. In the communication-game approach, Higgins (1981) has extended this notion, showing that communicators adapt in several ways to recipient needs. The communicators' own subsequent memory representations are then biased toward the message format tailored for the recipient's needs. For instance, if the recipient's prior knowledge is low, the message is supposed to be rich in detail, and so will the communicators own memory representation be characterized by the same grain size.

Grice's (1975) principle of cooperation and the four maxims of verbal communication—quality, quantity, relatedness, and manner—afford a sensible framework for understanding communication environments. The default assumption between speaker and listener (or writer and reader) is that all conveyed information validly reflects some aspect of reality (maxim of quality), is neither too scarce nor overly long (quantity), is related clearly to other aspects in the message (relatedness), and is not using strange and awkward words and style (manner). As a result, communicated information is characterized by a truth bias (maxim of quality; Granhag & Stroemwall, 2001; Rassin, 2000), a specifically chosen level of abstractness versus detail (quantity; Maass, 1999; Vallacher & Wegner, 1985), a level of internal coherence that exceeds the actual coherence of the world (relatedness; Kashima, 2000), and an avoidance of contents that cannot be expressed simply and clearly (manner; Conway & Schaller, 2007).

Using Allport's (1954) serial-reproduction paradigm, Kashima and colleagues (Kashima, 2000; Lyons & Kashima, 2003) let their participants communicate descriptions of stereotyped targets (e.g., gender targets) to others, who were then to retell the message to still other people and so forth, up to a fifth serial stage. From the beginning to the end of the communication chain, the ratio of stereotype-consistent to stereotype-inconsistent information increased steadily, thus reducing the complexity (quantity) and increasing the internal consistency (relatedness) of text. Further experiments showed that this was particularly the case when the task said communicators should communicate to others, but less so when the same task was labeled a (nonsocial) memory task. Thus, the choice of content did not reflect the communicators' re-

stricted capacity, but the impact of rules that shape the communication ecology (cf. Semin & Fiedler, 1988). This suggests an interpretation distinct from traditional stereotype theories, which emphasize intergroup conflicts, biased processing, or cognitive economy (Bodenhausen, 1990). Ironically, stereotyping can be fostered by the prosocial motive of cooperative communication.

The same holds for the linguistic-intergroup bias (Maass, 1999), that is, the tendency to communicate expected information (i.e., positive ingroup behaviors and negative outgroup behaviors) in more abstract terms than unexpected behaviors (i.e., negative ingroup behaviors and positive outgroup behaviors). This often replicated phenomenon (Karpinski & von Hippel, 1996; von Hippel, Sekaquaptewa, & Vargas, 1995; Wigboldus, Semin, & Spears, 2000) serves to stabilize and multiply stereotypical expectancies in media, literature, and conversation ecologies. However, recent studies using more refined methods clarified that this pervasive aspect of the communication environment need not arise from a self-serving or ingroup-serving motive. When motives and vested interests are pitted against expectancies, it turns out that expected information will be communicated abstractly even when it has negative implications for the self and the ingroup (Maass, Milesi, Zabbini, & Stahlberg, 1995; Wigboldus et al., 2000). Again, the prosocial motive to tune one's message toward the maxim of quantity (i.e., avoiding too much detail) suggests an ironic ecological source of social stereotyping. Such irony—pointing to unbiased or "innocent" causes of biased or undesirable results—is quite typical of the interplay of cognitive and environmental factors.

Group Decision Making

The maxim of quantity is immediately relevant to understanding one of the most prominent phenomena in group decision making, the *shared-information effect* (Larson, Foster-Fishman, & Keys, 1994; Stasser & Titus, 1985). In decision-oriented group discussions, thoughts and arguments that are shared by other group members and therefore add little new evidence are more likely to be uttered than unshared information, which has the potential to add something new. Decision-group environments thus tend to reduce the variability and to increase the redundancy of the information utilized. As a consequence, group decisions are systematically flawed when a so-called hidden profile is given, that is, when the shared information does not reveal the optimal solution, which is hidden in the unshared knowledge of individual specialists.

The shared-information effect seems to violate the maxim of quantity, because useful unshared information goes unmentioned, but it may actually reflect a compromise of the maxims of quantity and quality. Although shared information adds little new evidence, it is usually considered more valid and less idiosyncratic than unshared information (Greitemeier & Schulz-Hardt, 2003). Consensus among group members helps to fulfill the maxim of relatedness. Although a fully comprehensible explanation is not yet available (cf. Mojzisch & Schulz-

Hardt, 2005), the shared-information effect highlights the significance of information ecologies for social problem solving. Stasser and Titus's (1985) sampling model offers a viable account in terms of unbiased processes, by simply assuming that every group member samples arguments from his or her own knowledge.

A related and actually much older paradigm is the *group-polarization effect* (Lamm & Myers, 1978; Moscovici & Zavalloni, 1969; Myers, 1978). Group members tend to support and accentuate the predominant tendency in the group, giving rise to group decisions that are more polarized than the average individual decision. More recent research (Brauer, Judd, & Gliner, 1995) has shown that this is not merely due to the selectivity or reduced variability of the arguments raised in group discussions but can result from simply repeating the arguments representing the dominant tendency, that is, through increased information density alone. Again, from an ecological theory perspective, group polarization can be considered an interpersonal analog of the mere-thinking effect mentioned previously. Extended elaboration on a topic, whether in group discussion or by thinking alone, serves to increase the density of learning trials supporting a predominant information trend and hence leads to more extreme responses.

Social Hypothesis Testing

Since the pioneering work of Snyder and his colleagues (Snyder, 1984; Snyder & Swann, 1978; Swann, Giuliano, & Wegner, 1982), the process of social hypothesis testing is known to exhibit a systematic confirmation bias, reflecting the impact of distinct interaction rules on the information environment. Just as Grice's (1975) pragmatic approach, Snyder's (1984) theoretical analysis—deeply rooted in symbolic interactionism—emphasized the inherently cooperative nature of social-interaction environments. Thus, in order to test the hypothesis that one's interview partner is extravert, an interviewer is obliged to ask diagnostic questions related to extraversion and to refrain from asking less relevant questions about introversion and other traits. Such an information search strategy is called *positive testing* (Klayman & Ha, 1987); it serves to increase the density of information about the attribute that is in the focus of hypothesis. The interviewee, conversely, is obliged to cooperate with the interviewer's question focus. As the interviewer was interested in extraverted behavior, the interviewee is supposed to think and talk first about her extravert behaviors. (Had she been interviewed about introversion, she might have been able to talk about introversion as well.) This generalized tendency toward higher density of confirming yes responses than disconfirming no responses is well known in survey research as an *acquiescence effect* (Blau & Katerberg, 1982; Ray, 1983; Zuckerman, Knee, Hodgins, & Myake, 1995). Both tendencies together, positive testing in the interviewer (hypothesis tester) and acquiescence in the interviewee (target person), create an information ecology that fosters a confirmation bias. Even when the high acquiescence rate of confirming responses is equally high for extraversion and introversion ques-

tions, the enhanced density of observations for the focal attribute (extraversion) can explain a confirmation bias.

That density or sample size, rather than prior expectancies or the demands of the hypothesis-testing task, is the crucial factor that was tested by Fiedler, Walther, and Nickel (1999). Participants were free to ask questions about overt aggression and covert aggression observed in a male and a female target person, to test the hypothesis that male aggression tends to be overt whereas female aggression tends to be covert. In fact, the computer whose database they could use for information search was programmed to provide a constantly high proportion of 75% confirmative feedback, regardless of target gender and aggression type. Nevertheless, there was a marked bias toward the focal hypothesis. Frequency estimates and trait ratings revealed that the male target was judged to be higher in overt aggression and the female target was rated to be higher in covert aggression. The best predictor of this autoverification effect was the degree of positive testing (i.e., enhanced frequency of questions about male overt and female covert aggression).

However, importantly, neither prior beliefs nor the demands of the task focus could account for the full pattern of findings. When participants were asked to test the counterstereotypical hypothesis that the male target shows covert aggression and the female target overt aggression, a full reversal was obtained. Whether the focus was on a stereotype-consistent or -inconsistent hypothesis, the crucial factor was the density of stimulus observations. When judges witnessed the information search of another judge, it was possible to induce *negative testing* experimentally. Participants testing whether male aggression is overt could be exposed to a higher number of observations about female overt aggression. Density was shown to override both the hypothesis focus and the influence of stereotypical expectancies.

Analogous results were obtained in the aforementioned simulated classroom (Fiedler et al., 2002). Teachers supposed to test the hypothesis that girls are better in language whereas boys are better in science engaged in marked positive testing (asking many questions to girls in language lesson and to boys in science lessons), and the proportion of correct answers was constantly high. Consequently, they found support for the sexist stereotype. In contrast, when teachers were asked to test the reverse hypothesis—that in this class girls dominate in science and boys in language—they again engaged in (reverse) positive testing and actually found support for the counterstereotype. These findings only pertained to those gender targets who actually exhibited the necessary acquiescence effect (i.e., the high confirmation rate). Altogether, these results provide convergent evidence for differential information density as an important ecological factor.

The illusions resulting from hypothesis test strategies are particularly severe when judges engage in output-bound information search, as noted before. Participants in the study by Fiedler and colleagues (2000) were given a computerized data file to sample data relevant to estimating the probability $p(BC/M+)$ that a women has breast cancer (BC) given a positive mammogram (M+). In the database representing the ecological reality, the joint frequencies were distributed as follows:

4 BC and M+ cases
1 BC and M– cases
20 No BC and M+ cases
120 No BC and M– cases

Thus, the database was quite close to reality in that the base rate of BC was low (5 out of 145) but the hit rate of M+ given BC was clearly higher (i.e., 4/5 = 80%) than the false alarm rate of M+ given NoBC (20/140 = 14.3%). Due to the low BC base rate, the correct Bayesian solution in this task setting was $p(BC/M+) = 16.7\%$. The expectation that a woman with a positive mammogram actually has breast cancer is only 16.7%. Whether subjective estimates were highly inflated (as in previous research using such tasks; Eddy, 1982; Gigerenzer & Hoffrage, 1995) or quite accurate depended strongly on the search strategy. When sampling was output bound, contingent upon the criterion event BC, judges would typically draw all cases with BC and about the same number of cases without BC, receiving feedback as to whether the test result of these women was M+ or M–. Their resulting estimates reflected the BC proportion among M+ women in the sample quite accurately. But because the BC base rate was drastically inflated (now about one-half), these proportions were inflated too (64.0 %). In contrast, when sampling was input bound, considering women with M+ and M– and receiving feedback as to whether they had BC or not, the resulting estimates came rather close to the correct value (21.8%).

In general, to the extent that output-bound sampling overrepresents a low-base-rate event (e.g., BC) in the available sample, the actual rate will be highly overestimated. The ecological point here is that information sources (media, databanks, statistics archives) often enforce output-bound information search. For pragmatic reasons, the critical outcomes in question (e.g., HIV and car accidents) are much more visible and much more likely to be assessed in statistics than the relevant predictors (HIV test results, drinking alcohol). In Gavanski and Hui's (1992) terms, outcomes often afford a more natural and more visible sampling space than input factors, or independent variables. As a consequence, estimates of risks, diseases, and many other low-base-rate events are based on output-bound samples and therefore tend to be grossly inaccurate.

Memory as an Internalized Environment

A considerable part of the information ecology that informs behavioral decisions is internalized in memory (Anderson & Schooler, 1991). Most real problems call for the use of both externally provided and internally memorized knowledge. Hypothesis-testing processes use internal sources in the same fashion as externally provided information. Analogous to a group discussion, memory search can be conceived as a discussion with oneself or with one's autobiography. Not surprisingly, memory-based judgments and hypothesis tests have also

been shown to exhibit positive testing and confirmation biases (Koriat et al., 1980; Mussweiler, 2003).

Moreover, memory is subject to the same topological constraints as the external environment. Because memory provides more self-referent information than information about others, the impact or contribution of the self on social behavior tends to be overestimated (Ross & Sicoly, 1979). Self-referent information is not only high in density but high in resolution, or fine-grain size, reflecting that the distance to oneself is closer than to other persons (Fiedler, Semin, Finkenauer, & Berkel, 1995).

A distinct feature of memory, the internal part of the ecology, is its generative power. Merely prompting memory for particular contents—that is, considering, imagining, or mentally simulating and rehearsing possible contents—can instigate constructive processes that actively generate those contents (Koehler, 1991; Loftus, 1979; Wells & Gavanski, 1989). Merely imagining or explaining a possible event (accident, success experience) can raise the subjective belief in the truth of this event (Koehler, 1991). Or, merely focusing on an arbitrary target person identified only by her initials can let that focal person appear as above average on various judgment tasks (Klar & Giladi, 1997), presumably due to an increased virtual density of imagined or self-generated thoughts about the focal person or group (Price, 2001).

Although this active, generative property is most characteristic of internalized knowledge in memory, similar generative processes may be found in the external ecology. The notion of self-fulfilling prophecies (Jussim, 1986; Kukla, 1993; Rosenthal & Rubin, 1978) refers to the tendency to generate in active social interaction the very kind of information that is the focus of a question, quite comparable to the impact of imagination on memory. People who expect their interaction partners to possess some attribute will often treat them in a way that actually induces that attribute in the interaction partner (Snyder, Tanke, & Berscheid, 1977; Trope & Thompson, 1997).

The Dynamics of Social Comparisons

One particularly effective device for generating an environment that accords to one's motives, goals, and hypotheses is the selection of social comparison targets. As outlined in Festinger's (1954) old theory of social comparison processes, in order to determine our own identity, our abilities, relative attitudes, and the meaning of our sensations, we constantly need to compare ourselves with physical and social comparison targets. Physical comparisons help us to determine how strong, fast, or persistent we are (i.e., by comparing ourselves with weights or distances per time unit). But most of the time, when objective, physical comparisons are not available, we have to resort to social comparisons, using other persons and groups as graduators for our own attitudes and attributes.

Of course, the outcome of this process of self-definition depends crucially on the comparison environment, which in turn depends in part on the individual's motives and hypotheses that actively create an essential part of the information environment. People who are low in self-esteem or who belong to a stigmatized group are more likely to engage in safe downward comparisons that promise to foster one's self-esteem. In contrast, high self-esteem or membership in a successful group render upward comparisons more likely. In a similar vein, comparison direction may vary with the individual's regulatory focus (Higgins, 1998). Whereas a prevention focus induces a strategy to avoid threatening comparisons, a promotion focus may support engaging in exploring or even adventurous comparisons. Thus, ecological factors must not be considered purely independent variables, but in a genuine cognitive–ecological framework, ecological conditions are themselves shaped to a considerable degree by the individual's behaviors toward the environment (Higgins & Molden, 2003).

However, crucially, the choice of comparison is not determined by the individual's goals and motives alone (Wood, 1989). The range and number of available comparison targets can be severely restricted. For example, the intellectual development of a child in a school or family context may be hindered due to a lack of high-level comparisons (Zajonc, Markus, & Markus, 1979; Zajonc & Mullally, 1997). Moral rules of fidelity and incest taboo restrict the opportunities for social comparisons with sexual partners (Bischoff, 1972). Credentialist rules reduce the comparison and competition between people having different educational backgrounds. And segregation or discrimination practices may reduce the chances for comparisons with female leaders, gay child raisers, or members of different cultures.

Social Roles and Task Demands

Although the concept of social roles belongs to common sense, it only plays a minor role in current psychological theorizing. The most prominent exception here is Eagly's (1987) role account of gender stereotypes. As vividly illustrated in Hoffman and Hurst's (1990) experimental analog of Eagly's theory, individuals who play female as opposed to male roles will be perceived differently on relevant attribute dimensions, even when their actual position on those attributes has been carefully equated.

Genuinely Environmental Approaches

Ironically, when looking out for those most advanced theoretical approaches that come closest to the ideal of genuinely cognitive–environmental theories, one has to resort to some of the oldest sources. This section provides a cursory review of those seminal approaches, and how they map onto contemporary research.

Probabilistic Functionalism: Brunswik's Approach

Most prominently, Brunswik's (1955, 1956) probabilistic functionalism starts from the assumption that the distal entities that are the target of significant decisions and adaptive behavior—such as danger, risk, honesty, ability, or intention—are not amenable to direct perception.

Rather, they have to be actively inferred from more proximal cues that bear only probabilistic relations to the distal entity. For example, we have no sense organs for detecting the truth. Rather, lie detection and veracity judgments use multiple cues (like gaze, speech hesitations, pitch of the voice, etc.) that are at best weakly correlated with the objective truth (Vrij, 2000; Zuckerman, DePaulo, & Rosenthal, 1981). Nevertheless, because the brain uses multiple cues simultaneously, the aggregate accuracy of the entire cue system can be much higher than for individual cues. The process through which distal realities are actively reconstructed by the organism is extremely flexible and adaptive, characterized by cue substitution and "vicarious functioning." Thus, when particular cues are not available (e.g., the visual cues in lie detection when communications are presented only auditively), the inference process switches smoothly to using other, available cues. This occurs without effort and awareness. Thus, we continue to have stable depth perception when we cover one eye, although this eliminates the leading cue, disparity of the two retina images. Such adaptive and efficient cue utilization, leading to remarkable accuracy with even minimal information input (Ambady, Hallahan, & Rosenthal, 1995; Borkenau & Liebler, 1992; Funder, 1995; Kenney et al., 1992), holds for social judgments of likability, honesty, and many other personality attributes.

Brunswik's ecological approach, after a long period of being ignored, has finally given rise to Hammond, Stewart, Brehmer, and Steinman's (1975) social judgment theory (Cooksey, 1996), Gigerenzer and colleagues' (1991) probabilistic mental model approach, and several other developments in research on judgment and decision making (Juslin, 1994; Juslin & Olsson, 1997; Winman et al., 1998). In social psychology, it has inspired research on verbal and nonverbal communication (Zuckerman et al., 1981) and the study of accuracy and consensus in personality judgments (Funder, 1995). In all these domains, the description and analysis of the cue systems used for communication may be as central a research topic as the processes occurring within the individual.

Whether social judgments are accurate and correct depends not so much on the judge's effort, intelligence, or accuracy motivation but on whether the ecological input offers appropriate cues. Often, refraining from using too many cues and relying on a single, dominant cue can inform equally accurate or even better decisions than trying to exploit too many cues (Ambady & Rosenthal, 1992; Forest & Feldman, 2000; Gigerenzer & Goldstein, 1996). This less-is-more effect is at variance with the traditional tenet of dual-process models in social cognition, which presuppose that extended, more elaborated processing and effort expenditure are the keys to enhanced accuracy.

Affordances: Gibson's Approach

The emphasis on external stimuli and signals as determinants of human (and animal) behavior is also central to another environmental approach advocated by Gibson (1979). Though mainly concerned with visual percep-

tion, this approach is also relevant to the study of social behavior. Gibson's core concept of an *affordance* highlights the notion that the stimuli and behavioral options offered by the information ecology shape and restrict one's action space (Gaver, 1996; Valenti et al., 1991; Zebrowitz, 2002). Being offered an attractive job at the right time, meeting a romantic love partner, or being confronted with criminal temptations can determine a person's life forever. Affordances—conceived as environmental invitations, or opportunities hard to miss—are at the heart of social psychological topics such as role behavior (Eagly, 1987), demand characteristics (Orne, 1962; Shimp, Hyatt, & Snyder, 1991), and the impact of salience on attributions and behavior (Taylor, Fiske, Etcoff, & Ruderman, 1978). Salient stimuli and persons have been shown to attract more attention and more effective memory encoding, and are more likely to be perceived as causal origins than less salient sources (McArthur, 1981; Nothdurft, 1993).

However, notably, in a cognitive–environmental framework, affordances should not be misunderstood as purely external explanations. For an affordance to be effective, it has to meet a predisposition, motive, or propensity of the organism to respond accordingly. For example, the very preparedness of human observers to respond so sensitively to faces complements the affordance role that faces can play in triggering social behavior (Zebrowitz, Fellous, Mignault, & Andreoletti, 2003; Zebrowitz-McArthur & Baron, 1983). The schema of a baby face, for instance, has been shown to influence judicial judgments of guilt and punishment (Berry & Zebrowitz-McArthur, 1988). The same description of a crime led to different ratings of guilt and appropriate punishment when a photo showing the defendant's face was manipulated. Given a negligent crime due to naivety, less severe punishments were recommended for baby-faced than mature-faced defendants. In contrast, for an intentional offense, more severe punishments were recommended for baby-faced than mature-faced defendants. Apparently, guilt judgments depend on the fit between the nature of the crime and the surplus meaning of the face.

Domain Specificity: Simon's Approach

One intrinsic feature of ecological models is domain specificity. The notion that the environment can codetermine behavior entails, logically, the assumption that different environments, or domains, can drive behavior in different directions. Arguing from an evolutionary point of view, Cosmides and Tooby (1994) coined the metaphor of a Swiss Army knife to explain the way in which phylogenetic learning has equipped organisms with specific skills or devices for specific situations. Quite in line with Simon's (1956) bounded rationality notion, humans may not acquire general rules of logical reasoning, but they may rather apply specialized tools that can solve practical problems within specific domains. For example, a long tradition of research on Wason's (1966) selection task shows that people have no general understanding of logical implications of the form "if p, then q."

However, in the biologically important domain of detecting cheaters (Gigerenzer & Hug, 1992), they fully understand the implications of logically equivalent social contracts (Cheng & Holyoak, 1985; Cosmides, 1989), such as "If one drives a car, she must have a licence." Given such a rule, the cheater detector knows it is not merely important to look at people who drive a car (i.e., the p clause in "if p, then q") but also to monitor people who have no driving licence (the non-q clause).

The notion of domain specificity entails, logically, the assumption that adaptive intelligence is not striving for cognitive algorithms that provide optimal and universally correct solutions under all conditions. Rather, intelligence is content with satisficing algorithms or heuristics that provide viable local solutions in a given problem context, in accordance with Simon's (1956) notion of bounded rationality (restricted by limited capacity). An alternative, slightly different criterion for adaptive behavior is ecological reality (tuning organisms to learn those skills that fit the problem structure of the environment; Gigerenzer, Todd, & ABC Research Group, 1999).

In current social psychology, the most prominent variant of domain specificity is culture-specific variation (Markus & Kitayama, 1991; Nisbett, Peng, Choi, & Norenzayan, 2001; Triandis, 1995). Like other ecological factors, different cultures are characterized by information distributions that differ in density, variability, and redundancy. For instance, in the language input of people living in collectivistic cultures, the density and variety of verbs and process-centered terms is higher, whereas the density and variety of adjectives, nouns, and object-centered terms is lower than in individualistic cultures (Choi, Nisbett, & Norenzayan, 1999; Kashima, 2001; Rhee, Uleman, Lee, & Roman, 1995). This difference in linguistic input offers an explanation for why, in language development, Asian children show a relative advantage in understanding and using verbs as compared with nouns and object-centered terms (Choi & Gopnik, 1995; Tarif, Gelman, & Xu, 1999). This culture-specific impact on the ontogenetic learning input can in turn be assumed to trigger intercultural differences in thinking and reasoning, such as the lower rate of trait attributions (Choi et al., 1999; Miller, 1984) and of the correspondence bias (Miyamoto & Kitayama, 2002) in Asian (collectivistic) than in Western (individualistic) cultures, or their reduced use of static, logical categories in thinking and reasoning (Nisbett et al., 2001). A more extensive review of intercultural research can be found in Chapter 34 (Chiu and Hong, this volume).

Psychological Distance: Lewin's Approach

In Lewin's (1951) field-theoretic approach, psychological distance was a concept of central importance. In spite of the huge impact that Lewin had on the growth of social psychology after World War II, his notion of distance received little attention until very recently. Originally, the psychodynamics of distance had been contaminated with valence. As the distance from a reinforcing event decreases, the unpleasant, aversive aspects loom larger, whereas the pleasant, appetitive aspects are less apparent. Therefore, avoidance tendencies increase at a faster rate than approach tendencies with decreasing distance (Miller, 1944).

This basic asymmetry of positive and negative stimuli was given up by Trope and Liberman (2003), whose construal-level theory entails a new comprehensive conception of psychological distance, with rich theoretical and practical implications. Most of the research conducted within this framework refers to temporal distance, although the theory is also applicable to other dimensions, such as social, affective, spatial, or status distance. The central assumption underlying Trope and Liberman's (2000, 2003) theory says that behaviors and events in the far future tend to be construed at a higher level of abstraction, and more context independent, than behaviors and events in the near future. Thus, when we are making plans for next year, we think of doing more sports because it is inherently healthy, going to Vietnam for vacation because Vietnam is inherently attractive, or buying a convertible car that gives pleasure in summer. In contrast, when making decisions for tomorrow, we decide against sports because time is scarce, we recognize that other countries but Vietnam may be more familiar and easier to reach, and that the old used car will do it one more year, before the convertible dream can be realized in another far future. Far-future options tend to be represented by their inherent value, whereas the representation of present and near future is more sensitive to external constraints and circumstances that distract one from following the intrinsic value of goals and objects. As Liberman and Trope (1998) phrase it, the high-level construal induced from a distant perspective focuses on the desirability of goals, whereas the low-level construal induced from a proximal perspective revolves around the feasibility of actions.

Table 8.2 summarizes a number of findings about preference reversals in decision and choice that can be derived from, or explained within, construal-level theory. For example, the theory predicts, correctly, that of two decision options with the same expected value, the one with the higher outcome in case of success is preferred in the long run, but the one option with the higher likelihood of success will be preferred in the short run (Sagristano, Trope, & Liberman, 2002). For another example, when risk-related information is based on first-hand experience or direct observation (low distance), rare events are underestimated (consistent with the enhanced sensitivity to probabilistic information). However, when indirect, secondhand information is presented verbally or numerically (high distance), rare events are overestimated (Hertwig, Barron, Weber, & Erev, 2004; Weber, Shafir, & Blais, 2004). By the same token, construal-level theory can assimilate strong influences on decision making, and preference reversals, obtained when decision options are presented affectively (low distance) or purely descriptively (high distance; Hsee & Rottenstreich, 2004), when outcomes are decomposed or unpacked into their components (low distance) or considered globally (high distance; Fiedler & Armbruster, 1994; Tversky & Koehler, 1994), or when the decision process is at the beginning (high distance) or

TABLE 8.2. Influences on Decision Making and Sources of Preference Reversal That Can Be Derived from, or Assimilated within, Trope and Liberman's (2003) Construal-Level Theory

Distance dimension	Empirical evidence obtained with increasing psychological distance:	Sample reference
Temporal	Stronger impact of value component, lesser impact of probability component	Sagristano et al. (2002)
Affective	Increased consideration of scope (number of cases affected by decision) rather than affective value of a single outcome	Hsee & Rottenstreich (in press)
Grain size	Stronger planning fallacy, reflecting focus on planned option and failure to unpack multitude of alternative options	Kruger & Evans (2004)
Inclusiveness	Reduced attraction of a chosen option when all alternative outcomes are packed as one large category rather than many small categories	Windschitl & Wells (1998)
Investment	Reduced sunk-cost effect as long as commitment to decision is not too high	Arkes & Blumer (1985)
Commitment	More weight given to payoff as opposed to probability when task focuses on pricing (desirability) rather than choice (feasibility)	Slovic (1995)
Participation	Overweighting of rare events when infrequency is not experienced (firsthand information) but stated in summary statistic or verbal quantifier (secondhand information)	Hertwig et al. (2004)

has already reached a high degree of commitment (low distance, as in a so-called sunk-cost situation; Arkes & Blumer, 1985).

Cognitive–Ecological Rivalry: Trivariate Reasoning

Understanding the interplay of personal and (ecological) determinants of behavior can itself become an objective of psychological experiments. In many attribution experiments, judges are presented with behaviors that can be attributed to internal personality factors or to external factors in the environment. Let this paradigm be called *trivariate reasoning*, as the task involves three variables; two independent variables, X and Z, competing for the explanation of one dependent variable Y (cf. Spellman, 1996). Typically, Y is the behavior to be explained (e.g., a hostile act), X is a personal cause (e.g., aggressiveness trait), and Z is an ecological condition (e.g., media violence).

The tendency to give more weight to personal than to ecological factors in this trivariate paradigm is well known as the fundamental attribution bias (Ross, 1977). Moreover, the failure to take both determinants into account is evident in another major finding, the discounting effect (Kelley, 1973; Kruglanski, Schwartz, Maides, & Hamel, 1978; McClure, 1998; Morris & Larrick, 1995). To the extent that one factor is known to exert an influence, the judged impact of the other factor decreases. The discounting principle assumes that the impact of the primary factor, X, on the dependent variable Y, decreases when the secondary factor, Z, is known to be present. As illustrated in Figure 8.3, this is the model of a *spurious correlation*, in which Z can account for (part of the) influence of X on Y. As Z is partialed out (i.e., the X–Y relation is considered at separate levels of Z), the impact decreases or disappears.

However, discounting is but one way in which personal and ecological factors can codetermine an effect. Figure 8.3 reveals several other possibilities. The influence of the person (X) and the situation (Z) on behavior (Y) could be independent (orthogonal). Or, the inclusion of a secondary (external) factor, Z, could increase the relation of Y to the primary (internal) factor X—a constellation known as a *suppressor effect* (Conger & Jackson, 1972). This may occur when Z is correlated with that variance component of X that is uncorrelated with Y, thus absorbing "error" variance. (For example, Z might be a law that prohibits the individual from acting out her trait.) In such a suppressor situation, partialing out Z increases, rather than decreases, the relation of X and Y.

Trivariate problems as in Figure 8.3, calling for the integration of two or more determinants (e.g., internal and external; personal and environmental), are hard to solve, for researchers and research participants alike. This inherent difficulty of trivariate reasoning is emphasized in Simpson's paradox (Schaller, 1992a, 1992b; Spellman, Price, & Logan, 2001), which is based on the logic of a spurious correlation. In a typical task, participants are presented with a series of observations showing that more male than female applicants are accepted for a graduate program. The default explanation in terms of personality factors suggests that applicant gender (X) is a

Uni-causal influence. z has no impact

x —0.50— y 0.00   0.00 z $r^{*}_{xy.z} = r_{xy}$

Orthogonal pattern. z has independent influence

x —0.50— y 0.00   0.50 z $r^{*}_{xy.z} = r_{xy}$

Suppressor. z suppresses error variance in x-y relation

x —0.50— y −0.50   0.00 z $r^{*}_{xy.z} > r_{xy}$

Spurious correlation. z accounts for x-y relation

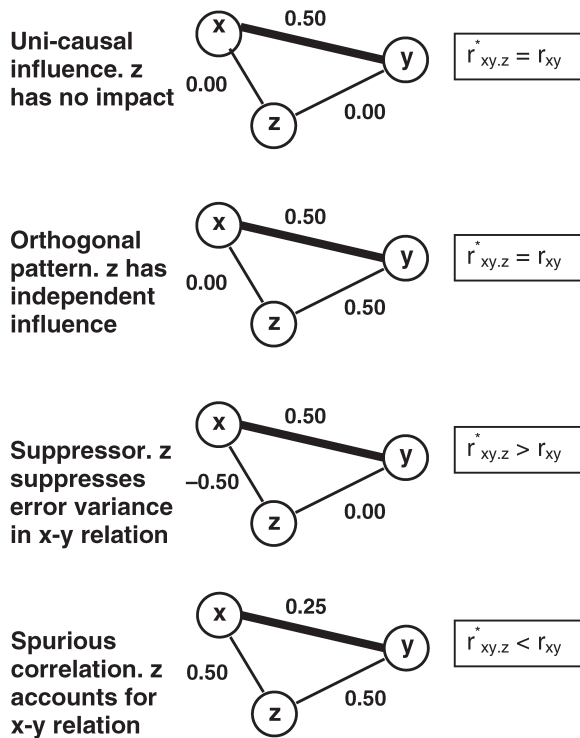
x —0.25— y 0.50   0.50 z $r^{*}_{xy.z} < r_{xy}$


FIGURE 8.3. Different trivariate relations describing the way in which behavioral effects on a dependent variable y are codetermined by an individual factor x and an ecological factor z. The ecological factor, z, may be ineffective, independent, increase, or decrease the impact of x on y, as evident in a partial correlation $r^{*}_{xy.z}$ is equal, larger, or smaller than the focal zero-order correlation r_{xy} between x and y.

significant determinant of graduate admission (Y). However, in fact, a second, ecological determinant (Z) is involved, the distinction between two different universities. If this factor is taken into account, it turns out that within both universities, the proportion of accepted women is actually higher. The solution of this paradox is that one university is much more prestigious and has a much higher rejection rate than the other. As more women than men apply to the prestigious university, it is possible that the absolute success rate for women is reduced although the relative proportion of successful women is higher at both universities. According to Schaller (1992a, 1992b), feministic motivation facilitates the recognition of a female advantage, as opposed to the global male advantage. Other findings (Waldmann & Hagmayer, 1995) demonstrate that the hidden female advantage is more likely to be noticed when a plausible causal model is available.

However, crucially, participants have a hard time refraining from discounting and to understand that both conclusions can be true at the same time. Although females are superior at university level, it remains true that male applicants are superior at the aggregate level. The partial correlation between gender and achievement, with universities partialed out (favoring females), is no more real than the zero-order correlation across universi-

ties (favoring males). After all, the rejection rates of the two universities can be interpreted differently. It is possible of course that the high rejection rate of one university is simply due to higher standards, but it is also possible that the high rejection rate reflects the high number of (inferior) females joining this university. So the ultimate solution of Simpson's paradox (as of many other ecological problems) is to recognize that both opposing conclusions hold at the same time. This level of cognitive–ecological understanding is extremely hard to meet (Fiedler, Walther, Freytag, & Nickel, 2003).

Ecological Correlations

The seemingly paradoxical relation between ecological and personal explanations is highlighted in the famous notion of an ecological correlation (Robinson, 1950). The correlation, say, between skin color (being Black) and illiteracy across a large representative sample of U.S. individuals amounted to +.203. However, the correlation between the proportion of Blacks and the proportion illiteracy across the Census Bureau's nine geographic divisions was as high as +.906. Thus, depending on what level of aggregation is considered, individuals or ecologies, quite different conclusions about the same correlation are valid. An implication, which suggests itself, is that social stereotypes may to an unknown degree reflect the existence of such ecological correlations (Fiedler & Freytag, 2004). The neglect of this exciting phenomenon in modern social psychology is symptomatic for the lack of theoretical models that integrate personal as well as ecological laws, within the same framework.

Ecological correlations may be involved in some of the most prominent research topics that draw on ecological variables. For example, with regard to gender stereotypes, the relationship between leadership and female participation is certainly negative across vocational ecologies (i.e., in high-leadership areas, the prevalence of women is low), even though individual females may be strong leaders within specific professions. Correlations at different aggregation levels may not only diverge in size but even reverse their sign. A stereotypical relation may hold at aggregate level while disappearing or even reversing at individual level. Because the statistical boundary conditions that produce or eliminate ecological bias are well understood (Hammond, 1973; Hannan, 1970), this approach has promising implications for stereotyping research.

In a similar vein, when social roles (Eagly, 1987; Hoffman & Hurst, 1990) are used as constructs to explain individual behavior, a high-level aggregation construct (roles) is used to explain individual behavior, again raising a problem of ecological correlations. The same holds for intercultural studies, when differences that exist between cultures (Kühnen, Hannover, & Schubert, 2001; Markus & Kitayama, 1991; Nisbett et al., 2001) are used to explain differences in individual behaviors. Equally prominent are evolutionary accounts (Cosmides & Tooby, 1992; Tooby & Cosmides, 1992) assuming that correlations that hold over large temporal periods can explain the behavior of individual persons nested in one

generation (for an enlightening critique, see Lewontin, 1979). The point here is not that analogies and explanations in terms of roles, cultures, or evolution must be misleading. The point is, rather, that the ecological-correlation framework—which specifies the limiting conditions under which such aggregate constructs can be supposed to predict individual behaviors—is known for decades but is still waiting to be applied in social psychology (cf. Slatin, 1969).

Dynamic and Complex Features of Modern Information Societies

Among the most interesting cognitive–ecological research designs are those written by the modern information society itself. The following research topics promise to be content valid and highly pertinent to the interaction of environmental stimulus input and the preparedness of individual cognition: advertising and consumer behavior (Miller & Berry, 1998), risk assessment and the interpretation of statistics (Gigerenzer et al., 1999; Hoffrage, Lindsey, Hertwig, & Gigerenzer, 2000), health-related decisions in light of health-related publications (Lindsey, Hertwig, & Gigerenzer, 2003), sampling bias in criminality assessment (Slatin, 1969), the impact of the Internet and other modern communication media (Gaver, 1996), the role of mass media in the formation of political attitudes, affordances and hindrances of globalization, communication problems related to worldwide migration movements, international law and translation problems, memory and cognition in elderly people, ecological and economical factors in education, political attitudes and action related to such existential topics as birth control, energy consumption, or AIDS, and various other highly prominent topics. A common denominator of all these challenges and threats of the new millennium is that psychological aspects of information transmission are of ultimate importance (Combs & Slovic, 1979). Hardly any other scientific discipline has to play a similarly responsible, crucial role as psychology, because the communication of problem-relevant information can be as important as the investment into medical, physical, geological, or astrophysical solutions, which are often far out of reach.

Publicizing Scientific Information

For example, the mad-cow disease in Europe, which had an incisive impact on economics and behavior around the turn of the century, has been almost forgotten and no longer influences consumer behavior, although the potential danger remains largely unchanged, just because the mass media have dropped this favorite topic. A number of recently published studies testify to the claim that dealing with information about problems and risk can be equally important as the problems themselves. Gigerenzer (2004a) provides compelling evidence showing that the number of people dying from highway accidents due to the media reactions to September 11, 2001, rose before the end of the year 2001 to a number higher than the primary victims of the terror attack. Equally pertinent is the Swets and colleagues (2000) finding mentioned earlier that given a positive result on both biologically independent HIV tests on the U.S. market and the likelihood of HIV is only about 15%. As physicians are not trained in statistics and unlikely to communicate risk information appropriately, the secondary risks in terms of suicide, stress, and disparate action may be in the same range as the original problem, HIV.

Legal decisions in the courtroom may be misled by the inability to understand inherently statistical proofs. Having learned that a perfect copy of a perpetrator's DNA occurs in only 1 of a million cases, judges and jurors may infer that a matching DNA yields strong evidence that a defendant is guilty. However, a closer examination of the prosecution environment may reveal that the matching DNA has been found in a computerized search of more than 2 million cases. So the probability that an innocent person has been misidentified may be twice as high (two cases expected) than the probability that the DNA belongs to the original (one case) perpetrator (Lindsey et al., 2003).

Dealing with the quality of statistical, technical, and political information is one task in modern information societies; dealing with the quantity of information overload is another task. Social psychologists have long been interested in selective exposure (Frey, 1986), selective information search (Jonas, Schulz-Hardt, Frey, & Thelen, 2001; Schulz-Hardt, Frey, Lüthgens, & Moscovici, 2000), and related strategies of self-determined reduction of information input. Modern information societies call for the study of external, ecological determinants of information reduction. On one hand, the media and the advertising industry determine the saliency and frequency (density) with which products, brand names, symbols, topics, role models, and threats are imposed on the people. On the other hand, rules of social conduct and cooperation (Clark & Schober, 1992; Grice, 1975) constrain the information that is likely to be published, broadcasted, or uttered in conversation. Thus, for political arguments to be raised in a political campaign, they have to be simplistic rather than difficult and refined. For a message to be distributed in advertising, it has to be financed by a company having vested interests. To be multiplied on the Internet, it has to appear in the upper positions of major search engines. In contrast, information that is "politically incorrect" or that could cause legal sanctions is unlikely to be publicized. In any case, the inevitable reduction of information jointly depends on deliberate selection decisions and externally determined restrictions of information flow.

That the outcome of this eminent ecological process can strongly impact social behavior is vividly demonstrated in the influence of media on aggression (Anderson et al., 2003; Bushman & Anderson, 2001). Other research shows that prudent media consumption can be the key to effective education (Hokanso & Hooper, 2000). Offensive advertising, say, for cellular phones, can change an entire generation's communication style. And the association with major brand names has become a significant part of social identity (Miller & Berry, 1998).

Less Can Be More

Given the tremendous problem of information overload, a major task for adaptive intelligence is optimal selection of information (Oaksford & Chater, 1994), and an intriguing insight from cognitive–ecological research is that less information can be more. The quality and accuracy of decisions and actions can decrease as the amount of input information increases. Based on both developmental data and computer simulation, Elman (1993) showed that the extremely complex task of language learning is facilitated by working-memory limitations and restricted length of input utterances. A similar demonstration was made by Kareev (1995, 2000) for contingency-based decisions, showing that small samples can inform better decisions than large samples. Too much thinking and information search can dissociate decisions from unconscious attitude components (Wilson & Schooler, 1991), causing inconsistency and disruption of behavior. And lexicographic, single-cue strategies can inform more accurate judgments than utilizing many cues for complex inference strategies (Gigerenzer & Goldstein, 1996; Goldstein & Gigerenzer, 2002).

CONCLUSIONS

Aside from those research traditions that can be traced back to a few famous environmentalists—such as Brunswik, Lewin, or Gibson—the roots of a modern cognitive–ecological approach can be found in an old question that has intrigued psychologists since the beginning of the discipline: Is behavior determined by the stimulus environment (Behaviorist position) or by the organism's built-in (and often innate) schemas and propensities (Gestalt position)? Does individual cognition reflect language as a sign system (Benjamin Whorf) or is language but a product of individuals' cognition (Roger Brown)? Is social cognition driven by affordances of the information society, including the mass media (Gaver, 1996) and the immersive virtual world of computers (Alley, 1990; Blascovich, Loomis, & Beall, 2002; Zebrowitz, 2002)? Or, do constraints arise in the cognitive processes of individual persons (Martin, 1990)?

In experimental social psychology, this debate about the external versus internal locus of causation is at the heart of some most prominent paradigms, such as attribution (Jones & McGillis, 1976; Kelley, 1967, 1973), the fundamental attribution bias (Ross, 1977), and the related correspondence bias (Jones, Riggs, & Quattrone, 1979). The basic finding here was that everyday social judgments tend to be biased toward internal causes (i.e., traits and intentions within the person), whereas the external constraints of the environment are often neglected and only considered under auspicious conditions. It appears that behavioral scientists' thinking and theorizing is subject to the same basic restriction and facing the same developmental task, to overcome this fundamental barrier. The task is not merely to admit that external, ecological factors can exert an influence but to develop refined models within which one can understand the joint operation of both classes of determinants. Just as in Inhelder and Piaget's (1958) ontogenetic approach to the development of higher-order (i.e., operational) intelligence is marked by the ability to understand the simultaneous influence of two factors (e.g., that the amount of water in a glass depends on both its height and diameter), current (social) psychology has to learn how to integrate individual and ecological influences within the same models. Up to now, the appearance of such models is conspicuously missing or lacking behind. With a few notable exceptions (e.g., Trope, 1986), the attribution to internal versus external causes is conceived as an either–or problem, a forced choice between either one or the other determinant. The discounting principle (i.e., tendency to allow for only one effective cause) seems to govern not only everyday attributions but scientific explanations as well. This is vividly evident in the popularity of numerous dual-process models in social cognition (Chaiken & Trope, 1999; Smith & DeCoster, 2000), which all tend to assume that either one or the other process is at work at a given time, but not both (for an exception, see Kruglanski & Thompson, 1999).

Given this persisting inclination toward monadic, monocausal explanations, the theoretical discounting of ecological processes would appear to represent the natural consequence of social psychology's focus on cognitive, affective, and motivational processes within the individual. Facing this situation, the present handbook review of research on information ecology had to some extent to be a preview of undone research. The major points conveyed in this review/preview can be summarized in the following basic principles:

1. To understand the structure of psychological processes within the individual, it is first of all necessary to analyze the structure and distribution of the stimulus environment that impinges upon the individual's mind.
2. In particular, the structure of the information ecology entails three aspects, the *density*, the *variance*, and the *redundancy* structure of stimulus distributions.
3. The location and movement of individuals and groups in the environment creates asymmetries and distinct topological relations (i.e., the self–other topology), which are at the heart of many phenomena in social psychology.
4. When individuals search for samples of information for decision making and problem solving, the sampling process is virtually never random but subject to sampling constraints leading to biases and shortcomings.
5. A considerable part of the information that impinges upon human's sensory system—through conversation, literature, mass media, Internet, teaching, or advertising—is self-made, reflecting a genuine interaction of both cognitive and ecological factors.

CHAPTER 9

Knowledge Activation

Jens Förster
Nira Liberman

In 1977, Higgins, Rholes, and Jones invited participants to an experiment that consisted of two apparently unrelated studies. The first study was a Stroop color-naming task, for part of which participants had to memorize words, supposedly to make the task more demanding; for some participants these were positive words (adventurous, self-confident, independent, persistent), whereas for other participants these were negative words (reckless, conceited, aloof, stubborn). The second study was an impression formation task in which participants read a description of Donald who performed a series of ambiguous behaviors that could be regarded as adventurous or reckless (e.g., Donald thought about crossing the Atlantic in a sailboat). Participants then wrote a free description of the target person and indicated how much they liked him on a rating scale. Results indicated that Donald was rated as more adventurous and less reckless by the positive priming group than by the negative priming group.

A typical priming experiment has two phases: (1) a priming phase in which participants are exposed to some information and (2) an ostensibly unrelated perception, memory, or judgment task in which participants' responses to a target stimulus are examined. The *afferent stage* of a priming experiment consists of a stimulus presentation (e.g., reckless or adventurous) that leads to activation of associated memory structures. The *efferent stage* of a priming experiment consists of activation of a memory structure in the process of responding to related target stimuli (Fiedler, 2003).

From the perspective of the participant, there is no relation between the two phases (the procedure described above is often referred to as the *unrelated task paradigm*). Thus, any effect of the first stage on the second stage is not noticed by the participant, ruling out conversational effects (e.g., thinking that the information of the first stage is useful) or motivational effects (e.g., wanting to conform to a specific behavior pattern).

It is argued that the first stage enhances the accessibility of the primed construct and that constructs with higher accessibility are more likely to be used than those with lower accessibility. In the study by Higgins and colleagues (1977), the behavior "thinking about crossing the Atlantic in a sailboat" could be perceived as both adventurous and reckless. A higher accessibility of one of these constructs leads to the perception of the target in terms of this construct.

In a typical priming task, people are not aware that they were affected by the first task. If directly asked how they formed their judgments, they would most likely reply that they based their judgments on the stimulus itself—they would say that the target person was, indeed, involved in reckless or adventurous activities (i.e., the judgment is "about" the target's behavior and not about the priming event). In logical terms, the influence of the prime is not justifiable—nobody would maintain that the target should be perceived differently because of a previous task of color naming. Yet, these effects occur reliably and have been replicated and used in many social psychological experiments.

In this chapter, we first propose some working definitions of priming effects as distinct from other effects of prior information processing on further target perception. Then, in the second part we review the main findings within the vast field of social psychological research on knowledge accessibility, including perceptual readiness, retrieval from memory, disambiguation, the effects of priming related to behavior and motivation, procedural priming, affective and evaluative priming, and chronic accessibility. The third part examines some theoretical principles that emerge from this review—including factors affecting decay rates and intensity of priming, how accessibility from different sources combines, and how applicability and accessibility compensate for each other. The fourth part examines metacognitive processes related to priming, and the fifth part examines the possible function of different priming effects—what do they serve and what would moderate such effects. The final part examines some applications of the principles of accessibility in social psychology. Specifically, we discuss using affective priming to measure attitudes, to assess motivations and personal concerns, and to understand processes of thought suppression. We do not review models of accessibility as these have been examined in detail elsewhere (see, e.g., Higgins, 1996; Huber, Shiffrin, Lyle, & Ruys, 2001; Wyer, 2004; Wyer & Radvansky, 1999).

DEFINITIONS

Let us begin with introducing a number of terms, starting with an attempt to define the effects of accessibility. As we will see, there are difficulties in many of these definitions; however, we believe that these difficulties, some of which originate from the fuzzy boundaries of these theoretical constructs, should not detract from their usefulness.

What Are the Effects of Accessibility?

First, we would like to delineate the domain of our discussion—which effects would be termed "effects of accessibility" and which effects will be left outside this definition. Generally, *accessibility is a temporary state that is produced by prior processing of a stimulus and thus activates knowledge*, be it semantic, procedural, experiential, or any other form (e.g., Tulving, 1983). By frequently activating certain knowledge structures accessibility can also become chronic. Generally, we are talking about the effect of prior processing on subsequent processing of a target stimulus. Not all such effects, however, should be labeled "accessibility." For example, priming (e.g., the experiment described at the outset of this chapter) is an accessibility effect, but persuasion per se is not an effect of accessibility, or at least not only an effect of accessibility. So, what is the theoretical principle that defines accessibility?

We would like to suggest that accessibility effects occur when effects of prior processing happen regardless of people's beliefs about the relevance of the prime to the

target, and regardless of their beliefs about the suitability of its influence on processing the target. For example, in subliminal priming, when people are unaware of processing the prime, they may not consider the relevance of the prime to the target. This is similar to the unrelated tasks procedure in which people are aware of processing the prime but do not consider it relevant to the second phase when the target is presented.[1] By being independent of the questions of relevance and suitability of influence, the effects of knowledge accessibility are insensitive to the propositional content of the prime (e.g., to its truth value, see Fiedler, 2003). Notably, unlike in processes of attitude change via persuasion, increased accessibility from priming would occur with both negated and affirmed primes (Fiedler, 2003; Mayo, Schul, & Burnstein, 2004; Strack & Deutsch, 2004), or regardless of the credibility of its source (Schul, Mayo, & Burnstein, 2004).[2]

Sometimes, effects of accessibility occur in conjunction with other effects. For example, people who watch a commercial may unknowingly be affected by it. They may rightly acknowledge the relevance of the entire commercial to their behavior and resist its effects (e.g., "They are trying to persuade me to buy diet toothpaste, but I do not need it and won't yield to that attempt.") and at the same time be affected by features of the commercial that they would not judge relevant for the focal judgment (e.g., they might end up thinking that the toothpaste is healthier because the commercial paired it with health-related stimuli). In this example, the part of the process that occurs regardless of the person's beliefs in its relevance and suitability (the effect of irrelevant health-related stimuli) would be termed an "effect of accessibility." This example illustrates the fact that sometimes accessibility effects may interact in complex ways with more deliberate, belief-based processes (e.g., persuasion). We return to this point many times when we discuss in more detail the various effects of accessibility and again when we discuss metacognitive processes.

By our definition, while some types of classical conditioning would not count as effects of accessibility, other types of conditioning may be viewed as effects of accessibility. Namely, when the unconditioned stimulus is diagnostic with respect to the conditioned stimulus (e.g., when the bell signifies that food is about to be served), then conditioning is not analogous to effects of accessibility because the association is based on a true informational, predictive value of the prime. However, if toothpaste becomes associated with health because it is shown on a commercial together with fresh fruits the association is formed irrespective of the person's belief in the relation between toothpaste and health and thus may be considered an effect of accessibility (see Walther, Nagengast, & Trasselli, 2005).

We should emphasize that belief-driven (conscious or unconscious) processes may alter the effects of accessibility. For example, if I believe that my judgments could have been affected by prior processing, I might want to counteract them. Such correction is not, by itself, an effect of accessibility, but it is related to accessibility and metacognitive knowledge. This is discussed further in the fourth part of the chapter.

There are other definitions of accessibility effects that, we believe, are not useful. One equates effects of accessibility with automatic processes and distinguishes them from controlled processes. Any process, including belief-based propositional computations, may be automated and become efficient, unaware, and unintended. For example, people may automatically yield to messages from an authority as a result of a reason-based process of learning and believing that doing so is useful. This will produce an automatic effect. One could argue that such processes had to be performed repeatedly in a nonautomatic manner in order to achieve automaticity, whereas effects of accessibility happen automatically (i.e., with no intention and with no awareness) with no prior learning. The latter claim, however, cannot be endorsed with certainty because it is possible that some learning process did, in fact, bring about at least some automatic effects of accessibility. For example, it is possible that people learned over time that stimuli in close temporal or spatial proximity are related to each other and therefore began using co-occurring stimuli to disambiguate each other. Although accessibility effects typically happen outside awareness, they are not unique in that other processes also may require little effort and occur with no awareness or intention. The reverse is also true—accessibility need not happen outside awareness. A person could be aware of an influence of a prime on subsequent processing but still have an effect of its accessibility. Part of the problem here is that automaticity itself has more than one property, with awareness being only one of them (see Bargh, 1994b). Second, it has also been proposed that accessibility does not alter knowledge structures (i.e., does not change availability) but, rather, alters only momentary activation potential, whereas other processes, such as persuasion, introduce a more long-lasting change in long-term memory. This distinction is problematic because momentary changes may amount over time to new associations and create new meanings (e.g., form associations between stimuli, such as between toothpaste and health). As we see later, procedural priming and chronic accessibility, in particular, involve changes in long-term memory (see Wyer, 2004). We thus propose to define effects of accessibility as effects that are insensitive to beliefs (but are, as we will see next, sensitive to associations). We are aware of the fact that the boundaries of this definition may be unclear. However, there are clear examples of effects that are produced by accessibility of knowledge and others that are not. Thus, the effect of priming on judging a target is a clear example of a knowledge accessibility effect, whereas when one is persuaded to try a product it is a clear example of an effect that is not driven by accessibility of knowledge. In the latter case it is not the mere accessibility of the idea that leads to trying the product but rather that some more complex processes are involved.

There are effects that are more difficult to classify one way or another, such as some types of conditioning, or procedural priming. Nevertheless, the existence of twilight does not mean that people are unable to distinguish between day and night, and thus we proceed to explore the category of accessibility with a number of further distinctions and terms that are used throughout this chapter. Generally, our terminology is consistent with that of Higgins (1996) and with Decoster and Claypool (2004).

- *Construct use* is a response in terms of a construct. For example, rating an ambiguous target as aggressive involves using the aggressive construct.
- *Availability* is presence in memory. People can only use a construct and be primed with a construct if it is available. For example, if one never associated "creativity" with the category of professors, priming "professor" would not bring "creativity" to mind. Availability is a necessary condition for accessibility.
- *Accessibility* is the activation potential of available knowledge (Higgins, 1996). Knowledge activation (e.g., by priming) increases its potential for further activation—that is, it increases accessibility (Bruner, 1957).
- *Applicability.* Accessibility is not sufficient to produce priming effects. Rather, accessible constructs affect perception and judgment only if they are applicable to the target (Higgins, 1989). For example, when primed with "dependency," participants found a female target but not a male target to be more dependent than neutrally primed control participants (Banaji, Hardin, & Rothman, 1993). The reverse was found for priming aggression. Notably, the target stimuli, which were behavioral descriptions of individuals, were the same for male and female targets. Yet, the primed construct was used more when the prime matched the social category ("dependent" for a female target, "aggressive" for a male target; for a recent meta-analysis of the effect of applicability on assimilative priming effects, see Decoster & Claypool, 2004, for an application to survey research see Todorov, 2000). Applicability should be distinguished from *consistency* (Higgins, 1996). Inconsistent constructs are applicable to a target that has an opposite meaning (e.g., the prime "dishonest" is applicable to an honest person, although inconsistent with it) more so than completely unrelated constructs (e.g., the prime "stupid" to an honest person). Thus, inconsistency naturally implies some applicability.
- *Ambiguity and vagueness.* A stimulus description is *ambiguous* when at least two alternative constructs are equally applicable to it (e.g., a target may be described as both adventurous and reckless), whereas a behavioral description is *vague* when no construct has more than weak applicability to it (e.g., when a behavior only weakly implies intelligence, e.g., "Brett read a newspaper," Higgins & Brendl, 1995). Perceptions and evaluations of ambiguous and vague stimuli, more than those of clear, unequivocal stimuli, are influenced by priming (and, in fact, by any manipulation, such as persuasion, conditioning, etc.).
- *Judged usability* is the perceived appropriateness of applying some knowledge to a stimulus (Higgins, 1989, 1996). Information that is both accessible and applicable may not be used if it is perceived as irrelevant or inappropriate. For example, when a person thinks a racist thought, such as "African Americans are hostile," is untrue or politically incorrect she might refrain from judging an African American person as hostile, even if the

construct of hostility is highly accessible to her (Devine, 1989). Judged usability is often viewed as a conscious process, but it is entirely possible that unconscious judgments of usability also occur; judgments may become automated, as any overlearned process can be. Regardless of whether it is conscious or not, judged usability is a metacognitive process and we discuss it and related metacognitive processes in more detail in the fourth part of the chapter.

EFFECTS OF ACCESSIBILITY

We turn now to review the different effects of accessibility—effects on perceptual readiness, memory, disambiguation, priming related to motivation and goals, procedural priming, affective and evaluative priming, and chronic accessibility.

Perceptual Readiness

In a classic demonstration of semantic priming, Meyer and Schvaneveldt (1971) measured the time it took participants to decide if a letter string was a word or not. This task, called the *lexical decision task*, often serves to measure perceptual readiness as produced by accessibility. It is assumed that a decision about a particular word would be facilitated by accessibility, and thus, lexical decisions should be shorter for more accessible constructs. The authors found facilitation of lexical decision when words were preceded by semantically related primes. For example, when the target stimulus was the word "building," lexical decision time was reduced if the semantically related word "house" preceded it. It is beyond the scope of this chapter to review the vast literature on semantic priming in cognitive psychology. Rather, we present only a few core findings that we found useful for a better understanding of related findings in social psychology.

Perceptual Readiness for Visual Stimuli

Conceptual priming may facilitate perception of visual features. Zwaan, Stanfield, and Yaxley (2002) presented participants with sentences such as "The ranger saw the eagle in the nest," or "The ranger saw an eagle in the sky," and then asked participants to view pictures and decide as quickly as possible whether the object in the picture was mentioned in the sentence. The pictures contained either features that matched the implied shape of the object or not (e.g., stretched wings or folded wings). Decisions were faster when there was a match between the sentence and the picture. These results suggest that sentences trigger perceptual simulations and not only activate semantic knowledge (see also Wyer, Adaval, & Colcombe, 2002).

Decay Rates of Priming Effects

In many of the studies in cognitive psychology, effects of semantic priming were found to decay extremely rapidly. For example, the effect of semantic priming on lexical decisions disappears if the target is presented a few seconds after the prime, or if another word intervenes between the prime and the target. Slower decay rates, however, appear with deeper processing of the prime and the target. For example, Becker, Moscovitch, Behrmann, and Joordens (1997) found that a decision on animosity (i.e., "Is it a living thing?") for both the prime and the target created a facilitation that lasted for much longer than a lexical decision (i.e., "Is it a word?"). With 10 intervening words the effects of priming were still evident with deep semantic processing but not with lexical decisions. The authors suggest that stronger effects after a delay (i.e., slower decay) stem from a larger degree of incremental learning that is characteristic of deeper processing. In our view, deeper processing of the target makes the task more similar to disambiguation (see below) than to pure perceptual readiness. Thus, we would expect slower decay and stronger effects for disambiguation than for perceptual readiness tasks.

Directional Associations

Concepts can be activated by interrelated networks, which are formed if two concepts are frequently activated together (Hebb, 1948). For example, Mussweiler and Förster (2000) reasoned that the concepts of "sex" and "aggression" became interrelated over socialization and that the strength of this association may depend on the direction (e.g., sex → aggression vs. aggression → sex). Specifically, because sexual situations often involve aggressive components (see, e.g., Koss, Gidyez, & Wisniewski, 1987), an automatic sex–aggression link could have developed. Consequently, activating concepts associated with "sex" should also activate concepts associated with "aggression." By contrast, many aggressive situations are free of sexual components and therefore "sex" would not be contiguous with "aggression," meaning that activation of aggression concepts should not activate sex concepts. A study using subliminal priming demonstrated this effect with a lexical decision task. When primed with mild sex concepts (e.g., the word "wet") participants were faster in identifying aggression-related words (e.g., "brutal"). However, this was not true for sex-related words after priming of aggression-related words, a finding that is consistent with the idea of a unidirectional link.

Inhibition of Competing Constructs

Primes facilitate related constructs, but they also inhibit competing constructs (see Förster & Liberman, 2005, for a review). For example, Ratcliff and McCoon (1996) presented participants with pictures of mundane objects (e.g., a lightbulb) and recorded naming latencies after being primed 1 week earlier with the same object or a graphically similar but semantically different object (e.g., a balloon). A no-priming control group was also included. The authors found that whereas semantically similar primes produced facilitation, graphically similar primes produced inhibition by increasing the response time relative to the control group.

Similarly, in linguistic processing, it has been found that homonyms initially activate all the semantic meanings (e.g., the word "bank" activates both the meaning of a financial institution and the meaning of a riverside). However, once a context is determined, the context-irrelevant meanings become inhibited (Swinney, Prather, & Love, 2000).

In Neely's (1977) classic study, participants performed lexical decisions in which the target words were preceded by signal words. In one condition, the signal "body" appeared consistently with targets that signified building parts (e.g., door) and, therefore, was reasoned to semantically prime body parts and simultaneously induce an "active set" for building parts. The study found that at longer delays (1,000 msec) between the prime and the target (stimulus onset asynchrony), the prime inhibited decisions about semantic associates (e.g., body parts) and facilitated decisions related to the active set (e.g., building parts). However, at shorter delays (250 msec), it facilitated decisions about the semantic associates but not about the active set. This has been interpreted to mean that novel associations have longer onset times, whereas more habitual associations are faster to exert influence. We should expect, therefore, that practicing an association would shorten onset times of its influence as a prime.

Macrae, Bodenhausen, and Milne (1995) exposed participants to targets that belonged to multiple stereotyped groups (e.g., an Asian woman). Beforehand, participants were subliminally primed with one of the category labels (women, Chinese). Using a lexical decision task, the study showed that such priming led to inhibition of concepts that were related to the other, nonprimed category (see also Fiedler & Schenck, 2001). In sum, it seems that primes have onset times that get shorter with practice. It also seems that priming causes inhibition of prime-associated constructs that may impede performance of the task at hand and may be delayed.

Retrieval from Memory

Cued Recall

After participants memorize a list of words (e.g., a list of objects from a number of categories), exposure to semantic associates of the learned items (e.g., the name of some of the categories) typically improves recall, a phenomenon that has been termed "cued recall." Thus, retrieval from long-term memory is assisted by priming, namely, by exposure to a semantically related item or a cue (see, e.g., Santa & Lamwers, 1974; Shimamura & Squire, 1984).

Part-Set Cuing Inhibition and Retrieval-Induced Forgetting

Sometimes retrieval cues impede rather than assist memory, a phenomenon that has been termed "part-set cuing inhibition" (for reviews of the empirical findings, see Anderson & Neely, 1996; Nickerson, 1984; Roediger & Neely, 1982). The paradigm typically requires partici-

pants to memorize a list of words from a small number of semantic categories (e.g., 40 words comprised of colors, trees, fish, and musical instruments). At recall, participants are presented with a different number of words from each category (e.g., one musical instrument, four colors, and four trees) as cues. The classic finding is that participants recall fewer of the remaining items in a given category when *more* words from that category are presented as cues (see, e.g., Rundus, 1973; Slamecka, 1968; Watkins, 1975). Anderson and colleagues (Anderson & Neely, 1996; Anderson & Spellman, 1995) have suggested that selective attention toward the rehearsed items inhibits accessibility of the other items.

Retrieval-induced forgetting refers to a somewhat related phenomenon. In these experiments, during the study phase, participants study several categories, each composed of several exemplars in a category-exemplar format (e.g., fruit-orange). After the study phase, participants engage in directed "retrieval practice" for half of the items from half of the studied categories. In this phase, they complete category-plus-exemplar stem cue tests (e.g., fruit-or___). After a retention interval, a final and unexpected category-cued recall test is administered in which participants are cued with each category name and asked to reproduce any exemplar of that category that they remember from any point in the experiment. It is typically found that performance on practiced items improves relative to the baseline condition (i.e., items from unpracticed categories), whereas performance on the unpracticed items from practiced categories falls below this baseline. Anderson and Bjork (1994) explained these effects by suggesting that during the retrieval practice phase the practiced items compete with the unpracticed items from the same category and thus inhibit them (see also Anderson & Neely, 1996; Anderson & Spellman, 1995).

It is worth emphasizing that semantically related cues typically enhance memory, but as demonstrated by the phenomena of part-set cuing inhibition and retrieval-induced forgetting, they may also reduce memory. Specifically, if the cue and the target compete with each other as potentially relevant responses, then the nonchosen response is inhibited, becoming less accessible than before.

Disambiguation

Perhaps of particular relevance to social psychology are studies on accessibility effects on perception of ambiguous social stimuli, as social stimuli are often ambiguous and evaluation and labeling constitute important parts of social perception. The example at the beginning of this chapter is a classic demonstration of priming effects on disambiguation of a social stimulus. Stemming from that research, a great variety of priming effects on disambiguation have been documented with varying priming procedures, contents, and social targets. For example, unscrambling sentences related to hostility leads to perceiving a vaguely aggressive behavior as more aggressive than unscrambling sentences unrelated to hostility (Wyer & Srull, 1989). We do not list all the variations in

content but, rather, attempt to mention only some extensions of the original paradigm that we believe are of particular theoretical or practical importance.

Priming of Stereotypes

A classic study by Devine (1989) showed that subliminally priming associations of the category of African Americans (e.g., Negroes, Blacks, and lazy) influenced hostility ratings of an ambiguously aggressive target. Importantly, individual differences in racism, as measured by the modern racism scale (McConahay, Hardee, & Batts, 1981), did not mediate the effect, thus suggesting that stereotype activation influences judgments independent from stereotype endorsement (i.e., regardless of participants' prejudice level). Recent research challenged this notion (see Kunda, 2000). Whereas some criticized the lack of sensitivity of the scale (Fazio, Jackson, Dunton, & Williams, 1995), others (Lepore & Brown, 1997; Wittenbrink, Judd, & Park, 1997) noted that the words Devine used were mostly negative and might have activated negative associates of the category of African Americans, which would not be activated by neutral primes. Using the Modern Racism scale, Lepore and Brown (1997) found no difference in stereotype activation for negative primes of the African American stereotype (rude, dirty, drugs) between people high and low in prejudice. For neutral primes (e.g., African and West Indians), however, only highly prejudiced individuals experienced automatic activation of the negative stereotype (see also Wittenbrink et al., 1997). This suggests that people low in prejudice do not automatically associate negative concepts with the stereotype of Blacks. However, if the negative aspects are primed, participants automatically activate the entire, culturally shared negative stereotype, regardless of prejudice level.

Contextual Priming

Primes may be hidden within the context of the target stimulus and affect its interpretation. Gilovich (1981) asked participants to render judgments about the wisdom of American intervention in a hypothetical international conflict that was described in a given scenario. Two familiar and evocative historical events were primed within the context of the scenario: One was the American intervention during World War II, and the other was America's involvement in the Vietnam War. For example, the World War II script was primed by describing a hypothetical, modern-day invasion in terms of a "Blitzkrieg invasion" that resulted in refugees fleeting to a neutral country in boxcars. The Vietnam script was invoked by describing the same invasion in terms of a "quick strike invasion" resulting in refugees' flight to a neutral country in small boats. Participants were also shown a map with contours and labels invoking associations either to Europe or to Southeast Asia. The results showed that participants primed with World War II were more in favor of direct U.S. intervention. Notably, the primes did not change anything substantial in the described situation. Presumably, if asked to justify their choice, none of

the participants would invoke these as the reasons behind their recommendations regarding U.S. foreign policy.

Labels and Expectancies

Social labels may serve as primes and direct subsequent perceptions. In a classic experiment by Darley and Gross (1983), participants watched a videotaped interaction of a child in an examination, performing ambiguously (her answers were sometimes correct and sometimes incorrect). Prior to watching the videotape, some participants were informed that the child comes from an upper-class family, whereas some participants were informed that she comes from a lower social class. Participants were asked to evaluate how well she performed in the videotaped situation. Social class biased the perceptions, such that performance was judged to be higher for the upper-class child than for the lower-class child.

We should note that many of the effects of labels and expectancies are not pure effects of knowledge accessibility because they might be justified in logical, propositional terms. For example, in the aforementioned study, the researchers could have asked participants to predict the child's grade point average 10 years later. In that case, it could be reasonable to predict higher performance based on social economic status, in light of the well-established relation between these variables. Notably, in Darley and Gross's (1983) study, the question concerned the videotaped performance rather than future performance. In addition, Darley and Gross found that labels created the bias only when they were presented prior to watching the videotape, but had no biasing effect if presented between the video and the judgment task.[3] Logical effects should be relatively insensitive to the order of presentation of information, unlike accessibility effects, which occur, by definition, only if the prime precedes rather than follows the target (Fiske & Taylor, 1991).

Expectancies can be enduring and can affect information processing. A recent study found a relation between alcohol cues and expectancies concerning sexual arousal for male participants, which in turn influence arousal-related judgments (Friedman, McCarthy, Förster, & Denzler 2005). More specifically, it was found that unconscious exposure to alcohol-related cues, relative to nonalcohol cues, increased the tendency to judge women as sexually attractive but had no effect on judgments of their intelligence. This, however, was true only for those who held a belief in the aphrodisiac qualities of alcohol. Those who did not expect alcohol to increase their sexual desire were unaffected by the alcohol-related primes.

Priming of Dimensions

Sherman, Mackie, and Driscoll (1990) demonstrated priming of dimensions of evaluation. They asked participants to choose between two candidates for an election who were described on dimensions of foreign policy and economic matters. One candidate was described as having positive features relevant to foreign policy and a neg-

ative feature relevant to economic matters, whereas the other candidate was described in the opposite way. Both candidates were also described by neutral information. After having been primed with either the dimension of foreign policy or the dimension of economic matters, participants based their choice of the candidates on the primed dimensions. Recall for information from the dimensions was also measured, and it served as a proxy of attention. Attention mediated choice in that people attended more to the primed dimension and used it in their decision.

Priming of Opposites

Closely related to the notion of priming dimensions is the idea that constructs may be associated with their bipolar opposites. Park, Yoon, Kim, and Wyer (2001) showed that "healthy" may prime "unhealthy." If the implication of the target information were closer to the latter, it would be used for the judgment. It was found that priming "good taste" and "bad taste" before evaluating artificially flavored milk resulted in an assimilation effect: Participants evaluated the milk more favorably after "good taste" primes compared with "bad taste" primes. However, when primed with "healthy" or "unhealthy," both conditions rated the milk more unfavorably than a control, no priming condition. The authors reason that because "healthy" is associated with "unhealthy," both are made accessible by the prime and can be used for the judgment. However, when the value of the target is unambiguous, such as the case in which artificial flavor (which has a bad reputation related to health) is added to milk, people are primed only by the bipolar opposite when primed with "healthy." Importantly, the study shows that when activating a concept increases the attention to information that exemplifies its bipolar opposite, it could appear as an automatic contrast effect (see below). Notably, it is possible to conceptualize the foregoing results as priming of a dimension. Namely, it is possible that the entire dimension of health was primed, and the milk was judged as less healthy simply because this end of the dimension was more applicable than the "healthy" end.

Assimilation and Contrast Effects in Knowledge Activation

The effects of accessibility do not always directly reflect the primed construct. Before describing these effects, however, we would like to clarify some terms. If a measure reflects the implication of the prime, it is called an *assimilation effect*, whereas if it reflects the opposite implications of the prime, it is called a *contrast effect*. Several mechanisms of contrast have been distinguished in the literature (see DeCoster & Claypool, 2004). Consciously or unconsciously attempting to avoid using the prime or to correct its influence is called a *correction effect*. When used as a standard, contrasting away from the prime is called an *anchoring effect*. If knowledge is made inaccessible below the baseline of activation it is called *inhibition*. In addition, correction often (but not always) results in a

contrast effect, although such contrast should be distinguished from that resulting from anchoring. The main difference is that correction is by definition a second-stage, metacognitive process that operates on a presumed previous influence of a prime and correction may or may not occur, whereas anchoring is a primary cognitive process that may happen by default.

The distinction between *effects* and *processes* is of central importance for understanding contrast effects. Suppose that after having been primed with "reckless," people judge a target person to be *less* reckless than an unprimed control group. Different processes could have produced the effect. For example, the participants might have been suspicious about the prime and decided not to use it or attempt to counteract its effect (judged the prime as unusable). Notably, this conscious process of correction may lead not only to contrast but also to assimilation (see Lombardi, Higgins, & Bargh, 1987) (e.g., if the person has an incorrect theory about the direction of the influence or if the correction was not strong enough) (Strack, 1992). Contrast may also occur if a prime is used as a standard of comparison, or an anchor. For example, if a person thinks that compared to the prime the target does not seem reckless, the person might judge the target to be "careful." It is also possible that the prime information is simply made inaccessible because, for example, people feel that the priming task has been completed and that anything relevant has already been "cleared" from their mental system, or, in other words, inhibited. Note that correction takes place after knowledge activation and before knowledge use (the efferent response stage), whereas inhibition takes place immediately after the activation state, regardless of whether or not a new target is encountered (the afferent perceptual stage). It appears that anchoring effects occur at both the afferent and the efferent stage, although more research is needed to clarify this issue.

In social psychological literature, assimilation and contrast are sometimes discussed at the level of effects (i.e., if researchers are interested in the end result of the priming manipulation) and at other times at the level of processes (e.g., if researchers are interested in the process of comparison). We discuss both.

Probably the most general framework that accounts for these effects is the inclusion–exclusion model by Schwarz and Bless (1992). It suggests that assimilation occurs when the target is included in the prime, whereas contrast occurs when the target is excluded from the prime. One can visualize the underlying metaphor with the prime and the target as two blots and the question of assimilation versus contrast as whether they are seen as one whole blot or two distinct blots. Fuzzier boundaries of either of the blots and a shorter distance between them would then promote assimilation. Moreover, a detailed, close look that concentrates on the differences may foster a perception of two blots (i.e., exclusion and contrast), whereas a more general, distal perspective and concentration on similarities may make them seem as one entity (i.e., inclusion and assimilation). Zooming in on the two blots is likely to produce a contrast, whereas placing both in a much wider context is more likely to re-

sult in viewing them as closer to each other and thus produces assimilation. Also, inclusion and exclusion are affected by motivation and habit—if one is motivated to assimilate the two stimuli, or if one habitually does so, assimilation would ensue. We believe that much research on assimilation and contrast can be viewed as an explanation for moderators that derive from the inclusion–exclusion model. We turn now to review some of this research. We focus here on the primary processes of anchoring and inhibition and later we discuss the secondary processes of conscious or motivated correction.

TRAITS, CATEGORIES, AND EXEMPLARS

In a series of experiments, Stapel, Koomen, and Velthuijsen (1998) found the typical assimilation effect after priming participants with sentences related to dependency: They judged an unrelated person to be more dependent than the nonprimed control group. Other participants, however, were primed with an exemplar, "Linda," who was described as a dependent person. Those participants rated the target to be less dependent than the nonprimed control group.

Exemplars typically have more distinct boundaries than concepts, and thus, according to the inclusion versus exclusion view, are expected to lead to contrast more often (see Stapel, Koomen, & van der Pligt, 1996). It is possible, though, that this tendency could be reversed when exemplars are vague and the concepts they stand for are clear. Förster, Kuschel, and Liberman (2006) found participants' extent of knowledge about an exemplar to be positively correlated with contrast. For example, when primed with a person who constituted a high standard for alcohol consumption (the British pop singer Robbie Williams), participants were more likely to assimilate estimates of their own alcohol consumption (how many days per months do you consume alcohol?) the less they knew about him. Because all participants knew that the exemplar is a pop singer, it appears that sometimes when exposed to an exemplar, participants may construe it in terms of the category, making assimilation more likely.

CLOSENESS AND SIMILARITY

Stapel and Koomen (2000, 2001; Stapel & Suls, 2004) examined variables related to the distance between the prime and the target. In an extensive research program, they showed that close, highly relevant, similar and indistinct standards lead to assimilation rather than contrast. Furthermore, affective assimilation (e.g., feeling happy), when comparing oneself to an upward standard, was shown to occur with attainable and controllable standards (for a review, see also Markman & McMullen, 2003), which may be assumed to be more psychologically proximal than unattainable standards. In a similar vein, Mussweiler and Bodenhausen (2002) asked male participants to compare themselves to either a very tidy, clean male or female person. Accessibility was measured with a lexical decision task and it was found that an ingroup, male target led to enhanced accessibility of standard consistent knowledge, whereas a female, outgroup target enhanced accessibility of standard-inconsistent knowledge.

Thus, close targets are more likely to produce inclusion and thereby lead to assimilation than psychologically distant targets.

EXTREMITY OF PRIMES

Using a modified version of the priming paradigm by Higgins and colleagues (1977), Herr, Sherman, and Fazio (1983) primed participants with moderate and extreme exemplars of animals in terms of ferocity and size and then asked them to judge a fictitious animal. The study found assimilation after moderate exemplar priming and contrast after extreme exemplar priming. Two studies conceptually replicated these results with hostility priming and judgment of an ambiguously aggressive target (Herr, 1986; see also Mussweiler, Rüter, & Epstude, 2004b). Furthermore, Dijksterhuis and colleagues (1998) argued that extreme and distinct exemplars, as opposed to mild and less distinct exemplars, give rise to a process in which one compares oneself to the target, a process that naturally produces a contrast (see also Stapel et al., 1996, 1997).

Extreme primes are, by definition, more remote from the target and thus are more likely to be excluded and lead to contrast than moderate primes. Indeed, if prime extremity does not accompany an increased distance to the target, it does not enhance the likelihood of contrast. Skowronski, Carlston, and Isham (1993) found assimilation effects for extreme exemplars such as "idiot" before judging a target that was labeled "mentally retarded."

SUBJECTIVE VERSUS OBJECTIVE SCALES

Mussweiler and Strack (2000) demonstrated that priming people with moderately high and low standards of drug consumption (Frank Zappa vs. Steffi Graf) led to assimilation on an objective scale (e.g., the number of times per month that one consumes drugs) and to a tendency of contrast on a subjective scale (e.g., what is the extent of drug consumption). This is also consistent with the inclusion–exclusion view: A subjective scale is adjusted according to the range of the judged set of stimuli (Parducci, 1965; Parducci, Perrell, & Marsh, 1969) and is therefore more likely to lead to zooming in on the stimuli, leading to contrast. An objective scale, on the other hand, is more likely to be wider than the distance between the prime and the stimulus and thus places them closer to each other than zooming in on only these two stimuli. We would predict that an objective scale that zooms in on the prime and the target would produce contrast much like subjective scales (see also Stapel & Suls, 2004).

INTERPRETATION VERSUS COMPARISON

Assimilation and contrast may ensue from different processing goals. In their interpretation–comparison model (ICM) of social comparison, Stapel and colleagues (Stapel, in press; Stapel & Koomen, 2000, 2001; Stapel & Suls, 2004; see also Blanton, 2001, for a related view) proposed a distinction between an *interpretation mindset*, in which people try to make sense of a target, and a *compari-*

son mindset, in which people compare a target to a standard. They suggested that the former produces assimilation, whereas the latter produces contrast, given that the standard is sufficiently extreme to be used as a comparison standard. Obviously, comparison, more than interpretation, involves distinguishing the target from the prime and thus exclusion. In their study, Stapel and Koomen (2001) primed participants with mindsets of interpretation (e.g., priming "comprehend" or "interpret") or comparison (e.g., priming "compare" or "differ") and demonstrated assimilation after interpretation priming and contrast after comparison priming.

TESTING HYPOTHESES ABOUT SIMILARITY VERSUS DISSIMILARITY

Processing goals may create assimilation versus contrast also by directing the search of information toward similarities versus differences between the target and the standard. This view was advanced by Mussweiler and Strack's selective activation model (SAM) (Mussweiler, 2003; Mussweiler & Bodenhausen, 2002; Mussweiler & Strack, 1999, 2000a; Strack & Mussweiler, 1997), which focuses on the comparison process itself. This model suggests that the process of comparative evaluation (such as "Am I athletic?") consists of selecting a standard (e.g., a friend or a neighbor), comparing oneself to the standard, and integrating knowledge. During the comparison phase, people search for and focus on hypothesis-consistent information. For example, comparing her athletic abilities with an extremely athletic standard, a person might try to examine the hypothesis "I am not athletic" and thus search her memory for confirming information (e.g., a situation in which she was lazy). Using lexical decision tasks, Mussweiler and Strack (2000a) found activation of selective information when people were exposed to moderate or extreme standards. For example, after comparison with a moderately low standard with respect to athletic ability, participants' lexical decisions were faster for words associated with "athletic" than with words associated with "unathletic," whereas the reverse pattern was found for a moderately high standard.

This selective accessibility mechanism from confirmatory hypothesis testing also applies to classic anchoring paradigms (Tversky & Kahneman, 1974). Mussweiler and Strack (2000b; see also Strack & Mussweiler, 1997) demonstrated that numeric anchors selectively activate information that is consistent with the high or low anchor. For example, in one study participants were asked whether the annual mean temperature in Germany is higher or lower than 20° C (high anchor) or 5° C (low anchor) and then asked to estimate the average temperature in Germany. The estimates reflected the typical assimilation effect, being higher after the high anchor than after the low anchor. In addition, a subsequent lexical decision task with summer-related and winter-related words showed faster lexical decisions for summer words after high anchors than after low anchors and the reverse for winter words. These results show that participants engaged in an anchor-consistent search that selectively activated semantic information used for the judgment.

In a recent demonstration of the search process, Mussweiler and colleagues (Mussweiler, 2001; Mussweiler et al., 2004a) primed a similarity versus dissimilarity search by introducing a first task in which participants searched for either similarities or dissimilarities. They showed that if participants searched for similarities in an unrelated first phase of the experiment, they engaged in a similarity search when exposed to moderate standards yielding assimilation. However, a dissimilarity search before exposure to the same standard yielded contrast.

GLOBAL VERSUS LOCAL PROCESSING

Including information and the search for similarities between the prime and the target requires global processing, whereas excluding information and the search for differences between the prime and the target requires local processing (Navon, 1977). For example, to include an exemplar into a category (e.g., Is a camel a vehicle?) a broadening of conceptual scope and more abstract representations might be necessary (Isen & Daubman, 1984). On the contrary, exclusion might involve focusing on concrete details that makes the exemplar distinct (e.g., deciding that a camel is not a vehicle involves noticing its distinct features that do not fit the category; see Friedman & Förster, 2002). As a result, focusing one's attention on abstract features (i.e., global processing) might lead to assimilation, whereas a focus on concrete information (i.e., local processing) might lead to contrast.

Förster and colleagues (2006) showed that global versus local processing (manipulated in a task used by Macrae & Lewis, 2002, a variant of the Navon, 1977, task, in which participants attend to either the big letter or the small letter when presented with a big letter that is made of small letters) may engender assimilation versus contrast. To give one example, in a social comparison task global processing led to assimilation even when the primes were extreme and even when the scale was subjective, and local processing led to contrast even when the primes were moderate or when the scales were objective. Moreover, in one experiment, selectively activated knowledge as measured with a lexical decision task was shown to mediate the assimilation effect on the judgment after global processing and the contrast effect after local processing: Consistent knowledge with the standard was activated when global processing was primed, whereas inconsistent knowledge with the standard was activated when local processing was primed. Further experiments showed that global processing also leads to assimilation in the classic Donald paradigm and in anchoring tasks, whereas local priming leads to contrast. Thus, it seems that global versus local processing styles predict inclusion versus exclusion and thus produce assimilation or contrast.

CONVERSATIONAL NORMS OF NONREDUNDANCY

Exclusion and inclusion may be motivated also by conversational norms. According to Strack, Schwarz, and colleagues, conversational norms of nonredundancy (Grice, 1975) can eliminate and even reverse assimilative

effects of priming (Schwarz, Strack, & Mai, 1991; Strack, Martin, & Schwarz, 1988). For example, a question about one's happiness with his or her marriage may prime knowledge that can be used in a subsequent question on "happiness with life in general," producing an assimilation effect. If, however, the questions are presented in close proximity to each other, thus emphasizing the relevance of the norm of nonredundancy, assimilation is eliminated.

COMBINATION OF THE MODERATORS OF ASSIMILATION VERSUS CONTRAST

Examining how the various factors mentioned earlier combine with each other is a matter of evolving research and a current debate in social psychology (e.g., Do implicit comparisons with extreme primes lead to assimilation or contrast?). Recently, Markman and McMullen (2003) proposed an integrative account of assimilation versus contrast effects in self-perception. Specifically, their reflection and evaluation model (REM) proposes a sequence of stages in which exclusion versus inclusion concerns initiate comparison or interpretation processes by specifying which information will be included in the construal of the target and which information will be excluded from it. Comparison (evaluation) and reflection (interpretation) then selectively activate knowledge, thereby making consistent or inconsistent knowledge accessible. *Reflective* processes involve experiential modes of thinking related to simulating situations (e.g., imagine myself being as smart as Albert Einstein), whereas *evaluative* modes of thinking involve using comparison standards as reference points to judge and evaluate reality (for a related view, see Epstein, Lipson, Holstein, & Huh 1992; Strack & Deutsch, 2004). In this model, reflective and evaluative processes are not mutually exclusive, and might operate simultaneously or consecutively. As noted before, the relative strength of these processes is determined by the extent to which various factors encourage a person to think about him- or herself and the standard as single units (e.g., inclusion) or as distinct entities (e.g., exclusion).

Behavior, Goals, and Accessibility

In this section, we examine the effects of priming on behavior. Some studies used standard priming procedures and examined their effects on subsequent behavior. Research in a different direction examined the effects of goals on the accessibility of goal-related constructs. The findings of this research uncovered special properties of accessibility from active goals, which are distinct from effects of simple priming on accessibility.

Priming of Behavior

Behavior has been shown to be affected by priming of various constructs. In what were perhaps the first studies using behavior as a dependent variable, Straumann and Higgins (1987) primed ideal versus ought (i.e., responsibilities, duties) discrepancies. Positive attributes that

were discrepant with ideal selves slowed down talking whereas positive attributes that were discrepant with ought selves speeded up talking. It was theorized that this was because discrepancies from ideals produce a dejection-related affect, which is known to slow down level of activity, whereas discrepancies from oughts produce agitation that tends to have the opposite effect.

Priming stereotypes appear to be of considerable interest for social psychology. In a now classic example, Bargh, Chen, and Burrows (1996) subliminally primed participants with either African American faces or Caucasian faces. The former condition was intended to prime aggression, as many Americans have been shown to associate African Americans with aggression (e.g., Devine, 1989). After priming, participants were filmed as they completed a boring computer task during which the computer unexpectedly crashed. Participants' behavior was more aggressive after having been exposed to African American faces than to Caucasian faces.

Researchers have found assimilation effects with other behaviors as well, including slower walking after priming of the elderly (Bargh et al., 1996), enhanced helping behavior after semantic priming (Walther, Müller, & Schott, 2001), and conformity after semantic priming (Epley & Gilovich, 1999). Recently, Shah (2003a, 2003b) demonstrated that priming participants with significant others activated goals associated with those people (see also Susan Andersen's work, reported later). For example, priming one's father, by subliminally presenting the words "father" and "dad" before each anagram, enhanced performance, commitment, and persistence on the task that was presented as a test of analytical reasoning. However, this facilitative effect occurred only for participants who were close to their father and whose fathers valued analytic reasoning.

Automatic mimicry represents another interesting case of priming of behavior. Chartrand and Bargh (1999) found that people tend to mimic the behavior and expressions of their interaction partners without being aware they are doing so. In this case, unlike in other studies, the prime is not a semantic stimulus but, rather, an observed behavior in an interaction, which produces similar behavior in the observer. Chartrand and her colleagues found that automatic mimicry increases liking between conversation partners and smoothens conversation, and argued, accordingly, that automatic mimicry serves a social function (for a review, see Chartrand, Maddux, & Lakin, in press).

CONTROLLING BEHAVIOR BY PRIMING: MYTH OR REALITY?

From a theoretical social cognitive perspective, the notion that behavior may be affected by priming may seem just a small leap from the established finding that priming affects cognition. From a different perspective, however, the idea that priming may change a person's behavior is far reaching and even unsettling. In the realm of consumer behavior and political voting, the possibility of altering such behavior using subliminal priming is frightening. But are such effects actually possible? The current answer is a cautious "yes" (Hassin, Uleman, & Bargh,

2005; Wyer, in press). Although such influence is possible, there are limitations on their effects.

Bargh, Gollwitzer, Lee-Chai, Barndollar, and Troetschel (2001) demonstrated that participants primed with cooperation behaved in a more cooperative way in a resource-dilemma task than did nonprimed participants. They also found that priming achievement via a word-search puzzle enhanced the tendency to persist in an achievement-related activity, in spite of the presence of an obstacle created as an instruction to stop working on the task. They concluded that primes may activate behavior if prior experience established a strong link from the primed semantic concept (e.g., cooperation) to a particular behavior (behaving in a considerate way in common-resource situations).

Other research demonstrated, more directly, that effects of priming on behavior depend on appropriate associations. Mussweiler and Förster (2000) found that sex-primed male and female participants showed enhanced perceptual readiness (i.e., faster lexical decisions) for aggression-related words. However, men and women differed in their *behavioral* responses to those primes as well as in the way these primes affected disambiguation. Specifically, behavioral effects of enhanced aggression were evident in men but not in women, whereas disambiguation effects were evident for women but not for men (sex-primed women rated an ambiguous target as more aggressive). The authors explain this pattern in terms of gender differences in experiences with sex, proposing that because women are usually the victims of sexual aggression and men the perpetrators (Koss et al., 1987), women might have learned to be sensitive to detecting aggressive behavior in males in those situations, while men might have learned to act more aggressively. Notably, even though both males and females seem to relate sex to aggression as measured by the lexical decision task, the implications of this perceptual readiness for behavior and judgment may be different for men and women. More theoretically, the study shows dissociation between the effect of priming on perceptual readiness, disambiguation, and behavior.

Other studies have found that priming affects behavior only if it is consistent with an already-existing motivation. Strahan, Spencer, and Zanna (2002) showed that priming people with thirst made them consume more beverages only if they were thirsty. Thus, a preexisting motive to pursue the goal seems to be necessary for priming to have an effect on behavior.

A similar demonstration of the need for a behavior-consistent motivation was shown by Aarts, Gollwitzer, and Hassin (2004), who used short paragraphs on a male's wooing behavior to prime males with the goal of having casual sex. They found that primed participants, compared to nonprimed participants, were more helpful toward a female confederate but not more helpful toward a male confederate (helping a woman had been shown to reflect gallantry). In addition, this study demonstrated that perceived goal appropriateness moderated the effect of priming on behavior. In one of the studies the paragraph used for priming was about a flirting protagonist who was engaged in a serious relationship. It was assumed that in this case casual sex would be morally unacceptable to the participants. Results indicated no priming effect on helping behavior in this condition, although participants gave no reports of being aware of either the effect of priming or the blocking effect of goal inappropriateness. These studies demonstrate that appropriateness limits the effects of goal priming on behavior.

Alternative focal goals may also block the effects of priming on behavior. Macrae and Johnston (1998) found that participants primed with helpfulness did not stop to help a confederate to pick up his pens (scattered on the floor) when they were in a hurry to the next experimental session. Concurrent activation of incompatible goals might also explain the fact that people do *not* get up in the movie theater to buy soft drinks when they are subliminally primed with these drinks during the film: They have the focal goal of watching the movie and not buying a soft drink (see Bargh et al., 1996).

Furthermore it is worth mentioning that behaviors are activated by a configuration of stimuli, some of which may be related to the situation at hand and others that may be activated by factors that occurred before the situation (i.e., primed concepts, or chronically accessible concepts). The same primed concepts can influence different behaviors, depending on the situation in which the behavior is relevant. For example, priming Black faces may elicit expressions of aggression in response to a frustrating situation but high motivation to perform well in a music contest (see Wyer, 2004).

In sum, it appears that priming (e.g., Coke) may affect behavior (e.g., buying Coke) under certain conditions, including (1) if there is a previously established conceptual link between the prime and the behavior in question (e.g., if people have the habit of drinking coke when thirsty); (2) if the general motive underlying the behavior is active (e.g., if people are at least somewhat thirsty); (3) if the behavior is appropriate (e.g., if there is no stigma attached to buying drinks in movie theaters); and (4) if there are no competing goals (e.g., to watch the movie instead of buying a soft drink). It is beyond our expertise to conclude whether, in light of these limitations, the effect of priming on behavior is worth commercial pursuit. We believe, however, that such effects have vast theoretical importance.

There are important yet unanswered questions in the domain of goal priming, including the differences between priming general motives (e.g., competitiveness) and specific goals or behaviors (e.g., working on a puzzle), the mechanism that underlies priming of goals and motives, and what determines how these motives will be channeled into specific situation-appropriate behavior. Future research will have to explain how we can know, in advance, whether a prime (e.g., glasses) would elicit semantic associates (e.g., lenses) or a related goal (e.g., I have to find my glasses). Future research has also to clarify what kind of behavior is activated by goal priming. If food is primed, what would determine whether people start salivating, making donations for a third-world country, or prepare a shopping list? Some research has begun to uncover the answers to some of the questions about goal priming.

Assimilation and Contrast

As with disambiguation, contrast effects have also been found with priming of exemplars as opposed to categories. Dijksterhuis and colleagues (1998) replicated a study (Bargh et al., 1996) showing that participants primed with concepts related to the elderly stereotype (e.g., Florida, old, and lonely) walked more slowly down a hallway compared to those primed with words unrelated to age (e.g., thirsty, clean, and private). In addition, some of the participants were primed with an old exemplar (the then 89-year-old Dutch princess Juliana). These latter participants showed a contrast effect in that they walked faster than a control, neutral prime group.

Taking a more functional perspective of priming, Cesario, Plaks, and Higgins (2006) argued that the activation of social categories is used for preparing interactions with a certain category member. In one study, they found that if undergraduates liked the elderly, they walked more slowly after the "elderly" prime, but if they disliked the elderly, they walked more quickly after the "elderly" prime. Thus, assimilation effects were only found for people who had a motivation to approach the elderly, whereas for those who wanted to avoid them, faster walking was observed, serving their motivation. Obviously, liking may be viewed as promoting inclusion within the liked category whereas dislike promoted exclusion.

Automatic Action–Situation Links: The Case of Habits

Aarts and Dijksterhuis (2000) argued that habits constitute strong goal–action links that cause an automatic activation of the action upon goal activation. They suggested that habits may evolve from controlled actions by means of repetition of the goal–action compound. In a series of studies, participants were primed with a reason to go to a certain location (e.g., shopping) and were then exposed to 40 different locations, for which they had to decide as fast as possible between different travel modes. Only some of the locations were possible to get to by bicycle. The frequency with which the participants used their bikes to go to the specified places (e.g., the university or the mall) was used as a measurement of participants' habit strength. In the experiment, faster responses were found for habitual bike users after goal priming only for those places visited by bike on a regular basis; no effect was found for the group not primed with the goal. The latter group allowed for elimination of the possibility that the effect was due to a simple associative link between cycling and some locations.

Effects of Priming on Performance

A study by Dijksterhuis and colleagues (1998) first demonstrated effects of priming on performance on intelligence tests. Participants wrote for 5 minutes about the typical activities, lifestyle, and appearance of either a professor or a secretary. A third control group was not primed. Participants then performed a general knowledge test. Priming of "professor" enhanced performance compared to the other two groups. This effect may seem controversial but only, according to the authors, if one thinks of ability-related performance as fixed and the measurement as error-free. The effects of priming, they argue, may stem from situational variations in motivation, concentration, and levels of aspiration, all of which could be affected by priming.

Priming also affects memory performance. Dijksterhuis, Aarts, Bargh, and van Knippenberg (2000) had two groups of young participants perform a lexical decision task either with subliminal primes of the elderly (e.g., the words *old*, *gray*, and *bingo*) presented before the target words in the task or with no priming. They found that participants primed with "elderly" who had frequent contact with elderly people performed worse in a surprise recall test of the target words than did participants who were not primed and participants who were primed but had infrequent contact. The authors interpreted this as an automatic assimilation of performance to the stereotypical elderly trait of forgetfulness (for similar results, see Dijksterhuis, Bargh, & Miedema, 2000; Dijksterhuis, Spears, & Lépinasse, 2001, study 2).

However, contrast effects on performance have also been reported. In a study by Levy (1996) old and young participants were subliminally primed with either positive elderly-stereotypical words (e.g., wisdom), or negative elderly-stereotypical words (e.g., senility). Memory performance was assessed both before and after priming. Assimilation effects occurred for elderly participants (i.e., reduced performance after negative primes and enhanced performance after positive primes), whereas young participants exhibited a slight contrast on two of the memory indices. It seems that an enhanced distance of the target (i.e., the self) from the prime (i.e., elderly) increased the tendency toward contrast rather than assimilation, as would be predicted by the inclusion–exclusion hypothesis.[4]

Flexibility of performance can be primed as well. A recent study (Hassin & Bargh, 2005) primed participants with semantic associates of flexibility (e.g., elastic and bend), and found enhanced performance on the Wisconsin Card Sorting Task (WCST; Berg, 1948), which assesses whether participants can detect changing rules.

Furthermore, effects of priming on creativity have been demonstrated by Förster, Friedman, Butterbach, and Sassenberg (2005) with priming concepts indirectly related to creativity. They primed participants with stereotypes of a punk or an engineer, words that were pretested as being associated with high versus low deviancy. It was shown that the punk prime increased creativity and impaired performance on analytical tasks, whereas the reverse was true for the engineer prime. Notably, in the pretests punks and engineers did not differ on the dimension of creativity. Thus, unlike Hassin and Bargh (2005) who primed the concept relevant to the task (flexibility) directly, the effects in this study cannot be explained by different activation of the creativity dimension but rather by a semantic link between deviancy and creativity.

It is entirely possible that contrasts in creativity could also be obtained via priming. For example, a highly cre-

ative exemplar prime, such as Leonardo da Vinci, might remind oneself of one's relative lack of creativity, thereby decreasing motivation, producing intimidation, or eliciting careful behavior, all of which hinder creative thinking (Friedman & Förster, 2001). This prediction awaits future testing.

Overall, effects of priming on performance have been found with intelligence tests, memory performance, flexibility, and creativity. In some of these areas, both assimilation and contrast were demonstrated, whereas in other areas, the possibility of a contrast waits for future examination. These effects demonstrate situational variations in ability and could be mediated by different goals, processing styles, motivation, or level of aspiration elicited by the primes.

The Effects of Goals on Accessibility: Differences from Semantic Priming

In the previous section we looked at the effects of priming on behavior. We now turn to examine the effect of goal activation on construct accessibility, especially how these effects differ with respect to their underlying processes from the effects of semantic priming.

PERSISTENCE OF ACCESSIBILITY

Whereas the effects of simple semantic priming decrease fairly rapidly (e.g., Srull & Wyer, 1979), the effects of goals on accessibility seem to remain as long as the goal is active. Goschke and Kuhl (1993) demonstrated this principle by having participants rehearse a series of actions and then informing them that they would either perform the actions (i.e., a goal) or observe another person performing them (i.e., a nongoal). Using a recognition test, they found a higher accessibility of the actions in the goal condition than in the no-goal condition, even when rehearsal of the actions was not possible in the intervening time. A similar persistence of the effect of goals was demonstrated by Bargh and Barndollar (1996), who activated achievement and found that delay increased, rather than decreased, the effects of priming.

POSTFULFILLMENT INHIBITION

Another difference between conceptual priming and goal priming is postfulfillment inhibition—a tendency for goal-related constructs to be inhibited after the goal is fulfilled. This effect was first described by Zeigarnik (1938), who demonstrated that people remembered interrupted tasks better than completed tasks (see Butterfield, 1964; Heckhausen, 1991). More recently, Marsh, Hicks, and Binks (1998; Marsh, Hicks, & Bryan, 1999), in an extended version of the paradigm by Goschke and Kuhl (1993) described earlier, used a lexical decision task to examine the accessibility of action-related constructs both before and after completion of the action. Replicating Goschke and Kuhl, before completion, accessibility of intended actions was enhanced relative to nonintended (i.e., to-be observed) actions. Moreover, after completing the action, accessibility of action-related constructs dropped below the level of the control, no-goal group, reflecting postfulfillment inhibition.

Recently, Fiedler, Schenck, Watling, and Menges (2005) conceptualized a state of an "open set" (or, in our terms, an unfulfilled goal) as a situation in which people try to fit an inappropriate label to a social interaction scene (e.g., the verb "to follow" to a scene that describes a person attacking another person), and a completed goal as a situation in which an appropriate verb is fit to a situation. They demonstrated inhibition after goal fulfillment and enhanced accessibility after lack of fulfillment.

It can be contended that positive feedback signifies a completed goal, whereas negative feedback signifies an incomplete goal. Consistent with this idea, Rothermund (2003) found inhibition of goal-related constructs after success feedback and increased accessibility after failure feedback. Altogether, postfulfillment inhibition is a general principle that can be observed when goals, as opposed to semantic concepts, are primed.

POSTFULFILLMENT INHIBITION VERSUS CONTRAST

Unlike contrast or correction, inhibition happens at the afferent stage of the priming process, before encountering the target. Therefore, postfulfillment inhibition is best demonstrated with measures of perceptual readiness (e.g., lexical decision) or perceptual interference (e.g., Stroop), because those measures preclude conscious suppression or contrast. It is interesting to examine whether some of the effects that were previously attributed to suppression or contrast due to comparison processes may instead reflect postfulfillment inhibition. One such attempt was recently advanced by Liberman, Förster, and Higgins (2005) who showed that unfulfilled priming tasks lead to enhanced accessibility, whereas a completed priming task leads to inhibition. Using a paradigm from Martin (1986), Liberman and colleagues (2005) asked participants to rate either 12 or 8 sentences on a certain trait dimension. Participants who were told to rate 12 sentences were interrupted after 8 sentences. Thus, all participants rated 8 sentences, but only for those planning to rate 12 sentences was stopping after 8 sentences experienced as an interruption. Accessibility of prime-related constructs was measured with both a lexical decision task and a disambiguation task. On both measures, they found enhanced accessibility after the interrupted priming task and reduced accessibility after completed priming. Thus, it is possible that some contrast effects may in fact reflect inhibition at the afferent stage rather than correction due to judged uselessness.

PROPORTIONALITY TO MOTIVATION STRENGTH

Förster, Liberman, and Higgins (2005) found that goal-related accessibility and postfulfillment inhibition were proportional to the motivation to achieve a goal. In their experiments, participants were instructed to search through a presented series of pictures for a target combination (glasses followed by scissors) and report it to the experimenter. The results reflected an increase in acces-

sibility of goal-related words before the combination was found and inhibition after the combination was found, when compared to a group of participants who watched the pictures without having a goal to find the target combination. Moreover, the authors manipulated the expectancy of achieving the goal (by telling participants that the target combination was present in 90% of the cases vs. only in 5% of the cases), the value of the goal (by telling participants that they would receive £1.00 vs. only £0.05 for finding the combination), or both expectancy and value. The experiments also included a no-goal, control group that merely saw the pictures without being given the goal of finding the target combination. As predicted, accessibility of goal-related words prior to fulfillment and inhibition after fulfillment were found in the high-expectancy and high-value conditions but not in the low-expectancy and low-value conditions. The combination of high value and high expectancy enhanced the effects. Therefore, the effects of expectancy and value on goal-related accessibility and on postfulfillment inhibition were interactive (i.e., multiplicative) and similar to the effects of expectancy and value on motivation (e.g., Atkinson, 1964; Fishbein & Ajzen, 1974; Vroom, 1966). It therefore appears that goal-related accessibility and postfulfillment inhibition are motivational phenomena that are proportional to the strength of the motivation.

MUTUAL PRIMING OF GOALS AND MEANS

According to goal systems theory, goals form a network that associates them with superordinate goals, subordinate goals (i.e., means), and competing goals (Kruglanski et al., 2002; Shah, Friedman, & Kruglanski, 2002). These networks may or may not be constructs that constitute common semantic associates of the goal. For example, the goal of buying groceries may be subordinated to a higher level goal of preparing a party and superordinate to the means of driving a car to the supermarket, but it is not necessary that groceries, party, and car would be associated with each other. Hence, another way to distinguish between the effects of goals and concept priming on accessibility is to look at the activation of superordinate goals, means, and competing goals. Indeed, Kruglanski and colleagues (2002) have shown using subliminal priming that lexical decision times for goal-related means were faster after priming goals, and lexical decision for goals were faster after were primed. Moreover, increased accessibility of the goal due to priming of means was associated with increased task persistence and better performance (Shah & Kruglanski, 2003).

Sometimes, an individual may have multiple means of achieving the same goal (the case of equifinality). It is possible to get to work by taxi, bus, or bike. It is also possible that the same means serve more than one goal: One can ride a bike for transportation, exercise, or entertainment (the case of multifinality). Shah and colleagues (2002) found that a goal's association with a means of fulfilling it is weakened by equifinality (by the presence of other available means; a fan effect; see Anderson, 1974, 1983). They showed that when primed with a goal, participants who listed fewer means toward that goal showed faster lexical decision for words related to these means. A similar effect was found with multifinality (i.e., the same means fulfilling more than one goal); the fact that some means (e.g., reading) were associated with many goals (e.g., entertainment, learning, and understanding) reduced the facilitative effect of primed means on perception of goals (see also Shah, Kruglanski, & Thompson, 1998).

ACTIVATION AND INHIBITION OF COMPETING GOALS

Goal shielding occurs when alternative goals are inhibited by pursuit of a focal goal. It has been demonstrated that priming chronic or situation-specific goals inhibited the accessibility of conflicting goal constructs compared to goal-unrelated concepts (Shah et al., 2002). In some of their experiments, goals were activated without the participants knowing, thus suggesting that self-regulatory tactics might be automatically engaged prior to conscious awareness. Moreover, a variety of motivational variables mediated the effect. They reflect the fact that inhibition increases with commitment to the goal and with the extent to which its attainment could substitute for the attainment of the alternatives. Inhibition also increased with need for closure and level of anxiety and decreased with level of depression. Presumably, these variables are related to a motivation to achieve closure on active goals.

Shah and Kruglanski (2002) also found that priming of alternative goals impedes performance on focal goals if the two goals are unrelated but facilitates performance on the focal goal if the two goals are related (see also Shah & Kruglanski, 2003). In a series of studies, participants completed anagrams after which they expected to perform a "functional thinking" task in which they were asked to list as many uses as possible for a box. While performing the anagram task, participants were subliminally primed with the other task by a brief presentation of the words "box use" before each anagram (participants in the control condition were primed with "view it"). It has been found that for participants who perceived the two tasks to be related, priming facilitated performance (as measured by both persistence and number of solutions), whereas for participants who perceived the tasks to be unrelated, priming interfered with performance. These studies demonstrate that priming of nonfocal goals may interfere with performance if the primed goal is unrelated to the focal goal but facilitate it if the two goals are perceived as related.

ACTIVATION OF SUPERORDINATE GOALS IN SELF-CONTROL SITUATIONS

When trying to resist temptations (e.g., drugs and sex), making higher-order goals (e.g., laws and religion) accessible can aid self-control. Recent research by Fishbach, Friedman, and Kruglanski (2003) showed that temptations activate higher-level goals that presumably help in self-regulation (i.e., to resist the temptation). Specifically, the authors subliminally primed temptation-related words (e.g., drugs, sex, and premarital) and found that

participants were much faster in making lexical decisions about words related to religious goals (e.g., prayer, bible, and god) than a control group that was primed with words unrelated to temptations (e.g., friends and talk). This effect also occurred under high cognitive load, when participants had to rehearse a nine-digit number during the task. Thus, it seems that people can learn to connect temptations directly with higher-order goals, in this case religious values, and that the accessibility of those higher goals might help self-control.

From this review, it seems possible to distinguish the effects of active goals on accessibility from the effects of concept priming on accessibility. Förster and Denzler (in press; Förster, Liberman, & Friedman, in press; see also Kruglanski, 1996) summarized some of the hallmarks of goal-related accessibility: (1) there is an increase in accessibility of goal-related constructs until the goal is fulfilled or abandoned; (2) inhibition of goal-related constructs occurs after goal fulfillment; (3) goal-related accessibility and postfulfillment inhibition are proportional to the motivation to pursue the goal; (4) goals can activate superordinate goals and/or subordinate means; and (5) goals can shield against competing goals.

Procedural Priming

Procedural priming refers to priming of procedures—at the priming phase people perform an action, and then (facilitating) carryover effects on performing other actions are examined (see, e.g., Schooler's [2002] notion of processing shifts). For example, solving addition problems facilitates solving other such problems. Notably, experimental demonstration of procedural priming does not involve learning in the sense that the action performed at the priming stage is overlearned to such an extent that a few more instances of practice make virtually no difference (e.g., adding numbers and inferring traits from behavior). The distinction between semantic priming and procedural priming is best exemplified in a study by Smith and Branscombe (1987), who replicated a classic study on the effect of priming on disambiguation (Srull & Wyer, 1979). In addition to the original priming group, in which participants unscrambled sentences describing hostile behaviors (e.g., leg her break he), they added a procedural priming condition, in which participants were presented with the same sentences in an unscrambled form and chose the matching trait (e.g., hostile). Note that inferring traits from behavior is, in fact, the procedure people have to do when judging the vaguely aggressive target person in the second phase. After either 15 seconds or 15 minutes participants rated the aggressiveness of a description of a vaguely aggressive behavior. Priming traits (i.e., unscrambling sentences) had an assimilative effect only after a short delay, but procedural priming continued to have this effect after a longer delay. It seems that participants practiced the procedure of extracting traits from behavior, and that making this procedural knowledge accessible facilitated making such inferences at the test stage. Moreover, it appears that the effect of procedural priming is more enduring than the typical accessibility effect from priming con-

cepts. In addition to these content-specific effects, there seem to be smaller, but reliable, *general* effects of procedural priming, in that after matching traits to behaviors, people are faster not only with these same traits but also with matching other behaviors to *different* traits (Smith, 1989; Smith, Branscombe, & Borman, 1988).

In a different domain, Higgins and Chaires (1980) demonstrated that priming may make procedures accessible that would enhance performance on the Duncker candle problem (Duncker, 1945), in which participants must recognize that a box filled with tacks can be used as a platform for a candle rather than just as a container for the tacks. The authors found an enhanced rate of solving the task after participants were primed with differentiated linguistic constructions (e.g., tray and tomatoes), as compared to undifferentiated linguistic constructions (e.g., tray of tomatoes). It seems that priming a differentiation procedure carried over to the following task that profited from performing this mental action.

In a related vein, Friedman, Fishbach, Förster, and Werth (2003) showed procedural priming effects on creativity. More specifically, participants were asked to complete visual tasks that forced them to focus perceptual attention on either a broad or narrow visual area. In an ostensibly unrelated task, participants performed a creative generation task (e.g., find as many creative ways to use a brick as possible). Participants primed with a broad focus produced more creative solutions than participants primed with a narrow focus. It was reasoned that the procedural priming expanded (or constricted) the focus of perceptual attention, a procedure that was carried over to the semantic network, and thereby improved (or diminished) creativity because creative generation profits from a broad conceptual scope (Förster, Friedman, Özelsel, & Denzler, 2006; Isen & Daubman, 1984).

Closely related to procedural priming is Schooler's (2002; Schooler, Fiore, & Brandimonte, 1997) theory of "processing shift," which assumes that a cognitive procedure that is activated in the course of engaging in one task stays remains active and is transferred to subsequent tasks. Transfer-appropriate processing shifts are said to result when the residually activated procedures are beneficial for subsequent processing, whereas transfer-inappropriate shifts are said to result when the procedures at hand impair subsequent processing. For example, Macrae and Lewis (2002) found that performance in a face recognition task was enhanced following a global processing task and was impeded following a local processing task.

Moreover, in social psychology, many researchers have used manipulations of "mindsets" to examine similar carryover effects. For example, action phase theory (Gollwitzer, 1990; Heckhausen, 1991) distinguishes between a predecisional stage, characterized by a deliberative mind state in which one contemplates alternatives and a postdecisional state, characterized by an implemental mindset in which attention is focused on doing rather than contemplating. Gollwitzer, Heckhausen, and Steller (1990) induced a deliberative mindset by making people contemplate personal change or an implemental mindset by making participants plan the ex-

ecution of a personal plan in detail. Participants were then asked to complete a fairytale that began with a description of a character with a decision conflict. Analysis revealed that deliberative mindset participants ascribed more deliberative and less implementational efforts to the protagonist of the fairytale than implemental mindset participants (for additional effects of implemental and deliberative mindsets, see Taylor & Gollwitzer, 1995). Thus, thinking in an implemental or deliberative way carried over to an unrelated task.

In construal-level theory (see Liberman, Trope, & Stephan, Chapter 15, this volume), high-level versus low-level reasoning may be manipulated through a mindset. For example, Fujita, Trope, and Liberman (2005) had participants think of *why* they would like to maintain social contacts (a high-level construal mindset) or *how* they would maintain social contacts (a low-level construal mindset) and then examined performance on an unrelated self-control task that involved squeezing a handgrip in order to obtain self-diagnostic information. It has been suggested that self-control would be facilitated by a high-level construal of the situation and thus would be enhanced by procedurally priming participants with thinking in high-level terms. Consistent with this prediction, it has been found that a high-level construal mindset enhanced self-control relative to the low-level construal mindset.

How can one distinguish between concept and procedural priming? For one thing, procedural priming seems to persist longer than concept priming. However, it seems that activation of semantic and procedural knowledge may occur simultaneously and might have independent effects on information processing. Smith (1990) argued that in some priming tasks, the process in the priming phase is both conceptually and procedurally similar to the test phase. For example, if people translate behavioral information into traits in the first phase and then have to judge a target's aggressiveness (a trait) on the basis of her described behavior, the priming task might confound procedural and concept priming. Further research is needed to distinguish between the two kinds of priming.

Finally, we would like to briefly address the question of contrast effects with procedural priming. It seems that procedural priming tasks do not tend to engender correction processes. This may be the case for several reasons, including lack of awareness of the effects of procedural priming or lack of motivation to counteract them. For example, if a person has been primed with a wider perception, and if this facilitates creative thinking, she might not be aware of its effect on creative problem solving or might not be interested in correcting for this influence. It is also possible that people would not know how to counteract or undo effects of procedural priming, as that would, typically, involve more complicated processes than adjusting one's response on a scale (e.g., the person must know which processes facilitate creative thinking or which mechanisms can be used to switch from one thinking style to another). Of course, it is sometimes possible to stop a priming procedure that we suspect of having undesirable effects on us (e.g., one may stop watching a detective movie if she thinks that it makes her too paranoid). Moreover, stopping an already elicited procedure may be easier than actually counteracting it. Notably, it is entirely possible that future research would uncover correction of procedural priming. However, it seems to us that such correction is less likely than correction of disambiguation.

Affective and Evaluative Priming

There is ample evidence showing that feelings can influence affect, behavior, and cognitions in both assimilative and contrastive ways. Our definition of accessibility is broad enough to include mood as a source of accessibility. These effects, however, are being discussed in detail in by Schwarz and Clore (Chapter 16, this volume) and are not addressed here.

Affective Priming

In a classic affective priming (or evaluative priming) paradigm, Fazio and colleagues (1986; for a review, see Fazio, 2000) showed that deciding on the valence of a strongly valenced word (e.g., love and delightful) is better facilitated when it is preceded by an evaluative-consistent prime word (e.g., sunshine) than by an inconsistent prime word (e.g., death; for a review on affective priming, see Klauer & Musch, 2003).

It has been argued that evaluative priming demonstrates response facilitation, such that a positive prime prepares participants to select the response "positive," which is accelerated if the target word is positive as well. When the task is changed into a pronunciation task (i.e., participants have to pronounce the target word rather than classify it as positive vs. negative), the effect is reduced considerably and sometimes even disappears (see Klauer & Musch, 2003). Nevertheless, the existence of evaluative priming with a pronunciation task (Bargh, Chaiken, Raymond, & Hymes, 1996) indicates that evaluation is elicited spontaneously and constitutes a necessary part of processing the stimulus.

Affective priming has also been demonstrated using a lexical decision task, in which faster decisions are expected after evaluative-congruent primes compared to evaluative-incongruent primes (Wentura, 1998, 2000). This task, however, has been criticized as well. Klauer and Musch (2003) argued that evaluative consistency (e.g., between the words "love" and "sunshine") elicits a feeling of plausibility, which facilitates affirmative responses, whereas evaluative inconsistency (e.g., "love" and "war") elicits a feeling of inconsistency, which facilitates negative responses. A critical test for this model was a study by Wentura (1998, 2000) in which the assignment of "yes" and "no" responses to words and nonwords in a lexical decision task was reversed. Consistent with the model, words preceded by evaluative-inconsistent primes yielded faster "no" responses than evaluative-consistent primes. The findings cast doubt on the conclusion that evaluative dimensions are processed automatically and facilitate the processing of subsequent stimuli of equal valence.

From a cognitive perspective, it might seem strange that an overlap of a single semantic feature (i.e., valence) would produce semantic priming (Huber et al., 2001; Huber, Shiffrin, Lyle, & Quach, 2002). However, it is possible that affective priming is not equivalent to semantic priming. Namely, primes may not activate all the evaluative-consistent constructs. One possible alternative is that the affective prime facilitates a response, such as approach or affirmation, and, therefore, similar responses to evaluative-consistent targets are facilitated. This would also explain why affective priming produces weaker effects with pronunciation tasks than with evaluative tasks, and why affective priming with a lexical decision task is sensitive to the type of response. Later we discuss the specifics of affective priming and its potential functionality.

Chronic Accessibility

So far, we have discussed situational manipulations of accessibility produced by priming. However, there are additional, more permanent sources of accessibility—chronic accessibility and high accessibility of certain constructs, which occur without priming. In a study by Higgins, King, and Mavin (1982), participants listed the traits of a person fitting the following categories: liked, disliked, frequently encountered, whose company they sought, and whose company they avoided. The descriptions were used to extract each person's chronically accessible traits by using the first trait listed as chronic (Higgins et al., 1982, study 2). One week later, participants were invited for another session in which they read a description of a target person that contained 12 individually tailored behaviors, 6 that moderately exemplified the chronic constructs of each participant and 6 that moderately exemplified nonchronic traits, which were yoked to be chronic traits of another participant. After evaluation of their responses, it was found that participants' impressions and memories of the target person were related to their chronic constructs rather than to the nonchronic constructs.

Chronic Accessibility as a Continuous Variable

Higgins and Brendl (1995) used a measure of chronicity (for the content "conceited"; Higgins et al., 1982) as a continuous variable, defined as the frequency of mentioning the term and its synonyms in descriptions of people. Participants were measured, and a few weeks later, they were called back to the lab to judge a vague social target on conceitedness. The authors found a strong relation between chronicity scores and conceitedness ratings. Lau (1989) found similar chronicity effects for political constructs and evaluating political candidates.

Bargh and Pratto (1986) used a color-naming Stroop task to measure perceptual readiness of chronic concepts, using the same criteria for chronicity as mentioned earlier (Higgins et al., 1982). They found more interference (i.e., higher accessibility) for chronic concepts than for nonchronic concepts. In addition, Bargh and Thein (1985) found that impressions and recall of a target person's behavior were better when they were related to a participant's chronic dimension than when they were unrelated to a chronic dimension.

Other aspects of efficiency of processing information related to chronic concerns have been demonstrated as well. Markus (1977) found that independent schematics (i.e., people who responded at the high end of both a self-descriptiveness and an importance scale for at least two of three independence-related traits) processed independent-related stimulus information faster and more consistently than independent aschematics (i.e., people who responded in the middle of the scale). Using the same chronic constructs and a dichotic listening task, Bargh (1982) showed that processing of chronically accessible information used fewer resources in the attended channel and more resources in the ignored channel.

Other research has focused on qualitatively different chronic concerns. In her work, Andersen (for a review, see Andersen & Chen, 2002) argued that representations of significant others are chronically accessible and thus have a special readiness to be activated by minimal contextual cues. In her social cognitive model of transference (Andersen & Glassman, 1996), evidence has been obtained showing that in encounters with a new person, representations of significant others may be activated, leading the perceiver to interpret the target person in ways that are derived from the activated representation. Research also showed that people respond emotionally, motivationally, and behaviorally to a target person in ways that reflect his or her relationship with the retrieved significant other. In their studies, Andersen and colleagues ask participants to describe significant others, and adjectives that were related to those people were extracted from these descriptions. These adjectives were then used in the second phase, a few weeks later, to describe a new target person. The authors showed that participants were more likely to interpret the behavior and to draw inferences from the behavior of the new target person in accord with the significant other to whom the adjectives were ascribed in the first phase of the experiment, although in themselves the adjectives did not afford such inferences. Moreover, the effects were reliably stronger than priming effects for stereotypes and other contents (see Chen & Andersen, 1999).

Put briefly, chronic concerns or beliefs can yield similar effects to frequent priming.

How Chronic Accessibility Develops

It has been suggested that chronic accessibility develops from repeated use of a construct (Higgins et al., 1982). However, it is not known whether goals and concerns play a crucial role in creating chronic accessibility. For example, while searching for a car to buy, one becomes sensitized to "for sale" ads on cars. However, it is unclear whether chronic accessibility would develop to the same extent if one were exposed to the same number of stimuli without having a relevant goal. The question of whether or not chronic accessibility reflects only extensive exposure or personal concerns still awaits empirical examina-

tion. Clearly, however, both personal concerns (i.e., goals, wishes, and preoccupations) and more extensive construct use create priming effects that last longer. Both constitute viable explanations for how chronic accessibility develops.

PRINCIPLES

We now discuss a number of general principles and theoretical questions that have been examined in the literature on priming. We refer to decay after priming, extent of priming, and to the question of how accessibility from different sources combines. We also discuss the compensatory relation between accessibility and applicability and the context-dependent effects of priming.

Decay after Priming

We have already looked at some findings on decay rates of different types of priming. It has been demonstrated that more extensive *semantic priming* causes the effects to decay slower. Srull and Wyer (1979) asked participants to judge an ambiguously aggressive target 5 minutes, 1 hour, or 1 day after the priming task. After 1 hour, when the number of primes was low (6 of 30 scrambled sentences were related to hostility), there was little or no priming effect, but when the number of primes was high, priming effects were observed after 1 hour and were even visible after 24 hours. Thus, it appears that more extensive priming slows the rate of decay of the priming effect. However, when other constructs compete with the primed construct in terms of accessibility, effects of priming on judgments disappear as quickly as a few minutes (Higgins, Bargh, & Lombardi, 1985; Higgins & Brendl, 1995). Similarly, in an experiment by Smith and Branscombe (1987), effects of semantic priming were found after 15 seconds but not after 3 minutes.

Other studies have shown that the effects of *procedural priming* can last as long as 1 week (see Smith, Stewart, & Buttram, 1992). Thus, procedural priming can be distinguished from semantic priming in that the former has a slower rate of decay.

In contrast to procedural priming, the effect of *affective priming* on evaluation appears to decay even faster than semantic priming. Klauer, Rossnagel, and Musch (1997) conducted a study based on the original affective priming study by Fazio and Williams (1986) and added six levels of delay between prime and target exposure (-100, 0, 100, 200, 600, and 1,200 msec). They found affective priming effects only for the 0 and 100 msec delays. Likewise, Hermans, De Houwer, and Eelen (2001) found affective priming effects after delays of 0 and 150 msec but not for 300 and 450 msec. Using a pronunciation task, the authors found a similar pattern for 150 msec delays, which so far is the longest delay for which affective priming effects were obtained.

As previously mentioned, active goals enhance accessibility of goal-related terms and produce a relatively slow decay (and may even produce an increase in accessibility over time after the onset of the goal) and is dependent on goal fulfillment (Liberman & Förster, 2005). For example, Bargh and colleagues (2001) showed that activation of an achievement goal by priming constructs related to achievement increased performance on an anagram task and that this effect increased over a delay (see also Goschke & Kuhl, 1993).

By definition, *chronic accessibility* has a slow decay rate, as it refers to accessibility that is not created by a recent exposure to an external prime. Because chronic accessibility is the result of extensive construct use or of enduring personal goals or concerns, it is possible to view the slow decay characteristic of it as similar to the slower decay rates produced by extensive exposure to primes and by goals and concerns.

In sum, the effects of affective priming are relatively short-lived. Effects of semantic priming last slightly longer, while procedural priming, goal activation, and chronic accessibility decay slowly. Goal accessibility may even increase in activation over time.

Extent of Priming

Priming seems to follow principles of learning in that it obeys Thorndike's (1898) *law of effect:* The more recently and frequently a stimulus–response bond is activated, the more effectively it is engrained. Thus, it is logical that frequent priming should produce stronger effects than less frequent priming. To demonstrate, Srull and Wyer (1979) manipulated frequency of priming by presenting people with 48, 24, 12, or 6 scrambled sentences related to hostility. Assimilation effects increased as the frequency of priming increased, especially after short delays (see also Srull & Wyer, 1980). Subsequent studies replicated the prime frequency effect with subliminal priming (Bargh & Pietromonaco, 1982; see also Devine, 1989). The effects of priming on performance are also influenced by frequency of priming. For example, Dijksterhuis and van Knippenberg (1998) found that extended priming of "professors" led to better performance on a general knowledge quiz.

In procedural priming, the number of priming episodes may be thought of as practice. It should not be surprising, then, that more extensive priming leads to stronger effects. More habitual actions become overlearned and automatic and are performed more easily than less habitual actions (Gupta & Cohen, 2002; Smith & Lerner, 1986).

Priming may also be manipulated in terms of quality, not only by quantity of priming episodes. Consistent with this notion, it appears that depth of processing of the prime is associated with more robust priming effects (for a review, see DeCoster & Claypool, 2004). For example, reading paragraphs or sentences related to a trait produced stronger priming effects (both assimilation and anchoring) than simply reading trait words or being exposed to exemplars associated with the trait. In cognitive psychology, extent of processing was found to produce stronger and more enduring priming effects (Becker et al., 1997).

All told, it seems that extent of priming is a universal principle.

To the best of our knowledge, there is no research on the extent of goal priming effects on the accessibility of goal-related constructs. Possibly, extended priming may enhance the chance that a goal would be activated; however, once a goal is active, two sources may further enhance accessibility of goal-related constructs: rehearsal, which relates to extent of priming, and motivation to pursue the goal, which is not necessarily related to extent of processing. In a study by Förster, Liberman, and Higgins (2005) accessibility increased with greater proximity to goal fulfillment. This effect may be due to increased rehearsal of the goal over time or may be an independent effect of increased motivation as goal fulfillment is perceived to be closer (i.e., the fact that goals loom larger closer to fulfillment, see Förster, Higgins, & Idson, 1998; Miller, 1944). In another study, Goschke and Kuhl (1993) endowed participants with a goal and then systematically prevented them from rehearsing it by asking them to carry out a visuospatial task requiring spoken responses as participants were approaching the goal. Nevertheless, they found increased accessibility.

From the available research, extent of priming seems to be a moderator that affects semantic, evaluative, behavioral, and procedural priming and the effects of priming on goal activation. The effect of goals on accessibility of goal-related constructs may be produced independently of extent of priming through strength of motivation.

Reinstatement of Priming Effects

In a computer simulation, Smith and DeCoster (1998) found that accessibility increases faster if it has been primed frequently before, an effect they labeled *savings in relearning*. That is, the increase of accessibility for an already-studied construct is greater than the increase of a newly studied construct. Savings in relearning is also known to exist in explicit memory, such as recall and recognition tasks, as well as in implicit memory (Carlston & Skowronski, 1994). For example, it has been found that memorizing paired associates made it easier to memorize the same list even after intervals of several years and even after the learning material can no longer be intentionally recalled (see Burtt, 1941; Ebbinghaus, 1885/1964). To our knowledge, there is no *experimental* evidence showing such effects with accessibility; however, the effect is important and needs further research.

It is interesting to consider the possibility that savings in relearning could also occur with affective, procedural, or goal priming. Is the reoccurrence of emotional distress facilitated by previous instances of such events, even if they occurred in the distant past? Or, would a goal to interrupt a colleague because of his sexist remarks, which you forgot over time, be easier to reinstate by priming?

An interesting effect of reinstatement of priming has been demonstrated by Kunda, Davies, Adams, and Spencer (2002), who had participants watch a videotaped interview of a Black person for 12 minutes. One might expect that due to the long exposure, the category of Blacks would be extensively primed and produce an especially high level of accessibility. However, contrary to the findings of previous studies on priming of stereotypes, stereotype accessibility (measured as a speed of lexical decision) was evident only if the participant realized that the Black person expressed an attitude that deviated from the participant's own attitude. The authors explain these results by suggesting that without the counterattitudinal remark, the extended exposure to the Black person created an individual perception of him that replaced the categorical perception. However, if the person in the interview behaved in a negative way, categorical information became accessible again. Thus, it seems that motivational factors can trigger reinstatement of accessibility.

Combined Effects of Recency and Frequency of Priming

Higgins and colleagues (1985) examined the relation between recent and frequent priming by priming two alternative constructs that were equally applicable to an ambiguous behavior (see also Bargh, Bond, Lombardi, & Tota, 1986). One construct was primed four times, while the other was primed only once at the very end of the priming task. Before the ambiguous target was introduced, there was either a 15- or 120-second delay. Results indicated that recent priming tended to affect the judgment after a short delay, whereas frequent priming tended to affect the judgment after a longer delay (see also Lombardi et al., 1987). These results are consistent with slower decay of frequently primed constructs.

A similar relation was found between chronic accessibility and recent priming. Using a procedure similar to Higgins and colleagues (1982), Bargh, Lombardi, and Higgins (1988) selected participants who had chronic accessibility for the traits "inconsiderate" or "outgoing," participants who had chronic accessibility for both traits, and participants who did not have chronic accessibility for either trait. A few weeks after this assessment, participants were called back to the lab and primed with the nonchronic trait. The delay between priming and presentation of an ambiguous target was also varied. The main finding was a pattern similar to the studies examining recent versus frequent priming, in that participants used the primed construct slightly more than the chronic construct after the short delay (15 seconds); the reverse was true after a longer delay (120 seconds). Recently, Wyer (2004) suggested that frequent and recent activation are qualitatively different. Whereas recent priming is transitory and reflects the resonance of knowledge representation with a probe cue, frequent activation lowers the activation threshold of knowledge representation. The former is said to resonate for awhile but later decays, whereas the latter is said to persist over time. More research is needed to confirm these distinctions.

Combining Accessibility from Different Sources

Extent of priming also may be enhanced by combining priming of different types. We discuss these effects in the following subsections.

CHRONIC ACCESSIBILITY AND SEMANTIC PRIMING

Bargh and colleagues (1986) selected chronic and non-chronic participants with respect to "kindness" and asked them to judge an ambiguously kind person weeks after the assessment. Some participants were subliminally primed with "kind" and some not. Construct-related impressions of the target person were stronger as a function of both chronic and situation-induced accessibility (see also Higgins & Brendl, 1995; see Smith & DeCoster, 1998, for a computer simulation).

PROCEDURAL PRIMING AND SEMANTIC PRIMING

Cumulative effects of procedural and semantic priming have been discussed in the ACT* model by Anderson and colleagues (Anderson, 1983; Pirolli & Anderson, 1985). According to this model, the effects of data strengthening (i.e., practice of a specific target item) and procedural strengthening (i.e., practice of the general process) on perceptual readiness are multiplicative. As noted before, some of the priming procedures may have combined procedural and semantic priming, such as when both priming and target perception involve inferring traits from written materials (Smith & Branscombe, 1987). Thus, it is possible that in these cases accessibility increased because both semantic and procedural priming were combined (see also Hannover & Kühnen, 2005).

Applicability and Accessibility Compensate Each Other

It has been shown that high accessibility of a construct may cause people to apply it to targets of low applicability, targets that would not elicit the construct in other situations. Higgins and Brendl (1995) used a vague (as opposed to an ambiguous) description of a person's behavior, one that was related to conceitedness no more than a no-information baseline. However, this vague description was spontaneously judged as conceited if accessibility was extremely high (e.g., chronics on the dimension that were, in addition, primed with conceitedness and tested very soon after priming). This finding reflects the fact that high accessibility may compensate for low applicability. Beyond its theoretical plausibility, this finding may shed light on the nature of interpersonal discrepancies in the construal of reality. People may tend to see and experience reality in a way that is unique and dependent on their highly accessible constructs, a way that may seem strange and unjustified to others without this view.

It would be interesting to examine the same principle with other types of accessibility. For example, would stronger motivation mean that a wider group of targets would be judged as goal related and increase in accessibility? The literature on learning seems to provide a positive answer to the first question—stronger reinforcements (i.e., a higher motivation) tend to produce a wider generalization over stimuli (Miller, 1944). This principle has far-reaching implications, suggesting the possibility that stronger goals may be substituted with less relevant stimuli. For example, would increasing the intensity of an aggressive motive (e.g., by thwarting more important goals of an individual) make the actor more likely to aggress toward weakly associated targets? It would be worthwhile also to examine whether high procedural accessibility produces transfer of the procedure to more remote, less relevant situations. These principles await further empirical examination.

METACOGNITIVE PROCESSES IN KNOWLEDGE ACTIVATION AND USE

In many cases, people do not know that their judgments and perceptions have been influenced by a prime. Sometimes, however, when they do learn about the possibility of such an influence, they might try to correct it, because they may regard the influence as illegitimate or wrong (i.e., if they believe that the accessible knowledge is unusable). For such a process, motivation and capacity to perform the correction are necessary. Correction often (but not always) results in a contrast effect (see "Effects of Accessibility"), but such contrast should be distinguished from a contrast that results from anchoring. To emphasize, the crux of the difference is that correction, by definition, is a second-stage, metacognitive process, one that operates on a presumed previous influence of a prime, whereas anchoring is a primary cognitive process, one that may happen by default (Decoster & Claypool, 2004). In this section we discuss secondary, correction processes but not anchoring processes (which were discussed earlier). We first review the conditions under which correction occurs and then discuss more general principles of metacognitive correction processes.

Awareness of the Influence of Priming

Awareness of a prime has been shown to result in a contrast effect, most likely because known primes might cause the prime to be seen as irrelevant (Lombardi et al., 1987). Likewise, blatant priming is more likely to create a contrast than subtle priming, possibly for the same reason (Martin, 1986; Newman & Uleman, 1990).

Source monitoring explanations have been advanced to explain effects of awareness on correction. Specifically, Martin (1986) argued that when priming is subtle, people may be unaware of the fact that the primed construct has been activated, and when later confronted with the target of judgment, they may commit a source monitoring error in assuming that the activated construct is their genuine reaction to the target (see Shrum, Wyer, & O'Guinn, 1998). By contrast, when blatantly primed, people are likely to remember the priming episode and be aware of the source of the activation. In this situation, people might judge it to be an inappropriate influence on their perception of the target and try to correct for this influence. Similar models have been proposed for the influence of affect (Schwarz & Clore, 1983) and body feedback (Förster, 2004) on judgments. Interestingly, Huber and colleagues (2001) recently proposed a somewhat similar source monitoring model to account for facilitation and inhibition effects of semantic priming in cognitive psychology.

Like awareness, memory of the prime also enhances the likelihood of a contrast effect. To test this hypothesis, Lombardi and colleagues (1987) divided participants into two groups—those who remembered and those who did not remember the priming events. They found assimilation for those who did not remember the primes and contrast for those who did remember. More directly, Strack, Schwarz, Bless, Kübler, and Wänke (1993) reminded some participants of the priming episode but did not remind others, and again found that the former produced contrast whereas the latter produced assimilation effects.

However, awareness of the prime is not necessary for a correction process to occur. This should come as no surprise, for repeatedly performed correction, as any overlearned process, may become automatic. For example, it has been shown that participants low on racism may automatically perform correction of stereotype-related primes in making judgments about stereotyped targets (for a review, see Devine & Monteith, 1999). Presumably, correction becomes automatic as a result of extensive practice of it in similar situations.

Motivation to Correct Judgments

Awareness of the prime is not sufficient for correction to occur, as people also need to be motivated to correct. Kruglanski (1989) proposed that people who chronically or temporarily avoid closure might be more motivated to inhibit highly accessible knowledge before responding. Indeed, research demonstrated that assimilation effects of priming are weaker for participants high in the need to avoid closure (Ford & Kruglanski, 1995; Thompson, Roman, Moskowitz, Chaiken, & Bargh, 1994). Similar effects were found with interpersonal differences in need for cognition: People high in need for cognition were theorized to possess an enhanced motivation to examine their judgments and feel more accountable for them. In line with this prediction, judgments were found to be less prone to assimilative effects of priming, presumably from an enhanced tendency to correct effects of priming (Martin, Seta, & Crelia, 1990, study 3). A high need to avoid closure and a high need for cognition may represent a general motivation to correct for effects of priming or currently accessible knowledge. We should note that such motivation does not need to be conscious in order to produce the effects.

In addition, there may be more specific motivations for people to correct suspected effects of priming. Correction may occur if the person finds the suspected effect of priming irrelevant for the judgment at hand, morally wrong, culturally objectionable, or socially undesirable, or if he or she thinks that such influence should be suppressed due to conversational norms. Regardless of the reason for the judged uselessness, the result is an attempt to correct for any influence.

For example, Devine (1989) showed that weakly prejudiced and highly prejudiced people have equal knowledge about the African American stereotype but nevertheless respond differentially to a stereotype-related prime if made aware of its activation and if resources to control for its assumed influences are available. If unaware of the prime, however, both groups show enhanced accessibility of stereotype-related constructs. Thus, it seems that people with low levels of prejudice know the stereotypes but refrain from using them when possible (see also Biernat & Vescio, 1993; Higgins & King, 1981, study 1). In that way, contemporary models of prejudice distinguish possession of stereotypical knowledge from endorsement of those stereotypes (see, e.g., Lepore & Brown, 1997; Plant & Devine, 1998).

Cognitive Capacity

Even if a person suspects an effect of priming and thinks that that effect should be corrected, he or she might not have enough cognitive capacity to do so. Martin, Seta, and Crelia (1990) conducted a priming experiment in which they manipulated motivation to correct the priming effect and cognitive load. They showed that assimilation occurred when either motivation or cognitive resources were low, but contrast occurred when both were high (see DeCoster & Claypool, 2004, for a meta-analysis on cognitive capacity as a moderator).

Furthermore, correction processes may differ in cognitive complexity. Strack and Hannover (1996; see Strack, 1992) distinguished between *recomputation* and *adjustment*. In the former case, a person goes back to the information or seeks new information to arrive at her judgment (e.g., "I gave the female student a C in math. I am probably prejudiced, so let me look at the exam again."). In the latter case, a person simply adjusts the judgment (e.g., "let me raise the student's grade to a C+."). Because recomputation is more effortful, it is more dependent on cognitive resources. Thus, people may resort to the simpler process of adjustment when resources are constrained. Yet, for adjusting a judgment (not recomputation), one needs to know both the direction and strength of the contaminating effect. Because such knowledge is often unavailable, adjustment might be problematic, as discussed next.

Knowing How to Correct

Even if people are aware of the prime, want to correct for its influence, and have the capacity to do so, they still may be incorrect about how to correct or not know *how* to do it. Cognitive processes, including the effects of priming, are not accessible to introspection, meaning that people cannot know via introspection what happened in their mind any more than they could know about what happened in their lungs (see Nisbett & Willson, 1977). Certainly, sometimes we are aware of how our mental system operates, but the source of this knowledge is not direct experience with the system at work but rather theories, supplemented with vague and often partial experiences. Similarly, we might have theories about our lungs and might try to imagine how they work if we inhale smoke and then cough. This, however, is not knowledge from direct experience but rather a theory that may not directly reflect reality. We shall refer to people's theories of how their minds work as metacognitive theories—

theories about cognition (see also Strack & Förster, 1998).

The source of metacognitive theories might be culturally shared truisms (e.g., "Commercials are trying to convince you to buy products."), ideologies (e.g., "It is wrong to discriminate by race."), or personal knowledge (e.g., "My best decisions are made on the fly."). Often, these are general theories that specify tendencies, allow for exceptions, and can be applied to specific cases. For example, a person might experience a sudden urge to buy a coke, wonder why that might be, and try to think whether she could have been influenced by a commercial recently seen on TV. She might invoke the reasoning that commercials influence people's behavior and therefore try to resist the urge to buy a coke. It is possible to apply a correct theory to specific instances in a wrong way. For example, in a specific case, the urge to buy a coke could have been there even without the commercial. In addition, a person might endorse a number of metacognitive theories, some of which might have opposite implications in a particular situation (e.g., commercials influence people's behaviors, but I have stable preferences for soft drinks that will not be affected).

Strack (1992) emphasized that in order for correction to yield accurate judgments, a person must know both the direction *and* the magnitude of the influence of the prime, which are also part of one's metatheories about the influence of primes. If a person (erroneously) thinks he was influenced in the opposite direction than the actual effect, an assimilation effect might occur even though he was aware and tried to correct for the influence. In a series of studies, Petty and Wegener (1993) demonstrated that the direction of correction depended on people's beliefs about the putative influence.[5] Thus, an assimilation effect can be produced by both correction and unconscious influences of accessible knowledge.

WHAT IS THE FUNCTION OF ACCESSIBILITY EFFECTS?

Functional Aspects of Semantic and Procedural Priming

Enhanced accessibility after using a construct is most likely functional for facilitating perception of related constructs, which would be beneficial if redundancy in the environment is expected (Neely, 1991). For example, it is functional that processing the word "nurse" would enhance the accessibility of the construct "doctor" because in many contexts these two stimuli tend to co-occur. Manipulation of the expectation of co-occurrence has yet to be investigated, but it may be that semantic priming is reduced when target descriptions contain disconnected sentences or word lists rather than more coherent texts.

In addition, decay rates may also be affected by functional considerations, for example, if faster decay occurs in contexts in which the expectation of redundancy means a more frequent occurrence of a related target. To illustrate, if we see an ant, another one might be within a small radius; however, if we see a mouse, another one might be around, but not within such a small radius. One would expect steeper decay of ants than of mice. Likewise, procedural priming may be functional if an expectation of repetition is assumed. If actions require repetition, it would be useful to retain the knowledge of how to perform an action after completing it. Savings in relearning may be interpreted in a similar way, as resting on the assumption that a once-learned action is likely to be needed in future situations.

Functional Aspects of Accessibility from Affect

As discussed earlier, affective priming can be thought of as having two components: (1) response facilitation of congruent stimuli (approach or affirmation and positive or avoidance or negation and negative), and (2) semantic priming, thereby facilitating processing, of other evaluative-congruent stimuli. Perhaps it is useful to consider the functionality of these components separately.

Response facilitation may be justified if stimuli of similar valence tend to appear in spatial and temporal proximity to each other; environments are somewhat valence redundant (e.g., "lake" signifies the presence of plants and of fish, which all have positive valence; "night" signifies dark, cold, and danger, which all have negative valence). If all positive stimuli elicit approach and all negative stimuli elicit avoidance, and if stimuli of similar valence tend to co-occur, then it is functional to preserve the response from a focal stimulus to other spatially and temporally proximal stimuli.

It is more difficult to justify semantic affective priming on logical grounds: Why would stimuli facilitate the processing of all other stimuli of equal valence? It appears that this would create activation of too many constructs. However, adopting a self-regulatory perspective, selective attention to valence-compatible cues makes sense. Similar to cognitive tuning models (e.g., Schwarz & Bless, 1991), one may assume that negative cues signal danger that needs to be eliminated. Thus, attending selectively to negative cues might facilitate goal attainment. Positive cues, on the other hand, might signal a benign environment, a state that needs to be maintained. Thus, in this case selective encoding of positive cues facilitates goal attainment.

Functional Aspects of Accessibility from Active Goals

It is reasonable to assume that a heightened accessibility of goal-related constructs helps in detection of stimuli in the environment that are instrumental for efficient goal pursuit, which contributes to the likelihood of goal attainment (see Ach, 1935; Gollwitzer, 1999; Kuhl, 1983; Liberman & Förster, 2005). For example, while searching for something (e.g., keys), it would be useful to activate concepts related to the target, such as its typical or likely locations (e.g., purse and bedroom) or typical activities for which the target is used (e.g., access to home and work), because the search target is likely to be in proximity to the associated ob-

jects or activities (e.g., the keys are likely to be in your purse on your desk at work). As long as the related objects and activities are activated, one is more likely to think of places where the keys are likely to be. It is therefore functional to retain a state of heightened activation of goal-related constructs until the goal is fulfilled. What is more, it is easy to see the functionality of suppressing competing goals (e.g., sending a memo to one's boss) for the successful pursuit of the focal goal (e.g., finding the keys). Without such suppression, people would be easily sidetracked by competing goals and would lose sight of a more pressing goal.

Furthermore, inhibition of the search target upon goal fulfillment is also functional because goal-related constructs can interfere with other tasks. Clearing them from the system allows other goals to be more easily pursued after fulfillment. In cybernetic models of goal hierarchies (Carver & Scheier, 1999; Vallacher & Wegner, 1987), goal attainment (e.g., watering plants) is followed by a reinstatement of a higher-order, superordinate goal (e.g., arranging the room for a romantic dinner) that was the reason for pursuing the original, subordinate goal. In this view, constructs related to the fulfilled goal (e.g., water, watering can, and fertilizer) are irrelevant and could potentially interfere with successful performance of the next task at hand (e.g., cooking or cleaning). "Clearing up" the mental system from such constructs thus may be highly instrumental (see also Gollwitzer, 1999; Kuhl, 1983; Liberman & Förster, 2005; Mayr & Keele, 2000).

Recently, Hedberg and Higgins (2005) showed that decay curves of accessibility after goal fulfillment are moderated by chronic accessibility of promotion (accomplishments, growth, ideal) versus prevention (security, responsibility, oughts) concerns. For predominant promotion-focused participants, decay was fast, whereas for predominant prevention-focused participants, accessibility increased after goal fulfillment. This was presumably the case because in a promotion focus, individuals pursue goals by ensuring engagement with means of advancement and ensuring against missing opportunities. After goal completion, a decreased accessibility of goal-related concepts frees up cognitive resources for new, upcoming pursuits, thereby supporting promotion goal pursuit strategies. In a prevention focus, individuals pursue goals by ensuring rejections of mistaken paths to the goal and against committing such mistakes. After goal completion, and before any necessity to pursue another goal, a maintained high accessibility of goal-related concepts preserves cognitive resources for the activity that the person has carried out successfully so far, and thus supports prevention goal pursuit strategies. In general, these studies reflect a dynamic mental system that is able to prepare action without people being aware of the processes.

It is interesting to think from a functional perspective about the proportional relationship between motivational strength and goal-related accessibility and post-fulfillment inhibition. We believe that a high motivation to fulfill a goal means that the individual is ready to invest energy in goal pursuit, giving it a high priority over other goals. Enhancing the accessibility of goal-related con-

structs could help in fulfilling the focal goal, but at the same time, it could interfere with achieving other goals (Shah et al., 2002). For example, enhanced accessibility of "keys" and its associates could help in finding the keys, but it would probably detract attention from simultaneously pursuing other goals that require attention (e.g., engaging in a conversation). Thus, because of its potential costs, enhanced accessibility of goal-related constructs should be proportional to the emphasis one is ready to assign to the pursuit of this particular goal (i.e., to motivation).

It is also reasonable to assume that highly motivating goals are more likely than less motivating goals to suppress (or put "on hold") other important alternative goals. For example, a high motivation to respond to sexist remarks in a conversation with a colleague may suppress the important goal of self-presentation, but a weak motivation would not suffice to produce such suppression. Therefore, as a rule, turning to the next goal pursued after completion of a previous goal is likely to be more important if the previously fulfilled goal was highly motivating. Attending to this important goal is then facilitated by strong inhibition of the constructs related to the previous goal. Thus, the more motivating the initial goal was, the more functional it is to inhibit its related constructs after goal fulfillment in order to turn back to the important alternative goal that was suppressed.

In sum, it is easy to see how a system that incorporates priming effects of different types has evolved from a functional need. It is also possible, however, that functionality is not only an evolutionary explanation of how these effects came to exist but also an important factor that influences the effects of priming in humans today. Thus, we believe that the notion that priming effects are functional is not only interesting in its own right but also serves to derive interesting predictions regarding possible situational moderators of priming effects.

APPLICATIONS OF PRINCIPLES OF ACCESSIBILITY IN SOCIAL PSYCHOLOGY

Lessons learned from priming research were applied to many content domains in social psychology, including study of cross-cultural differences (Hannover & Kühnen, 2005), consumer psychology (Wyer, in press), and research on basic motives, such as terror management (Pyszczynski, Greenberg, & Solomon, 1999). In the present chapter, however, we chose to focus on three other domains: measurement of stereotypes, measurement of goals and concerns, and uncovering the processes involved in thought suppression.

Measurement of Attitudes: Using Affective Priming

Because affective priming facilitates processing of evaluative-congruent targets, Fazio and Williams (1986) suggested that the extent of such priming should be stronger with primes for which strong attitudes exist. If so, the extent to which a stimulus primes positive versus

negative targets should reveal the strength of the individual's positive (vs. negative) attitude toward the prime. This notion has been put to use in modern social psychology. For example, Dunton and Fazio (1997) primed participants with African American versus Caucasian faces and examined the speed with which participants could classify adjectives as positive versus negative. They found that the extent to which African American faces primed negative adjectives was indicative of their attitudes toward African Americans. Subsequent studies found that this measure also correlated with behavior. For example, it predicted students' anticipated comfort in interacting with African American students (Towles-Schwen & Fazio, 2003) and maintenance of eye contact with an African American interviewer (Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997). Importantly, this method, often termed an implicit measure of attitudes, does not measure explicitly expressed attitudes, which often correlate only with controllable behaviors. For example, explicit attitudes, as measured by the modern racism scale, predicted explicitly stated evaluations of the African American interviewer but did not predict less controlled behaviors, such as maintaining eye contact with him or her. The reverse was true for implicit attitudes, which were measured as the extent of affective priming (Dovidio et al., 1997; for a review, see Olson & Fazio, 2002). Affective priming has been used to measure attitudes toward social groups as well as toward other attitude objects, including smoking (Sherman, Rose, Koch, Presson, & Chassin, 2003) and TV programs (Frings & Wentura, 2003).

There are other ways to measure attitudes implicitly, primarily with the Implicit Associations Test (IAT; Greenwald, McGee, & Schwartz, 1998; see Olson & Fazio, 2002, for a review of the differences between the measures). Importantly, implicit measures of attitudes are not invariant; they are sensitive to many factors, including context, motivation, and practice. This should not be surprising in view of the fact that all priming effects are sensitive to these factors.

It is beyond the scope of this chapter to review all the ways in which implicit measures of attitudes differ from explicit measures. One aspect particularly relevant to the principles of knowledge accessibility is that explicit attitudes are more susceptible to control and correction processes than implicit attitudes. Therefore, discrepancies between implicitly and explicitly measured attitudes should exist when correction processes are likely to operate. In other words, when people suspect they were biased, are motivated to correct the bias, have the capacity to perform the correction, and posses the knowledge of how to do it, differences between implicit and explicit attitudes should be apparent. The case of racial attitudes is a prime example (Olson & Fazio, 2002), but other examples include attitudes toward objects of temptations (e.g., smoking and partying) and ambivalence. For example, if one considers visiting museums important but boring, the concept of "museums" will be ambivalent for the person and would likely elicit discrepancies between implicit and explicit attitude measures.

Measuring Goals and Concerns: Using Goal Accessibility and Chronic Accessibility

We have already shown in this chapter that active goals and concerns enhance the accessibility of related constructs. This principle implies that accessibility may be used to uncover goals and concerns. Within regulatory focus theory (Higgins, 1987, 1997), this idea was used to measure the strength of dispositional promotion focus (the strength of one's hopes and aspirations) and dispositional prevention focus (the strength of one's duties and obligations). Specifically, Higgins, Shah, and Friedman (1997) developed a computerized measure that examines the time it takes participants to list "ideals" and "oughts," using this information to evaluate one's standing on them (see Higgins et al., 1997; Shah & Higgins, 1997). A faster overall response time for ideals indicates a stronger concern for them and indicates a promotion focus, while a faster time for "oughts" indicates a prevention focus. This personality measure has been used widely in research (e.g., Förster et al., 1998; Förster, Higgins, & Strack, 2000; Higgins et al., 1997; Shah & Higgins, 1997, to name a few).

Accessibility may be used to assess other dispositional concerns as well. To give some examples, accessibility of depressive contents can be used as a measure of depression or accessibility of achievement-related contents as a measure of achievement concerns. In fact, traditional projective tests, such as the Thematic Apperception Test (TAT; Murray, 1938), may be viewed as tests of accessibility (Sorrentino & Higgins, 1986). It may be contended that these tests operationalize accessibility as ease of retrieval from memory, or perceptual readiness and high accessibility as indicative of a high concern with the contents in question. For example, a high concern with achievement is revealed in the TAT as a high frequency of achievement-related themes in one's interpretations of scenes in pictures (Atkinson, 1954; McClelland, 1953). We should note that from the perspective of contemporary social and cognitive psychology, what often appear to be problematic in projective tests are not the assumptions about the connection between accessibility and people's concerns. Rather, it is the assumption that such concerns are necessarily reflective of a stable personality characteristic and the lack of objectivity in coding the contents of the participants' responses.

Suppression of Thoughts: Using Principles of Goal-Related Accessibility to Uncover Motivations

It is hard, if not impossible, to suppress thoughts. Moreover, suppressed thoughts rebound after suppression and become more frequent than without suppression (Wegner, 1994). Macrae, Bodenhausen, Milne, and Jetten (1994) suggested that this rebound effect is due to high accessibility caused by priming of the suppressed construct during the suppression stage. In their study, they measured accessibility of skinhead stereotypes using a lexical decision task after asking participants to sup-

press skinhead stereotypes. Those asked to suppress showed higher accessibility after suppression when compared to those who did not engage in suppression. More recently, Liberman and Förster (2000) conceptually replicated the effects and added a condition in which participants expressed the stereotype after suppression. For example, in one of the studies they asked participants, who first suppressed stereotypes of African Americans in a story they wrote, to take the perspective of a racist and write a second story using racial stereotypes. It was found that participants who first suppressed stereotypes and then expressed them, inhibited racist constructs. The authors suggested the motivational inference model (MIMO) of postsuppressional rebound, which claims that suppression instructions introduce or enhance a motivation to think about the suppressed thought. Expression after suppression fulfills this motivation and is followed by a postfulfillment inhibition. Without prior motivation to use the construct, construct use would have enhanced the accessibility of the construct (see Förster & Liberman, 2004, in press). The finding that expression of suppressed thoughts reduced, instead of enhanced, accessibility speaks for the activation of goals rather than semantic priming, which would increase from two sources of accessibility (suppression and expression; for further evidence and additional implications of the model, see Förster & Liberman, 2001). These studies allowed for clarification of the nature of suppression. Previous models viewed enhanced accessibility of a suppressed construct as accessibility due to construct use, whereas MIMO explains it as goal-related accessibility; empirical evidence has shown support for the latter view.

CONCLUSION

There is abundant research on the effects of knowledge accessibility on affect, cognition, and behavior. Theories about these effects are also slowly emerging. We believe that there is much to gain in considering the similarities between different effects and by applying general, overarching principles to explain them. This chapter has tried to examine some of the findings on knowledge accessibility and principles that these findings instantiate. We also discussed how these phenomena and principles may be used to examine, extend, and test models in social psychology. Future research will have to develop integrative models to explain the effects and, in particular, include a discussion of functional aspects of accessibility.

ACKNOWLEDGMENTS

NOTES

1. This definition diverges from Wilson and Brekke's definition of mental contamination as undesirable or subjectively wrong influences on processing of targets. In our definition of priming, priming effects occur whether or not a person considers such effects desirable, as they are simply independent of such judgment. In other words, a desirable effect of priming (e.g., when a person does want to yield to the effects of prior mental processes on subsequent processing of a target) would not be considered a mental contamination, but it would, nonetheless, remain an effect of priming. Of course, undesirable demonstrations of priming effects are especially strong because they rule out conscious, strategic, and deliberate processes.
2. This does not mean that there won't be any difference between negated or affirmed primes, or between priming by a credible versus discredited source. These differences, however, may be related to secondary, metacognitive correction processes, rather than to the primary effects of accessibility, as discussed in the fourth part of this chapter.
3. This effect is similar to Srull and Wyer's (1980) finding in that priming "hostility" influenced a target's person behavior only if the concepts were primed before the behavioral information and had no effect when they were primed afterward.
4. One may wonder why Dijksterhuis et al. (2000) and Levy (1996) obtained different results after subliminally priming young participants with the elderly stereotype. Seibt (2003) suggests that one clue to the apparent contradiction are the primes used in the two studies—Dijksterhuis et al.'s primes were neutral (e.g., old and gray), whereas Levy's primes were either negative and related to forgetfulness (e.g., Alzheimer's, senile, dementia, and diseased) or positive and irrelevant to memory (e.g., guidance, wise, and alert). It is possible that in Levy's studies, the younger participants were either repelled by the negative valence of the primes and contrasted themselves away from them (in the negative condition) or did not associate the primes with memory performance (in the positive condition).
5. Strack, Förster, and Werth (2005) were able to change people's memory judgments by suggesting opposite theories of contaminating influences.

Causal Explanation

From Social Perception to Knowledge-Based Attribution

DENIS HILTON

Being able to infer causes and communicate reasons provides both humans and other primates with considerable adaptive and organizational advantages. For example, some Diana monkeys in the wild are able to infer, on hearing a chimpanzee's alarm call for *Leopard!*, that a leopard must be present, and utter the Diana-ese warning call for *Leopard!* to their own conspecifics, thus giving them a "reason" to hide (Zauberbühler, 2000a, 2000b). More generally, the automatic recognition of emotional reactions in others can enable animals to make inferences about what caused those reactions and thus learn about the nature of their environment. For example, Blair (2003) argues that emotional expressions serve as unconditioned stimuli that enable a conspecific to evaluate the eliciting stimulus as positive or negative; for example, if another animal reacts negatively to a eating a food, then a conspecific can learn to avoid this food "because" it is disgusting.

These findings in animals suggest that they possess basic causal inference processes that they share with humans, and whose conclusions are communicated—whether automatically or intentionally—to others. However, while humans have both innate action and emotion recognition systems (see below) as well as general-purpose associative learning algorithms for detecting covariations that they share with other animals (e.g., Shanks & Dickinson, 1988), they also uniquely possess other faculties relevant to causal explanation, such as a "social cognition" module, mental simulation of causality, and conversation. In this chapter, I examine these faculties before moving on to examine more traditional concerns of attribution theory such as the covariational analysis of causality, the dispositional inference process, and the question as to whether this last process is accompanied by a tendency to underestimate the influence of situational causes on behavior (e.g., Gilbert, 1998; Trope & Gaunt, 2003).

FRAMEWORKS FOR STUDYING CAUSAL ATTRIBUTION AND EXPLANATION: KNOWLEDGE STRUCTURES, COVARIATIONAL ANALYSIS, AND CONVERSATIONAL EXPLANATION

Heider's (1958) book *The Psychology of Interpersonal Relations* has influenced social psychological thinking about attribution through two routes—one indirect, and the other a direct one. The indirect route was taken through artificial intelligence and cognitive science and came about through Heider's influence on Schank and Abelson's (1977) knowledge-structure approach to text understanding and question answering. Schank and Abelson's approach extends Heider's conceptual analysis of key concepts (e.g., "can" and "ought") and personal causality in the naive analysis of action, through explicating automatic and unconscious inference processes that enable goal-based explanations of action sequences described in narrative texts (Carbonell, 1981; Wilensky, 1981, 1983). The knowledge-structure approach has

spawned social psychological analyses of attribution processes (Abelson & Lalljee, 1988; Hilton & Slugoski, 1986; Lalljee & Abelson, 1983; Read, 1987), and we shall see that its emphasis on goal-based explanation is consistent with recent work in developmental psychology and neuroscience on "theory of mind" in children (Malle, 2004). The approach also bears important formal similarities with recent work in artificial intelligence and cognitive psychology that has used structural modeling to understand the role of counterfactuals in causal reasoning (Pearl, 2000; Sloman & Lagnado, 2005).

As is widely known, Heider's book also had a direct impact on attribution theory through the interpretations given it by Jones and Davis (1965) and Kelley (1967). In contrast to the knowledge-structure approach, this "lay scientist" perspective on causal attribution focuses on more deliberative causal reasoning processes, such as covariation analysis and discounting. It has several central assumptions, namely, (1) the partition into internal (dispositional) and external (situational) causes; (2) the analysis of covariation information in establishing causality; (3) a hydraulic model of causation that assumes that causes are polar opposites; that is, a cause can be internal or external but not both; and (4) the comparison between lay and scientific models of causal inference. The "lay scientist" perspective led to a concern with the issue of bias and error in lay causal attribution as compared to normative models of judgment, which was quite natural given social psychology's concerns with accuracy in impression formation and the concurrent growth of interest in heuristic and biases in reasoning and judgment (Nisbett & Ross, 1980).

However, both the knowledge-structure and "lay scientist" perspectives share an important limitation. They both see causal attribution as an essentially cognitive process by which an isolated individual forms a mental representation of the world. This is consistent with Heider's early work on the philosophy and psychology of visual perception, but it fails to do justice to the social aspects of ordinary causal explanation. In Heider's use of the term, "attribution" is a cognitive process whereby one can trace a product to its origins, such as when one attributes a reflection in a window to the light from the sun, or a painting to an Old Master. However, as (Hilton, 1990, 1991) notes, *explanation* is a form of social interaction, constituting a three-place predicate whereby *someone* explains *something* to *someone else*. For example, I can attribute the 9/11 attacks to someone, but that is not the same as explaining the attacks to him. Good explanations should therefore obey conversational principles such as relevance to another's informational needs (Grice, 1975; Slugoski, Lalljee, Lamb, & Ginsburg, 1993) and may also obey societal imperatives such as social control (Tetlock, 2002). The knowledge-structure and covariational approaches therefore need to complemented with question-answering systems (cf. Lehnert, 1978). This allows us to see, for example, that people may change their explanations simply in order to take another's person's perspective into account (causal backgrounding), not because they have changed their own mind about the causes of an event (causal discounting).

Three Ways to Explain the Verb Effect on Causal Explanation?: Covariation, Knowledge Structures, and Conversational Principles

The three approaches described above are not incompatible and can deliver complementary insights. For example, they can illustrate diverse aspects of the verb effect on causal explanation (Brown & Fish, 1983; McArthur, 1972), whereby verbs describing emotion (e.g., *Ted admires Paul*) are typically attributed to the stimulus, whereas verbs describing actions (e.g., *Ted cheats Paul*) are more likely to be attributed to the person. In addition, the English language (like many others) has a rich vocabulary of adjectives that describe variability in the disposition of those stimuli to elicit emotions (*likable, loathsome*, etc.) but few derived from state verbs to describe variability in the enduring disposition of people to experience emotions (e.g., *likeful* and *loathive*). In contrast, natural languages have far more adjectives derived from action verbs for describing variability in the disposition of people to produce actions (*charming, deceitful*, etc.), than they have to describe variability in the disposition of people to be acted upon in certain ways (*charmable, deceivable*, etc.).

Thus, the "lay scientist" approach would explain verb effects on causal attribution in terms of causal schemata (i.e., assumed patterns of covariation–Kelley, 1973; see also Rudolph & Försterling, 1997). In general people assume that actions tend to covary with the actor (*few others do it to y*; *x does it to many others*) whereas emotions tend to covary with the object (*many others feel the same way about y, x feels the same way about few others*). Attribution of actions to actors and emotions to stimuli would thus follow from the covariation rule. In particular, Brown and Fish (1983) conjecture that the hardwired nature of emotional recognition systems will make them consensually shared by conspecifics and thus very diagnostic about the nature of the eliciting stimuli, whereas actions that are under the control of higher-order cortical structures will be more diagnostic about agents' personalities.

However, knowledge structures can refine and even inverse these basic attributional patterns. For example, emotional reactions can enable us to make inferences about the person experiencing them when they are "disproportionate" to their object (Smith, 1789/2002). Thus an adult who expresses wild delight at receiving an ice cream might seem "childish," whereas someone who carries on regardless after receiving news of the death of a loved one would seem "unfeeling." World knowledge, here in the form of higher-order knowledge about general patterns of behavior, tells us that such reactions are abnormal and therefore need explaining. Research using facial expressions (Trope, 1986) and emotional responses presented in verbal scenarios (Brown & van Kleeck, 1989) shows that people do indeed make these kinds of dispositional inferences about the person when they display inappropriate emotional reactions. Such attributions serve the important function of creating "cognitive balance" (Heider, 1958) in a way that is very consistent with current connectionist models of how cognitive systems achieve equilibrium (Read, Vanman, & Miller, 1997).

Finally, conversational constraints such as the requirement to be informative to others (Grice, 1975) can influence the explanations that are generated. When asked to explain a normal event such as *The policeman protects Paul*, people tend to focus on something unusual about Paul (e.g., he is a celebrity), as it would be very uninformative to mention the policeman as a cause, even though protection is strongly associated with a policeman's role. Indeed, it is the socially shared nature of common knowledge about policemen's roles that makes this redundant to mention in an explanation to an adult (including to an experimenter). However, as would be predicted by Gricean principles, people will instead refer to the policeman's role when asked to explain the event to a 4-year-old, as young children may be expected not to know what it is that policemen generally do (Hilton & Slugoski, 2001).

In sum, the covariational, knowledge structure, and conversational perspectives may best be thought of as highlighting different aspects of the attribution and explanation process. Through innate expectations or through observing covariations we may develop knowledge structures of varying levels of abstraction, such as *people are sad on hearing bad news* and *policemen protect people*. But if we observe something that does not fit our covariation-based expectations (e.g., someone does not look sad upon hearing bad news), then attribution processes are likely to be triggered. However, if someone else asks us to explain an event, I focus on something that is informative from their point of view, not from ours.

PLAN OF THIS CHAPTER

In the first part of this chapter I begin by tracing the origins of the attribution process in the automatic causal perception of motion. We will see that social perception appears to be "Kantian" in that action and emotion perception are based in large part on innate and hardwired specialized modules that are directly stimulated by certain kinds of cues. These innate social perception modules form the basis of a "naive psychology" that yields knowledge structures that enable explanation of sequences of human behavior.

In the second part I review evidence that these knowledge structures support causal explanation through counterfactual reasoning using mental simulation. These simulations may yield complex causal chains that produce an event to be explained, whereas in ordinary explanation we usually talk about only one or at most two factors as "the" cause. In the third part I show that people skillfully and intuitively use conversational intuitions to select "the" factor from these complex cognitive representations that is most relevant to mention in a conversation about causes. These conversational inference and explanation processes mostly seem to occur automatically and outside conscious awareness in adults.

In the fourth part I show how the aforementioned knowledge structure and conversational perspectives can illuminate issues and resolve problems in the analysis of variance (ANOVA) framework of the classic lay scientist approach (Kelley, 1967). In particular, attention to the role of prior knowledge in the inference process, the different kinds of causal inference (e.g., causal explanation of events vs. dispositional attribution to entities), and the conversational pragmatics of experimental conversations about causes suggests that people may be rather more rational and less biased in their causal attributions than early studies have suggested (McArthur, 1972). In the fifth part, I extend the knowledge-based approach to the analysis of discounting processes (Jones & Davis, 1965) and again show that evidence for bias is less strong and less general than might be supposed from well-known studies in this paradigm (e.g., Gilbert, Pelham, & Krull, 1988; Jones & Harris, 1967).

THE DEVELOPMENT OF FOLK PSYCHOLOGY: ACQUISITION OF KNOWLEDGE STRUCTURES FOR CAUSAL EXPLANATION

In this section I first examine evidence from neuroscience and developmental psychology to establish what humans inherit in their "social cognition" module and then consider how, in combination with learned knowledge acquired through experience, this can mature into a folk theory of psychology that is used to interpret and explain human behavior. In particular, neuroscience research has painted a picture of the human brain as containing a highly specialized set of modules for various aspects of perception, memory, and inference, which differs from the British empiricist approach of Hume and Mill to causal inference that has influenced social psychological research, with its focus on general-purpose covariation analysis.

Is There an Innate Social Cognition Module?

Social Perception through Observation of Movement

People have a natural disposition to see self-propelled movement as expressing intentional agency. Heider and Simmel (1944) demonstrated this disposition by creating a cartoon in which colored geometric figures (like a green square, a red triangle, and a blue square) moved around a black frame in a quasi-random fashion, before the black frame disintegrated at the end of the sequence. A remarkable 49 of 50 observers described the dots' movements in the language of description for human behavior: The dots were described as *chasing*, *following*, *avoiding* each other, and so on. Oatley and Yuill (1984) showed a version of the cartoon to participants with titles that expressed higher-order themes such as "jealous lover." For example, the observers had no difficulty in attributing emotions such as anger to the figures that "explained" why they then went on to destroy the "house" (the frame that disintegrated).

Neuroscience research suggests that perception of motion is integrated with the attribution of intention and causality in the human brain, in particular in brain circuits that recruit the superior temporal sulcus (STS),

which has been found to be "sensitive to biological motion, but more generally to stimuli that signify intentions or intentional activity" (Gallagher et al., 2000, p. 19; see also Allison, Puce, & McCarthy, 2000). For example, Castelli, Happe, Frith, and Frith (2000) used cartoons inspired by Heider and Simmel to induce perception of dot motion either in terms of intentional behavior or as random movements They found that observers perceiving the dot movements as intentional selectively activated the temporal parietal junction (which is very close to the STS), the basal temporal gyrus, the extrastriate cortex, and the medial prefrontal cortex, whereas those perceiving the dots as moving randomly selectively activated the occipital cortex. Grossman and Blake (2002) found that the posterior STS was selectively activated by 12 moving-point displays that give the impression of a human walking, but not by scrambled dot movements. On the other hand, other areas involved in the recognition of objects and bodies, such as the extrastriate body area (EBA) and the lateral occipital cortex (LOC) did not show differential activity in response to scrambled and nonscrambled "walking dot" displays.

Perception versus Knowledge of Causality

Impressions of causality based on visual perception of motion seem to be impervious to top-down knowledge, as when we still "see" dots that collide with each other screen as causing each other to move even when we "know" that their coordinated movement is simply the result of careful computer programming. They are thus a prime candidate for "System 1" thinking based on automatic pattern recognition rather than more deliberate, inferential "System 2" thinking (Sloman, 2002).

Blakemore and colleagues (2001) used patterns inspired by Michotte (1963) that either gave an impression of causality, as in the "launching effect" when a blue ball rolls horizontally across a screen and collides with a stationary red ball, which then moves off screen, compared to noncausal sequences where the red ball rolls across the screen but moves round the stationary red ball by passing under it, or visual transient events where the blue ball rolls across a screen and then changes color to red. Bilateral activation of the STS and activity in the left intraparietal sulcus was greater for causal than for noncausal sequences, regardless of whether participants had been told to make a judgment about the direction of motion of the ball or a judgment about whether there was a causal relationship.

The attribution of intention to self-propelled objects seems to be hardwired in human beings and universal across cultures. Thus, Morris, Nisbett, and Peng (1995) report no difference between Americans and Chinese in perceiving internal force, external force, and animacy of moving dots in Michotte-style entraining and launching movements. Cultural differences did, however, emerge when they presented similar displays using fish (either alone or in groups). Americans tended to perceive that the fish moved more under internal influence whereas the Chinese were more likely to perceive that movement was due to external influence. Although *perceptions* of

causality in Michotte-style launching and entraining movements are not different between Americans and Chinese, some differences emerge in verbal explanations they give (Peng & Knowles, 2004): Americans were more likely to attribute the dot's movements to "dispositional explanations" (e.g., weight and mass, composition, inertia, and shape), whereas Chinese were more likely to produce "contextual explanations" (e.g., the other object, gravity, friction, and wind). These findings suggest that while visual perception of causality is hardwired, universal, and "direct," verbal explanations of these movements may appeal to culturally specific "naive theories" of physics.

The Perception of Equifinality in Infants and Children

The principle of equifinality, which Heider (1958) characterized as "the invariance of the end and variability of the means" (p. 101), is a core assumption of his analysis of commonsense explanation of human action. In Heider's theory of personal causality, intentions make good causal explanations because they economically focus on the factor that makes the most difference to an outcome: "Attribution to personal causality reduces the necessary conditions essentially to one, the person with intention, who, within a wide range of environmental vicissitudes, has control over the multitude of forces required to create the specific effect" (Heider, 1958, p. 102).

Children appear to be endowed with an "intentional stance" to interpret behavior from an early age. For example, even 6-month-old infants appear have developed expectations about goal-directed action. Using a habituation procedure, Woodward (1998) found that infants of this age expect animate objects (specifically, human hands) to do things such as reach for objects they were just reaching for previously but do not expect inanimate objects that resemble human hands (e.g., a garden tool "claw") to "reach" toward the familiar object in similar circumstances. In a related vein, Tomasello, Carpenter, Call, Behne, and Moll (2005) review evidence showing that children encode movements in terms of intentional actions; for example, they imitate what an adult is *trying* to achieve by a movement and do not imitate the adult's actual physical movements (e.g., when impeded) in a literal-minded way.

In a striking demonstration of infants' understanding of equifinality, Gergely, Nádasdy, Csibra, and Bíró (1995) habituated infants to a small self-propelled dot "jumping" over an obstacle when approaching a large dot. Later, with the obstacle removed, 12-month-old infants showed surprise when the same jumping motion was repeated. Even at this age, children seem to show an innate sense of counterfactual trajectories (as if the child asks herself "With the obstacle gone, why would the small dot still "jump" and not go directly to the large dot as it could (and should) have done?"). Even these very young children therefore appear to understand "equifinality," as they did not show surprise at the small dot now going directly to the large dot (even though this was a new motion).

The Development of a Theory of Mind

Premack and Premack (1995) argue that the development of a "theory of mind" from infancy to early childhood will go through three stages: (1) automatic activation by movement of the perception that an agent is intentional; (2) interpretation of interactions of moving objects as "helping" or "hindering" each other; and (3) at about the age of 4 years, the development of a "theory of mind" similar to that of adults with the predicates, *see, desire and believe*. Social interaction and involvement in conversation may be important here: Harris (1996) suggests that after learning language and engaging in conversation, children are able to learn that others have beliefs different from theirs and thus move from a "desire" psychology (using words such as "want") at the age of 3 years to a "belief–desire" psychology at the age of 4 years (using words such as "think" as well as "want"). This helps them succeed on "false belief" tasks that require a child to take into account another child's incorrect beliefs (Wimmer & Perner, 1983). Consistent with this view, Carpendale and Lewis (2004) review evidence that acquisition of a "belief psychology" is associated with factors associated with quality and quantity of social interactions. For example, children tend to be later in success on the false-belief task if they have fewer siblings, experience less family talk about mental states, and suffer from deafness or attachment anxiety. Lack of language and communication may also help explain why deaf children with hearing parents who cannot communicate with them in sign language, like children younger than 4 years of age, have difficulty on "false-belief" tasks (Woolfe, Want, & Siegal, 2002; see also Tomasello, Call, & Hare, 2003, for related evidence on chimpanzees).

Mentalizing: Development of Higher-Order Attributional Inference

Although direct perception of agency is available through the visual system, causal judgments of the kind described by attribution theories in social psychology seem to require higher-order inferential processes (cf. Lieberman, Gaunt, Gilbert, & Trope, 2002). Evidence that attribution of beliefs is a higher-order process may be surmised from work suggesting that genetic disorders cause problems in the development of a mature "theory of mind." Thus autistic children appear to have difficulties with tasks involving attribution of mental states that require inference rules similar to the noncommon effects principle of Jones and Davis (1965). Although autistic children are able to perceive the direction of gaze, unlike normal or mentally retarded children they are unable to infer that if a cartoon figure is looking at one kind of chocolate bar rather than another, it is because he or she prefers that bar (Baron-Cohen, Campbell, Karmiloff-Smith, Grant, & Walker, 1995).

Autists are thought to have problems in "mentalizing," by which Frith and Frith (2003) mean the activity necessary for understanding narratives (as opposed to incoherent sequences of text) that require attributions of beliefs and intentions to story characters (Schank &

Abelson, 1977). Mentalizing recruits the temporal poles and the medial prefrontal cortex (MFPC) as well as the STS involved in visual perception of motion and causality. The fact that mentalizing involves centers such as the MPFC, which has direct links to the STS and the temporal poles, suggests that adult attributional inference in understanding stories integrates brain circuits involved in the visual perception of causality with the MPFC, that is also recruited by higher-order reasoning processes about social rules (Adolphs, Bechara, Tranel, & Damasio, 1995).

Personal Causality in Commonsense Explanation: A Revision of Heider

What does the matured "theory of mind" look like in adults? We may surmise that it has many of the characteristics given by Heider (1958) in his analysis of personal causality. However, Malle (1999) suggests that Heider's formulation suffered from some incoherences that led his theory of personal causality to be conflated with the person–situation distinction that came to dominate later attribution research. Malle proposed a modified version of Heider's "naive psychology" that incorporates the notion of belief, desire, intention, skill, and awareness, part of which is reproduced in Figure 10.1. First, Malle makes a distinction between intentional and unintentional actions. While unintentional actions can be partitioned reliably into internal and external causes, intentional ones cannot. For example, explanations of accomplishments (McArthur, 1972) that refer to internal factors such as "Jennifer got into Oxford because she is intelligent" rather than external ones such as "Jennifer got into Oxford because the exams were easy" seem to say meaningfully different things about Jennifer and about Oxford. However, phrases that on the surface mark person versus situation factors in explaining intentional actions such as "Jane bought the house because she wanted privacy" versus "Jane bought the house because it was secluded" (Ross, 1977) seem to appeal to the same underlying general motive–action–outcome schema that motivates intention-based systems for understanding human action (Abelson, 1975). They both seem to say or imply the same thing about Jane (she likes privacy) and the house (it is secluded), and in this respect they have much the same deep meaning.

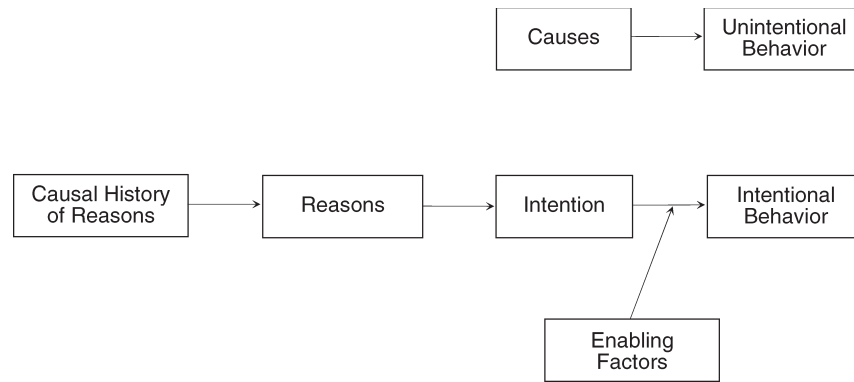
Malle (1999) argues that intentional explanations appeal to the subjectivity rule: that is folk explainers cite "only those mental states as reasons that (as far as they know) the agent considered and in light of which he formed his decision to act" (p. 36). Sometimes the reason will be explicitly marked: as in explaining why Anne watered her plants "because she *wants* them to grow faster" or unmarked as in "so they'll grow faster." This factor alone (see Malle, 1999, for others) renders it quite difficult to code intentional actions for internality or externality. Using probes such as "Imagine you invited someone to lunch. Why would you?" Malle (1999, expt. 2) generated 489 reason explanations than were then coded using the separate person–situation categories of traditional attribution theory and the scheme of folk ex-


FIGURE 10.1. Malle's depiction of folk theories of behavior.

planation: mental state markers (present or absent); reason content (person or situation); and reason type (belief or desire). The major findings were that 74% of all person attributions referred to reasons with mental state markers (e.g., "I asked somebody out for dinner because I *wanted* to get to know this person better" and "I applauded the musicians because I *enjoyed* their performance") whereas 90% of situation attributions were assigned to unmarked reasons with situation content (e.g., "I watered the plants because *they were dry*" and "I applauded the musicians because *they were good*"). In other words, although person attributions tended to mark mental states and situation attributions did not, they both can express similar underlying ideas about why the action was undertaken (e.g., I *enjoyed* the performance and the musicians *were good*"). As we shall see in the section on conversational pragmatics, the unmarked elements may in fact be presupposed as being true but backgrounded parts of the larger causal explanation (causal backgrounding), which is not the same thing as no longer believing them to have any causal role at all (causal discounting).

Other Sources of "Naive Theories" about Cause–Effect Relationships

Although, the social cognition module equips humans with the kinds of knowledge structures ("theory of mind") needed to understand human action, two other sources of general knowledge about others' behavior that are important for developing a "naive psychology" should briefly be noted.

Emotion Perception

Humans appear to be equipped with brain structures that seem to be tuned to the perception of particular emotional reactions (Keltner, Ekman, Gonzaga, & Beer, 2003); for example, the perception of sad faces activates the left amygdala and the right temporal lobe, whereas perception of angry faces activates the right orbitofrontal cortex and cingulate cortex. Bilateral lesions to the amygdala impair the ability to recognize fearful facial expressions and vocalizations but not the ability to recog-

nize facial expressions of sadness, disgust, or happiness. Recognition of many emotional expressions thus appears to be accomplished without reference to higher-order cortical structures. As was noted in the discussion of the verb effect on causal explanation, emotional expressions will generally be attributed to the presence of environmental stimuli, unless contextual knowledge suggests that they are inappropriate over- or underreactions.

Associative Learning of Causal Relationships

Although I do not have the space to go into detail, it is important to note that humans can *learn* causal relations from experience. They often appear to do so by using simple associative heuristics that are shared by other species (Rescorla & Wagner, 1972; Shanks & Dickinson, 1988; for applications to social attribution tasks, see van Overwalle, 2003; ; van Overwalle & Rooy, 2001a, 2001b; van Overwalle & Timmermans, 2005). These general-purpose "Humean" associative learning heuristics use cues to causality such as spatial and temporal contiguity to build associations that are strengthened by repeated co-occurrence of events (Hume, 1888). They take as inputs multiple observations and output universal causal generalizations (Hilton, 2002).

EXPLAINING THE COURSE OF EVENTS: KNOWLEDGE-BASED COUNTERFACTUAL SIMULATIONS

In the previous section, we have seen how innate "Kantian" structures for interpreting perceptions of actions and emotions, can combine with acquired generalizations to furnish the knowledge structures that can be used to interpret human behavior in terms of "stories"— sequences of emotional reactions that generate intentions that generate plans that in turn generate actions that bring about new emotional reactions, and so on (Schank & Abelson, 1977). In this section, we consider how such *general* knowledge structures drive the counterfactual simulations that can be used to explain *particular* instances of human behavior.

Causal Induction versus Causal Ascription: Acquiring versus Using Knowledge

One problem in comparing the layperson to a scientist is that science is typically concerned with causal induction, whereas lay causal inquiries are typically concerned with causal ascription. Whereas science characteristically answers abstract questions about *types* of event (Why do apples fall? Why do species evolve? How do minds retrieve memories? Why do people show ingroup favoritism?), commonsense causal inquiries are context-specific and typically concerned with explaining why a *particular* event occurred when and how it did. This point is well put by legal philosophers Hart and Honoré (1985), who wrote:

> The lawyer and the historian are both primarily concerned to make causal statements about *particulars*, to establish on some particular occasion some particular occurrence was the effect or consequence of some other particular occurrence. The causal statements characteristic of these disciplines are of the form 'This man's death was caused by this blow.' Their characteristic concern with causation is not to discover connexions between types of events, and so not to *formulate* laws or generalizations, but is often to *apply* generalizations, which are already known or accepted as true and even platitudinous, to particular concrete cases. (pp. 9–10)

As an example, Hart and Honoré consider the case of a man who has died as a result of being shot. The causal generalization that *lack of oxygen in the brain causes death* would not explain why this man dies when and how he did, being true of all deaths. Rather, the pragmatic interests of the lawyer, doctor, and layman would be to identify the *abnormal condition* that distinguishes this man's state, being dead, from the normal state (being alive). The explanation that he died because he was shot identifies a factor that made a difference to the course of events and gives new information that is relevant to the question about the cause of this particular death. On the other hand, the answer that he died because of lack of oxygen cannot explain this particular death, even though it is more likely to be true, and to have a higher covariation with death than being shot.

In ordinary commonsense explanation, we use knowledge of *general* relationships to ascribe causes for *particular* events. Whereas science seeks to *gain* new general knowledge through causal induction (e.g., by testing the causal efficacy of a new drug in controlled experimental trials), commonsense causal explanation *uses* prior knowledge to generate mental simulations that explain particular events that attract attention, for example, if they are surprising (e.g., a known drug such as aspirin fails to have its expected effect). While commonly unspoken, psychologists ignore the role of these axioms in lay causal explanation at their peril. Next, I examine how such knowledge structures are used to support counterfactual simulations in reasoning about causality.

Counterfactual Simulation in Explaining the Course of Events

Recent work in artificial intelligence has suggested that intervention through manipulation—doing things to the world—provides a fundamentally different way of learning about causality to observation of covariation (Pearl, 2000; see also Halpern & Pearl, 2005a, 2005b). Manipulation enables interventions to be conducted on causal chains to see whether an effect still occurs. It also effectively neutralizes the effect of earlier events in the chain that are cut out of the picture (Pearl uses the metaphor of "surgery" to describe this operation) and can thus establish whether the manipulated factor influences the outcome, independent of prior events in the chain. Mental manipulation can also be carried out in counterfactual *simulations* (cf. Kahneman & Miller, 1986), where reasoning based on general knowledge is used to calculate "trajectories" about what should happen if a counterfactual intervention (which did not actually happen) is imagined. For example, in assessing the causes of the crash of the Concorde in 2000, I may mentally "undo" the occurrence of a catastrophic fire in the engines and make a projection that the accident would not have occurred if there had been no fire. I would thus conclude that the fire was on the causal trajectory that led to the accident, whereas if I mentally mutate the speed at Concorde took off (imagine it was traveling faster when it took off) or the kinds of passengers on board (imagine that they were all French rather than German), my mental simulation would find that these factors would make no difference to the outcome. I would therefore conclude that the Concorde's speed at takeoff or the kinds of passengers it was carrying were not on the causal trajectory that led to the accident.

Experimental work has suggested that people do use counterfactual reasoning of this kind to make these kinds of causal judgments (Sloman & Lagnado, 2005) This kind of counterfactual reasoning needs general "covering laws" (Hempel, 1965) to drive inferences about what should happen if a particular event in a causal chain is changed. In interpreting the physical world these may take the form *catastrophic engine fires cause accidents*, or *objects impacting at others at high speed cause damage*, or in political behavior *the strong do what they will, and the weak do what they must* (cf. Tetlock & Lebow, 2001). These inference rules constitute universal causal generalizations that express relationships between *types* of entity that hold across space and time rather than between *particular* entities that are located in space and time (Hilton, 2002; see also Oestermeier & Hesse, 2001). They are modeled as structural equations linking *variables* in Halpern and Pearl's model and are used to calculate the consequences when particular states of the world (called *values*) are altered in a counterfactual simulation (e.g., one imagines what would have happened if Concorde's fuel tank had *not* been impacted by debris at high speed during takeoff).

Some general inference rules about intentional behavior are probably innate, such as the equifinality rule, *If people have a goal, then they will circumvent obstacles to that goal*, whereas other rules will be learned through experience and acculturation, such as scripts like *People always buy something on their visit to supermarkets* or *People sometimes trip up over other people dancing* (Hilton & Slugoski, 1986; Schank & Abelson, 1977), or *If at a party, people tend*

to look happy (Chun, Spiegel, & Kruglanski, 2002; see also Kruglanski, 1988). These general beliefs about type relationships can also be expressed as conditional probabilities (e.g., *If instructed to write a counterattitudinal essay, then people usually produce an unconvincing text*) (cf. Morris & Larrick, 1995). While people in different cultures may acquire different cultural generalizations (Kashima, Siegal, Tanaka, & Kashima, 1992; Morris, Ames, & Knowles, 2001), the fact that these knowledge structures are socially shared means that they will hardly ever be *given* as explanations but will, rather, be presupposed as shared background knowledge in conversations about causes between members of the same group.

General beliefs about what "usually" or "often" happens can the influence the generation of "if only" counterfactuals and responsibility attributions. For example, Catellani, Alberici, and Milesi (2004) showed that participants who held stereotyped expectancies about rapes (as measured by the endorsement of rape myths) generated more "if only" counterfactuals that focused on the victim's rather than the perpetrator's behaviors, and in particular on things that the victim could have done but did not do. In turn, generation of these counterfactuals about what she could have done (but did not) was associated with higher attribution of responsibility for the rape to the victim.

Goal-Based Explanation and the Generation of Counterfactuals

Below I show how Heider's principle of equifinality can generate the inferences necessary to buttress counterfactual reasoning about human action. To illustrate, let us return to the example of the Concorde crash. The Concorde crashed shortly after it hit some debris that had just fallen off a Continental Airlines aircraft that had just taken off from Roissy Airport at Paris. The debris hit the underside of the Concorde's fuel tank and pierced it. This caused fuel to leak out, which caught fire in the atmosphere, leading to a catastrophic fire in the engines, resulting in the crash. Described in this way, many people considered the presence of the debris on the runway to be the cause, as its presence on the runway was abnormal, and counterfactual reasoning tells us that if the Concorde had not hit it, the crash would not have occurred. Although the debris falling off the earlier aircraft is abnormal, people do not intuitively consider this to be a cause, reflecting the principle that causality is not traced through the proximal abnormal condition to the distal abnormal condition (Hart & Honoré, 1985; see Hilton, McClure, & Slugoski, 2005, for relevant empirical results).

Now imagine that the debris had been deliberately placed on the runway by a saboteur hoping to bring about the accident. Here, the presence of the debris on the runway would now seem to be a "means" to the saboteur's "end." In this case, Hart and Honoré (1985) would predict, as Hilton and colleagues (2005) have shown, that causality will be traced through the proximal abnormal condition (e.g., the presence of debris on the runway) to the distal one (e.g., the saboteur's action). This

may be because equifinality-driven counterfactual reasoning now tells us that that even if the debris had not been on the runway, the Concorde would still have crashed (somehow), as the saboteur would have found another way to bring the crash about. In this sense, the debris on the runway is no longer a necessary condition for the Concorde crash, although it is still a necessary part of the causal trajectory that caused the Concorde to crash when and how it did. Note that in contrast the physical distal cause of the accident (the faulty maintenance of the Continental jet that caused the debris to fall off) does not plausibly support a counterfactual of the kind "Even if the Concorde hadn't hit the debris, the faulty maintenance of the Continental jet would still have found a way to make the Concorde crash on another occasion").

Models based both on Schank and Abelson's (1977) framework and Mackie's (1980) theory of counterfactual reasoning have been convergent and successful in predicting what parts of a story people find important and remember. Both give highly convergent predictions, suggesting that they draw on related intuitions, although Mackie's analysis performed slightly better (Trabasso & Sperry, 1985; Trabasso & van den Broek, 1985). A seeming anomaly for these models is that they assume that people create complex underlying representations of the conditions necessary for the occurrence of an event, yet they typically only mention only one or two factors as "the" cause of an event in ordinary causal explanation. A theory of causal selection is therefore needed to understand how people select causes from conditions in conversation, and I turn to this question below.

CONVERSATIONAL PROCESSES IN EXPLANATION

Audience Effects on the Selection of Causes from Conditions

If counterfactual reasoning reveals that there is a plethora of necessary conditions for an event, the problem of causal selection arises, as normally we only mention one or two factors in conversation as "the" cause (Hesslow, 1983, 1988). In particular, we should be sensitive to the questioner's perspective when giving explanations through giving them explanations that are not only true but informative, relevant, and clear to the inquirer (cf. Grice, 1975; Hilton, 1990).

Slugoski and colleagues (1993) demonstrated that people follow these conversational principles in interpersonal explanation. They had participants read a detailed case history about a youth who had committed a crime, which included personality information about the youth, and situational information about the circumstances in which the crime occurred. Participants were then asked to explain the crime either to an interlocutor who knew a lot about the boy's personal history but not the circumstances of the crime or to another interlocutor who knew little about the boy's personal history but a lot about the circumstances of the crime. Slugoski and colleagues found that explainers varied their explanations so as to

complement the questioner's prior knowledge: that is, interlocutors who already disposed of information about the boy's personal history received explanations that emphasized situational factors, and vice versa for the interlocutors who already knew of the situational circumstances surrounding the crime. Slugoski and colleagues' results are consistent with the idea that the explainers are identifying the condition that is abnormal from the interlocutor's point of view (Hilton & Slugoski, 1986). Similar reasoning has been applied by McGill (1989) to explain how changes in presupposed contrast cases can explain actor–observer and success–failure asymmetries in explanation.

Conversational constraints may also govern the formulation of fuller conjunctive explanations for audiences that have little relevant background information. Kashima, McKintyre, and Clifford (1998) found that Australian participants who had to imagine that they had to explain mundane behavior (e.g., going to the Melbourne cricket ground to watch a football match) to other Australians referred primarily to desires (e.g., wanting to watch the match) in their explanations. However, when asked to imagine explaining the event to a tourist, they referred to both desires and beliefs (e.g., "Michael likes football and knows that teams play football at the MCG"), presumably because participants recognized that strangers could not be expected to share the relevant beliefs. Kashima and colleagues obtained this result only with open-ended explanations, not with rating scales, suggesting that only verbally given explanations are sensitive to Gricean constraints (cf. Cheng & Novick, 1991; McGill, 1991). In a similar vein, Malle (in press-a, in press-b) reports a meta-analysis of actor–observer asymmetries in explanation that finds that observers only report more person causes than actors when open-ended explanations are coded, not when rating scales are analyzed. Malle suggests that this may reflect greater use of mental state markers (e.g., referring to beliefs and desires) by observers compared to actors in free explanations, rather than any underlying differences in patterns of attribution.

Abnormality in Commonsense Explanation and Attribution of Responsibility

The general inference rules encapsulated in the knowledge structures used in goal-based explanation will drive inferences about what normally should happen in a given situation. For example, we will probably assume from general world knowledge that food is inexpensive and easily available for an American or European who has stopped in to eat at a restaurant. However, if we learn that an Ethiopian refugee has just enjoyed a meal, we will change our assumptions about what is normal in the situation. Here we would attribute this behavior to the condition that is in fact abnormal in these circumstances, namely, the availability of food (Hart & Honoré, 1985; Hilton & Slugoski, 1986). Consistent with conversational principles of causal explanation, which require an explanation to be informative and relevant (Grice, 1975; Hilton, 1990), McClure and Hilton (1997) indeed found

that goals were perceived as more informative and relevant explanations for routine actions, but preconditions were judged as more informative and relevant explanations for actions when their presence was exceptional (e.g., food is available in Ethiopia).

Types of Causal Question and the Relevance of Explanations

People also have clear intuitions about what kind of causal question is appropriate to a given situation. Experiments on question answering about human behavior in narratives (Graesser, Robertson, & Anderson, 1981) show that "why" questions are typically answered by going up a goal hierarchy from an action (e.g., "Why did the prince get a horse?") to a goal ("Because he wanted to get to the castle"), whereas "how" questions typically involved descending from a goal ("How did he get to the castle") to an action that forms part of a plan to attain the goal ("By getting a horse"). Accordingly, McClure, Hilton, Cowan, Ishida, and Wilson (2001; see also Malle, 1999) found that actions that are normally difficult for the actor to perform, such as passing a difficult exam or a poor man taking a trip round the world, provoke "how come" questions that are most frequently answered by explanations that refer to preconditions (e.g., He's a stats whiz" or "He won the lottery"). On the other hand, "why" questions about routine actions tended to elicit explanations that focused on goals, while questions about "what caused" routine actions focused about equally on goals and preconditions (McClure & Hilton, 1998). Each kind of question set up different expectations about relevance. Thus, while goals were perceived as most informative and relevant to "why" questions, both preconditions and goals were perceived as equally informative and relevant responses to "what caused" questions.

Causal Backgrounding versus Causal Discounting

We have seen previously that factors such as the perceived knowledge and interests of the audience and the kind of causal question posed will change what people focus on and background in a conversationally given explanation. This kind of *backgrounding* of explanations that are still believed to be true but become less relevant to mention in a conversation about causes is not the same thing as *discounting* a causal explanation because one no longer believes it.

In *causal backgrounding*, we drop an explanation because it is no longer informative or relevant to mention in a conversation about causes, not because we no longer believe it to be part of the larger causal story responsible for the occurrence of the target event. For example, context may change what people call a cause by changing what is perceived as normal in the circumstances. Suppose we learn that a hammer strikes a watch, and the watch face breaks. Most people here assume that the watch broke because the hammer hit it. Now suppose that we now learn that this happens as part of a routine testing procedure in a watch factory. In this case, people tend to prefer the explanation that the watch broke be-

cause of a fault in the glass (Einhorn & Hogarth, 1986), as this is the abnormal condition that makes the difference between this watch that breaks and other watches that do not break in the circumstances under consideration. Nevertheless, people still believe that the hammer hit the watch and that this was necessary for the watch to break but now consider the hammer strike to be a less informative and relevant explanation than the fault in the glass (Hilton & Erb, 1996).

In contrast, in *causal discounting*, we drop an explanation because we no longer believe it to be true. For example, suppose a particular individual has contracted cancer. His lawyer may argue that working in an asbestos factory is the cause, thus trying to get his employers to pay compensation. In order to falsify this argument, his employers' lawyers may counter that this worker has smoked for many years, and that this is likely to be the cause of his cancer (Einhorn & Hogarth, 1986). Experimental research does in fact confirm that the activation of the rival asbestos pollution hypothesis does indeed lead people to consider the initial smoking hypothesis to be less probably true (Hilton & Erb, 1996).

Distinguishing causal backgrounding from causal discounting enables us to determine when rival explanations are complementary ways of looking at the same thing or are genuinely competitive (if one is true, the other is probably false). For example, a doctor may explain a victim's lung cancer to his wife by pointing out that he smoked heavily (thus differentiating him from his twin brother who did not smoke and who did not get cancer). But she might explain the same patient's cancer to another doctor by referring to the genetic disposition of members of his family to get cancer, thus explaining why this man got cancer when other heavy smokers did not. But *tuning* her explanation in this way to make it informative to her audience is quite different to *changing* her explanation because she instead now believes an alternative hypothesis (e.g., the man got cancer because he worked in an asbestos factory).

In summary, alternative causal scenarios are genuine rivals in causal discounting (as they are in medical diagnosis) because each particular outcome normally has only one causal history, thus justifying the "hydraulic" assumption made by Morris and Larrick (1995) that events to be explained normally only have one "cause." As we shall see later, knowing when it is appropriate to apply this hydraulic assumption as a normative standard helps determine whether people over- or underdiscount causes.

LOGIC AND KNOWLEDGE IN THE ANOVA FRAMEWORK

As we have seen previously, the knowledge-structure and conversational approaches are quite naturally able to deal with the question of how explanations are selected from sequences of conditionally dependent events, where the occurrence of later events in the causal chain is dependent on the occurrence of earlier ones. But as Kelley (1983) himself recognized, his ANOVA frame-work, with its assumption of conditional independence due to the orthogonal contrast of variables (person, stimulus, occasion), cannot apply to causal chains of events. To overcome this problem, Spellman (1997) proposed a covariational model based on successive reconditionalization (but see Mandel, 2003, for a critique).

In this section, I show that even the relatively simple case of conditional independence presupposed in Kelley's (1967) ANOVA framework came to be loosely formulated, thus sowing confusion about what is and is not a normative causal judgment, giving rise to misconceptions that persist to this day in both theoretical formulations and experimental and questionnaire methodologies. I then show that the knowledge-based, pragmatic approach presented earlier, together with refinements in models of the causal inference process, can illuminate and resolve these problems. I then extend this knowledge-based approach to the discounting principle in the next section.

Implicit Knowledge in the ANOVA Framework

Kelley (1967), following Mill's method of difference, defined a cause as "that condition which is present when the effect is present and which is absent when the effect is absent" (p. 154). Given an event such as *Virginie liked "Helène et les garçons,"* this logic implies that certain "control conditions" need to be examined to test the effect of certain causes. In Kelley's view, the layperson might identify three possible causes: the person (e.g., something about the TV watcher); the stimulus (e.g., something about the TV serial); or the occasion (e.g., something about the day on which the TV serial was seen). To test these three causal hypotheses, the lay scientist should construct and examine three experimental control conditions. The lay scientist should therefore use Mill's method of difference (Jaspars, Hewstone, & Fincham, 1983) to determine which factor made the difference between the occurrence and nonoccurrence of the event and was thus a cause of the target event.

For example, if one wanted to test the hypotheses that something about this particular TV watcher was the cause of her enjoying the program, one would obtain *consensus* information by comparing her reaction to that of other people watching the program at the same time. If it turned out that Virginie liked the program but no one else who watched it did (low consensus), then we might infer that something about Virginie was the cause (or part of the cause) of her enjoyment, as the effect (enjoyment) occurred when Virginie, but not others, was watching. Virginie might be a TV addict, for example. However, if everybody who watched the program enjoyed it (high consensus), then the effect (enjoyment) occurred even when Virginie was not watching and therefore something about her cannot be the cause.

A similar analysis can be applied to determining whether something about the TV serial caused Virginie to enjoy it or not. If it turns out that Virginie liked *Helène et les garçons* but not other programs she has watched (high distinctiveness), then something about this particular TV serial must be the cause (or part of the cause) of

the effect. One might infer that it is a very entertaining TV serial, for example. However, if Virginie enjoys every TV serial that she watches (low distinctiveness), then nothing about *Helène et les garçons* can be the cause of her enjoyment, as she enjoys TV serials regardless of whether the television is showing this particular one or not.

Finally, a similar logic applies to the analysis of whether the occasion plays a role in Virginie's enjoyment of the TV serial. If Virginie enjoys *Helène et les garçons* when she watches it on her birthday but at no other time (low consistency), then something about the occasion may be a cause (or part of the cause) of her enjoying the program. If, on the other hand, she enjoys *Helène et les garçons* every time she watches it, then her enjoyment cannot be explained by the particular occasion, as it occurs both on this particular occasion and on others.

Thus, through use of Mill's (1872/1973) method of difference, people will attribute causality to the factor whose presence makes the difference to the event occurring or not. According to this logic, a configuration of low consensus, low distinctiveness, and high consistency (LLH) should lead to an attribution to something about the person, such as *Virginie is a TV addict*, whereas a configuration of high consensus, high distinctiveness, and high consistency (HHH) such as the one below should lead to stimulus attributions, such as *Helène et les garçons is an entertaining program.* McArthur (1972, 1976) presented verbal vignettes to subjects and found that covariation information of this type did indeed have a considerable effect on subjects' attributions as predicted. On the basis of these results, Orvis, Cunningham, and Kelley (1975) proposed a template-matching model of attributional inference. However, shortcomings in McArthur's experimental methodology and Orvis and colleagues' model led to confusion about what the Kelley ANOVA framework *should* predict for all eight information configurations.

Problems with the Early Formulations of the Kelley ANOVA Model

In retrospect, Kelley's (1967) framework, and the early experiments that tested it (McArthur, 1972, 1976; Orvis et al., 1975) are as notable for what was left out as what was included. First, a fully crossed person × stimulus × occasion (2×2×2) design comprising eight experimental cells is needed to test three hypotheses about why a target behavior occurred (is it due to the person; the stimulus; or the occasion?), Yet Kelley only described information in four cells: the target behavior; consensus information (high or low); distinctiveness information (high or low); and consistency information (high or low). This corresponds to a fractionated cell design (Jaspars et al., 1983; see Figure 10.2).

A second and related omission concerns the response methodology used by McArthur (1972, 1976) and Orvis and colleagues (1975). In addition to the three main-effect causes that are possible (person, stimulus, or occasion) each event should in principle be explicable in terms of four interactions of causes, such as person × stimulus; person × occasion; stimulus and occasion; and person × stimulus × occasion (Jaspars et al., 1983). However, these early studies only presented one interactional response option explicitly to participants, namely, that of attribution to some combination of the person, stimulus, and circumstances, and asked participants to specify which of those factors interacted in a space that was provided for them. This was unfortunate, as the third "main effect" attribution response option was to "something about the particular circumstances," which could also mean a "freak combination of factors" as well as "something about the particular time/occasion." The response format clearly mattered, for when the four interactional attribution options were explicitly specified, the proportion of participants' interactional attributions went up from 35% in McArthur's (1972) experiment to 61% (Jaspars, 1983) and 47% (Hilton & Jaspars, 1987). A final problem was that no "null attribution" response format was presented, indicating that there was no effect to be explained, as would be the case if the target behavior did not deviate from expectations (Hilton & Slugoski, 1986).

World Knowledge and the Missing Dimensions of Covariation

The "empty cells" of the ANOVA framework meant that experimental participants in the McArthur paradigm could "fill" these cells with assumptions from their own general world knowledge. As Hilton and Slugoski (1986) demonstrated, these knowledge-based assumptions could have dramatic effects on the attribution process. Consider first the following example of a high-consensus, low-distinctiveness, and high-consistency (HLH) information configuration:
FIGURE 10.2. The missing dimensions of covariation in Kelley's cube (Cheng & Novick, 1990).

Ralph trips up over Joan dancing

Almost everyone who dances with her trips up over Joan dancing

Ralph trips up over almost everyone else he dances with

Ralph almost always trips up over Joan dancing

This configuration produces strong attributions in McArthur's (1972) experiment to "some combination of Ralph and Joan" as the probable cause of the outcome. The high-consensus information is judged as very informative about Joan (Everyone trips up over her) just as the low distinctiveness is informative about Ralph (he trips up over everyone else), leading them both to be judged as clumsy (Hilton & Slugoski, 1986, expt. 1; Hilton, Smith, & Kim, 1995).

However, consider the formally equivalent HLH configuration below for a behavior that is quite normal in its context:

Sally buys something on her visit to the supermarket

Almost everyone buys something on their visit to this supermarket

Sally buys something on her visit to almost every supermarket she visits

Sally almost always buys something on her visit to this supermarket

In this case, when given the option, people tend to shrug their shoulders and conclude that "Nothing special about Sally, the supermarket or the present occasion" caused her to buy something on her visit (Hilton & Slugoski, 1986, expt. 2). Here the HLH covariation information is redundant with socially shared scripts (Schank & Abelson, 1977) about what people normally do, and each of the three items of covariation information is judged as uninformative about Sally, the supermarket, and the present occasion. Indeed, giving such redundant information violates basic rules of conversation that require an interlocutor to be informative (Grice, 1975; Hilton, 1990; Turnbull, 1986; Turnbull & Slugoski, 1988). Indeed, nothing needs to be explained here except why the *speaker* was so obtuse as to pose such a nonquestion in the first place! (Answer: He's an attribution theorist . . .).

Drawing on the analysis of Hart and Honoré (1985), Hilton and Slugoski (1986) argued that the layperson uses knowledge about what is normal to identify the *abnormal conditions* that caused an event to happen, and these are dignified as causes. Thus while the roles of Ralph, Joan, and the present occasion are all necessary conditions for the trip to occur, only Ralph and Joan can figure as explanations, because they are unusually clumsy dancers. In contrast, there is nothing unusual about the present occasion, as Ralph almost always trips up over Joan dancing. In particular, Hilton and Slugoski showed that Ralph and Joan were seen as two sufficient causes in the foregoing example: The preferred response option was "Something about Ralph and something about Joan (even when they are not together)" caused them to trip over each other dancing. Hilton (1988) showed that

these generalizations from world knowledge, called norms, could be used to fill out the missing information in the ANOVA framework. Two examples are shown in Figure 10.3, corresponding respectively to the dancing and the supermarket examples, but collapsing over the time (consistency) dimension for simplicity. They show clearly that in the dancing example, an ANOVA on the high-consensus, low-distinctiveness (HL) data matrix that includes the norm *People sometimes trip up over each other dancing* would yield two "main effect" explanations ("Ralph" and "Joan"), whereas one on the high consensus, low distinctiveness (HL) data matrix that includes the norm *People usually buy something on their visits to supermarkets* would yield no effects at all ("Nothing special about either Sally, the supermarket of the present occasion caused her to buy something on her visit to the supermarket").

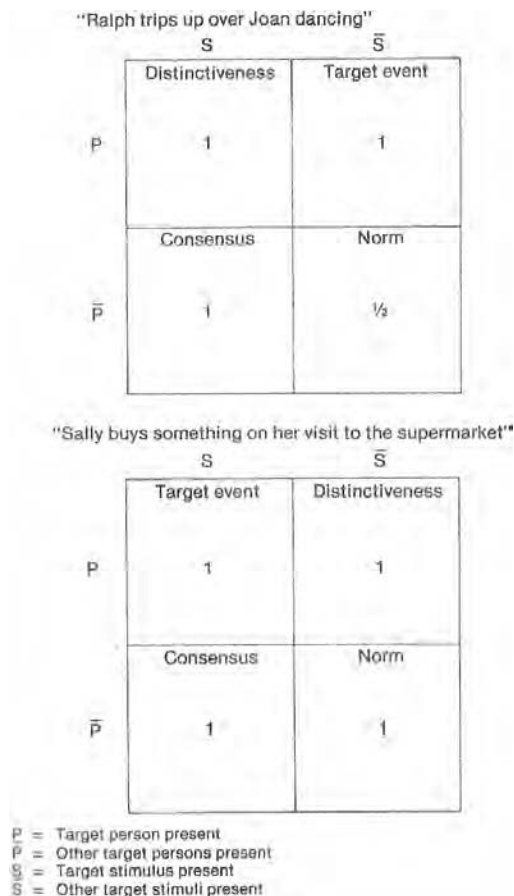
In subsequent research that both presented information in all eight cells and used full response formats (Cheng & Novick, 1990; Försterling, 1989, 1992), participants' attributions were found to correspond closely to the patterns that would be expected from a normative ANOVA. But by the time that the twin stable doors of full configurations of covariation information and complete


FIGURE 10.3. Covariation matrices completed by implicit knowledge of norms (Hilton, 1988).

response sets had been closed, the horse of causal reason had bolted into the fields of judgmental bias and error. To further muddy these fields, two further problems caused confusion: namely, the influence of experimental methodology on the attributions that were produced and the failure to make a clear distinction between causal explanations and dispositional attributions.

The Use of Covariation Information in Causal Inference

A first issue was that in McArthur's (1972; 1976) experiments with incomplete covariation configurations and response sets, consensus information appeared to have much less effect than distinctiveness information, thereby contributing to the impression that people "underuse" consensus information in causal judgment (Nisbett & Borgida, 1975; Nisbett, Borgida, Crandall, & Reed, 1976), an impression that has had a long shelf life (Fiske & Taylor, 1991; Försterling, 2001). In fact, experiments that present complete response sets show strong effects of consensus information on causal explanations referring to the person when both incomplete (Hewstone & Jaspars, 1987; Hilton & Jaspars, 1987; Hilton et al., 1995; Jaspars, 1983; see Iacobucci & McGill, 1990, for supplementary analyses and a review) and complete covariation configurations are presented (Cheng & Novick, 1990; Försterling, 1989, 1992; van Overwalle, 1997).

In establishing the consensus–person and distinctiveness–stimulus inferential links, the aforementioned experiments also clarified the *direction* of effects of covariation information on causal attributions. Thus, Orvis and colleagues' (1975) "template-matching" model had postulated that high-consensus information should lead to stimulus attributions and low-distinctiveness information to person attributions. However, Orvis and colleagues had based their model on an inductive analysis of McArthur's (1972) results, which were of course biased by her incomplete response methodology (see above). Orvis and colleagues did, however, correctly postulate that low consistency would lead to circumstance (occasion, time) attributions, as would be predicted by Mill's method of difference.

Causal Explanation versus Dispositional Attribution from Covariation Information

However, introducing a distinction between causal explanations and dispositional attributions helps resolve the foregoing inconsistencies. While Orvis and colleagues' (1975) analysis and others (e.g., Anderson, 1978; Medcof, 1990) that proposed consensus–stimulus and distinctiveness–person inference rules have proved to be incorrect concerning *causal explanations*, these inference rules conform to fundamental intuitions concerning *dispositional attribution*, where "dispositions" can be properties of a person or entity to produce a target behavior in a wide range of situations. Whereas causal explanations depend on Mill's method of difference (which also underlies counterfactual reasoning), the induction of general dispositions requires Mill's method of agree-

ment (Hilton et al., 1995; van Overwalle, 1997). Thus if I notice that Sung-Hee is afraid of Fido, Richard is afraid of Fido, and even Mark is afraid of Fido, all these observations of low distinctiveness in fear responses *agree* in one respect: Fido is always present. We can conclude that Fido seems to have a general tendency to produce fear, just as supermarkets have a general tendency to produce shopping behavior.

Of course, to characterize Fido as a *fierce* dog, we have to compare him to the average dog, because all dogs are fierce to some extent. Trait attributions presuppose implicit comparison standards—a rich Sri Lankan is likely to have less money than a rich American, and maybe even less than a poor American, even though she is rich by Sri Lankan standards (Rips & Turnbull, 1980; see also Jones & McGillis, 1976). Consequently, such trait attributions require the application of both the method of difference (showing that Fido is fiercer than the average being in his category, in this case dogs) and the method of agreement (showing that Fido induces fear in a lot of people). Participants do indeed follow these rules of inference for dispositional attribution to the person, the stimulus, or even the occasion (Hilton et al., 1995; van Overwalle, 1997).

The Functions of Covariation Information: When and Why Is It Needed?

Numerous information search studies showed that people consistently use distinctiveness information to answer causal questions about the person and consensus information to answer causal questions about the stimulus (Alicke & Insko, 1984; Bassili & Regan, 1977; Garland, Hardy, & Stephenson, 1975; Hansen, 1980). This of course appears to be inconsistent with the consensus–person and distinctiveness–stimulus inference rules based on the method of difference. However, Hilton, Smith, and Alicke (1988) argued that if participants could already infer relevant consensus information from world knowledge to identify "something special" about the target person, then they would then search distinctiveness information to check the reliability of their judgment. For example, if I learn that Severiano scores 67 on the Marbella Natural Alhambra golf course, and I already know that par (the norm for good players on golf courses round the world) is 72, then I can infer the relevant consensus information that Severiano is a good player because he did better than other players on this golf course. However, to check the reliability of this inference, I need to know whether Severiano usually does well on this course (consistency information), and how he does on other courses (distinctiveness information). Thus, if I do not have the requisite general knowledge about par, I will first need to know how other people did on this course (consensus information) to evaluate whether Severiano did well or not.

Hilton and colleagues (1988) accordingly generated fictitious sporting scenarios where participants were given the equivalent of golfing par for a number of sporting accomplishments (e.g., the average time taken to run a track of a given type). As predicted, when participants

were uninformed of the relevant (track) norms, they were more likely to seek consensus information when asked a causal dispositional question "How good an interstate cross-country runner is Mike Gatting?" but sought distinctiveness information when they had the relevant norms. Prior knowledge of norms affected preference for consensus information only when the question was causal: When a social comparison question was asked that required participants to evaluate the quality of the target's performance, consensus information was always preferred, regardless of whether or not participants had been informed of the norm (see Smith, Hilton, Kim, & Garonzik, 1992, for an extension of this analysis to causal inferences about the stimulus or situation). A final implication of this analysis is that as children acquire world knowledge, the focus of their search in response to causal questions about the person should change from consensus to distinctiveness information. This is exactly the pattern observed by Hortacsu (1987): the information search strategies of children at the age of 9 years corresponded to that of the adults in Hilton and colleagues' "normless" condition, whereas those of children at the age of 17 years corresponded to that of adults in the "normful" condition.

Implications of the ANOVA Framework: From Hydraulics to Rarity

The ANOVA model clearly presupposes that person, stimulus (situation), and occasion causes are manipulated orthogonally, as in an experimental design. Consequently, in this framework there is no reason to expect that the presence of a "person" effect should imply the absence of a "stimulus" or "occasion" effect. This is clearly in contradiction to a "hydraulic assumption" about causality, where internal and external causal attributions should "compete" for causal strength, and strengthened belief in one cause should lead to discounting of the other. However, research has disconfirmed the general validity of the hydraulic assumption: Thus when internal and external attributions are measured separately, they do not correlate (e.g., Fincham, 1985; Lalljee, Watson, & White, 1982; Miller, Smith, & Uleman, 1981; Wimer & Kelley, 1982). Nevertheless, despite its conceptual incompatibility with the ANOVA model and its lack of empirical support, the hydraulic model has become ingrained in attributional methodology, for example, through the use of bipolar scales to measure internal versus external attributions (see McClure, 1998, for a review).

In fact, the ANOVA framework suggests that event normality will determine *how much* explanation is needed. Normal or predicted events do not need explanation (Hastie, 1984; Hilton & Slugoski, 1986; Kanazawa, 1992; Weiner, 1985). Conversely, "extreme" events require more explanation than "moderate" ones (McClure, Jaspars, & Lalljee, 1993). In terms of the ANOVA framework, when covariation information shows that an event is rare (e.g., there is low consensus, high distinctiveness, and low consistency), then participants prefer interaction explanations that refer to a combination of the person, stimulus, and occasion (Cheng & Novick, 1990; Försterling, 1989; Hilton & Jaspars, 1987; Jaspars, 1983). It seems that people may prefer such conjunctive explanations when covariation information suggests that a combination of several unusual factors is necessary to produce an event, and the event to be explained is rare, extreme, or has multiple backgrounds (McGill, 1990).

Conclusions: Implications for Attribution Research

The refinements of the ANOVA model point to several important conclusions. First, normal adult attribution is *knowledge based* in that people use prior world knowledge in the form of universal generalizations stored in scripts, plans, goals, and norms (Hilton & Slugoski, 1986; Schank & Abelson, 1977). Second, once Kelley's (1967) ANOVA analogy had been properly specified and tested, either with complete information sets (Cheng & Novick, 1990; Försterling, 1989) or incomplete sets fleshed out with world knowledge (Hilton & Slugoski, 1986; Novick, Fratianne, & Cheng, 1992), people's causal inferences appear more rational than was previously thought. Third, a distinction between causal explanations and dispositional attributions reveals that these are different causal questions that require different rules of inference and informational premises. Both information search and utilization studies show that people do search and use the appropriate information (Hilton et al., 1988, 1995; Smith et al., 1992; van Overwalle, 1997). Fourth, the ANOVA framework is logically compatible with the coexistence of many factors that combine to produce an effect but incompatible with the monocausal "hydraulic" model of causality.

In conclusion, the early models of the attribution process failed to explicate the difference between causal explanation and dispositional attribution, the role of Mill's methods of difference of causal inference, and the significance of base rate information in the form of presupposed world knowledge. Yet it was the layperson, not the attribution theorist, who found herself accused of being a "poor scientist" who failed to follow normative models, and who underused consensus and base rate information in the attribution process (Fiske & Taylor, 1991; Nisbett & Ross, 1980; Ross, 1977; Trope & Gaunt, 2003). The systematic nature of this misunderstanding and misrepresentation of the nature of lay causal inference is perhaps to be found in the metaphysical bases of current experimental psychology. Experimental psychologists typically manipulate situational factors and seek to eliminate "noise" from participants through procedures such as random assignment of participants to experimental conditions. Consequently, many attribution researchers have attempted to understand attribution processes solely on the basis of experimentally presented information. Yet it is precisely the *interaction* between the prior knowledge that the experienced layperson brings to bear and information available in the judgmental situation that constitutes the mill of the knowledge-based causal attribution process.

The conceptual and methodological problems of the early models and experiments continue to generate am-

biguity in the interpretation of attribution phenomena. For example, Choi and Nisbett (1998) cite a Korean study by Cha and Nam (1985) that found extensive use of consensus information using McArthur's response methodology, which showed "underuse" of consensus information in American participants. However, strong use of consensus information has been found in American subjects when complete response methodologies are used (Hilton et al., 1995). This suggests that cross-cultural research in the area would benefit from closer attention to the more recent conceptualizations and methodology. Similarly, the surprise evoked by the finding that East Asian participants still show correspondence bias in Jones and Harris's (1967) attitude attribution task (Krull et al., 1999) would probably be clarified if researchers adopted the normative model and experimental methodology proposed by Morris and Larrick (1995), which I turn to below.

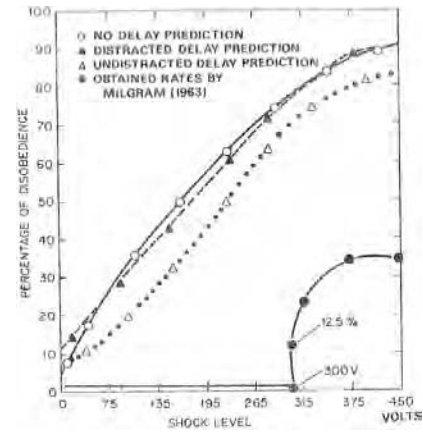
FIGURE 10.4. Comparison of predicted and actual disobedience rates.

KNOWLEDGE-BASED DISCOUNTING: A NORMATIVE FRAMEWORK

One of the chief reproaches made against the "lay scientist" has been his or her failure to sufficiently discount attributions to the person in the light of situational information. Perhaps the most striking demonstration comes from Milgram's (1974) study of obedience to authority. To everyone's surprise (including Milgram's), in the classic version of this study 26 of 40 participants in the "teacher" condition went up to the full level of shock despite the clear indications that this was dangerous to the "learner." All teachers of social psychology know of the surprise value of this experiment, which is to make the point that even ordinary people can be led to acts of barbarism under appropriate situational pressure. Observers who learned about the experimental paradigm "showed the fundamental attribution error, that is, they consistently and dramatically underestimated the degree to which subjects in general would yield to those situational forces that compelled obedience in Milgram's situation" (Ross & Anderson, 1982, p. 136). Jones (1990) considered the fundamental attribution error to result from "correspondence bias," which he nominated as "a candidate for the most robust and repeatable finding in social psychology" (p. 138).

Correspondence Bias: Inaccurate Beliefs or Faulty Inference Processes?

However, it is important to note that this attribution error is more likely to be due to faulty premises (in the form of inaccurate beliefs about human nature) than to flaws in the attributional reasoning process itself. Given the erroneous subjective expectancies shown in Figure 10.4, which amount to the low-consensus information that *Few people go to the maximum shock level*, it is quite easy to see how observers would quite "logically" infer from Mill's method of difference that the cause of a teacher's going to the limit would be "something about the teacher" (Bierbrauer, 1979). The fundamental attribu-

tion error appears to result from the wrong premises—inaccurate prior beliefs about the power of situational pressure in the Milgram experiment—which lead logical inference processes to the wrong causal conclusion.


However, apart from the Milgram study and some other exceptions (e.g., Shweder, 1977) there are few actuarial data that enable assessment of whether people's general theories about human nature or other aspects of their environment are correct or not. But we can still assess whether people's attributions are consistent with their situational theories if we have an appropriate normative model to derive causal inferences from subjective beliefs about general cause–effect relations. This will allow us to evaluate whether people's causal inference processes from their subjective beliefs are consistent with those beliefs, even if we have no actuarial data to evaluate the accuracy of those beliefs (in the form of situational theories) per se. In this way we can at least evaluate whether the judge has used faulty inference processes that lead her into self-contradiction, in the form of a conclusion that does not follow from her assumed premises (cf. Henle, 1962).

Rational Discounting in the Attitude Attribution Paradigm

The "attitude attribution" paradigm devised by Jones and Harris (1967) has frequently been adduced to support the existence of a fundamental attribution error (e.g., Ross & Anderson, 1982). In the original version participants read about a group of students who either had a choice or no choice in writing an essay for or against Fidel Castro. In the no-choice condition, participants were told that students had been assigned at random to two experimental conditions, whereby half were obliged to write an essay for and half against Castro. The key finding is that in no-choice conditions, participants are more likely to infer that students who wrote pro-Castro essays are more likely to have pro-Castro attitudes than students who wrote anti-Castro attitudes. Thus the information about situational pressure made little differ-

ence to the tendency to attribute the essay to underlying attitudes, as this tendency was almost as strong as that obtained in choice conditions. But is this an error, or even a bias?

In fact, a striking analysis and experiment by Morris and Larrick (1995) suggests that we can eliminate inferential error as a cause of participants' judgments in Jones and Harris's attitude attribution paradigm. They show that given participants' beliefs about situation–behavior linkages in this experimental paradigm, their dispositional attributions are just what would be expected by a Bayesian analysis of discounting. Morris and Larrick's analysis of discounting takes four factors into account: the prior probability of causes; the sufficiency of the causes for effects in question; the independence of causes; and the number of possible causes for an effect. Of these, the prior probability of the causes (a pro-Castro disposition, and instructions to write a pro-Castro essay) and the perceived sufficiency for writing a pro-Castro essay are directly relevant to the Jones and Harris (1967) discounting paradigm, as random assignment to experimental conditions ensures that the causes are independent (there is no reason to assume that there are more Castro sympathizers in the forced-choice condition compared to the free-choice condition), and only two causes are being considered. Assessments of participants' beliefs showed that the target cause (the underlying attitude) was perceived as relatively rare (people assumed that 23% of the population would be pro-Castro) whereas the situational cause is relatively common (participants knew that 50% of the participants in the no-choice condition had been instructed to write a pro-Castro essay). Morris and Larrick then solicited participants' beliefs about general situation–behavior linkages in the population tested, namely, their expectancies that participants with a pro-Castro attitude would write a pro-Castro essay and that a participant asked to write a pro-Castro attitude would do so. Given participants' beliefs that pro-Castro attitudes are in the minority (23%), and the causes of a pro-Castro essay were strongly but imperfectly sufficient for compliance to occur, Morris and Larrick were able to calculate what a Bayesian inference model would predict. As can be seen from Table 10.1, participants' judgments correspond very closely indeed to the "rational baseline" (Jones & McGillis, 1976) defined by the normative Bayesian model.

In a second experiment, Morris and Larrick (1995) demonstrated that the "hydraulic assumption" that motivates discounting will be appropriately used in cases in which the co-occurrence of causes in the world is known to be inversely related. Thus they manipulated association between causes by informing participants that (1) causes were independent, as assignment of experimental participants to instruction conditions was randomized; (2) causes were positively associated, as 80% of the participants assigned to write pro-Castro essays already held pro-Castro attitudes; and (3) causes were negatively associated, as 80% of those associated to write anti-Castro essays held pro-Castro views. In line with a normative Bayesian model of causal inference, participants showed no evidence of discounting when the causes were in-

TABLE 10.1. Prior Beliefs, Beliefs in the Sufficiency of Causes, and Dispositional Attributions in Morris and Larrick (1995, expt. 1)

dependent (in line with an ANOVA-style orthogonal manipulation of causes), a "hydraulic" pattern of discounting when the causes were negatively associated (in line with the hydraulic assumption), and an inverse pattern of "overdiscounting" when the causes were positively associated. Morris and Larrick's normative approach thus suggests that, given the participants' premises, there is no inferential error.

Morris and Larrick's results suggest that if there is a fundamental attribution error (FAE), it is due to incorrect situational theories, not to faulty inference processes from those theories. In addition to incorrect situational theories, Gilbert and Malone (1995) argue that the FAE has three other major causes: lack of awareness of situational constraints; incomplete corrections of dispositional inferences; and inflated categorizations of behavior. For reasons of space I only review the first two of these and refer the interested reader to relevant reviews (Gawronski, 2004; Pelham & Krull, 2000). Apart from the attitude attribution paradigm, evidence for the FAE has been chiefly drawn from three basic experimental paradigms: the silent interview paradigm (Snyder & Frankel, 1976); the quizmaster paradigm (Ross, Amabile, & Steinmetz, 1977); and attributions for immoral behavior (Bierbrauer, 1979).

The Silent Interview Paradigm: The Effect of Question Focus and Cognitive Resources

A research program by Krull and colleagues suggests that attributional processes can be biased by question focus to either the person or situation, but these tendencies can be corrected if the judge has sufficient cognitive resources. They found that when participants who had a dispositional attribution task watched a silent videotape of a woman purportedly being interviewed about a topic, they made stronger dispositional attributions for the target's emotional expressions and behavior when concurrent memory load was high rather than low (Gilbert, Pelham, & Krull, 1988). Conversely, when only situational questions were asked, the reverse pattern of results was obtained: participants made stronger attributions to the

situation under high rather than low memory load (Krull, 1993; Krull & Erickson, 1995).

Results obtained from the "silent interview" paradigm therefore do not overall support the idea of there being a "dispositional set" in the sense of their being an automatic tendency to make dispositional attributions *per se*, the interpretation initially favored by Gilbert and colleagues (1988). Rather, these results are consistent with general information integration models. Thus if the dispositional question is posed first, cognitive load will prevent integration of situational information into the judgment process, whereas if the situational question is posed first, cognitive load will prevent integration of dispositional information (Trope & Alfieri, 1997; Trope & Gaunt, 1999, 2000). In line with this view, participants high in need for closure may truncate these later information integration processes even when they are not under cognitive load, whether the initial question focus is on the person or the situation (Webster, 1993).

Lack of Awareness of Situational Constraints: The "Questioner Superiority" Effect?

Ross and colleagues (1977) assigned participants arbitrarily to the role of a quizmaster, contestant, or observer in a mock game show. The quizmaster is then instructed to think up 10 challenging general-knowledge questions and pose them to the contestant, who is usually unable to answer more than four questions correctly. The most interesting finding is that participants tend to perceive the quizmaster as having more general knowledge than the contestant, even though it is the quizmaster who can choose which questions to ask. Gilbert and Malone (1995) argue that observers fail to see "the invisible jail" in which the questioners were trapped, and so "concluded that the quizmasters were genuinely brighter than the contestants" (p. 25). However, Gawronski (2003) varied the difficulty of the questions asked and found while quizmasters were overall judged to have more general knowledge than contestants (thus replicating the questioner superiority effect), this effect was considerably reduced when the questions were difficult, thus suggesting that the observers were well aware of the "jail" in which contestants had been placed.

Motive in Attributions about Morality

Work on motive attributions shows that certain kinds of situational cause will have different effects on dispositional attribution. For example, Reeder, Kumar, Hesson-McInnis, and Trafimow (2002) show that aggression in response to a provocation (e.g., an insult) leads to less attributions of immorality than aggression that was motivated by a financial incentive. Motive attributions also lead to discounting in the Jones and Harris (1967) attitude inference paradigm; thus Fein (1996) reports data showing that people do not commit the correspondence bias in when they are led to suspect that the actor wrote the essay for personal gain. In a like vein, Reeder, Vonk, Ronk, Ham, and Lawrence (2004) show that learning that a student had a ulterior motive for helping a profes-

sor (she knows this will improve her chances of winning a monetary award) leads to discounting (people consider her to be a less helpful person), whereas learning that she helped because she was instructed to by her boss (the departmental secretary) does not lead to such discounting. Although the situational cause was rated equally highly in both cases, the kind of motive they respectively implied had different effects on dispositional attributions. The finding that dispositional attributions were still quite strong in both motive conditions indicates that people can consider situational factors to be strongly causal *and* to have major implications about the actor's personality. Such patterns of causal explanation and dispositional attribution sit uneasily with the hydraulic model of internal versus external causality and seem more consistent with the idea that people form complex representations of how events come about.

Summary: Discounting and the Fundamental Attribution Error

Having accepted that people often do discount (see McClure, 1998, for a review), work in the area seems to be moving in the direction of (1) distinguishing causal discounting from causal backgrounding; (2) establishing normative models that allow us to decide when people do discount appropriately; and (3) identifying factors such as resource limitations and processing style that may truncate this discounting process. At the descriptive level, the universality of the correspondence bias has been called into question; rather, people discount either dispositional or situational causes as a function of the information-processing task, whether they have adequate information-processing resources, and the perceived relevance of information. Even if, as Lieberman and colleagues (2002) argue, people make more dispositional inferences in Western society because these kinds of questions get asked more often, this is a *sociological* fact about cultural orientations, not a psychological one about cognitive biases.

Nevertheless, in at least one domain, that of Milgram's experiment, people fail to discount situational pressures adequately, such as when they attribute obedience to the brutal personality of the confederate. This may well be because people hold inaccurate "situational theories" about behavior in this situation rather than due to faulty inference processes from these informational premises. More research on the accuracy of situational theories thus seems to be warranted, especially as there is still very little research that investigates either the accuracy of situational theories across domains or how these situational theories would be deployed in a Bayesian judgment process of the kind described by Morris and Larrick (1995). Other lines of inquiry that seem to warrant investigation are whether people reason from qualitatively different expectations or "norms" in certain situations, such as moral behavior, or whether correspondence bias will be particularly pronounced when the attributor will wish to exert social control over the actor by holding him or her responsible for his actions (Tetlock, 2000). In sum, much theoretical and empirical work remains to be done to

fully understand whether, when, and why discounting happens.

CONCLUSIONS

Causal explanation remains a fundamental topic of research in philosophy, psychology, and cognitive science. Research in these fields has added to our understanding of attribution and explanation processes since the classic "lay scientist" formulations. It has shown that although the human mind is equipped with associative learning heuristics that are economical (though not infallible) general-purpose methods for detecting covariations that are shared with other animals, humans seem to have a specific social cognition module, are capable of counterfactual simulations to evaluate explanations, and are able communicate explanations that take into account others' knowledge and viewpoints.

Improvements in clarifying the nature of explanation and in formulating normative models of the attribution process have shown that even when people are required to perform "scientific" causal analyses, they do so rather better than earlier work would suggest (e.g., Jones & Harris, 1967; McArthur, 1972). So it is the layperson who uses world knowledge to integrate missing base-rate information into the ANOVA-style attribution process when the experimenter omits to provide it (Cheng & Novick, 1992), and who uses this world knowledge to discount situational causes in a way that is compatible with Bayes's theorem (Morris & Larrick, 1995). When required to, the layperson seems better able to perform full-blown "scientific" analyses of his environment in order to arrive at reliable and accurate representations of reality than he would be credited with by early formulations of the "lay scientist" model.

I conclude by noting that the fact that people can be quite accurate in causal inference invites reconsideration of issues in attribution*al* theory, the study of how attributions impact emotions and behaviors (see Anderson, Krull, & Weiner, 1996; Försterling, 2001; Kelley & Michela, 1980). For example, Försterling (2002) reviews evidence that differences in patterns of attribution reflect "logical" inferences from the assumed patterns of covariation that people have, not differences in their causal inference processes.

In addition, accurate causal inference processes can help people adapt better to their world, in contrast to Taylor and Brown's (1988) suggestion that attributional biases in the form of "positive illusions" can be adaptive for health outcomes.

Thus Försterling and Morgenstern (2002) have shown that realism in causal attributions can lead to more favorable performance outcomes. They show that giving participants accurate rather than self-enhancing feedback for task performance in a learning phase enables individuals to specialize in tasks that they are good at in the subsequent test phase, and thus improve their chances of gaining a financial reward for the best performance. One of the beneficial effects of realism is that accurate feedback may help individuals to identify and invest in areas

of competitive advantage, whereas positive illusions may lead individuals to overestimate their chances of success and thus lose their investments. A question for future research will be to identify environments in which accuracy in attributions is more likely to be adaptive than positive illusions, and vice versa.

The Role of Metacognition in Social Judgment

RICHARD E. PETTY
PABLO BRIÑOL
ZAKARY L. TORMALA
DUANE T. WEGENER

The capacity for complex thought is one of the traits that distinguish us as humans. Although social psychologists have been concerned with thinking and thought processes from our earliest history (e.g., Allport, 1924; James, 1890), the contemporary social cognition movement catapulted the importance of thought processes to center stage within the field (e.g., Fiske & Taylor, 1991; Moscowitz, 2004). This thinking is sometimes very effortful and deliberate, and at other times it is more simple and automatic (Chaiken, Liberman, & Eagly, 1989; Kruglanski & Thompson, 1999; Petty & Cacioppo, 1986). Furthermore, our thinking is on occasion quite objective but at other times contaminated by various biases (see Eagly & Chaiken, 1993; Petty & Wegener, 1998, for reviews).

Although many distinctions such as those just noted can be made about thoughts, in this chapter we are concerned with a distinction between primary and secondary cognition. Primary thoughts involve our initial associations of some object with some attribute, or a projection of some object on some dimension of judgment such as "the flower is red" or "I like the flower" (McGuire & McGuire, 1991). Our thoughts can be directed at any object including other people, the environment, and ourselves. Following a primary thought, people can also generate other thoughts that occur at a second level, which involve reflections on the first-level thoughts (e.g., "Is that flower really red or pink?" and "I am not sure how much I like that flower"). *Metacognition* refers to these second-order thoughts, or our thoughts about our thoughts or thought processes. Some authors have con-

ceived metacognition more broadly as people's knowledge about their own and *others*' mental states, processes, and beliefs (Jost, Kruglanski, & Nelson, 1998; Wright, 2001). In this chapter, however, we focus mostly on research examining the role of thinking about one's own thoughts and thought processes because that is the domain in which most of the social metacognitive research has been conducted.

The topic of metacognition has received considerable theoretical and empirical attention in the past decade, being considered one of the top 100 topics of psychological research (Nelson 1992). Within the field of cognitive psychology, the study of metacognition has traditionally focused on how people monitor and control their own mental functioning, especially in the domain of memory (e.g., Koriat & Goldsmith, 1996; Nelson & Narens, 1994). For example, research has found that the stronger one's feeling of knowing about a piece of information, the more time one is willing to spend searching for it (e.g., Costermans, Lories, & Ansay, 1992). The motivation to complete the search is particularly intense when one has the subjective experience that the information is on the tip of the tongue and thus about to emerge into consciousness (see Yzerbyt, Lories, & Dardenne, 1998a). Thus, metacognitive processes are consequential in guiding further thinking and action.

In addition to cognitive psychology, where the formal study of metacognition emerged, the idea that people think about their thoughts and thought processes is prevalent in a number of other psychological domains. For instance evaluating one's thoughts is critical to some forms

of clinical practice. Indeed, the main goal of cognitive-behavioral therapy is to get individuals to further think about their maladaptive thoughts with the goal of inducing doubt in them (e.g., Beck & Greenberg, 1994; Ellis, 1962). Metacognition also plays a prominent role in the context of consumer psychology (Alba & Hutchinson, 2000; Wright, 2001). For instance, Friestad and Wright (1994) have noted that people's naive theories of attitude change play an important role in determining how individuals deal with persuasion attempts (see also Campbell & Kirmani, 2000; Friestad & Wright, 1995).

Before beginning our review of social psychology's research on metacognition, it is useful to discuss the dimensions along which metacognitive thought might be organized. In particular, we note that the dimensions of metacognitive thought can be organized along many of the same dimensions that have proven useful for understanding primary thoughts, as well as some unique dimensions. Within social psychology, thought coding is particularly prominent in research on attitude change. In this literature, thoughts generated in response to a persuasive message are typically classified into the following categories by judges or the participants themselves: target (is the thought about the message content or the source, etc.), origin (e.g., does the thought stem from the message content or is it uniquely generated by the message recipient), valence (e.g., is the thought favorable or unfavorable toward the proposal), and number (e.g., are there many or few thoughts—see, e.g., Cacioppo, Harkins, & Petty, 1981; Greenwald, 1968; Wright, 1973). Coding thoughts for target, origin, valence, and number has provided a very fruitful approach for understanding some of the psychological processes that underlie attitude formation and change (see Eagly & Chaiken, 1993; Petty, Ostrom, & Brock, 1981).[1] Interestingly, when participants are asked to judge their own thoughts in persuasion research, they are in essence being asked to engage in metacognition because they are asked for their thoughts about their thoughts (e.g., how favorable toward the issue is your thought?). There is no presumption in the literature on primary cognition, however, that people necessarily think about their thoughts in this way on their own—only that these post hoc categorizations are useful for predicting what attitudes people will adopt. Because these categories have already proven effective for classifying primary thoughts, we postulate that they can also serve to understand thoughts at the metacognitive level of thinking.

Thus, in this chapter we use the same categories to describe metacognitive thought. In primary cognition, the dimensions often refer to some objective reality that judges or the participants themselves are asked to determine. For example, with respect to the target of the thought, a judge or the participant might be asked if the thought is about the message itself or about the source of the communication (e.g., Chaiken, 1980). With respect to origin, a judge could determine whether the thought reflected original thinking or merely restated the message content (e.g., Greenwald, 1968). With respect to valence, a judge or the participant might be asked if the thought reflects some positive or negative reaction to the

message (e.g., Petty, Wells, & Brock, 1976). Perhaps attesting to the rather objective nature of these assessments, judges' and participants' ratings often correlate quite well (see Cacioppo et al., 1981). As we describe further below, with metacognitive thought, the focus is on the individual's *perception* of his or her own thought, regardless of its relation to any objective reality. In metacognition, the issue is whether the person spontaneously thinks about the target, origin, valence, quantity, or some other dimension of his or her thoughts and whether these second-order thoughts are consequential.

In this chapter, we refer back to these various dimensions of thought as needed in reviewing the empirical literature. The main function of our organizing structure is to facilitate and highlight the similarities between studies coming from diverse domains in social psychology (e.g., research on the self vs. attitude change). Our review of the literature is organized into four substantive content areas. Within each area we focus on the types of thoughts people have about their primary thoughts and the consequences of these thoughts. We also address, when relevant, thoughts people have about their thought processes and issues for future research. Before reviewing the core areas in which metacognition has been applied, we elaborate the dimensions of metacognition that are most studied in the literature.

TYPES OF THOUGHTS ABOUT THOUGHTS

Briefly described, the *target* dimension of metacognition refers not to what the thought is actually about but what the person perceives it to be about (cf. Higgins, 1998a). For example, a person might wonder: Is the thought about my friend? Is the thought about me? Among other things, this type of metacognition can help individuals to classify their thoughts into categories as a first step in marking them for further control and change (e.g., Ellis, 1962). The *origin* of a thought refers to its source. Where did the thought come from? That is, a person can wonder if the thought is his or her own, or if it merely reflects the statements or sentiments of others (e.g., Greenwald, 1968). People are more likely to act on thoughts that are perceived as connected to or originating from the self (see Wheeler, DeMarree, & Petty, 2005). Perhaps the most commonly studied aspect of thought is its *valence*. That is, regardless of the target of the thought or its origin, does the person perceive it to reflect something positive or negative with respect to its target? Finally, *amount* refers not to how many thoughts are actually generated but to the perceived quantity of thoughts. For example, people might think that they possess very few or many thoughts about a given topic, and as we review shortly, such thought attributions have important implications for social judgment and behavior (e.g., Schwarz, Bless, et al., 1991).

In addition to these aspects of thought, two additional dimensions are uniquely metacognitive and have achieved the most conceptual and empirical attention. First, one can assess one's *evaluation* of a thought. That is, regardless of the perceived target, origin, valence, or

number of thoughts generated, people can assess their thoughts as good or bad, desirable or undesirable, appropriate and wanted, or not. When thoughts are unwanted, people might try to suppress them (Wegner, 1994). Or, if the thoughts are seen as inappropriate or bad, people might try to correct for their anticipated impact on judgments or action (Wegener & Petty, 1997).

Second, people can have varying degrees of *confidence* in their thoughts, ranging from extreme certainty to a high amount of doubt.[2] Thus, two people might have the *same* thought with respect to a given proposal or target, but one person might have considerably more confidence in that thought than the other. Thoughts held with more confidence have a larger impact on judgments (e.g., Petty, Briñol, & Tormala, 2002). Given the attention that research in social psychology has dedicated to the study of confidence, in the next section we describe this dimension in more detail.

Before turning to confidence, however, it is worth noting that the different categories of metacognitive thoughts likely relate to each other. For example, a thought whose origin is perceived as the self might be evaluated more favorably than one with a perceived external origin (e.g., Greenwald & Albert, 1968). Or, thoughts about targets for which we are perceived to have more knowledge than other people might be held with more confidence (Kruglanski et al., 2005). Furthermore, it is possible to consider third-order cognition in which people are asked to make one metacognitive judgment about another. Thus, after asking about the evaluation of a particular thought, one can ask about the confidence in that evaluation. Or, after asking about the confidence in one's thought, one can ask whether this confidence is appropriate, and so forth. To our knowledge, no research to date has systematically examined third-order cognition.

METACOGNITIVE CONFIDENCE

A subjective experience that constitutes one of life's greatest metacognitive challenges is the sense of epistemic certainty or uncertainty (e.g., Kruglanski 1980, 1989; Nelson, Kruglanski, & Jost, 1998). Although certainty could presumably apply to various aspects of one's judgment (e.g., am I certain that this is *my* belief?), social psychological theory has paid special attention to the perceived *validity* of one's judgments. For example, in lay epistemic theory (Kruglanski, 1980), following the generation of a thought or hypothesis, people are said to want to test and validate the thought. Within dual-process models of persuasion such as the elaboration likelihood model (Petty & Cacioppo, 1986; Petty & Wegener, 1999) and the heuristic–systematic model (Chaiken, Liberman, & Eagly, 1989), people are postulated to seek a certain level of validity, confidence, or certainty in their judgments. When the gap between a person's current level of judgmental confidence and the desired level is high, they should engage in greater information-processing activity (see Chaiken et al., 1989). Underlying these notions is the assumption that people generally seek to hold accurate judgments (Festinger, 1954), that uncertainty is aversive, and that deliberative information processing is often a good way of obtaining accuracy and reducing uncertainty (cf. Sorrentino, Bobocel, Gitta, Olson, & Hewitt, 1988). In fact, inducing a general feeling of doubt, whether explicit (Tiedens & Linton, 2001) or implicit (Petty, Tormala, Brinol, & Jarvis, 2006), has provoked greater information processing. Indeed, incongruencies of all sorts have increased information-processing activity (e.g., Baker & Petty, 1994; Maheswaran & Chaiken, 1991; Smith & Petty, 1995; Ziegler, Diehl, & Ruther, 2002), presumably by inducing some doubt or confusion that might be resolved with thinking.

Thus, metacognitive confidence generally refers to a sense of validity regarding one's thoughts or judgments, though it is possible for certainty to be applied to other aspects of attitude-relevant beliefs (e.g., certainty that the attitude is my own). Studying metacognitive confidence is important mainly because confidence affects whether people translate their individual thoughts into more general judgments or evaluations, and whether these judgments in turn are influential in guiding behavior. There is great deal of empirical evidence suggesting that beliefs held with great conviction are a more potent foundation for judgment and behavior than more tentatively held beliefs (e.g., Berger & Mitchell, 1989; Briñol & Petty, 2004; Fazio & Zanna, 1978; Pieters & Verplanken, 1995; Swann & Ely, 1984; Tormala & Petty, 2002).

Logically, one might expect that highly confident thoughts, beliefs, and attitudes determine actions because confident beliefs stem from a truly accurate perception of reality. That is, common sense would suggest that confidence should emerge from objective sources such as the amount and quality of information people have. For example, the more time a person has to see something, the more confident the person should be in his or her identification of it. However, an objective basis to confidence seems to be the exception rather than the rule. For example, when people were asked to predict the behavior or the personality of patients, prosecutors, dating partners, roommates, or strangers, there was no relation or only a modest correlation between confidence and predictive accuracy (e.g., Deffenbacher, 1984; Dunning, Griffin, Milojkovic, & Ross, 1990; Jacoby, Bjork, & Kelley, 1994; Oskamp, 1965; Swann & Gill, 1997; Wells & Murray, 1983). Numerous studies have shown that the confidence with which people hold their beliefs can be affected by different factors that do not necessarily increase the validity of beliefs. For example, the more frequently people think about their thoughts, the more confidence they have in them (e.g., Koriat, Lichtensetein, & Fischhoff, 1980), the more a judgment is repeated, the more confidence is increased (e.g., Shaw, 1996), the more details that are included in a given thought, the more confidence is increased (e.g., Gill, Swann, & Silvera, 1998). In addition to these factors, confidence has been found to be affected by several other situational (e.g., Yzerbyt, Schadron, Leyens, & Rocher, 1994) and personality (Schaefer, Williams, Goodie, & Campbell, 2004) variables.

Research on decision making has also provided a number of important examples of how peoples' judgments of confidence can be independent of their accuracy. According to Griffin and Tversky (1992), for instance, confidence judgments require the integration of different kinds of evidence such as the extremity of the available information and the weight or predictive validity of that information. For example, when evaluating a letter of recommendation for a graduate student written by a former teacher, a person may consider how positive the letter is (i.e., extremity) and how credible or knowledgeable the writer is (i.e., weight). According to Tversky and Kahneman (1974), people tend to focus mostly on the extremity of the evidence leading them to underutilize other variables that control predictive validity. As a result, Griffin and Tversky argue that overconfidence occurs when extremity is high and weight is low, whereas underconfidence takes place when extremity is low and weight is high.

In this research, as in most of the literature on decision making, confidence judgments refer exclusively to the estimation of how likely it is for an answer (e.g., a judgment or a decision) to be correct, and criteria of accuracy are typically available. In social psychological research it is much less common to use objective criteria of accuracy as people's thoughts often relate to judgments or actions involving people, groups, political views, and so forth. Although one can determine whether one's confidence in the likelihood of a red ball coming out of an urn is well placed, it is not possible to determine whether one's confidence in an attitude toward a presidential candidate is accurate in any objective sense. Yet, a subjective sense of accuracy or confidence has important implications such as determining if one will vote for the candidate based on one's attitude. Within the social psychological literature, judgmental confidence has been tied to the extremity of the attributes a target possesses and the certainty that the target does or does not possess those attributes (Griffin & Tversky, 1992; Petty et al., 2002), one's confidence in the likelihood that a target possesses a certain attribute, and one's confidence in the desirability of that attribute (Briñol, Petty, & Tormala, 2004), as well as other sources such as the ease with which information comes to mind (Haddock, Rothman, Reber, & Schwarz, 1999).

Although metacognitive ideas have been applied to various topics in social judgment, in the next sections we focus on some of the most heavily researched areas of social psychology in which the role of metacognition has been examined. These are memory and cognitive fluency, attitudes and persuasion, the self and individual differences, and bias correction. In the final section, we outline several key conclusions and general principles of the reviewed work.

MEMORY AND COGNITIVE FLUENCY

Metacognition is deeply rooted in the study of human memory—in particular, people's theories about and perceptions of their memory (e.g., Costermans et al., 1992; Strack & Förster, 1998), their knowledge (e.g., Koriat, 1993), and their learning (e.g., Dunlosky & Nelson, 1994). Jacoby and colleagues, for instance, proposed that memory often involves not a literal search for stored information, but rather a series of inferences based on "cognitive feelings" (e.g., Jacoby, Kelley, & Dywan, 1989; see also Clore & Parrot, 1994). One such feeling is familiarity, which people interpret as indicating that something is known, or remembered (e.g., Jacoby, Kelley, Brown, & Jasechko, 1989). Another such feeling involves the ease or fluency with which information can be retrieved from memory (e.g., Benjamin & Bjork, 1996; Koriat & Levy-Sadot, 1999; Nelson & Narens, 1990). It is this feeling of fluency that has received the most attention in social metacognition research. Next, we provide an overview of classic and contemporary findings on fluency. In so doing, we also review the current state of knowledge with respect to two very influential effects in social psychological research: ease of retrieval effects and mere exposure effects.

Ease of Retrieval

We begin with the notion that people sometimes base judgments on the subjective experience of fluency with which information comes to mind. In their seminal research on the availability heuristic, Tversky and Kahneman (1973) found that people sometimes perceive events as more likely or common if examples of them come to mind easily. In their now classic work on ease of retrieval, Schwarz, Bless, and colleagues (1991) expanded on the earlier research by directly pitting the subjective ease of information retrieval against the actual content of the information retrieved. Schwarz, Bless, and colleagues asked participants to rate their assertiveness after recalling 6 versus 12 examples of their own assertive behavior. They found that people viewed themselves as more assertive after retrieving 6 rather than 12 examples. The logic behind this effect was that people based their judgments of assertiveness on the subjective experience of the ease with which assertive behaviors could be retrieved from memory. When it was easy, because only a few behaviors were requested, people concluded that they must be pretty assertive. When it was difficult, because many behaviors were requested, people inferred that they must not be very assertive. What made this finding so intriguing was that it demonstrated that in at least some contexts people forsake the content of accessible information in memory (e.g., having many assertive behaviors activated) and instead base judgments on the subjective experience of memory (e.g., ease or difficulty). Of course, these effects depend on the perceived diagnosticity of the feeling of ease or difficulty (see Schwarz, 1998, for a review). In the Schwarz, Bless, and colleagues studies, for example, ease of retrieval had no impact on judgments of assertiveness when ease was attributed to an external source.

Since the Schwarz, Bless, and colleagues (1991) research, the ease of retrieval notion has been applied to a number of domains. In the attitudes domain, for instance, it had been found that the easier it feels for people to generate positive thoughts about an object or issue, the more people like that object or issue (Haddock,

Rothman, & Schwarz, 1996; Tormala, Petty, & Briñol, 2002; Wänke, Bless, & Biller, 1996; Wänke, Bohner, & Jurkowitsch, 1997). In addition to attitudes, ease of retrieval can influence a variety of other judgments, such as likelihood estimates (e.g., Hirt, Kardes, & Markman, 2004; Wänke, Schwarz, & Bless, 1995), risk assessments (Grayson & Schwarz, 1999; Rothman & Schwarz, 1998), stereotypes (Dijksterhuis, Macrae, & Haddock, 1999; see also Rothman & Hardin, 1997), attitude certainty (Haddock et al., 1999), judgments of interpersonal closeness (Broemer, 2001), and feelings of self-doubt (Hermann, Leonardelli, & Arkin, 2002). Recent research has shown that ease of retrieval can affect not only explicit but also implicit measures of attitudes (Gawronski & Bodenhausen, in press). Behavior can also be affected. For example, Keller and Bless (2005) found that when people were asked to recall negative stereotypes about their own group, their performance on an ability test was worse when they recalled few (easy) rather than many (difficult) pieces of information.

Although the basic ease effect appears to be quite robust, there have been divergent findings with respect to moderating and mediating factors. For instance, are ease effects most likely to occur under high or low thinking conditions? Researchers originally assumed that ease effects are heuristic in nature and, thus, most likely to operate when thinking is low (see Schwarz, 1998). Some evidence has been produced that is consistent with this notion (Grayson & Schwarz, 1999; Rothman & Schwarz, 1998; Ruder & Bless, 2003). Other research, however, has pointed to the exact opposite conclusion—that ease effects are more likely to operate under high thinking conditions, when people have the motivation and ability to attend to and interpret their own cognitive experience (Hirt et al., 2004; Tormala et al., 2002; Wänke & Bless, 2000).

This controversy may stem in part from different perspectives on the mechanism responsible for ease of retrieval effects. The argument for low thought conditions is based on the notion that ease effects stem from availability inferences (Schwarz, 1998). Difficulty in generating favorable arguments for a tax cut, for example, indicates that few favorable arguments exist, so the tax cut is not worth supporting. Effects might be viewed as emerging mainly when thinking is low because that is when heuristics are most likely to impact judgments (Chaiken, 1987). Other research (Tormala et al., 2002), however, suggests that ease effects can be mediated by feelings of confidence or validity associated with the particular arguments or thoughts retrieved. The easier it is to generate a list of arguments supporting a tax cut, the more confident people are that those arguments are valid (see also Wänke & Bless, 2000). People have been found to be particularly attuned to thought confidence and validity under high thinking conditions (Petty et al., 2002). Although research has identified multiple mechanisms by which ease effects can occur, each begins with the assumption that people perceive their ease or difficulty in thinking—a metacognition. What differs in the accounts is what inferences people make based on this perceived ease. It seems likely that the different mechanisms each contribute to ease effects in different situations.

Mere Exposure

A well-known phenomenon that predates ease of retrieval research is that of mere exposure. The mere exposure effect occurs when attitudes toward stimuli become more favorable as a consequence of repeated exposure to those stimuli (Zajonc, 1968). In one early demonstration of this phenomenon, Kunst-Wilson and Zajonc (1980) presented people with a series of polygon images and found that even when these images could not be consciously recognized, the more often they had been presented, the more they were liked. This effect has now been demonstrated with a wide variety of stimuli such as foreign words, photographs, music, ideographs, and nonsense syllables (see Bornstein, 1989, for a review). Moreover, it has been shown that mere exposure can affect mood, and that this mood can spread to other, related stimuli that were not even presented (Monahan, Murphy, & Zajonc, 2000). To account for mere exposure effects, two general explanations have been proposed: perceptual fluency and perceived familiarity.

A great deal of research suggests that previous or repeated exposure to stimuli can make those stimuli easier to process, and that this *perceptual fluency* enhances subsequent liking. Specifically, the feeling of perceptual fluency, or ease of processing, is thought to be misattributed to a positive evaluation of the stimulus (Bornstein, 1989; Bornstein & D'Agostino, 1994; Jacoby, Kelley, Brown, & Jasechko, 1989). Of importance, though, perceptual fluency can also be attributed to other stimulus dimensions (Mandler, Nakamura, & Van Zandt, 1987). For instance, previously presented names seem more famous (Jacoby, Woloshyn, & Kelley, 1989) and previously presented statements seem more true (Begg, Armour, & Kerr, 1985), even when those statements are explicitly identified as false (Skurnik, Yoon, Park, & Schwarz, 2005). When stimuli already have some meaning, or tend to elicit a dominant response in one direction or another, repeated exposure can accentuate that dominant response (Brickman, Redfield, Harrison, & Crandall, 1972). Repeatedly presenting negative information, for instance, can make that information seem more negative (Cacioppo & Petty, 1989; Grush, 1976). One possible reason for these polarization effects is that one's positive assessments of positive information seem more valid or plausible as exposure increases, as do one's negative assessments of negative information (Kruglanski, Freund, & Bar-Tal, 1996).[3]

As an alternative to the perceptual fluency account, some research suggests that mere exposure effects might at least partially derive from feelings of *familiarity* (see Bornstein & D'Agostino, 1994; Lee, 2001). In fact, Lee (1994, 2001) found that people generally prefer old (familiar) to new (unfamiliar) stimuli, even when the old stimuli have not been *repeatedly* presented. Furthermore, some research suggests that the feeling of familiarity enhances liking even when the familiarity does not stem from any prior exposure at all. Moreland and Zajonc (1982) found that people responded more favorably to faces when those faces felt familiar because they were similar to other ones that had been viewed. The associa-

tion between familiarity and liking is so strong that stimuli that are already positive are also likely to be perceived as familiar (Corneille, Monin, & Pleyers, 2005; Garcia-Marques, Mackie, Claypool, & Garcia-Marques, 2004; Monin, 2003). As with perceptual fluency, however, some studies have qualified this view, suggesting that the feeling of familiarity stemming from repeated exposure can foster liking or disliking, depending on other contextual factors (e.g., Klinger & Greenwald, 1994; for a similar finding, see Smith et al., 2006).

Although the perceptual fluency and familiarity explanation of mere exposure effects have been pitted against one another in the literature, these mechanisms might ultimately be somewhat intertwined. For example, Whittlesea, Jacoby, and Girard (1990) found that stimuli presented with greater visual clarity were perceived as being more familiar, and more likely to have appeared previously, than stimuli presented with less visual clarity. Furthermore, perceptual fluency stemming from repeated exposure can make a stimulus feel more familiar and enhance liking in this manner (e.g., Jacoby & Kelley, 1987; Jacoby, Kelley, Brown, & Jasechko, 1989).

Other Sources of Fluency

In addition to ease of retrieval and mere exposure, there are a number of other sources of processing fluency. The classic perceptual fluency effect—that easy-to-process stimuli are evaluated more favorably than difficult-to-process stimuli—has been produced using a diverse set of experimental manipulations. Line drawings, for example, tend to be liked more and produce more positive affect when they have greater rather than less figure–ground contrast, when they have been presented for a longer rather than shorter amount of time, and when they have been preceded by a similar rather than dissimilar prime (Reber, Winkielman, & Schwarz, 1998; see also Winkielman & Cacioppo, 2001). In addition, words tend to be easier to process and judged as more pleasant when they are embedded in a predictive rather than nonpredictive semantic context (e.g., Whittlesea, 1993).

Other Effects of Fluency

Confidence

In addition to affecting people's evaluations of stimuli, as noted earlier, processing fluency can also influence feelings of confidence. For example, recall that the ease of generating thoughts can affect the confidence with which those thoughts are held (Tormala et al., 2002). Other forms of processing fluency have also been shown to affect confidence (see Koriat & Levy-Sadot, 1999, for a review). For example, Gill and colleagues (1998) used a priming procedure to make certain kinds of impressions of a person easier to form following a paragraph about that person. Gill and colleagues found that when judgments were made more easily, because of priming, those judgments were also held with greater confidence. Norwick and Epley (2003) found that participants were more confident that a given statement was true when the statement was easy rather than difficult to read. Busey, Tunnicliff, Loftus, and Loftus (1995) presented participants with a series of faces to study for a later recognition test. When participants were tested under bright rather than dim viewing conditions, which made the faces easier to see, participants were more confident in their recognition judgments. Borrowing from the mere exposure paradigm, researchers have also found various forms of repetition to increase confidence. Repeating questions, for instance, increases confidence in the answer retrieved (e.g., Hastie, Landsman, & Loftus, 1978). Similarly, repeated expression of one's attitude increases attitude certainty, and this effect can stem from the objective ease, or accessibility, with which the attitude comes to mind (Holland, Verplanken, & van Knippenberg, 2003).

Perceived Knowledge

Another metacognition associated with cognitive fluency involves people's perceptions of their own knowledge (see Koriat & Levy-Sadot, 1999, for a review). As but one example, Werth and Strack (2003) presented people with trivia-type questions and answers in an easy-to-read or difficult-to-read color scheme. When the colors made the question and answer easy rather than difficult to read, participants were more likely to assume they knew the answer all along. This *feeling of knowing*, it turns out, can have important implications for thought and behavior. Under some conditions, the feeling of knowing has a positive impact on information processing. The greater one's feeling of knowing an elusive item in memory, the more time one will spend searching for that item before giving up (e.g., Costermans et al., 1992; Koriat, 1993; Nelson & Narens, 1990; Yzerbyt, Lories, & Dardenne, 1998). Under other conditions, though, perceived knowledge has a negative impact on information processing. In particular, the more one thinks one knows about a topic, the less likely one is to seek new information on that topic (Radecki & Jaccard, 1995). These effects are particularly intriguing given that the correlation between perceived and actual knowledge tends to be quite low (e.g., Glenberg, Wilkinson, & Epstein, 1982; Krosnick, Boninger, Chuang, Berent, & Carnot, 1993; Radecki & Jaccard, 1995).

Caveat

As the preceding review indicates, much of the research on processing fluency suggests that the experience of ease is positive. In fact, some recent work explicitly concludes that fluency is by its very nature a pleasurable experience (for a review, see Reber, Schwarz, & Winkielman, 2004; Schwarz, 2004). Based on most of the research we have reviewed, this conclusion makes sense. Indeed, easy-to-process stimuli tend to be rated more favorably than difficult-to-process stimuli (e.g., Bornstein, 1989; Jacoby, 1983; Lee & Aaker, 2004). Easy-to-process pictures have been shown to elicit greater positive affect than do hard-to-process pictures (Winkielman & Cacioppo, 2001). Easy-to-generate thoughts or argu-

ments, whether positive or negative, tend to be viewed as more valid (Tormala et al., 2002), frequent (Schwarz, 1998), or generally diagnostic of what one thinks. In short, processing fluency has typically been viewed as inherently positive in some way.

However, recent research has determined that the meaning of ease is malleable (e.g., Winkielman & Schwarz, 2001), and changing the meaning of ease can modify the normal ease of retrieval effect. In one study, for instance, Briñol, Petty, and Tormala (2006) reported that under some conditions people can be induced to view easy-to-generate thoughts as *less* rather than more diagnostic of what they think. Briñol and colleagues manipulated the meaning of ease by leading some participants to believe that cognitive ease was a positive sign of mental functioning whereas difficulty was a negative sign. Other participants received the exact opposite information. When ease was described as positive, Briñol and colleagues replicated the usual ease effect—participants were more favorable toward an issue after they generated an easy rather than difficult number of arguments in favor of it. When ease was described as negative, however, this effect was reversed—participants were less reliant on their thoughts when those thoughts were easy rather than difficult to generate. In other words, although there may be a default tendency to think easy-to-generate thoughts are more plentiful, valid or desirable, this tendency can be changed (see also Freitas, Azizan, Travers, & Berry, 2005; Schwarz, 2004). The implications of this effect for other fluency effects have yet to be fully explored, but this initial finding suggests that the impact of the cognitive experience of ease on social judgment may ultimately prove more complex than is typically presumed.

ATTITUDES AND PERSUASION

One of the first areas in social psychology to be concerned with metacognition was that of attitudes and persuasion. In particular, researchers have been interested in various metacognitive properties of attitudes as indicators of the attitude's strength, though the early work on this topic did not link explicitly to the "metacognitive" moniker. *Attitude strength* refers to the extent to which an attitude persists over time, guides behaviors and other judgments, and is resistant to influence attempts (Krosnick & Petty, 1995). Wegener, Downing, Krosnick, and Petty (1995) noted that for many aspects of attitude strength, there were both objective and subjective indicators. That is, for virtually every postulated objective indicator of an attitude's strength such as the actual speed with which an attitude comes to mind (accessibility; see Fazio, 1995), or the amount of information people can generate regarding their attitudes (knowledge; see Wood, Rhodes, & Bick, 1995), or the amount of thinking they have done about their attitude (Petty, Haugtvedt, & Smith, 1995), there is a parallel measure of the *perceived* ease of attitude access or amount of knowledge or thought. However, there are some subjective perceptions, such as attitude certainty and importance, for which there are no objective counterparts.

In an influential paper, Bassili (1996) referred to the subjective perceptions regarding one's attitudes as *meta-attitudinal* indicators and contrasted them with the more *operative* or objective indicators that tapped more directly into attitude structure or process. Notably, Bassili was rather critical of meta-attitudinal features of attitudes, arguing that they are typically not represented with the attitude object or closely related to the factors that determine attitudes. He argued that because people are often not aware of the processes leading to their judgments (Nisbett & Wilson, 1977), reports of how much knowledge was behind one's attitude or how quickly one's attitude would come to mind would not relate very well to operative measures of these constructs. Furthermore, he argued that "second order judgment (i.e., judgment about judgment) requires a level of intrapsychic awareness that people seldom have" (p. 640; see also Roese & Olson, 1994).

After conducting two studies comparing meta to operative indicators of strength in their abilities to predict attitude stability and resistance to change, he concluded that "operative measures have more predictive validity than meta-attitudinal measures" (p. 651). Although this conclusion is consistent with the data he reports for indices collapsed across various meta and operative measures, it is important to note that his data also show that one metameasure in particular—attitude certainty—either did as well as or outperformed the operative measures in predicting attitude consequences.

Thus, our point of view on the utility of metacognitive measures of attitude strength is a bit different. Consistent with Bassili (1996), we think it is unlikely that there are a large number of subjective assessments that are directly linked to attitudes. That is, it may not be the case that perceptions of accessibility, knowledge, and so forth are linked to most attitudes. In contrast to Bassili, however, we argue that many attitudes at least have a validity, certainty, or confidence tag (Petty, 2006; Petty & Briñol, 2006; Petty et al., 2006). Indeed, considerable research is consistent with the idea that when people come to disbelieve or have some doubt in an idea (i.e., hold the idea with less than complete certainty), this idea can be marked with a negation or doubt tag (Clark & Chase, 1972; Gilbert, Tafarodi, & Malone, 1993; Mayo, Schul, & Burnstein, 2004).

We review research in four topic areas. First, we examine research that assesses metacognitive strength features of attitudes and how these features affect various consequences. Second, we discuss research that examines how metaperceptions of an attitude might be affected by accepting or rejecting a persuasive message. Next, we discuss research in which metaperceptions of one's attitude-relevant thoughts determine persuasion. Finally, we briefly mention work regarding metacognition about the processes of persuasion.

Metacognitive Properties of Attitudes: Certainty and Others

As noted earlier, there are many potential thoughts people could have about their attitudes such as how quickly

they come to mind, how many others share their view, and so forth (Wegener et al., 1995). Nevertheless, several perceptions of attitudes have received the most attention and we discuss these next.

Attitude Certainty

The most studied metacognitive aspect of attitudes and the one of most long-standing interest (e.g., Allport, 1924) is the certainty or confidence with which an attitude is held. Certainty generally refers to a sense of validity concerning one's attitudes (Gross, Holtz, & Miller, 1995). Although certainty naturally covaries with extremity (i.e., people tend to feel more certain as their attitudes deviate from neutrality; e.g., Raden, 1989), certainty and extremity are conceptually distinct such that a person can have high certainty in the validity of a neutral attitude, or express an extreme attitude with low confidence. A number of determinants of attitude certainty have been examined. People tend to be more certain of their attitudes when they are based on direct experience (e.g., Fazio & Zanna, 1981), when they come to mind easily (Haddock et al., 1999), when others agree with the attitude (e.g., McGarty, Turner, Oakes, & Haslam, 1993; Visser & Mirabile, 2004), and when people have done much prior thinking about the attitude object (Abelson, 1988) unless that thinking arouses conflicting thoughts (Liberman & Chaiken, 1991). Some individual differences have also been related to attitude certainty (e.g., uncertainty orientation–Sorrentino & Short, 1986; dogmatism–Palmer & Kalin, 1991), though it is not clear whether the certainty effects of these individual differences are independent of attitude extremity. Attitude certainty, at least with respect to political issues, tends to increase from young adulthood to middle age but then declines sharply as one becomes elderly (Visser & Krosnick, 1998). Given the declines in memory accessibility as one ages (Varhaeghen & Salthouse, 1997), it would be interesting if declines in attitude accessibility are partially responsible for the declines in certainty in one's later years.

Attitude certainty has been associated with a number of important attitude-relevant outcomes. In particular, attitudes held with greater certainty are more resistant to change (e.g., Tormala & Petty, 2002), persistent in the absence of a persuasive attack (Bassili, 1996), and more predictive of behavior (Fazio & Zanna, 1978) than attitudes about which there is doubt. In fact, attitudes may have to reach a certain level of certainty before action is initiated (Gerard & Orive, 1987). Certain attitudes may be more resistant to change because certainty induces a confirmatory information-seeking style (e.g., Swann & Ely, 1984), and certain people are more likely to assume that others agree with them (Marks & Miller, 1985). Gross and colleagues (1995) suggest that it is useful to distinguish "true confidence" in one's attitude from "compensatory confidence." The former is based on knowledge or social support whereas the latter actually reflects an absence of confidence. We suggest that the latter might be revealed in low confidence on an implicit measure. Gross and colleagues argue that those with compensatory confidence

may be most likely to project their attitudes onto others and respond to counterattitudinal messages with a feeling of threat rather than challenge (see Blascovich, 1992).

Importance, Ambivalence, and Knowledge

Other metacognitive features of attitudes that have been examined with some frequency include attitude importance, ambivalence, and knowledge. Although these constructs are often determined by the same factors as attitude certainty and produce similar effects, the accumulated evidence suggests that there are sufficiently different antecedents and consequences to treat them as distinct (see Visser, Bizer, & Krosnick, 2006, for a comprehensive review). For example, in one study (Visser, Krosnick, & Simmons, 2003), despite an overall positive correlation between importance and certainty on the issue of global warming, it was found that as people were exposed to more media reports on global warming, the importance of global warming increased but certainty in one's attitudes decreased.

Attitude importance has been defined as the extent to which people attach significance to their attitude and care about it (Krosnick, 1988). Because importance is viewed as something attached to the attitude (Boninger, Krosnick, & Berent, 1995), it is appropriately viewed as a metacognitive feature. However, in much research on attitude importance, what is typically measured is the perceived importance of the attitude *object* rather than the attitude itself (e.g., how important is the *issue* of global warming to you personally"; Bizer & Krosnick, 2001, emphasis added; see also Holbrook, Berent, Krosnick, Visser, & Boninger, 2005; Krosnick et al., 1993; Visser et al., 2003).[4] Because of this, the construct as operationalized is closely related to the construct of issue involvement, which concerns the personal importance people attach to particular attitude objects and issues (e.g., Thomsen, Borgida, & Lavine, 1995; Petty & Cacioppo, 1990; Petty, Cacioppo, & Haugtvedt, 1992). Furthermore, when manipulations of attitude importance have been attempted, they too have been closely related (if not identical) to manipulations of issue involvement (i.e., manipulating the personal relevance of the *issue*; e.g., Bizer & Krosnick, 2001; Boninger et al., 1995). To add further confusion, some researchers have measured attitude importance (e.g., "I consider my attitude toward smoking to be important") but have referred to it as *issue* importance (van Harreveld & van der Pligt, 2004).

At the conceptual level, it seems likely that attitude importance and issue importance would often go together (see Boninger et al., 1995). Nevertheless it also seems quite easy to distinguish between attitude and issue importance in some circumstances. For example, a person might think that the issue of capital punishment is very important but care little about what particular attitudinal position is adopted with respect to it. On the other hand, another person might be committed to adopting particular opinions that agree with his or her ingroup but the issues themselves are of little consequence. In an early paper, Zimbardo (1960) distinguished the involvement

people can have with an issue and the involvement with one's particular attitudinal response. The more recent conflation of attitude and issue importance is potentially misleading if the constructs are conceptually distinct and can induce different psychological consequences, at least in some situations. For example, Petty and Cacioppo (1990) argued that the increased importance of any particular attitudinal *issue* would lead to enhanced information seeking and processing with respect to the issue, whereas the increased importance of any particular attitudinal position (i.e., caring about whether you favored or opposed a topic) was more likely to lead to a biased seeking and processing style.

Recognizing a distinction between the importance of the attitude issue (or object) and the particular attitudinal position may help to clarify what appear to be surprising findings in the literature. For example, Bassili (1996) found that attitude importance was positively rather than negatively related to attitude change as would be expected if importance tapped into attitude strength. However, because the measure of attitude importance he used actually assessed the importance of the issue rather than the importance of the person's attitudinal position, this positive relation makes sense if increased importance of the issue led people to pay more attention to messages about the issue and they changed in response to processing these messages (Petty & Cacioppo, 1979). Indeed, rated issue importance has been associated with enhanced information-seeking activities (e.g., Visser et al., 2003).

Similar points might be made about other traditional attitude strength assessments. For instance, although researchers have referred to *attitude ambivalence*, the actual assessment of ambivalence, both objective and subjective, concerns whether or not people actually have (e.g., Kaplan, 1972) or perceive themselves to have thoughts about the attitude *object* or *issue* that are mixed in valence or one sided (e.g., "I do not find myself feeling torn between the two sides of the *issue* of capital punishment"; Newby-Clark, McGregor, & Zanna, 2002, emphasis added; see also Connor, Povey, Sparks, James, & Shepherd, 2003; Priester & Petty, 1996; Tourangeau, Rasinski, Bradburn, & D'Andrade, 1989). Thus, what has been studied in the literature might more properly be called objective and subjective *issue ambivalence* in that the person's thoughts are mixed with respect to the attitude object rather than the attitudinal position per se. Although it has not been studied, it is presumably possible for people to be ambivalent about their attitudinal positions per se, but this would require assessment of whether people had both positive and negative thoughts *about their attitude* rather than about the issue.[5] It seems quite possible for a person to be rather ambivalent about an issue (i.e., there are some good and bad things about capital punishment) but quite *un*ambivalent with respect to the particular attitude position held (i.e., my thoughts about being neutral are all positive; I do not feel ambivalent about having an ambivalent attitude). Similarly, people might have little ambivalence with respect to the attitude object (i.e., all thoughts about oneself are positive) but recognize that there are both good and bad things about being

so favorable (e.g., others might think you are competent but conceited). This might well explain why ambivalence and certainty have been only weakly correlated. That is, ambivalence has been assessed with respect to the attitude object or issue whereas certainty has been about the attitude itself.

Finally, it is worth noting that the same distinction can be made regarding *attitude knowledge*. Again, what has typically been assessed has been perceived knowledge about the issue under consideration (see Davidson, 1995; Wood et al., 1995) rather than the attitude per se. The distinction in this case has to do with whether people are being asked to make a subjective assessment of what they know about an issue (e.g., capital punishment) versus what they know about a particular attitudinal position (e.g., strongly opposing capital punishment). Although these two constructs are likely to share much variance, it is also easy to imagine divergence. For example, people could feel that they have a lot of information about the attitude issue in general but relatively little in support of the particular position they favor. Or, they might think they have much information in support of their position but relatively little information overall because they are completely ignorant of the other side. The more overall information they believe they have (on both sides), the more certain they might be in the validity of the attitude, whereas the more information they believe they have in support of a particular side, the more extreme their attitude might be.

The effects of perceived knowledge have paralleled the effects of amounts of actual knowledge (e.g., see Johnson, 1994; Wood et al., 1995). First, high perceptions of knowledge lead attitudes to be more predictive of behavior (see Davidson, 1995, for a review). In addition, people who believe they are already well informed on an issue are less likely to seek additional information on that topic, especially if they are also high in the need for cognitive closure. But, if those high in perceived knowledge are provided with information, they are more likely to think about it, differentiating strong from weak arguments (see Kruglanski et al., 2005), and are less reliant on issue-irrelevant cues (Ellis, 1996). Kruglanski and colleagues (2005) note that one's perception of one's own knowledge is an important factor to consider in understanding source credibility effects. That is, they argue that it is the gap between one's own perceived knowledge and that of the source that determines the source's impact (see also Ellis & Kruglanski, 1992).

Attitude Certainty and Persuasion

Having reviewed some definitional issues with respect to metacognitive features of attitudes, we now turn to how the most studied metacognitive strength feature, attitude certainty, can be affected by receipt of a persuasive message. The voluminous research on persuasion has naturally focused on whether or not an attitude changes in valence or extremity as a result of message exposure. More recent research, however, has studied how the certainty with which people hold their attitudes can be affected following persuasion or resistance.

Confidence in Old and New Attitudes as a Result of Exposure to Persuasive Messages

First, consider a situation in which people receive a persuasive message and do not change their attitudes in response to it. Traditional analyses assume that when attitudes fail to change, the persuasive message has been ineffective. Yet, Tormala and Petty (2002) argued that when people resist a persuasive message they sometimes contemplate their own resistance and as a result, the confidence with which they hold their initial attitude can change. In particular, in several studies, Tormala and Petty showed that when people believe they have effectively resisted a strong persuasive message, certainty in their original attitudes is increased. When people believe they have resisted a weak message, certainty does not increase because people are uncertain as to whether they would have been able to resist a stronger message.[6]

Subsequent research (Tormala & Petty, 2004a) showed that this metacognitive effect was only present among individuals who were prone to engaging in considerable amounts of thought (i.e., those high in need for cognition; Cacioppo & Petty, 1982) or in situations that fostered high amounts of thinking (e.g., a topic high in personal relevance; Petty & Cacioppo, 1979). Furthermore, just as certainty in one's original attitude can be increased when people believe they have resisted a message with strong arguments, so too can their certainty be increased when they believe they have resisted a message from an expert (Tormala & Petty, 2004b). Resisting a message from a nonexpert is not very diagnostic with respect to one's attitude because one does not know whether the attitude could have survived an attack from someone more knowledgeable.

What if people are trying to counterargue a message but are unsuccessful in doing so? In a series of studies, Rucker and Petty (2004) found that people who process a message with an intent to find fault, but are unsuccessful in counterarguing, become more convinced in the validity of their *new* attitude than people who processed the same message in a more objective manner. Rucker and Petty argued that when the arguments in a message are very strong, both people who are processing objectively and those trying to find fault will realize that there are many positives to the proposal. Only people who are trying to find fault and fail, however, will realize that there are few negatives to the proposal. Because these individuals will realize that they considered both sides of the issue (i.e., positives and negatives), they will have more confidence in their new attitudes. This logic implies that if the message arguments are very weak, it is people who are trying to be favorable and fail who will have more confidence in their old attitudes than people who are being objective. This is because everyone will realize that the proposal has many flaws (due to the very weak arguments) but only people who were trying to be favorable will realize that there are no positives. Because these individuals will have considered both sides of the issue, confidence in their attitudes will be enhanced (Rucker & Petty, 2004).

The studies we just reviewed suggest quite clearly that following an attempt to resist persuasion, people sometimes reflect on their resistance and its meaning for their attitudes. In the examples just provided, certainty in either an old or a new attitude was increased as a result of reflection on one's attempted resistance. These outcomes are depicted in Figure 11.1, along with situations in which confidence in either old or new attitudes can be

Trying to Counterargue

Able to Counterargue → Resist (no change)

- Impressed with ability (resisted strong arguments; seemed; easy to resist; counterarguments seemed good) → **More Confidence** in Old Attitude
- Unimpressed with ability (seemed very difficult to counterargue; counterarguments seemed bad) → **Less Confidence** in Old Attitude

Unable to Counterargue → Succumb (change)

- Impressed with inability (tried very hard; was difficult to counterargue; counterarguments seemed bad) → **More Confidence** in New Attitude
- Unimpressed with inability (did not try very hard; many distractions; counterarguments seemed good) → **Less Confidence** in New Attitude

FIGURE 11.1. How confidence in one's old and new attitude can be affected when people are able to counterargue and resist or are unable to counterargue and change. From Petty, Tormala, and Rucker (2004). Copyright 2004 by the American Psychological Association. Adapted by permission.

decreased as a result of reflection on one's resistance.[7] For example, Figure 11.1 suggests, and recent research confirms, that if people resist changing to a message but believe that their counterarguing attempt was flawed in some way (Tormala, Clarkson, & Petty, 2006), or that they resisted by illegitimate means (e.g., rejecting a minority source; see Tormala, Petty, & DeSensi, in press), certainty in one's attitude can be decreased (see Petty, Tormala, & Rucker, 2004, for additional discussion).

A Metacognitive Approach to Attitude Change

The notion that people can hold both old and new attitudes with varying degrees of confidence has important implications for an analysis of what happens when attitudes change. Traditional models of persuasion hold that when attitudes change, the old attitude just disappears or is incorporated into the new attitude (e.g., see Anderson, 1971). More recent constructivist perspectives on attitudes (e.g., Schwarz & Bohner, 2001) hold that attitudes are newly constructed on each occasion when they are needed and thus there is no residue from prior attitudes. In contrast, our metacognitive model of attitudes (MCM) incorporates the notion that both old and new attitudes can coexist with differing levels of confidence (Petty & Brinol, 2006; Petty, Wheeler, & Tormala, 2003; Petty et al., 2006).

In particular, consistent with various "negation tag" models of judgment (e.g., Gilbert et al., 1993; Mayo et al., 2004), the MCM holds that when people shift from one attitude to another, the old attitude can be tagged as invalid or low in confidence (see Figure 11.2 for a person who starts out liking chocolate cake but then comes to dislike it after reading a message about its fat content). An important implication of this model is that if people do not retrieve the associated invalidity tag that is linked to a rejected attitude, then the two opposing evaluations (old and new) could be jointly activated producing an ambivalent-like state. Notably, this ambivalence would not be *explicit* because when thinking carefully, people would recognize that they only truly endorse one side. However, when not thinking carefully, activation of both evaluations (without invalidity tag) could produce a state of *implicit ambivalence*.[8]

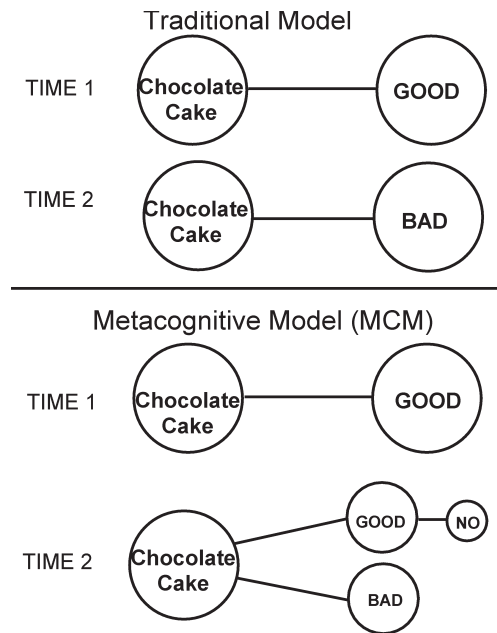
To examine this possibility, in a series of studies, Petty and colleagues (2006) created initial attitudes in participants and then changed them for one group, and reinforced them for another group. Thus, at time 2, there were two groups of individuals who felt positively or negatively about some attitude object. The only difference was that one group had always felt positively or negatively whereas the other group used to feel the opposite way (i.e., their attitudes were changed). Petty and colleagues reasoned that if people who used to feel differently experienced some implicit ambivalence, they should engage in greater information processing with respect to a message relevant to the attitude, just as do individuals who experience explicit ambivalence (e.g., Maio, Bell, & Esses, 1996). Consistent with this idea, when people had a new attitude that conflicted with their old one,


FIGURE 11.2. Comparison of the metacognitive model (bottom panel) with the traditional model (top panel) of attitude change. From Petty, Tormala, Briñol, and Jarvis (2006). Copyright 2006 by the American Psychological Association. Adapted by permission.

their attitudes were more influenced by message quality than when there was no conflict with an old attitude. In research on the MCM to date, confidence in old and new attitudes was not assessed. Yet, the results from this research are consistent with the notion that attitudes have validity tags that, depending on their activation, can influence peoples' reactions to attitude-relevant objects.

Thought Certainty and Persuasion: Self-Validation Effects

In addition to considering the consequences for attitude confidence of attempts at attitude change, persuasion researchers have also begun to study how metacognitive processes might contribute to attitude change itself. Perhaps the best example of this comes from the *self-validation hypothesis* (Petty et al., 2002). The key idea of this hypothesis is that just as attitude confidence is an important determinant of which attitudes predict behavior, thought confidence is an important determinant of which thoughts predict attitudes.

Considerable research has demonstrated that when people care about an issue or are motivated and able to think for other reasons, the number and valence of thoughts they have in response to a message determines the extent of attitude change (see Eagly & Chaiken, 1993; Petty et al., 1981; Petty & Wegener, 1998, for reviews). The self-validation hypothesis suggests that in addition to number and valence, it is also important to consider thought confidence. Research has shown that measuring the confidence people have in their thoughts to a persua-

sive message enhances prediction of the attitudes that are formed over and above a consideration of the valence and number of thoughts (e.g., Petty et al., 2002).

Furthermore, direct manipulations of thought confidence have a similar impact. In one study, for instance, following exposure to a message containing strong or weak arguments and a typical thought listing task (see Cacioppo, Harkins, & Petty, 1981), people were asked to think about situations in which they had felt confident or doubtful in their thinking (see Petty et al., 2002). Those who generated instances of confidence became more certain of the validity of their thoughts than those who generated instances of doubt. Furthermore, this confidence led to greater persuasion when the message arguments were strong and to less persuasion when the arguments were weak. This is because confidence led people to rely on the favorable thoughts generated to the strong arguments and the unfavorable thoughts they generated to the weak arguments. Individuals who were induced to doubt the validity of their thoughts were less reliant on them in forming attitudes even though the number and valence of thoughts was the same as those induced to feel confidence.

The self-validation framework provides a new explanation for how variables can impact attitudes. For example, prior research on head nodding had assumed that nodding one's head in a vertical (vs. horizontal manner) produced more positive attitudes either because vertical head nodding biased thinking in a favorable direction (Wells & Petty, 1980) or because head nodding served as a relatively simple affective cue (Tom, Pettersen, Lau, Burton, & Cook, 1991). The self-validation hypothesis suggested another possibility—that just as vertical head movements from others give us confidence in what we are saying, our own vertical head movements could give us confidence in what we are thinking. In a series of studies, Briñol and Petty (2003) found that head movements affected the confidence people had in their thoughts, and thereby had an impact on attitudes. Thus, when thoughts to a message were mostly favorable, vertical movements led to more confidence in the favorable thoughts generated and to more favorable attitudes than when horizontal movements were made. When thoughts were mostly unfavorable, however, vertical movements led to more confidence in the unfavorable thoughts generated and to less favorable attitudes than when horizontal movements were made.

The self-validation hypothesis proposes a new role that variables can play in persuasion situations in the context of the elaboration likelihood model of persuasion. That is, in addition to serving as cues, arguments, or affecting the number and valence of thoughts that come to mind (see Petty & Cacioppo, 1986), variables can also influence the confidence people have in their thoughts and thus whether they are relied on in forming attitudes. The self-validation hypothesis therefore provides a new mechanism by which classic persuasion variables can have an impact on attitudes.

For example, prior research has shown that the expertise of the source and a person's mood can serve in multi-ple roles (e.g., argument, cue, and affecting processing; see Petty & Wegener, 1998, for a review). Research on the self-validation hypothesis has shown that expertise and mood can also affect thought confidence. Source expertise presumably affects thought confidence because expert sources are more likely to present accurate information. If people can be more confident in the information presented by experts (Kaufman, Stasson, & Hart, 1999), then they can also be more confident in their thoughts regarding this information (see also Kruglanski et al., 2005). The mood prediction follows directly from the finding that people feel more confident when in some moods (e.g., happy) than in others (e.g., sad; Tiedens & Linton, 2001). In relevant research, Briñol, Petty, and Tormala (2004) showed that when the likelihood of thinking is high and people learn of the source's expertise after they have processed the message, source expertise influences thought confidence (see also Tormala, Briñol, & Petty, 2006). Briñol, Petty, and Barden (2006) have shown that in similar situations, people are more confident in their thoughts when placed in a happy rather than a sad mood following a message. If people are more confident in their thoughts about a message when they learn the message is from an expert and when they are in a happy mood, this means that source expertise and a happy mood can increase persuasion relative to a nonexpert and a sad mood when the arguments are strong but decrease persuasion when the message arguments are weak.

Finally, we remind readers that the self-validation hypothesis provides an alternative explanation for some cognitive fluency effects. For example, Tormala and colleagues (2002) found that people were more reliant on their thoughts when they were asked to generate an easy rather than a difficult number of them. In addition to the classic ease-of-retrieval effect, perceptions of fluency and thought confidence might be involved in other persuasion phenomena. Consider the voluminous work on matching and tailoring in persuasion. Matching refers to instances in which a message is matched to some aspect of an individual. For example, an image appeal might be presented to a person high in self-monitoring (Snyder & DeBono, 1985), or an emotional message might be presented to a person whose attitudes are based primarily on affect (e.g., Fabrigar & Petty, 1999; see Briñol & Petty, 2005; Petty, Wheeler, & Bizer, 2000, for reviews of matching work). According to a fluency account, if a message matches the person in some way, it may be easier to process. In one demonstration of this logic, regulatory fit (see Higgins, 2000) was shown to enhance processing fluency. Lee and Aaker (2004) presented promotion- and prevention-focused individuals with persuasive messages framed in terms of gains or losses. Participants reported that it was easier to process the messages when they matched (gain frame-promotion focus or loss frame-prevention focus) rather than mismatched (gain frame-prevention focus or loss frame- promotion focus) participants' regulatory focus. Furthermore, participants were more persuaded by the messages under matched rather than mismatched conditions. Although there are several

possible explanations for this effect (see Petty et al., 2000), it may be that the processing fluency stemming from regulatory fit leads message thoughts to be held with more confidence (see also Cesario, Grant, & Higgins, 2004). To the extent that the thoughts to the message are primarily favorable, enhanced confidence would increase persuasion. This fluency explanation for various matching effects should be examined in future research.

It is noteworthy that the self-validation findings results have been most pronounced under high thinking conditions. For example, research on head nodding (Briñol & Petty, 2003), source expertise (Briñol, Petty, & Tormala, 2004), and ease of retrieval (Tormala et al., 2002) showed that these variables affected confidence in thoughts for high- but not for low-need-for-cognition individuals and affected confidence when issue involvement was high but not when it was low. Relatively high elaboration presumably enhances self-validation effects for at least two reasons. First, if people have few thoughts, then thought confidence will have little effect. Second, the same variables that would increase elaboration (e.g., issue importance) would also likely increase thinking about one's thoughts. If people do not care enough to generate thoughts in the first place, they are hardly likely to care enough to think about the validity of their thoughts.

Metacognition about Persuasion Processes

Earlier in this section we noted that people sometimes think about their resistance to persuasion and generate inferences about their attitudes based on this resistance. More generally, research suggests that people have developed naive theories about the persuasion process, including what kinds of strategies they would use to persuade others (e.g., Bisanz & Rule, 1989), what strategies might be effective in persuading them (Friestad & Wright, 1994, 1995), and what strategies they use to resist influence (Jacks & Cameron, 2003). However, there is little (if any) empirical work on how these naive theories influence actual persuasion. Such research could be quite informative.

Although there is little accumulated research about how people's chronic persuasion theories affect attitudes, some work has begun to explore how people's online theories of attitude change can modify the persuasion process. For example, research by Mazursky and Schul (2000) suggests that people sometimes reflect on their information-processing strategy following receipt of a persuasive message so that they can modify it for future messages if the initial strategy proves ineffective. In two studies investigating this issue, they gave people information about a consumer product along with information about the source of the information. For half of these individuals, one piece of information provided by the source was said to be invalid, whereas the other half did not learn this. Then, all participants received another message about a new consumer product either from this source or from a more credible one. Some of the decision makers were highly involved with the consumer product whereas others were not. When consumers had not received any prior invalid information, judgments of

the involved participants appeared to be based on their effortful consideration of the evidence presented whereas those less involved relied on simple cues, consistent with much work on dual-process models of persuasion (e.g., Chaiken et al., 1989; Petty & Cacioppo, 1986). That is, high-involvement participants took longer to make their decisions than low-involvement individuals (an indication of their more deliberative processing), and low-involvement individuals relied more on the credibility of the information source (see Petty, Cacioppo, & Goldman, 1981). However, when recipients had received some invalid prior information, participants appeared to change their information-processing strategy. That is, now it was the low-involvement individuals who took more time to evaluate the messages, and it was the high-involvement individuals who relied more on the source credibility information.

THE SELF AND INDIVIDUAL DIFFERENCES

We have seen that metacognition can play a role in various attitudinal phenomena. One of the most studied attitude objects is the self (Baumeister, 1998). The self includes one's cognitive representation of oneself, composed of self-schemas and self-knowledge, as well as one's evaluation of oneself, or self-esteem. Similar to any other attitude object, the relevant beliefs (self-concept) and evaluations (self-esteem) toward the self can be accompanied by metacognitions about their origin, content, evaluation, amount, and so on. This section reviews the importance of considering various metacognitive aspects of the self.

Like research on attitudes, most of the metacognitive research in the self domain has focused on the *confidence* dimension. That is, researchers have studied peoples' subjective certainty about the validity of their cognitive representation of themselves and their self- evaluations. Similar to the literature in other domains, confidence typically has been measured by asking people to rate the degree to which they were certain or uncertain about their self-beliefs or their self-esteem.[9] Across different measurement and induction techniques, research reviewed in this section reveals that it is critical to consider confidence in order to understand the functioning of the self-concept and self-esteem. In the first part of this review, we cover research examining the consequences of *self-concept confidence* for various outcomes. Next, we describe studies dealing with *self-esteem confidence* and its implications for a variety of relevant areas. In the final section, we move from the study of metacognition regarding general beliefs and evaluations about the self to the domain of metacognition about more specific self-dimensions. Thus, the last section explores metacognition and individual differences.

Consequences of Self-Concept Confidence

Similar to the literature in attitude strength (e.g., Petty & Cacioppo, 1986; Petty & Krosnick, 1995), self-beliefs that are held with greater confidence are also more stable,

more resistant to change, and more predictive of behavior. For example, people who report greater certainty about their self-beliefs have been found to be more stable in their self-views (Pelham, 1991). Furthermore, Pelham and Swann (1994) showed that people are more likely to actively solicit self-consistent social feedback (i.e., to actively seek out feedback that supports their existing self-views) in domains in which they are most certain. Pelham and Swann also showed that interaction partners are more likely to confirm peoples' confident rather than doubtful self-views. In short, when people report high confidence in their self-views, they are likely to behave and to be perceived in ways that are consistent with those personal views (see also Pelham, 1991).

The confidence with which self-beliefs are held can influence not only individuals' stability and consistency but also other important dimensions, such as resistance to change. Similar to the literature in attitude strength (e.g., Bassili, 1996; Gross et al., 1995), self-beliefs that are held with greater confidence are more difficult to change. Swann and Ely (1984) found, for instance, that people who reported being relatively uncertain about their personality (e.g., extraversion) showed more change in response to a series of leading questions (i.e., a technique that leads people to provide evidence that confirms the premises in the leading questions) than those who were certain about their self-concept. In follow-up research, Swann, Pelham, and Chidestu (1988) replicated this finding and showed not only that individuals high in self-belief certainty resist leading questions better than those with relatively lower certainty but that boomerang effects can also occur. That is, leading questions can cause confident people to change in a direction opposite to the leading questions when encouraged to make statements that are consistent with but more extreme than their own beliefs.

Subsequent research has shown that self-belief confidence can also influence how people resist other forms of influence. For example, Sedikides (1995) found that relative to participants who reported uncertainty about their traits, those who expressed more self-belief certainty were more resistant to the biasing influences of a mood induction (happy, sad, or neutral). This research suggests that being certain about oneself can lead to more resistance to information about both the specific beliefs about which one is certain and the more general factors (e.g., mood) capable of influencing those beliefs.

In a different line of research, Baumgardner (1990) found that certainty in self-attributes not only causes people to be more resistant and to behave in a more consistent and stable way but can also promote a sense of control over future outcomes, thus generating positive affect. Specifically, in one study Baumgardner manipulated confidence by providing participants with bogus feedback about their personality in which they were led to believe that based on their previous responses, the experimenter was uncertain or certain about the assessment of them. Although not empirically tested, the implied assumption in this experiment was that the confidence expressed by the experimenter influenced

participants' self-certainty. As anticipated, self-concept certainty led to positive self-affect as assessed by participants' self-rating. This suggests that the confidence with which self-beliefs are held can influence not only what people think and do but also how they feel.

Also paralleling the literature of attitude strength, the confidence with which people hold their self-related beliefs (e.g., "I'm intelligent") has a number of implications for behavior. In general, to the extent that individuals are certain of their self-beliefs, they are more likely to act in ways that are consistent with them. For example, a person who is certain that he is humorous and lazy is likely to choose situations that allow him to be funny and avoid those that demand his being productive. In research conducted to test this idea, Setterlund and Niedenthal (1993) manipulated self-concept certainty by asking participants to describe three times in which they acted in a way consistent (confidence) or inconsistent (doubt) with traits previously rated as highly self-descriptive. The result was that individuals who were manipulated to feel certain about their self-concept were more likely to use the self to guide decisions in a subsequent task in which they had to choose situations that allowed them to express aspects of their identity.[10]

In another study, Briñol and Petty (2003) found that self-belief confidence can influence self-esteem. As part of a supposed graphology study, participants were required to think about and then write down their best or worst qualities using their dominant or nondominant hand. Writing with the dominant hand was presumed to induce more confidence in the self-beliefs generated compared to the nondominant hand. Then, participants rated the confidence in their self-beliefs and reported their self-esteem. As expected, using the nondominant hand decreased the confidence with which people held the self-beliefs they listed. This occurred despite the fact that the actual quality of the self-beliefs did not vary across the hand conditions. As a consequence of the differential self-belief confidence, the effect of the direction of self-beliefs (best vs. worst qualities) on self-esteem was significantly greater when participants wrote their beliefs with their dominant rather than their nondominant hand. This study demonstrated that inducing doubts about possessing positive qualities tended to undermine self-esteem whereas inducing doubt about possessing negative qualities tended to enhance self-esteem. Furthermore, this study showed that the changes in self-esteem were mediated by changes in the certainty of the self-beliefs listed.

Finally, it is worth noting that although most of the research described in this section deals with confidence as the main metacognitive dimension, other metacognitive aspects occasionally have been explored in relation to self-beliefs. For example, Pelham (1991) found that positive self-beliefs rated as important were associated with more stability than positive self-beliefs considered relatively less important (see also Sedikides, 1995). Although this result shown for *self-belief importance* is similar to those found for self-belief confidence, importance and confidence are two relatively independent forms of metacognition (see discussion in the attitude section).

Consequences of Self-Esteem Confidence

As noted earlier, people can have confidence in their self-related beliefs as well as in their overall evaluation of the self. Similar to the outcomes described in the foregoing section, the confidence with which people hold their self-esteem has been found to have a number of important implications for different domains.

First of all, self-esteem confidence seems to moderate a variety of well-established findings in the self-esteem literature. For example, there is ample evidence that relative to individuals with high self-esteem, those with low self-esteem feel uncomfortable with success (presumably because of its inconsistency with their negative self-evaluation) and that as a consequence further success tends to be avoided. In a pioneering study, Marecek and Mettee (1972) showed that only participants with low self-esteem who also reported relatively high self-esteem certainty avoided success. Another illustration of the moderating role of self-esteem certainty can be found in the literature on self-handicapping. Self-handicapping refers to actions oriented to inhibit (or handicap) one's own performance in order to protect oneself from others' potential attributions that a failure, if it occurred, was due to the lack of ability (e.g., Arkin & Oleson, 1998). In their landmark study, Berglas and Jones (1978) found that individuals who were induced to doubt their abilities (by failing to solve insoluble problems) handicapped their own performance (by choosing a supposedly inhibiting drug in anticipation of a second set of similar problems) more than individuals induced to trust their abilities (by receiving success feedback on previous soluble problems). Extending this notion to the domain of self-esteem confidence, Harris and Snyder (1986) found that participants who were uncertain of their self-esteem were more likely to self-handicap (by low preparation for an upcoming test) than those who reported higher self-esteem certainty.

As another example of the moderating role of self-esteem confidence, consider work on discrepancy reduction. Social psychological literature has clearly documented that people can simultaneously hold incompatible beliefs, attitudes, feelings, and behavioral tendencies regarding oneself and others, and that these internal discrepancies are unpleasant and often result in negative affect and psychologically undesirable outcomes (e.g., Abelson & Rosenberg, 1958; Heider, 1958; Higgins, 1987; Kaplan, 1972; Newcomb, 1968; Norton, 1975; Osgood & Tannenbaum, 1955; Priester & Petty, 1996). A common approach to dealing with discrepancy is enhanced thinking or information processing (e.g., Abelson et al., 1968; Aronson, 1969; Festinger, 1957). By considering additional information, individuals may hope to gain enough information for one or the other side of the discrepancy in order to resolve or minimize the inconsistency, or at least the subjective discomfort that results from the discrepancy (e.g., Briñol, Petty, & Wheeler, 2006; Katz, Wackenhut, & Hass, 1986; Maio et al., 1996). For example, Woike and Baumgardner (1993) found that participants whose global and specific self-esteem were incongruent expressed greater interest in learning more about themselves than those whose self-worth was congruent. Importantly, however, this effect was only evident for participants who reported high confidence in their global and specific self-evaluations (see also Marsh, 1993).

Perhaps the domain of self-consistency is the area in which self-esteem certainty has been studied most extensively. Specifically, research suggests that self-esteem certainty can help to shed light on the classic debate concerning the potentially opposing human motivations for self-verification and self-enhancement. For example, people prefer feedback that is consistent with their own views when they report being certain of those views, but they prefer positive feedback when those views are less confidently held (Pelham, 1991). In line with this finding, as noted earlier, Swann and Ely (1984) found that participants who reported being certain of their traits tended to convince others to see them as they saw themselves. When participants reported being relatively uncertain about their traits, however, others saw them according to their own expectations. Extending this work from perceptions by strangers to perceptions by known others, Pelham and Swann (1994) found that self-views (both self-beliefs and self-esteem) matched other's views more strongly when those self-views were reported to be relatively certain. Taken together, these findings suggest that the need to be consistent operates mostly for aspects of the self-concept that are held with more confidence (see, Wright, 2001, for a review).[11]

In closing this section, it is important to consider not only the consequences of self-concept confidence but also some of its potential antecedents (for an extensive review of antecedents and consequences of self-certainty, see, DeMarree, Petty, & Briñol, in press). Similar to the literature on attitude certainty, theory and common sense suggest that the certainty of people's self-views is likely to be grounded in the *amount* of information they have about themselves as well as the *consistency* of this information. However, as described earlier in this section, self-concept confidence can depend on and be affected by other more transitory variables in the situation, such as the hand with which self views are written (Briñol & Petty, 2003) and the behavior of the experimenter (Setterlund & Niedenthal, 1993). In addition to these factors, and given that certainty in self-views is considered to be socially desirable, it seems possible that self-concept confidence might result from other operating motives related to impression management.[12]

Individual Differences

As just reviewed, people can differ in their self-concepts and self-esteem as well as the confidence with which these constructs are held. There are other differences among individuals in which certainty plays a part. The term "individual differences" refers to how people vary with respect to factors such as personality, motives, and abilities. Importantly, some conceptualizations of individual differences can be understood as metacognitions to the extent that they refer to thoughts people have about their thoughts or thought processes. Consider, for

example, the *need for cognition* (NC; Cacioppo & Petty, 1982), which refers to stable individual differences in the tendency to engage in and enjoy effortful thought. Consistent with the schema outlined in this chapter and an analysis of the NC scale items, people's judgments about their own NC represent an *evaluation* of thinking (e.g., "I find satisfaction in deliberating hard for long hours"). Although the NC scale has focused mostly on enjoyment of thinking (i.e., the evaluative component), NC also is related to the assessment of the *amount* of thinking (e.g., "I usually end up deliberating about issues even when they do not affect me personally"). That is, judging our own NC might imply thinking about how much we tend to think and how much we enjoy thinking. Importantly, in the NC scale, these assessments are not about any particular thoughts (as in most metacognition research) but are about thought processes in general.

People appear to have good insight into their own enjoyment of thinking and tendency to engage in it as the NC scale has proven to be a robust predictor of a wide variety of cognitive activities (see Cacioppo, Petty, Feinstein, & Jarvis, 1996, for a review). Individuals high in NC not only tend to think more about any given attitude object (e.g., Cacioppo, Petty, & Morris, 1983) but also devote more attention to their own thinking. As a result, high NC has been related to metacognitive processes described in this chapter such that individuals high in NC are more likely to evaluate their own thoughts for validity (Briñol & Petty, 2003; Briñol, Petty, & Tormala, 2004; Petty et al., 2002; Tormala et al., 2002), to engage in controlled (Martin, Seta, & Crelia, 1990; see Wegener & Petty, 1997) and automatic (Petty, DeMarree, Briñol, & Horcajo, 2005) bias correction processes, and to draw different metacognitive inferences based on their responses to persuasive messages (e.g., Tormala & Petty, 2004a).

Need for closure (NFC; Webster & Kruglanski, 1994) is another individual difference variable that could be understood as metacognitive in nature. NFC refers to people's desire for a definitive answer on some topic as opposed to confusion and ambiguity. Thus, NFC taps into a person's thoughts about their own thinking with some items explicitly linked to confidence in thinking ("I usually make important decisions quickly and confidently"). If a person high in NFC generates a thought that is assessed as a definitive answer to address the situation, that person should have confidence in that thought and should consider it an appropriate thought. Importantly, NFC represents a stable individual difference as well as a situationally evocable state. As a chronic dimension, the desire for definitive knowledge has been measured with the NFC scale (for properties of the scale, see Webster & Kruglanski, 1994; see also Neuberg, West, Judice, & Thompson, 1997). In general, being high in NFC has been shown to reduce the extent of information processing, to magnify primacy effects, to increase reliance on theory-driven versus data-driven processing, and also to enhance reliance on initial anchors and primes (see Kruglanski & Webster, 1996, for a review).

There are a variety of other individual differences variables that may be relevant for metacognition because they refer to different aspects of mental activity, such as causal uncertainty (Weary & Edwards, 1994), field dependence (Witkin et al., 1954), self-monitoring (Snyder, 1974), uncertainty orientation (Sorrentino & Short, 1986), need to evaluate (Jarvis & Petty, 1996), self-awareness (Carver, & Scheier, 1981), preference for consistency (Cialdini, Trost, & Newsom, 1995), resistance to persuasion (Briñol, Rucker, Tormala, & Petty, 2004), and defensive confidence (Albarracín & Mitchell, 2004). Although these variables deal in one way or another with how people think about their thinking, they do so in a relatively direct way. That is, most of the items contained in the scales consist of direct statements about thinking, rather than second-order thoughts such as the ones described earlier for NC. For example, the self-doubt scale (Oleson, Pohlmann, Yost, Lynch, & Arkin, 2000) measures individual differences in uncertain feelings about one's competence and ability. This scale contains items, such as "More often than not I feel unsure of my abilities." These self-doubt judgments take place at the direct, first level of cognition and are different from, for example, the second-order judgments described in the section on self-concept certainty.

A clear illustration of this distinction between people's self-perceptions and metacognitions can be found in the literature of individual differences relevant to minority groups. For example, social psychologists have developed numerous measures to assess individual differences in attitudes toward many groups considered to be stigmatized in some way (see Briñol & Petty, 2005, for a review). However, there are not only individual differences in evaluations of minority groups (which constitutes a direct judgment) but also individual differences in chronic motivations to control for prejudice toward these groups (which refers to the *evaluation* dimension or appropriateness of the former judgment). Among this second group of measures are the Motivation to Control Prejudiced Reactions scale (Dunton & Fazio, 1997), the Internal and External Motivation to Respond without Prejudice scale (Plant & Devine, 1998), and the Humanitarianism–Egalitarianism and Protestant Ethic Scales (Katz & Hass, 1988). As described in more detail in the next section, these instruments are effective in predicting differences in public and private endorsement of stereotypes as well as motivation to correct one's social judgments for inappropriate content.

BIAS CORRECTION

Our last domain of metacognition relates a number of types of thoughts about thoughts, including assessments of thought content (valence and source of the thought), evaluation, and validity. Although these various metacognitive assessments come into play in bias correction, the essence of correction rests in evaluation of the thought or judgment as relatively good or bad, wanted or unwanted, appropriate or inappropriate. As noted earlier, this evaluation of the thought can be distinguished from identification of the thought as being relatively positive versus negative toward the target. Thus, one can perceive

the thought as good or bad, appropriate or not, regardless of whether the thought itself is a positive or a negative one (e.g., "it is inappropriate to be favorable toward criminals"). Individuals' evaluations of their thoughts and perceptions can have sweeping effects on judgment and behavior. When a thought or perception is viewed as bad, unwanted, or inappropriate, people might try to avoid or to modify the thought or perception. People might also try to limit the effects of that thought or perception on subsequent judgments and behavior.

Thoughts or perceptions can be viewed as unwanted or inappropriate for a variety of reasons. In general, these reasons can be summarized by saying that perceptions are viewed as inappropriate or unwanted when they do not serve the perceiver's current judgment goals (Wegener & Petty, 1997). As noted earlier, in many cases, the judgment goal is likely to be arriving at a "correct" or "accurate" view of the target (Chaiken et al., 1989; Festinger, 1954; Petty & Cacioppo, 1986). Therefore, if a thought or perception is viewed as inaccurate, people are likely to be motivated to improve those thoughts or perceptions by using one of a number of possible strategies for bias correction. Of course, many other goals and motivations are possible. People might want to view themselves as possessing generally positive qualities (see Kunda, 1990) or a specific positive quality such as good health (e.g., Ditto & Lopez, 1992). In contrast, as reviewed earlier, people with negative self-views might be motivated to continue to view themselves negatively (e.g., Swann & Ely, 1984). In some cases, goals are more socially oriented, as when people are motivated to uphold procedural justice for courtroom defendants, even if accuracy is better served by judging the defendant as guilty (e.g., Fleming, Wegener, & Petty, 1999). In research on need for closure, people have been shown to view certain thoughts and ideas as unwanted precisely because they oppose the goal of making a quick decision (e.g., Kruglanski & Webster, 1991).

Corrections can be distinguished from the previously discussed metacognitions by considering the extent to which the issue of bias is salient to individuals (see Wegener & Petty, 2001; Wegener, Petty, Smoak, & Fabrigar, 2004). When bias is not salient, people may seek goal-appropriate perceptions of targets (often valid or correct perceptions). Seeking correctness would bear similarities to the *promotion* orientation described by Higgins (1998b). When seeking correctness, many of the previous types of metacognitions are likely (e.g., how confident am I in my judgment). However, to the extent that potential for bias is salient, people become more oriented toward taking steps to identify and avoid any biases at work (Wegener & Petty, 1997; similar to Higgins's *prevention* orientation).

We discuss three different types of corrections guided by a sense that one's cognition are somehow unwanted or inappropriate. These corrections are attempts at *subtracting* reactions to biasing factors when forming perceptions of targets, attempts to use *theories of bias* in seeking to formulate appropriate (goal-consistent) perceptions of targets, and attempts at *suppressing* or *inhibiting* a particular thought from coming to mind in the first place.

Subtraction of Reactions to Biasing Factors

Much of the research on bias correction from the 1980s and early 1990s focused on *partialing* or *subtraction* of reactions that are viewed as inappropriate because they are inferred to be responses to some irrelevant contextual variable rather than to the target. For example, research on Martin's (1986) set–reset model generally begins with blatant priming of responses consistent with one interpretation of an ambiguous target. Overlap in reactions to the prime and to the target result in *setting*, which is a default misattribution to the target of reactions that were really reactions to the prime (i.e., the context in which the target is judged). That is, the default perception is that reactions are "about the target" (Higgins, 1998a) rather than about the context.[13] Setting is said to produce assimilation to the context, which is consistent with traditional priming effects (e.g., Higgins, Rholes, & Jones, 1977; Srull & Wyer, 1979). For example, Martin and colleagues (1990, study 3) blatantly primed participants with the concept *persistent* or *stubborn* and then gave participants target materials that were ambiguous with regard to whether the target was persistent or stubborn. Consistent with the idea that "setting" to blatant primes requires relatively little thought, perceivers who were low in NC (Cacioppo & Petty, 1982) assimilated judgments of the target to the primed concept.

However, when motivation and ability to think are sufficiently high, the set–reset approach suggests that perceivers *reset* (i.e., partial out reactions to the context). Overlap in valence between reactions to the target and reactions to the context can lead to confusion over which reactions belong to the context and which to the target. Thus, attempts to partial out reactions to the context could result in some reactions to the target being misattributed to the context. When this occurs, resetting not only reduces assimilation to the context but can result in contrast (i.e., judgments of the target that are even less like the context than if the context were not present). Consistent with this idea, perceivers high in NC in the Martin and colleagues (1990, study 3) research contrasted their judgments of the target away from the blatantly primed concepts.

Similarly, the inclusion–exclusion model (Schwarz & Bless, 1992a) treats *inclusion* of information in one's representation of the target as the default mental operation and treats *exclusion* of the information as requiring greater cognitive effort. Inclusion–exclusion studies typically begin with a target that can either be a superordinate category (within which a specific member of the category can be included or excluded) or a subordinate member (or subset) of a category (to which characteristics of the category as a whole can be ascribed or excluded). When the context information is *subordinate* to the target category, including that information in the representation of the category leads to assimilation of the category to the exemplar. For example, thinking of an extreme exemplar, such as a popular athlete, could increase perceivers' positivity toward the athlete's gender or ethnic group (e.g., Bodenhausen, Schwarz, Bless, & Wänke, 1995; Coats & Smith, 1999; Schwarz & Bless,

1992b). Exclusion of the exemplar can reduce the assimilation (if the exemplar is simply subtracted) or can lead to contrast (if oversubtraction occurs, similar to resetting, or if the excluded exemplar serves as a standard of comparison for the category; Schwarz & Bless, 1992a). The standard of comparison could directly influence perceptions of the target (as in judgment theories like adaptation-level theory, Helson, 1964, or social judgment theory, Sherif & Hovland, 1961) or could redefine the meaning of the response scale anchors (as in variable perspective theory, Ostrom & Upshaw, 1968).

If information *superordinate* to the target comes to mind, that superordinate information can lead to assimilation if the target is included in the superordinate category. This inclusion also sets the stage for generation of additional features of the target using the category. Similar to encountering subordinate information, exclusion of superordinate information also leads to a decrease in assimilation or to contrast. This could be because of subtraction of features associated with the category or because of establishment of an extreme standard of comparison.

Like the set–reset approach, inclusion versus exclusion is determined, in part, by whether a particular type of information is regarded as appropriate for inclusion in the representation of the target. Most studied determinants of inclusion versus exclusion directly reflect attention to the role of categorization in context effects. For example, information that is representative of the target category should generally be included, whereas information not representative of the target category should be excluded. Lack of representativeness could be caused by factors such as temporal distance between the context and target (Strack, Schwarz, & Gschneidinger, 1985), lack of feature overlap between context and target (Herr, Sherman, & Fazio, 1983), or receipt of information from separate, potentially inconsistent sources rather than from a single source (Hilton & von Hippel, 1990). Similarly, information is more likely to be included when category width is high (e.g., asking about politicians in general after asking people about three political scandals) but excluded when category width is low (e.g., asking about a particular politician not involved in the previously rated scandals; Schwarz & Bless, 1992b). Finally, when stimuli are presented together, they are more likely to be perceived as a unit, resulting in assimilation, but when stimuli are presented sequentially, they are perceived separately, resulting in contrast (e.g., Seta, Martin, & Capehart, 1979; Wedell, Parducci, & Gieselman, 1987).

Similar to the set–reset approach, Schwarz and Bless (1992a) also noted that exclusion of reactions can occur when participants realize that previously encountered stimuli (e.g., primes) other than the target may have created the reactions (e.g., Lombardi, Higgins, & Bargh, 1987; Strack, Schwarz, Bless, Kübler, & Wänke, 1993). Schwarz and colleagues have also shown that conversational norms can motivate people to deliberately exclude information from target categories. For example, Schwarz, Strack, and Mai (1991) asked participants about their marital satisfaction and about their general life satisfaction. When people reported their life satisfaction af-

ter their marital satisfaction, the correlation between these measures was high, presumably because people included the recently activated information about marital satisfaction when reporting life satisfaction. However, when the questions were described as assessing two areas of life that may be important for overall well-being, the correlation between the items decreased substantially because marital satisfaction information was presumably excluded from ratings of life satisfaction (see also Strack, Martin, & Schwarz, 1988).

Attempts to partial or subtract perceptions include a variety of features that are highly metacognitive. People have to identify the likely sources of thoughts and reactions and have to determine whether those reactions are informative about the target as currently construed. If the thought or reaction is to be subtracted, there likely has to be some cognitive mechanism for setting the thought aside and focusing attention on the included thoughts instead. In the subtraction research conducted thus far, few measurements of such metacognitive mechanisms have been included. For example, one might imagine that in order to set aside a particular reaction, some type of monitoring of that reaction might have to take place. If so, then as in the thought suppression work described shortly (e.g., Wegner, 1994), the thought or reaction that is set aside might actually become rather accessible in memory as the monitoring occurs. Similarly, few studies have measured perceptions of appropriateness or of attributions of reactions to targets versus contexts. Therefore, although many of the manipulations used in this research would seem to suggest that these types of metacognitions are involved, future research could benefit from more direct assessment of them.

Theory-Based Correction

An alternative view on the metacognitive activity of bias correction relies on peoples' perceptions of the bias(es) at work in a given setting.[14] For some time, researchers have noted that people might realize that a bias is at work and might make efforts to overcome that bias (e.g., Higgins et al., 1977; Strack, 1992; Thompson, Fong, & Rosenhan, 1981; Wyer & Budesheim, 1987). Early attention to lay beliefs or theories about biases focused on the fallibility of such perceptions. For example, Wilson and his colleagues have shown that people often believe that factors affect their perceptions even when the factors do not, and people often believe that they can resist influences that they cannot (e.g., Nisbett & Wilson, 1977; Wilson & Brekke, 1994; Wilson, Houston, & Meyers, 1998).

Despite the potential inaccuracy of beliefs about bias, social perceivers may use such perceptions in attempts to avoid bias. The flexible correction model is a theory of bias correction based on social perceivers' use of naive theories of bias (Petty & Wegener, 1993; Wegener & Petty, 1995, 1997). Research guided by this approach has shown that people correct their judgments in different directions when they hold theories of opposite biases (e.g., Wegener & Petty, 1995; Wegener, Petty, & Dunn, 1998), even when those opposite theories of bias are for different people perceiving the same context and target

(Wegener & Petty, 1995). People correct for biases they believe exist, even if there is no real bias (e.g., Wegener & Petty, 1995). This can then create the opposite bias, as when corrections for perceived negativity toward the dislikable source of a persuasive message leads that source to be more persuasive than a likable source (Petty, Wegener, & White, 1998; see also Schul & Goren, 1997).

Corrections for perceived bias also mean that people sometimes correct primarily for one bias (the one most salient or for which clear beliefs exist), even if other biases truly influence perceptions of that same target. For example, Sczesny and Kühnen (2004) showed that people believe that gender can bias judgments of leadership qualifications but do not hold similar beliefs about physical features associated with masculine versus feminine appearance. When encountering mock application materials (including photos), research participants showed different corrections for gender versus physical features. When cognitive load was high (and metacognitive activity was likely curtailed), participants were more likely to employ male than female applicants and people who possessed masculine rather than feminine features. When cognitive load was low, however, research participants overcorrected effects of gender (the bias for which relevant naive theories existed), such that female applicants were viewed more favorably than male applicants. In contrast, the biasing impact of masculine versus feminine features (for which no naive theories existed) remained unchanged.

Research on theory-based correction also illustrates the breadth of domains in which corrections for bias occur. Studies of theory-based correction have been conducted in domains as diverse as affect and judgment (e.g., Berkowitz, Jaffee, Jo, & Troccoli, 2000; DeSteno, Petty, Wegener, & Rucker, 2000), impression formation (Isbell & Wyer, 1999; Stapel, Martin, & Schwarz, 1998), stereotyping (Lepore & Brown, 2002; Strack & Mussweiler, 2001), persuasion (Petty et al., 1998; Schul & Goren, 1997), recognition memory (Förster & Strack, 1998), and courtroom judgment (Thompson et al., 1981; Wegener, Kerr, Fleming, & Petty, 2000).

Consistent with the idea that online metacognition is most likely when motivation and ability to think are high, most studies of theory-based correction that have manipulated or measured motivation or ability to think have shown greater theory-based correction with high levels of thinking (e.g., DeSteno et al., 2000; Sczesny & Kühnen, 2004). There may be important exceptions to this general pattern, however. For example, if certain corrections are performed repeatedly, they may become less effortful (see Wegener & Petty, 1997; cf. Glaser & Banaji, 1999), even automatic. In one study, for instance, Maddux, Barden, Brewer, and Petty (2005) assessed the automatic evaluations that Whites had of Black versus White targets in particular contexts. The White participants varied in their motivation to control racial prejudice as assessed with a scale developed by Dunton and Fazio (1997). People who are high in motivation to control prejudice are presumably highly practiced in controlling any prejudiced reactions they might be feeling.

When people high and low in motivation to control prejudice evaluated Blacks versus Whites in innocuous settings (e.g., church and garden), neither group showed much prejudice replicating prior research (see Barden, Maddux, Petty, & Brewer, 2004; Wittenbrink, Judd, & Park, 2001). However, when the same Black and White targets were evaluated in settings that might suggest anti-Black bias (e.g., jail and dingy factory), those low in motivation to control prejudice showed an anti-Black bias, but those high in motivation to control prejudice showed a significant pro-Black bias, consistent with the idea that they were (over)correcting their judgments. Because the attitude measure tapped automatic evaluative responding (see Fazio, Sanbonmatsu, Powell, & Kardes, 1986), this research is consistent with the idea that highly practiced corrections can be executed automatically in certain contexts.

Some biases might be so salient or obvious that people would adjust their ratings without much additional consideration of the target. This might occur in studies of the sleeper effect in persuasion when a *discounting cue* says that the previous message was false and, in fact, the opposite position has stronger support (e.g., Gruder et al., 1978). Such strong discounting cues are necessary for production of the sleeper effect (see Kumkale & Albarracin, 2004). From a theory-based correction point of view, strong discounting cues might produce a sleeper effect because they alert message recipients to an obvious bias that brings about an initial adjustment of ratings without theory-guided "reprocessing" of the initial information (after all, why go back to pay attention to the false information). If initial processing of the information was high and the message is encountered prior to the discounting cue (two other requirements for the sleeper effect, see Kumkale & Albarracin, 2004; Petty & Cacioppo, 1986), the relatively nonthoughtful correction only temporarily shifts ratings, whereas attitudes based on initial thinking about the information are more likely to persist over time. In other circumstances, however, more thoughtful corrections could lead to persisting "corrected" views (Wegener & Petty, 1997), which would undermine the sleeper effect (see Priester, Wegener, Petty, & Fabrigar, 1999, for additional discussion). Whether corrections are accompanied by considerable or little thought is a fertile area for future research.

There might also be circumstances in which high levels of initial thinking make biases harder to identify and to correct (Petty & Wegener, 1993). For example, high levels of elaboration should lead to a great deal of integration of perceptions with existing knowledge structures (Petty & Cacioppo, 1986). Depending on the type of knowledge available about (or related to) the target, the highly integrated view of the target may seem justified by the existing information. In other words, if the reactions to the target seem to be an accurate reflection of available information, it may be that the people would view their opinions of the target as relatively appropriate and unbiased. Of course, this would undermine any need to correct the perception of the target (see Wegener, Clark, & Petty, 2006; see also Schul & Burnstein, 1985). High

levels of integration could also spread the bias across many disparate perceptions, which might also make identification of bias and correction more difficult.

Although significant research supports the possibility of corrections based on peoples' perceptions of bias, much work remains to be done. Future research will likely address more directly the metacognitive mechanisms at work when people spontaneously identify potential biases. It could be that people use accessible or salient theories to guide searches for potential bias, but there could be a variety of additional cues to bias such as a mismatch between past and present perceptions of the target, matches between the valence of a salient situational factor and the current perceptions, or others (see Wegener et al., 2001, for additional discussion).

Thought Suppression

On some level, if it were possible, keeping biased thoughts from coming to mind at all would be the ideal way to avoid bias. Yet, research on thought suppression attempts have suggested limited utility in this strategy. For example, Wegner and his colleagues have found that many types of thoughts become hyperaccessible after initial attempts to suppress them (e.g., Wegner, 1994; Wegner & Erber, 1992). In one study, Macrae, Bodenhausen, Milne, and Jetten (1994) asked participants to write a paragraph about a day in the life of a skinhead either with or without instructions to avoid stereotypical thoughts about the target. Later, a lexical decision task showed that the stereotype of skinheads was more accessible (i.e., people were faster to recognize stereotype consistent words as words) when the initial essay had been written while attempting to suppress stereotypical thoughts. According to Wegner and colleagues, this ironic hyperaccessibility of the suppressed content comes from a monitoring process that scans conscious thought for the presence of the unwanted material. As this process checks for the to-be-suppressed material, it repeatedly activates the concept in memory.

Consistent with online metacognitive activity being more likely when motivation and ability to think are high, attempting to suppress thoughts is an attention-consuming activity (Macrae, Bodenhausen, Milne, & Wheeler, 1996), and ability to suppress is undermined with time pressure (e.g., Wegner, Erber, & Bowman, 1993, described in Wegner, 1994). Thought suppression may become easier and more effective in avoiding rebound with practice (Kelly & Kahn, 1994; Monteith, Sherman, & Devine, 1998; cf. Smith, 1994; Wegner, 1994). Some reasons for this may include that people who practice suppressing particular thoughts might also have more replacement thoughts (i.e., thoughts that distract one from the to-be-suppressed concept) at the ready (e.g., Monteith et al., 1998; Wegner, Schneider, Carter, & White, 1987) and more practiced individuals may become less likely to have the unwanted thoughts come to mind in the first place (e.g., Fazio, Jackson, Dunton, & Williams, 1995; Lepore & Brown, 1997).

Although there is sufficient evidence that attempts to suppress thoughts can make the thoughts more accessible at a later point in time, it is important to note that many studies of thought suppression allow for other types of correction in addition to or instead of suppression per se. For example, Wyer, Sherman, and Stroessner (2000) showed that suppression of stereotypes toward African Americans resulted in application of primed stereotype-consistent concepts to a race-unspecified target but not to an African American target. Moreover, this restriction in use of primed stereotype-consistent material for a race-identified target only occurred when people had sufficient cognitive capacity to engage in the metacognitive work of correction. Although it is possible that people resuppressed the primed concepts when encountering the African American target, it seems more likely that research participants were using one of the other corrective mechanisms to limit the impact of the primed concepts on judgments of the target. For example, Dunton and Fazio (1997) noted that motivation to control prejudice might create overcorrections for automatically activated negative reactions through the types of theory-based correction proposed in the flexible correction model (Petty & Wegener, 1993; Wegener & Petty, 1997; see also Maddux et al., 2005). When the race of the target was unspecified in the Wyer and colleagues research, perceivers might not have realized that their perceptions of the target could be biased by the activated reactions, thereby opening the door to the bias (see Monteith et al., 1998; Sczesny & Kühnen, 2004; Strack & Hannover, 1996; Wegener & Petty, 1997).

In addition to suppression of thoughts per se, one could also talk about suppression of judgments or behaviors. That is, rather than focusing on keeping a thought from coming to mind, people might focus on making sure a thought does not become an action (cf. Monteith et al., 1998). In the *social judgability* approach, Yzerbyt and his colleagues (1994) have pointed out that people might withhold judgments when they do not feel justified in making a judgment. This might often occur when people perceive the amount of information about the target to be insufficient for forming an accurate view of the target (e.g., Darley & Gross, 1983; Yzerbyt, Leyens, & Corneille, 1998). Interestingly, this caution in judgment can be overcome by people believing they have received individuating information about the target even if they really did not (Yzerbyt et al., 1994). Therefore, the perception of having received sufficient information can lead to greater willingness to use stereotypes in formulating judgments. The willingness to make stereotype-consistent judgments is likely due, in part, to perceiving the judgment as more appropriate or less biased when based on an information base that seems sufficient. The social judgeability research also provides a potential bridge between thought evaluation and perceptions of confidence/validity. As noted earlier, perceived lack of accuracy can lead to perceptions of thoughts or reactions as unwanted or inappropriate. In the Yzerbyt and colleagues research, people express greater confidence in their judgments when they believe they have received in-

dividuating information. That is, when people lack confidence in the validity of their reactions, they are unwilling to use those reactions for judgments, but when people possess greater confidence, they are willing to use those reactions.

Even when people prefer not to be prejudiced toward a target, inability to inhibit the use of stereotype-related information can influence the likelihood of making judgments biased by the target's group membership. For example, elderly perceivers, who have trouble inhibiting a variety of types of thoughts about available information (Hasher & Zacks, 1988), also are more likely to provide stereotypical judgments, even if they are instructed to avoid race-related information and even when older perceivers profess greater motivation to avoid prejudiced responding (von Hippel, Silver, & Lynch, 2000).

Comparison of Strategies

To date, there is precious little research directly comparing subtraction, suppression, and theory-based corrections. In an initial attempt, Strack and Mussweiler (2001) compared *recomputation* of judgments (i.e., setting aside of biased information and formulation of perceptions based on remaining information; Strack & Hannover, 1996; Strack & Mussweiler, 2001; cf. Schwarz & Clore, 1983) with *adjustment* of responses (generally consistent with theory-based corrections or subtraction). Strack and Mussweiler designed studies so that recomputation would lead to more stereotypical judgments (because available information was highly stereotype consistent), but adjustment would lead judgments to be less stereotypical. When participants received a brief resume about a hypothetical job applicant, an instruction asking people not to be influenced by gender led to less stereotypical ratings of the applicant. This could have been due to theory-based correction or to subtraction effects. However, when a large number of stereotype-consistent behavioral episodes were presented about the target, the same correction instruction led to an increase in stereotypical ratings (consistent with recomputation). In a follow-up study, Strack and Mussweiler provided participants with the large number of behavioral episodes but varied whether perceivers were given a goal of forming an accurate judgment or of being fair and not using gender to make judgments. Similar to the earlier study, the accuracy goal led to judgments that were consistent with the presented information. However, the fairness goal led to judgments that were less consistent with gender stereotypes.

In two studies, Dove, Wegener, and Petty (2001, 2003) used a similar design but made the same amount of information either available or unavailable just prior to judgment. When the information was available, judgments were consistent with recomputation. However, when information was unavailable, judgments were consistent with theory-based corrections. It is possible that recomputation is more likely when perceivers form their opinions in an online rather than memory-based fashion (Hastie & Park, 1986). Yet, there might also be a variety of settings in which memory-based recomputation is feasible. When participants received a conditional correction instruction (i.e., they were asked to correct if they perceived anything as biasing them; see Stapel et al., 1998), both the recomputation and theory-based correction patterns were more pronounced for people high in NC (Cacioppo & Petty, 1982).

How to interpret such effects remains a matter for discussion. Strack and Mussweiler (2001) interpreted their results as signifying a preference for recomputation when both options were open to social perceivers. However, some type of adjustment might happen more often, with recomputation limited to situations in which social perceivers see recomputation as feasible and reliable (Dove et al., 2001, 2003). At any rate, comparisons among the correction processes are just beginning. There are likely to be a host of moderators of such outcomes. For example, it seems unlikely that accuracy-based instructions would always result in recomputation when information is available about the target. This should depend on factors such as the accessibility and salience of the theory of bias as well as the salience of the biasing agent itself (Wegener et al., 2001). Undoubtedly, future work will include additional comparisons of the correction processes, including studies of moderators of when each process dominates.

BASIC PRINCIPLES AND NEW DIRECTIONS

In this chapter, we described social psychology's major research findings on metacognition. Consistent with most prior literature (e.g., Jost et al., 1998), we defined metacognition as second-order thoughts, or thoughts about our primary thoughts or thought processes. That indeed constitutes a basic principle in human cognition:

- *Principle 1: There is primary and secondary cognition. Primary thoughts are those that occur at the direct level of cognition, involving initial associations. Following a primary thought, people can also generate other thoughts that occur at a second level which involve reflections on the first-level thoughts or the process that generated these thoughts.* Perhaps the most important conclusion of the work we reviewed is that in general, second-order cognition has an impact on first-order cognition. This is summarized in principle 2.

- *Principle 2: Second-order cognition can magnify, attenuate, or even reverse first-order cognition.* When increasing confidence in an attitude causes it to exert a larger impact on behavior than it did previously, metacognitive factors are exerting a magnifying effect on one's attitudes (see Fazio & Zanna, 1978). When people shaking their heads while listening to a message rely on their thoughts less than they would have if they had not been shaking, metacognitive factors are exerting an attenuating factor on one's thoughts (see Briñol & Petty, 2003). When people want to control for their perceived biases and then show an opposite bias, metacogitive processes are reversing the effects of first-order cognition (see Petty et al., 1998; Wegner, 1994).

In reviewing the relevant literature, we argued that the same categories that have proven effective for classifying primary thoughts could also be used to categorize metacognitive thoughts. This is summarized in principle 3.

• *Principle 3: Second-order thoughts can be coded into the same categories that have already proven effective for classifying primary thoughts, such as target, evaluation, number, and confidence.* By grouping the many specific metacognitions into meaningful categories, we aimed to provide a useful guide to organize and facilitate access to key findings across diverse literatures in social psychology.

The main areas of social psychological research in which metacognition has been examined most extensively are (1) memory and cognitive fluency, (2) attitudes and persuasion, (3) the self and individual differences, and (4) bias and correction processes. Although different categories of metacognition were examined in these different areas, it is clear that across areas, the most studied dimension has been the confidence one has in one's thoughts and judgments. As reviewed, confidence has proven to be relatively independent of accuracy and has been shown to be affected by a wide variety of situational and individual variables.

One area that has not been explored much in prior research concerns the various bases of confidence. For example, in one study Haugtvedt and Petty (1992) found that although both high and low NC individuals changed their attitudes in response to a message from a high credible source and developed equivalent levels of confidence in these attitudes, the confidence stemmed from different sources. In particular, for those high in NC, confidence increased as the number of message arguments they could recall increased. For those low in NC, however, confidence was tied to the perceived credibility of the source. Though speculative at the moment, it seems quite plausible to argue that different bases of confidence might lead to different outcomes (see also Gross et al., 1995). For example, it could be that some bases of confidence are more likely to be consequential than others.

In addition to examining the content underlying confidence, it would also be important to examine the processes leading to confidence judgments. For example, just as primary judgments can be based on much or little thought (Kruglanski & Thompson, 1999; Petty & Cacioppo, 1986), so too can second-order cognition. That is, people's judgments of confidence can be based on a careful consideration of the reasons why they should be confident, or they can result from a simple inference based on shaking one's head. To the extent that second-order cognition follows the same principles as primary cognition, one would expect thoughtful confidence to be more long lasting and consequential than confidence that stems from simple cues and inferences.

Finally, it would be worth studying whether metacognitive judgments are formed online or are retrieved from memory (Hastie & Park, 1986). Just as primary judg-

ments can operate in either way, so too do we propose that this holds for metacognitive judgments. To date, there is no research conclusively demonstrating that metacognitive tags (e.g., certainty and importance) have any structural basis in memory, though some research is certainly consistent with this possibility. These considerations lead us to our first speculative postulate that is worthy of research attention.

• *Principle 4: The content and process bases of metacognitive judgments are likely to be as consequential as are the bases of primary cognition.* In addition to examining confidence (and other metacognitive constructs) based on different content and process considerations, a potential avenue for future research would be to assess various metacognitive properties with implicit measures. This raises the possibility that just as some researchers have argued that primary cognition can be held at explicit and implicit levels, so too might this be the case with secondary cognition. That is, a person might have high confidence in some judgment at the explicit level but low confidence at the implicit level. Furthermore, this implicit uncertainty could potentially guide thinking and behavior (e.g., Briñol, Petty, & Wheeler, 2006). As described earlier in this chapter, for example, when attitudes are changed, people may sometimes have high confidence in their new attitudes at the explicit level but low confidence at the implicit level due to the conflict with the old attitude (Petty et al., 2006). This leads to our second speculative principle.

• *Principle 5: Although explicit metacognitive activity is generally more likely to take place when people have the motivation and ability to attend to and interpret their own cognitive experiences, metacognition might also operate outside awareness with important consequences for social judgment and behavior.* Indeed, the possibility of assessing mental constructs at the implicit level might open the door for a new generation of research relevant to metacognition. For instance, a common characteristic of most of the research covered in our review is that metacognitive activity is more likely to take place when people have the motivation and ability to attend to and interpret their own cognitive experience. Research on bias correction has shown, for example, that in order to correct for mental biases, people need to identify the likely source of their thoughts, determine whether those reactions are informative, and spend time and attention trying to modify, suppress, substitute, and/or correct those thoughts (Petty & Wegener, 1993; Wilson & Brekke, 1994). In contrast to all these mental activities that require extensive cognitive effort, recent research has shown that correction processes can also occur automatically if the correction is a highly practiced one (Maddux et al., 2005). Future research should explore what variables moderate the relationship between explicit and implicit metacognition. In sum, although most of the research covered in this chapter has focused on the power of explicit metacognition to modify the impact of explicit primary cognition, both primary and secondary thoughts may also operate outside awareness with important consequences for social judgment and behavior.

NOTES

1. People's primary thoughts can also be classified into other dimensions such as fluency (e.g., how accessible the thought is) or time (e.g., how recent the thought is; see also Cornoldi & Vianello 1992), but these dimensions are used infrequently in coding thoughts.

2. With respect to these dimensions, it is possible for objective judges to try to infer the person's perception, but this has not been attempted in research to date.

3. The positive effect of mere exposure is most likely when conditions favor minimal processing of the repeated stimuli (Bornstein, 1989). As stimulus processing increases, it becomes more likely that only positive items will enhance in favorability whereas negative items will decrease. When tedium or boredom sets in with excessive exposure, even positive items can be rated more negatively (Cacioppo & Petty, 1979).

4. Boninger et al. (1995) argue that this is to avoid confusion on the part of research participants (see also Abelson, 1988), and because measures of attitude importance and issue importance are highly correlated. Yet, in some individual studies, researchers have asked about attitude importance per se (e.g., "how important is your attitude toward the issue of doctor assisted suicide to you personally"; Haddock et al., 1999).

5. For example, one might imagine that with respect to objective ambivalence, one could get very different ambivalence scores if one asked: What are the good and bad things about same-sex marriage (the attitude object) versus What are the good things (bad things) about being very favorable toward (or being very opposed to) same-sex marriage?

6. In a somewhat similar vein, when people refuse to engage in an attitude consistent behavior for a high incentive, they become even more extreme in the direction of their initial opinions than when they refuse for a lower incentive. Presumably, people reason that if they did not go along and were given a high incentive to do so, their original attitude must really be valid. Increasing attitude extremity is one way to assert the validity of the attitude (Darley & Cooper, 1972). If attitudes did not become more extreme as a result of the manipulation, it would be reasonable to expect that confidence in the original attitude would have increased via similar attributional reasoning.

7. Of course, if people counterargue their own position rather than an external message, they can lose confidence in their attitude; Koriat et al., 1980).

8. The MCM is compatible with a "dual-attitudes" approach (i.e., the proposition that a person can hold conflicting implicit and explicit attitudes) in many respects. It diverges in part because the dual-attitudes approach emphasizes that each attitude operates in different situations and has ignored the possibility of joint activation (e.g., see Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Wilson, Lindsey, & Schooler, 2000).

9. Although directly asking people to rate their certainty has been the most used procedure to assess confidence, other, more indirect techniques sometimes have been used such as the intraindividual standard deviation of self-esteem scores (see, e.g., Wright, 2001, for a review). Alternatively, these indirect measures can be considered *consequences* of self-certainty.

10. Although the manipulation in this study was intended to influence certainty, it might have just primed consistency or inconsistency, thus accounting for the results. Because a manipulation check for confidence was not provided, the issue remains unclear.

11. Because most of the studies conducted in this domain have been correlational, the presumed directionality of some of the effects remains unclear. For example, consider the studies in which self-certainty was described as leading to different forms of self-consistency, such as asking for confirmatory feedback (e.g., Pelham, 1991; Pelham & Swann, 1994). It would be plausible to argue the opposite directionality. That is, self-belief confidence might be the product, rather than the precursor, of interpersonal congruence. This argument can also be applied to the relationship between self-esteem certainty and other concepts, such as self-esteem stability and self-esteem clarity. Future research would benefit from designs in which confidence is manipulated rather than measured (e.g., Briñol & Petty, 2003).

12. To the extent that certainty in self-views is considered to be socially desirable, those with higher impression management concerns should be more likely to report greater certainty in their self-conceptions. Also, because individuals with higher self-esteem are more likely to present themselves in a positive way than are those with lower self-esteem (e.g., Baumeister, Tice, & Hutton, 1989), it may be the case that esteem differences in confidence reflect differing impression management concerns (e.g., Wright, 2001, see also Baumgardner, 1990; Story, 2004). Indeed, some other consequences of self-concept certainty described in this chapter (e.g., stability, resistance, and prediction of behavior) might also be partially due to impression management. Furthermore, people may report feeling confident in a given self-view in order to compensate for other unrelated internal doubts (e.g., McGregor, 2003; Rhodewalt & Morf, 1995).

13. Attributing reactions to the target or the context is quite similar to source monitoring in research on memory, wherein perceivers attempt to determine the cause of recollective experiences such as familiarity of a target (see Mitchell & Johnson, 2000).

14. For comparisons of theory-based correction with the "partialing" approaches, see Strack (1992), Wegener and Petty (1997), and Wegener, Dunn, and Tokusato (2001).

CHAPTER 12

Principles of Mental Representation

ROBERT S. WYER, JR.

Judgments and decisions are rarely made in a cognitive vacuum. They are influenced not only by the information we receive in the immediate situation at hand but also by knowledge we have acquired in the past. However, people rarely use all the knowledge they have acquired that is potentially relevant to a judgment they wish to make. Rather, they apply only a subset of this knowledge that comes to mind most quickly and easily (cf. Chaiken, Liberman, & Eagly, 1989; Simon, 1957; Taylor & Fiske, 1978). Many factors can influence the accessibility of concepts and knowledge in memory (for a review, see Higgins, 1996a). A major determinant, of accessibility, however, is the manner in which judgment-relevant knowledge is organized in memory and the associations that have been formed between its features and those of the object being judged.

This chapter reviews the general principles that govern the construction and use of mental representations. Carlston and Smith (1996) described many such principles in the first edition of this book (see also Smith, 1998; Wyer & Carlston, 1994; Wyer & Srull, 1989). This chapter is distinguished from earlier ones in its emphasis on the representation of knowledge of the sort we acquire through experiences outside the laboratory. In particular, it focuses on the representation of familiar activities of the sort we experience as a normal part of daily life, and on the implicit theories we derive from these experiences. I also consider the representation of larger bodies of propositional knowledge that people acquire about the world in general. Before entering into this discussion, however, it is necessary to consider whether a conceptualization of mental representations is at all important in accounting for social psychological phenomena. Is this particular cognitive trip really necessary?

GENERAL CONSIDERATIONS

Theories of mental representation are inherently metaphorical. They must consequently be evaluated on the basis of their utility and not their validity in describing the physiology of the brain. Moreover, it is often difficult to distinguish empirically between the effects of representational processes that occur at the time knowledge is acquired and the effects of retrieval processes that occur at the time it is used. John Anderson (1978) noted that for every theoretical account of memory phenomena in terms of different memory representations and a single retrieval process, a mathematically equivalent account can usually be constructed in terms of a single memory representation and different retrieval processes. Nevertheless, it is difficult to account for many social phenomena without recourse to assumptions about representational processes. For one thing, there is often little correlation between the judgments of an object and the content and implications of information about the object that one can recall (Dreben, Fiske, & Hastie, 1979; Greenwald, 1968; Lichtenstein & Srull, 1987). In some instances, the relation may even be negative (Dreben et al., 1979; Lichtenstein & Srull, 1987). Finally, the type of information recalled is highly contingent upon recipients' goals at the time they receive the information, inde-

pendently of their goals at the time of retrieval (Hamilton, Katz, & Leirer, 1980; Srull, 1981).

The problem noted by Anderson (1978) would be less serious if there were widespread agreement concerning the nature of retrieval processes. In fact, however, several alternative theories of retrieval have been proposed. To provide a framework for discussing the principles that govern the construction and use of mental representations, it is useful to outline briefly the theoretical formulations that have been used to describe memory organization and retrieval and the type of knowledge to which these formulations are normally applied.

THEORIES OF MEMORY RETRIEVAL

Associative Models of Memory

Two classes of theories assume that cognitive elements are organized in memory in the form of an associative network. These elements, which can be either single concepts or more complex bodies of knowledge are represented by nodes, and their associations are represented by pathways connecting them. The identification of the individual elements contained in these representations could proceed either in parallel or sequentially.

Parallel Processes

Parallel search processes are commonly exemplified by spreading activation models of memory (cf. Collins & Loftus, 1975; Higgins, Bargh, & Lombardi, 1985; Wyer & Carlston, 1979). According to these models, the activation of a particular node in the representation (presumably as a result of thinking about the cognitive element to which it refers) elicits excitation that spreads along the pathways connecting it to other nodes. The excitation accumulates at the peripheral nodes, and when the excitation at a node reaches a particular threshold, the element located at the node also becomes activated (thought about). Excitation then spreads from this node to others, and so on. Pathways that reflect stronger associations are assumed to be shorter or easier to traverse. Consequently, elements that are strongly associated with the element one happens to be thinking about are likely to be identified first.

Once an element is deactivated (no longer thought about), the excitation at the node corresponding to it gradually dissipates. However, as long as some residual excitation exists, the element can be more easily reactivated by new excitation that impinges on it from other sources. These and other assumptions permit this model to account for numerous phenomena, including the effects of frequency and recency of thinking about a concept or knowledge unit on its accessibility in memory and, therefore, on the likelihood of identifying and using it in a new situation to which it is potentially applicable (Higgins, 1996a; Higgins et al., 1985; Srull & Wyer, 1979; but see Liberman & Förster, 2000, for a qualification on the effects of actually using a concept on its subsequent accessibility).

Sequential Search Processes

Other conceptualizations of memory retrieval (cf. Anderson & Bower, 1973; Hastie & Kumar, 1979; Srull & Wyer, 1989) assume that search proceeds successively. That is, a search that begins at one node proceeds to a second node along the pathway that connects them, from this node to a third that is connected to the second, and so on. When two or more paths are connected to a given node, the path that reflects the strongest association is selected. If a "dead end" is reached (i.e., an element is identified to which no new paths are connected), the search is reinitiated. Each time a path is traversed, the association between the two elements it connects becomes stronger, and so the likelihood that it is traversed again is increased.

These two versions of an associative network are typically applied to different types of phenomena. The parallel-processing version is particularly useful in conceptualizing the spontaneous activation of knowledge that occurs in the absence of any particular goal that requires it. The sequential-processing version more easily characterizes a deliberate, goal-directed search of memory in pursuit of a specified objective

The cognitive elements that compose an associative network model include single noun and attribute concepts (e.g., Collins & Loftus, 1975) or configurations of features that are stored in memory as a whole (Bower, 1981; Wyer & Carlston, 1979). In one conceptualization of social memory (Carlston, 1994), entire systems of concepts (cognitive, behavioral, visual, affective, etc.) are assumed to be interconnected by associative pathways.

Retrieval Cue Models

A second class of memory models makes few assumptions about the organization of information in memory. These models assume that when information is required for a particular purpose, a set of features is compiled that are relevant to this objective and these features serve as retrieval cues for concepts and knowledge that contain them. The cognitive mechanisms that characterize these retrieval processes, and the knowledge representations to which they are applied, can vary.

Resonance Models

Ratcliff (1978) conceptualized memory search in terms of a tuning-fork metaphor. That is, activating a set of retrieval cues causes these cues to "vibrate" and other units of knowledge that contain these cues then resonate with it. The degree of resonance increases with the similarity of the retrieval cues to those contained in the representation. Therefore, knowledge units whose features are more similar to those of the probe set are activated more quickly. However, the conceptualization makes no specific assumptions about the organization of these knowledge units in memory, each of which is stored independently of one another. (For recent applications of the conceptualization in theories of social memory and judgment, see Luna, 2005; Wyer, 2004.)

Exemplar (Independent-Trace) Models

Hintzman (1986) assumed that each stimulus configuration one encounters leaves its own memory trace that is stored independently of others. When information is sought for a particular purpose, a set of retrieval cues relevant to this objective is compiled, and all memory representations that contain these features are simultaneously activated. This aggregation is experienced as a composite array in which features that are common to the greatest number of representations are weighted most heavily. A new, more abstract representation may sometimes be formed on the basis of these common features, and this representation can then itself be stored in memory. Thus, the knowledge units that are stored in memory can refer not only to specific experiences but also to abstract configurations that result from the cognitive operations that are performed on them.

Distributed Memory Models

Most memory models assume that long-term memory has infinite capacity. Thus, differences in the retrieval of information reflect differences in its accessibility and not its availability. The spontaneous recall of a childhood experience that one has not thought of for nearly 50 years testifies to the apparently validity of the assumption that nothing is ever really forgotten. Nevertheless, the assumption that each experience has its own memory trace seems intuitively implausible. One set of conceptualizations that avoids this assumption is exemplified by parallel distributed processing, or connectionist theories of memory (Humphreys & Kashima, 2002; Smith & deCoster, 1998, 1999). These conceptualizations assume that units of knowledge are not stored in specific memory locations but rather as an array of values along a finite number of discrete dimensions. Suppose for simplicity that 10 dimensions can each take on 10 different values. Then, a total of 10^{10} different patterns can potentially be distinguished. A given experience with values along these dimensions might be represented by a unique combination of these values. To this extent, an enormous amount of information can potentially be stored in a small amount of memory space. A new stimulus may activate an array of these values along with values along other dimensions that have been associated with this array in the past, leading the stimulus to be "recognized" and other associated features to be spontaneously inferred. Although this conceptualization is based on quite different assumptions, many of its implications are similar to those of the independent-trace model proposed by Hintzman (1986).

Retrieval from "Very-Long-Term" Memory

A conceptualization of memory search by Norman and Bobrow (1979) is particularly useful in conceptualizing many memory phenomena that occur outside the laboratory. Suppose a person wishes to recall the names of his high school classmates. To do this, the person might first compile a general descriptor (e.g., "high school") that serves as a retrieval cue for representations in memory that contain its features. These representations may contain the names of some classmates but not all of them. Therefore, a new descriptor might be compiled ("football team," "rock band," "graduation dance," etc.) and the representations retrieved by this descriptor may contain additional names. Descriptors can be at different levels of specificity (e.g., "rock band" or "playing a gig at Mary's New Year's Eve party"). The set of representations that is identified by a general descriptor does not necessarily include those that are identified by a more specific one (Wyer & Srull, 1989).

This conceptualization can easily account for memory phenomena that other conceptualizations find difficult. For instance, it can explain how a chance juxtaposition of cues that have not recently been thought about in combination (e.g., "Mary" and "New Year's Eve parties") can spontaneously stimulate the recall of an experience (Mary's New Year's Eve party) that had not been thought about in years. On the other hand, it can also account for tip-of-the-tongue phenomena (for an elaboration, see Wyer & Srull, 1989).

Reconstructive Memory Models

People do not encode into memory all the features of an experience at the time they encounter it. When they are later asked to recall the experience, therefore, they might often need to fill in gaps by inferring elements that were not contained in the memory representation they formed at the time the experience occurred. This could be done on the basis of other experiences they had in similar situations. Thus, a person who remembers eating a Big Mac during a particular visit to McDonald's might infer that he paid the bill, based on previously acquired knowledge that this event is a normal occurrence in the type of situation at hand. The mental representations that result from these reconstructive processes are presumably stored in memory and can later be retrieved and used as bases for describing the experience at a later point in time. In this case, features that have been added in the course of reconstructing the experience may function in much the same way as the features that had originally been stored.

Hybrid Models

A model suggested by Wyer and Srull (1989) combines features of both a network model and a retrieval cue conceptualization. According to this model, long-term memory comprises a set of "referent bins," each containing knowledge pertaining to a particular referent. Each bin is designated by a header, or set of features, that is strongly associated with the referent and serves to circumscribe its contents. The units of knowledge within a bin can theoretically be of many types and can be coded in difference sense modalities. Thus, they can include visual representations of the referent, trait descriptions or trait–behavior configurations, sequences of observed events, or more general characterizations of the referent

in certain circumscribed types of situations. These knowledge units are theoretically stored in a given bin independently of one another, in the order in which they are constructed.

If information about a referent is necessary for a particular purpose, a set of retrieval cues is compiled that is relevant to this objective and a bin is identified whose header contains these cues. A probabilistic top-down search is then performed for a particular knowledge unit that can be used to attain the objective, and a copy of the representation is retrieved and placed in working memory. After it has been used, this copy (along with any new referent-related new representation that is formed) is returned to the top of the bin from which it was drawn.

Thus, the identification of a goal-relevant body of knowledge is a function of processes similar to those assumed by a retrieval cue model. However, the identification of a specific knowledge unit within this domain can depend on fortuitous past experiences that have led the unit to be represented frequently and, therefore, to be located near the top of the bin. Finally, the search of features *within* a given knowledge unit depends on the nature of the knowledge unit itself but is often assumed to occur in the manner implied by a sequential search, associative network model.

The bin metaphor is useful in conceptualizing many of the phenomena of concern in social psychological research. At the same time, it has difficulty in accounting for the spontaneous comprehension of information about familiar people and events of the sort one encounters outside the laboratory (cf. Wyer, 2004; Wyer & Radvansky, 1999). Its primary advantage may be its eclecticism regarding the different types of mental representations that are formed of social information. In the next section, we first summarize briefly the general types of knowledge representations that are likely to exist in memory, focusing in particular on those that are constructed outside the laboratory. After doing so, we propose a number of principles that govern their formation and use.

TYPES OF MENTAL REPRESENTATION

The types of mental representations that exist in memory reflect the types of knowledge one acquires. Perhaps the most fundamental distinction to be made is between *declarative* knowledge and *procedural* knowledge. Declarative knowledge concerns the referents of everyday life experiences (persons, objects, events, social issues, and relations among these entities). Procedural knowledge refers to the sequence of actions that one performs in pursuit of a particular objective (driving a car, using a word processor, making an inference on the basis of a set of relevant facts, etc.). The two types of knowledge are interrelated. For one thing, declarative knowledge can provide the material on which procedural knowledge operates. Moreover, procedures (e.g., the steps involved in changing a flat tire or obtaining a meal at a restaurant) can be stored as part of declarative knowledge and con-

sulted in deciding how to attain the goal to which they pertain.

On the other hand, this consultation is often not performed. John Anderson (1982, 1983; see also Smith, 1984, 1990, 1994) conceptualizes procedural knowledge as a set of cognitive "productions" in the form of "if [X], then [Y]" rules, where [X] is a configuration of perceptual or cognitive features and [Y] is a sequence of cognitive or motor acts that are elicited automatically when the precondition [X] is met. These productions, which are acquired through learning, may be performed with little conscious cognitive mediation.

A large proportion of social behavior is unquestionably mediated by cognitive productions similar to those that Anderson postulates. As Smith (1990) points out, many phenomena that have typically been attributed to declarative knowledge processing could be governed by procedural knowledge instead. Bargh's (1997) groundbreaking demonstrations of situational influences on overt behavior that occur in the absence of conscious cognitive activity may also be manifestations of the role of procedural knowledge.

Be that as it may, the bulk of research and theory in social psychology has focused on declarative knowledge representations. The work reviewed in this chapter reflects this focus. The representations that have been postulated to exist can vary along many dimensions. They can be specific to a particular instance or can pertain to people and events in general. They can be coded verbally, visually (cf. Kosslyn, 1980; Shepard & Metzler, 1971), or in other sense modalities. They may be based on personal experience or on verbal descriptions of another's experience. Finally, their features may either be temporally or spatially constrained, as in a human face or a series of causally related events, or have no particular relationship except for their common association with their referent. In the latter regard, Mandler (1979, 1984) distinguishes between *categorical* representations, whose features have no a priori relatedness, and *schematic* representations, whose features are organized according to specifiable spatial, causal, or temporal rules. Further distinctions have been made between episodic and semantic knowledge representations (Tulving, 1983), between exemplars and prototypes (Colcombe & Wyer, 2002; but see Barsalou, 1990), and between situation models and generalized representations (Wyer, 2004). The latter distinction is of particular utility in the present context.

Situation Models

Johnson-Laird (1983, 1989; see also Kintsch, 1998) postulates that people construct mental simulations, or models, of the world in which they live. These mental models can pertain to places (e.g., the configuration of rooms in one's house or the United States) or procedures (e.g., how to change a tire). A specific type of mental simulation, proposed by Radvansky and Zacks (1991; see also Zwaan & Radvansky, 1998), is a *situation model*, which pertains to one or more events or states of affairs that are situationally and temporarily constrained (i.e., that occur

in a specifiable, although not necessarily specified, time and place). For example, the representations of "the book is on the table" and "a boy kicked the football" might constitute situation models of conditions that exist at a particular time and place. In contrast, "the boy owns the football" and "the book is boring" do not. Wyer and Radvansky (1999; Wyer, 2004) expanded the construct of a situation model to include *episode models*, or entire sequences of temporally ordered events that are thematically related.

Many features of a situation model are often coded nonverbally, in a mental image that conveys their spatial and temporal relations. Thus, the mental simulation of "the boy kicked the football" requires a mental image of a boy engaged in this activity. If the event is directly experienced or observed, the model of it is likely to be coded in a form that resembles the way it was experienced. Correspondingly, if the event is described orally or in writing, it may be coded metalinguistically. In this case, however, a mental image may be formed spontaneously as well (cf. Wyer & Radvansky, 1999).[1]

The role of situation models has been examined in research on not only language comprehension (Kintsch, 1998; Zwaan & Radvansky, 1998) but also spatial memory (Taylor & Tversky, 1992) and observational learning (Magliano, Dijkstra, & Zwaan, 1996). The construct of an episode model is of particular utility in conceptualizing the mental representation of everyday life experiences or, for that matter, descriptions of others' experiences that one hears or reads about (see, e.g., Wyer, 2004). In this regard, Schank and Abelson (1995) assert that all important social knowledge is stored in memory in the form of stories. Although this claim may be overly zealous (Brewer, 1995; Hastie & Pennington, 1995), it is perhaps not too far off the mark.

Generalized Representations

Social psychological research and theory have focused largely on generalized representations of knowledge that are not directly tied to a specific experience. Unlike situation models, which are formed spontaneously in the course of comprehension, generalized representations are typically constructed in the course of deliberative goal-directed processing (e.g., to form an impression, to make a behavioral decision, or simply to remember the information well enough to communicate about it to others). Some representations can be in the form of propositions that are learned independently of the specific instances to which they apply. Thus, we might learn that honesty is the best policy, or that cigarette smoking is bad for the health, without any direct knowledge of an event that exemplifies these propositions. In other cases, we might abstract commonalities from a number of instances in order to infer a person's attributes on the basis of observations of the individual's behaviors or derive a general conclusion on the basis of propositions that logically imply it. Finally, we might describe an experience in abstract terms in the course of telling others about it. Two types of generalized representations of particular importance pertain to entities and events.

Entity Representations

Generalized entity representations refer either to specific persons, objects, or places or to more general groups or categories. Each representation may contain alternative names of its referent along with a set of features that characterize it. Thus, the representation of a particular person, John Smith, might be characterized by the names "John," "Smitty," and "Mr. Smith," abstract trait descriptors ("honest," "hostile," "intelligent," etc.); and general behaviors that the individual commonly performs ("reads poetry," "swears at slow drivers," etc.). These features could compose an associative network in which the concept is denoted by a central node and the features by peripheral nodes that are associatively linked to it. An attribute (e.g., trait) concept might be represented similarly. The most common type of generalized entity representation investigated in social psychology is a *person stereotype*, consisting of a set of traits and prototypical behaviors that are associated with a general category of individuals (African Americans, women, lawyers, etc.)

Although the features that compose an entity representation are all associated with a concept of their referent, they do not necessarily have any direct relationship to one another. In the example, it makes as much sense to describe John Smith as someone who is "honest, intelligent and shouts and slow drivers" as it does to describe him as someone who "shouts at slow drivers, intelligent, and honest." Thus, in Mandler's (1979, 1984) terms, the representation is typically *categorical*.

Event Representations

A generalized event representation is composed of a sequence of temporally and thematically related events and states of affairs. It is distinguished from an episode model in that the states and events that compose it are coded metalinguistically and may not occur at specific points in time. On the other hand, the individual events that compose the representation are temporally or causally related. Such representations are therefore *schematic* rather than categorical (Mandler, 1979, 1984).

Several types of generalized event representations can be distinguished. *Scripts* are prototypical sequences of events that occur routinely in a particular situational context (Schank & Abelson, 1977). *Histories*, on the other hand, characterize unique sequences of temporally related events that occur over a period of time. They can refer either to events in one's own or another's life or to real-world events involving several different individuals. The time periods to which histories pertain often overlap. Nevertheless, they are presumably stored in memory independently.

IMPLICIT THEORIES

A sequence of temporally related events and states may often compose an implicit theory about the causes and consequences of certain types of actions. A theory can apply to a particular individual (e.g., oneself), a group

(e.g., sorority member) or people in general and might concern either a particular type of situation (e.g., dating, employer-employee relations, a parent–child interactions) or a more general one. The events and states that compose a theory are not localized in time. Instances of a theory can potentially occur in many situations. Consequently, the theory can be applied in comprehending new experiences and construing their implications. It might also be used as a guide in making behavioral decisions.

A theory can be conceptualized as consisting of two or more temporally related propositions, each depicting a different event or state of affairs. In combination, they can exemplify a general principle or generalization. For example, the theory that people get what they deserve might be composed of the segments "P is good (bad)" and "Good (bad) things befall P." A more detailed theory about romantic relationships might consist of the sequence: "P and O meet" P and O fall in love; P and O have a misunderstanding; P and O fight and break up; P and O resolve the misunderstanding; P and O make up and live happily ever after." This more detailed representation might be equivalent to a *story skeleton* of the sort postulated by Schank and Abelson (1995) to guide the interpretation of specific stories that people tell.

THE CONSTRUCTION
OF MENTAL REPRESENTATIONS:
GENERAL CONSIDERATIONS

Current conceptualizations of the mental representation of knowledge have their roots in two more traditional bodies of research and theory. One avenue of inquiry was focused on general characteristics of cognitive organization, such as the way in which the concepts that compose one's cognitive system are differentiated and interrelated (e.g., Harvey, Hunt, & Schroder, 1961; Rokeach, 1960). These characteristics were typically assumed to depend on the personality of the cognizer as well as the domain of knowledge to which the concepts pertained. Numerous measures were proposed to assess individual differences in these structural characteristics (Harvey, Reich, & Wyer, 1968; Scott, 1963, 1969). Alternative measures of the characteristics were often uncorrelated (Wyer, 1964) and their implications for behavior and judgments were not firmly established. Related measures, however, have been used successfully to assess the differentiation and integration of domain-specific sets of cognitions (Linville, 1982; Suedfeld, Tetlock, & Streufert, 1992; Tetlock, 1992). As Gruenfeld (1995) has shown, however, differences in these characteristics can often reflect the effects of communication goals that exist in the social situation in which they are assessed rather than differences in the structure of cognitions on which the communications are based.

The second avenue of early research and theorizing was generally guided by the assumption that people organize their beliefs and attitudes in a manner they consider to be consistent (Abelson et al., 1968; for an analyses of the assumptions underlying representative theories, see Wyer, 1974). Specific theories varied in their assumptions about the criteria for consistency, which in some cases were logical (e.g., Festinger, 1957; McGuire, 1960) and in other cases were hedonic or affective (Heider, 1958; Osgood & Tannenbaum, 1955; Rosenberg, 1956). The theories also placed different emphases on (1) deliberate attempts to maintain cognitive consistency in the face of conflicting information (cf. Abelson, 1959; Festinger, 1957; Lerner, 1970) and (2) the spontaneous formation of consistent sets of cognitions in the course of comprehension (Heider, 1958; McGuire, 1960).

Consistency theories nevertheless agreed in several respects. First, people are motivated to understand the world in which they live and to predict the consequences of their own and others' actions. To attain this objective, they develop a general set of rules they can use to comprehend the information they receive. Furthermore, when this information is incomplete, they often use these rules to infer unmentioned characteristics of the objects or events to which it pertains. Furthermore, if the information conflicts with their prior knowledge about its referents, people may deliberately modify their cognitions about the referents in a way that reestablishes consistency with these cognitions. The implications of cognitive consistency theories are implicit in the principles that have more recently been proposed to govern the construction and use of mental representations. This will become clear in the discussion to follow.

Our discussion begins with two general principles. The first simply recognizes that representations can be formed at two stages of information processing:

> **Principle 1.** Mental representations are formed either (1) spontaneously, in the course of comprehending new information, or (2) deliberately, in the course of attaining a specific objective to which this information is relevant.

Because different processes occur at each stage of cognitive activity, the representations that are formed can also differ. In each case, it is important to note that the construction of a mental representation is usually not itself a goal of information processing. Rather, representations are typically by-products of processing that occur for other reasons. Nevertheless, principle 2 applies.

> **Principle 2 (Parsimony).** The representations that are constructed of information and stored in memory are no more complex than necessary to attain the processing objective to which they are relevant.

Likewise, the processing that leads a representation to be constructed is itself no more extensive than is necessary to attain the goal at hand. Thus, for example, people often base their comprehension of information on the concepts and knowledge that come most easily to mind, without searching for alternative criteria that are equally or more applicable (Higgins, 1996a). Taylor and Fiske (1978) and Chaiken (1987; Chaiken et al., 1989) make a similar assumption in conceptualizing judgment processes. Although individ-

ual differences may exist in the motivation to think extensively about the implications of information (cf. Cacioppo & Petty, 1982), the role of parsimony is pervasive. In fact, several other principles we propose are more specific versions of principle 2.

We first consider the processes that occur at the comprehension stage. Then, we turn to those that occur in the course of more specific goal-direct processing.

COMPREHENSION-BASED MENTAL REPRESENTATIONS

The Role of Mental Imagery in Comprehending Social Information

Visual Imagery in the Comprehension of Verbal Information

To comprehend events of the sort they observe or read about, people often construct a mental simulation of these events that has nonverbal components. Groundbreaking studies by Bransford and his colleagues (Bransford, Barclay, & Franks, 1972; Bransford & Johnson, 1972) are illustrative. For example, apparently anomalous sentences (e.g., "The haystack was important because the cloth would rip") that are normally hard to remember are easily recalled when they are preceded by a single word ("parachute"). The added word presumably activates a mental image of an event that gives the statement meaning (e.g., a parachutist landing in the hay rather than in a tree), and this image facilitates its later recall. Similarly, ostensibly anomalous paragraphs can be given meaning, and thus are recalled better, when they are accompanied by a picture or, in some cases, a title, that facilitates the formation of a mental image of the events being described (Bransford & Johnson, 1972; Bransford & Stein, 1984).

Although the construct of a visual image is metaphorical,[2] several more recent studies of text comprehension (e.g., Black, Turner, & Bower, 1979; Garnham, 1981; Glenberg, Meyer, & Lindem, 1987) provide evidence of its utility. Glenberg and colleagues (1987), for example, asked participants to read a description of a man's activities that began with either "John put on his sweatshirt and went jogging . . . " or "John took off his sweatshirt and went jogging. . . . " The sweatshirt was never again mentioned in either story. Nevertheless, participants identified the word more quickly in a later recognition memory task in the first condition than in the second. In the first condition, a mental image of John wearing the sweatshirt apparently persisted throughout the story, and so the feature was more accessible in memory at the time the recognition task was performed.

Garnham (1981) found that people found it easier to distinguish between "The hostess bought a mink coat from the furrier" and "The hostess bought a mink coat at the furrier's" than to distinguish between the structurally identical statements, "The hostess received a telegram from the furrier" and "The hostess received a telegram at the furrier's." This is presumably because the mental images elicited by the first two statements are very similar, whereas the images elicited by the last two statements are quite different.

Although these examples pertain only to visual images, images in other sense modalities could also be involved. To this extent, the following two principles are tenable:

Principle 3. When people directly observe an event, the representation they form in the course of comprehending it is typically coded in the same modalities in which the event is experienced.

Principle 4. When people receive a verbal description of an event, the representation they form in the course of comprehending it consists in part of a nonverbal image of the event as well as a metalinguistic coding of it.

Observations versus Verbal Descriptions

Although the mental simulations that people form from verbal descriptions of a situation are often analogous to those they would form from direct observation, they are not identical. Most obviously, the visual images that are formed from written descriptions may be less detailed (see note 1). On the other hand, several features that are not specified in the verbal description of an event may often need to be added in order to construct a simulation of it. Barsalou (1993) postulates the existence of "perceptual symbols" that people can use to construct mental pictures of objects and events they have never observed. Thus, we can comprehend the statement "a tiger walked into the classroom and sat down to take notes" without ever seeing such an event, based on previously formed symbols of the elements to which the statement refers. Similarly, we can imagine an acquaintance engaged in activities that we have never observed by applying a perceptual symbol that we formed of the individual in other situations. (For a theoretical explication of these processes, see Wyer, 2004.)

Although the representations formed from verbal descriptions can differ in content from those that are formed through observation, they are normally similar in structure. Verbal descriptions often refer to discrete events (e.g., "John reached for an hors d'oeuvre. Someone bumped his arm, and he spilled his Bloody Mary over Mary's white dress."). In contrast, an observation of these events consists of a continuous stream of activity. It is unlikely, however, that this continuous activity is stored in memory. Newtson (1973, 1976) postulated that people who observe a continuous stream of behavior extracted static frames that denote the transitions ("breakpoints") between one meaningful act and the next, and that these frames, stored in memory, permit the action sequence to be reconstructed. Ebbesen (1980), on the other hand, proposed that a single frame pertaining to each meaningful action is extracted that is typical of the action as a whole (e.g., a static picture of John in the act of reaching for an hors d'oeuvre). To this latter extent, the nonverbal frames that compose the representation of an observed sequence of behaviors might correspond to the images that are formed from verbal descriptions of these behaviors.

An important difference between the representations is nevertheless implied by principles 3 and 4. That is, nonverbal descriptions of events may not be spontaneously coded linguistically, as this coding is not necessary in order to construct a mental simulation of it (principle 3). In contrast, verbal descriptions of events and states are likely to be coded into memory linguistically as well as nonverbally (principle 4). This is partly because the referents of the verbal description must be identified before a mental simulation can be formed.

Wyer, Adaval, and Colcombe (2002; see also Wyer, 2004) evaluated implications of this coding asymmetry. Participants who had been shown pictures of a sequence of temporally related events (e.g., a day in school) took longer to verify the occurrence of these events when they were described verbally than when they were portrayed in similar (but not identical) pictures. This suggests that the pictures were not spontaneously coded verbally at the time they were presented, and so a verbal recoding was necessary at the time of judgment in order to verify them. In contrast, participants who had initially received verbal descriptions of the events verified them just as quickly on the basis of a picture as they did on the basis of a semantically equivalent verbal description. In this case, a mental image of the events had apparently been formed at the time the verbal descriptions of them were presented, and so a recoding at the time of judgment was not required.

Constraints on the Construction of Nonverbal Representations

The representations that are formed in the course of comprehending situation-specific states and events are equivalent to situation models of the sort described earlier in this chapter. However, a question arises concerning the number of such representations that are constructed from a given body of information. The answer to this question is implied by the general rule of parsimony (principle 2). In the present context, a more specific principle is suggested.

> **Principle 5.** People will construct no more mental representations of information than are necessary in order to comprehend it.

Radvansky and his colleagues (Radvansky, Spieler, & Zacks, 1993; Radvansky & Zacks, 1991) confirmed this principle. Radvansky and Zacks (1991) asked participants to learn sets of one, two, or three sentences. In some cases, the sentences described different objects in the same location ("The book is on the table"; "The cup is on the table," etc.) In other cases, they described the same object in different locations ("The book is on the table"; "The book is on the chair," etc.). It is easy to imagine several things in a single location. However, it is impossible to imagine the same thing in several different locations simultaneously. Therefore, according to principle 5, people should construct a single mental representation in the course of comprehending the first set of sentences but different representations when comprehending the second set.

Radvansky and Zacks (1991) reasoned that if people construct a different representation of each statement, the presence of one representation is likely to interfere with the identification of others. Consequently, the time to verify a given statement should increase with the number of statements presented (i.e., the number of representations that were formed and, therefore, the amount of inference). This was true in single-object, multiple-location conditions. In multiple-object, single-location conditions, however, participants are able to form a single representation from the statements in combination, and so the interference in retrieving the representation should be minimal. This was also the case; the statements in this condition were verified quickly regardless of the number presented.

A second constraint on the construction of situation models should also be noted. Mental images are necessarily restricted to events and states that occur at a specific time and place. If the situations described by verbal information are not so constrained, an image (and, therefore, a situation model) is unlikely to be constructed. That is:

> **Principle 6.** When people encounter verbal descriptions of events or states of affairs that are not constrained to a specific time and place, they comprehend these descriptions in terms of semantic concepts alone, and do not form mental images of them.

Using a similar procedure, Radvansky, Wyer, Curiel, and Lutz (1997) demonstrated the applicability of principle 6 to the representation of events. Some participants received information that a person bought either one, two, or three objects that could all be found in a drugstore (i.e., a toothbrush, shaving cream, and aspirin). Others received information that the person bought one, two, or three objects that were found in different stores (e.g., a toothbrush, a diamond ring, and a bicycle). Response times in the multiple-location condition increased with the number of items presented, whereas recognition times in the single-location condition were independent of the number of statements presented.

In other conditions, however, the statements pertained to ownership rather than purchase behavior. Thus, they described states of affairs that were not temporally constrained, and so mental images were unlikely to be formed in the course of comprehending them. Rather, the statements are likely to be coded into memory propositionally, perhaps forming a generalized entity representation of the sort described earlier. Consistent with this assumption, the time to verify a statement about ownership increased with the number of other statements presented regardless of relatedness of the objects described.

A further determinant of whether events are integrated into a single representation is their thematic relatedness. People undoubtedly do not construct a single mental representation of their life experiences. Rather, they

form different representations of events that are thematically unrelated.

> **Principle 7.** The mental representations that people form in the course of comprehending information are domain and theme specific. If information that pertains to different persons or to situations that are not thematically related, a different representation is formed of each.

Perhaps because the validity of this proposition seems almost self-evident, there is surprisingly little research to support it. In a study by Wyer and Bodenhausen (1985), however, people read a story about events that occurred during the course of a cocktail party. Some of the events described were thematically related but were mentioned at different points in the story. Participants recalled these events together and in chronological order regardless of when they were described. However, they recalled unrelated events that occurred near the end of the story before events that were mentioned earlier. Thus, participants apparently integrated thematically related events into a single representation in the course of comprehending them and stored the representation in memory as a single unit of knowledge. However, they stored each knowledge unit independently in the order they were formed, in a manner implied by a "bin" conception of memory (Wyer & Srull, 1989). Consequently, they later recalled more quickly the ones they had stored more recently (those near the top of the bin).

The Impact of Prior Knowledge on the Representation of New Experiences

The comprehension of new information necessarily requires the activation and use of previously acquired concepts and knowledge. This knowledge can potentially influence the mental representations that are formed from the information in two, apparently opposite ways. On one hand, the image component of a situation model that is formed in the course of comprehending information may require features that were not specified, and these features might be added to the representation that is formed. On the other hand, when aspects of new information are redundant with prior knowledge and can be reconstructed on the basis of it, these aspects may omitted from the new representation.

Comprehension-Based Intrusions

To reiterate, the construction of a mental image sometimes requires the addition of features that were not specified in the information on which it is based. The addition of this feature to the representation may be reflected in memory later on, appearing as an intrusion error. This possibility is summarized in the following principle:

> **Principle 8.** People who comprehend information may spontaneously make inferences about features

that are necessary in order to interpret it. These inferences become part of the representation that is formed and, therefore, are later recalled as actually having been mentioned.

Barclay (1973; Barclay, Bransford, Franks, McCarrell, & Nitsch, 1974) found evidence of these intrusions in memory for simple sentences, and a more detailed analysis of their occurrence is provided by Graesser, Singer, and Trabasso (1994) in conceptualizing prose comprehension phenomena. Intrusions can also result from attempts to comprehend more complex sets of information. Spiro (1977), for example, asked participants to read an account of a heated argument between an engaged couple over having children. After reading the story, the experimenter incidentally remarked that the couple was happily married. Participants in the course of comprehending this latter information apparently made inferences about what might have happened in the interim. These inferences became part of the mental representation they formed of the story and stored in memory and their later use of this representation as a basis for recalling the sequence produced errors. (For example, they recalled that the woman found out she couldn't have children, or that the man changed his mind.)

The Role of Generalized Representations in the Comprehension of New Information

Many features of the events we experience in daily life are similar to those we have encountered in the past. It seems unlikely that we encode and store these redundant experiences in detail (but see Hintzman, 1986). This possibility, which is consistent with the rule of parsimony noted earlier, is captured by the following more specific principle:

> **Principle 9.** If new information can be comprehended in terms of a previously formed knowledge representation, features that can be reconstructed on the basis of this representation will only be retained if they are necessary in order to reconstruct other information that is presented.

Graesser, Gordon, and Sawyer (1979) proposed a theory of prose comprehension that makes use of this principle. They assumed that when people read about events that exemplify those that compose a previously formed, generalized event representation (e.g., an event prototype or a script), these events are not retained in memory. Rather, people retain only a "pointer" to the generic representation along with a set of translation rules that permit the features of the preexisting representation to be instantiated in terms of the more specific features of the exemplar. Events that occur but are not specified in the generic representation are simply appended as "tags." Thus, suppose someone learns that John went to Yeng Ching's, decided to order chicken fried rice, said "hi" to Mary as she passed by his table, paid $15.80 for the meal, and left. This sequence could be represented

by (1) a pointer to a generic representation of a restaurant visit along with translation rules (customer = John, restaurant = Yen Ching's; meal = chicken fried rice, etc.) and (2) a tag describing the interaction with Mary.

A problem with Graesser and colleagues' (1979) conceptualization lies in its failure to specify how the location of unexpected events that occur is reconstructed. However, an extension of this conceptualization by Trafimow and Wyer (1993) solves this problem. They assumed that events that are redundant with a more general representation are not retained *unless* their retention is necessary in order to localize the point at which the unexpected events occur. Thus, in the preceding example, the decision to have chicken fried rice is redundant with a generic event, "ordered the meal." Nevertheless, it might be retained because it is necessary in order to localize the interaction with Mary. This conceptualization implies that the greater the number of unexpected events that occur, the more theme-related events are likely to be retained. This prediction contrasts with the effect of additional events when the events are treated as independent. In the latter case, the likelihood of recalling a particular item typically decreases with the number presented (Anderson & Bower, 1973; Rundus, 1971). Trafimow and Wyer obtained support for these predictions. That is, they found that the recall of prototype-related events increased with the number of unrelated events contained in a prose passage when participants were aware at the outset of the prototype to which they pertained. When this prototype could not immediately be identified, however, the reverse was true.

Trafimow and Wyer's results suggest a criterion for determining when people use a generalized representation as a basis for comprehending information and when they do not. By applying this criterion, Colcombe and Wyer (2002) showed that people are unlikely to form and use a generalized representation spontaneously. This only occurs when they are exposed to several exemplars of the generalized representation in close temporal contiguity and have an implicit objective of thinking about them in relation to one another. (For a similar conclusion, see Gick & Holyoak, 1983.)

More important, we found that although people use generalized representations to comprehend unfamiliar persons' behavior, they do *not* use them to comprehend events that they imagine themselves or a well-known other performing. In the latter case, people appear to comprehend experiences in terms of an *exemplar* of their own or the other's experience that they have previously formed and stored in memory. This makes intuitive sense. That is, people rarely need to think about different instances of their own behavior in relation to one another and, therefore, may rarely be motivated to extract a generalized representation of it. Rather, they may simply use a recent exemplar of the routine to understand and predict the events that occur. These considerations give rise to the following principle:

> **Principle 10.** People use a generalized representation to comprehend new information if and only if an ex-

emplar (e.g., a situation model) that can be used for this purpose is not easily accessible in memory.

Principle 10 implies that most daily life experiences that we encounter with no particular goal in mind are likely to be represented in memory as situation (e.g., episode) models rather than as abstractions of these experiences. However, the principle may only apply to conditions in which (1) comprehension is the primary objective and (2) the information is of the form to which a situation model is relevant (events that are situationally and temporally constrained). When people have other, more specific objectives, they are likely to construct generalized representations that are relevant to the attainment of these objectives. We now turn to this possibility.

THE FORMATION OF GENERALIZED REPRESENTATIONS

Many mental representations are constructed in the course of more deliberative goal-directed processing. For example, people often wish to form an impression of a person or object, to explain an event that has occurred, to predict a future occurrence, or to make a behavioral decision. In these cases, they might intentionally abstract commonalities among specific experiences that will be useful in attaining their objective, using learned rules of inductive or deductive reasoning. In still other cases, people wish to describe an experience they have had to someone else. Then, they may recode the experience in linguistic terms that they can communicate verbally. In each case, the mental representation that is formed in the course of this goal-directed activity is stored in memory and, therefore, can later be retrieved for use in attaining other objectives to which it is relevant.

Many conceptualizations of goal-directed representational processes assume the following principle:

> **Principle 11.** When people consciously think about two cognitive elements in relation to one another, an association is established between them. The strength of this association increases with the frequency and duration of this cognitive activity. Once the association is formed, thoughts about one of the associated elements are likely to stimulate thoughts about the second.

This principle is implicitly and explicitly applied in conceptualizing not only the content and structure of human thought systems in general (McGuire & McGuire, 1991) but also the representations formed in more specific knowledge domains, including the organization of beliefs about causally related events (McGuire, 1960, 1981; see also Shah & Kruglanski, 2000, 2003), the construction of implicit theories, and the formation of person impressions. These conceptualizations are described in the pages that follow.

The Content and Structure
of Human Thought Systems

The most comprehensive attempt to conceptualize the mental representation of real-world knowledge was proposed by McGuire and McGuire (1991). The McGuires were concerned with the manner in which people construct representations of both real and hypothetical events in the course of thinking about them. Based on the type and implications of the thoughts that individuals spontaneously generated in response to a proposition about a real or hypothetical event, they were able to draw conclusions about the associations that are typically formed among the propositions that compose general world knowledge. Moreover, by identifying participants' cognitive responses to events that made target propositions more or less likely, they drew conclusions about the motivational and cognitive processes that underlie the formation of these associations. They proposed four basic postulates:

1. *Utility maximization.* Events stimulate thoughts about consequences that are similar to the events in desirability. That is, desirable (undesirable) events stimulate thoughts about possible consequences that are also desirable (undesirable).
2. *Congruent origins.* Events stimulate thoughts about antecedents that are similar to them in desirability. That is, desirable (undesirable) events stimulate thoughts about desirable (undesirable) causes.
3. *Wishful thinking.* Desirable events stimulate thoughts about why the events are likely to occur, whereas undesirable events stimulate thoughts about why they will not occur.
4. *Rationalization.* Events that appear likely to occur stimulate thoughts about desirable consequences, whereas events that are considered unlikely stimulate thoughts about undesirable consequences.

These principles are consistent with those assumed in several other areas of research. Kahneman and Miller (1986) note that the contemplation of social information (e.g., "Mr. X is a 26-year-old assistant professor who earns $50,000 a year") activates a personal or social norm that is used as a basis for comparison and, if the information's implications deviate from this norm, to consider possible explanations for it. The spontaneous generation of counterfactuals may be a reflection of these processes.

Principle 11 may also apply to both the McGuires' conceptualization and Kahneman and Miller's. According to this principle, the cognitive activity that results from thinking about the antecedents and consequences of an event leads propositions pertaining to the events to become associated in memory. To this extent, thinking about one proposition should increase the likelihood of recalling the other and, therefore, to use it as a basis for judgment at a later point in time. Wyer and Hartwick (1984) obtained evidence consistent with the utility-maximization and congruent-origins postulates. They showed, for example, that asking participants to report

their belief in a proposition stimulated them to search for an antecedent (a reason why it might either be true or false) and, if a proposition describing such an antecedent happened to be accessible in memory at the time, to identify and use it as a basis for this belief. Correspondingly, asking persons to report the desirability of the event specified in a proposition stimulated them to search for a possible consequence and to use an easily accessible proposition describing such a consequence as a basis for this judgment. The associations that participants formed on the basis of this cognitive activity increased the likelihood that calling their attention to one proposition would cue their recall of the other. Thus, participants were more likely to form an association between a conclusion, C (e.g., "Global warming will make life unbearable by the end of the decade"), and an antecedent, A (e.g., "Air pollution controls are not being enforced") if they had previously reported their belief in C when A was easily accessible in memory, or if they had reported the desirability of A when C was easily accessible. In contrast, reporting their belief in A or the desirability of C under these conditions did not have these facilitating effects.

The Representation of Causal Relationships

People are undoubtedly more likely to base their belief in a conclusion (C) on their belief in a particular antecedent (A) when the two propositions are associated in memory. However, the actual impact of A depends on the extent to which people believe that C is more likely to be true if A is true than if it is not. A model of belief organization proposed by McGuire (1960) and refined by Wyer (1974; Wyer & Goldberg, 1970) captures these possibilities. McGuire argued that people organize their beliefs syllogistically and that, consequently, beliefs in a proposition should be predictable from beliefs in the propositions that logically imply it. Thus, for example, the proposition, C, might be viewed as the conclusion of two mutually exclusive sets of premises, (1) A; if A, then C, and (2) not-A, if not-A, then C. Wyer and Goldberg (1970) postulated that if beliefs were in units of subjective probability, the belief in C, P(C) could be an additive function of beliefs the two sets of premises that imply it, or

$$P(C) = P(A)P(C/A) + P(\sim A)P(C/\sim A) \qquad [1]$$

where P(A) and P($\sim$A) [=1 − P(A)] are beliefs that A is and is not true, respectively, and P(C/A) and P(C/$\sim$A) are beliefs that C is true if A is and is not true, respectively. Numerous empirical studies confirmed the validity of this equation in describing belief formation and change (for a review, see Wyer & Hartwick, 1980).

McGuire (1960) noted that inconsistencies might exist among people's beliefs because they have not recently thought about the beliefs in relation to one another. If this is so, however, calling people's attention to the beliefs in temporal proximity should stimulate them to reduce these inconsistencies. Evidence of this "Socratic effect" was obtained by Rosen and Wyer (1972). That is, when people report their beliefs in propositions of the

sort to which equation 1 pertains in two sessions 1 week apart, their beliefs are more consistent, as defined by the equation, in the second session than they were at first. This effect is less apparent when people report their beliefs in the premises of syllogistically related propositions before reporting their belief in the conclusion during the first session of the experiment (Henninger & Wyer, 1976). Perhaps people find it easy to change their belief in a conclusion to make it consistent with their beliefs in premises, and so they make this change immediately upon encountering it. However, changing beliefs in premises to make them consistent with a previously reported belief in a conclusion requires more cognitive work, and thus it takes more time to occur.

A more interesting contingency was observed in 2000 by Norenzayan and Kim (unpublished data). They found that the Socratic effect observed by Rosen and Wyer (1972) was restricted to North Americans. That is, Asian participants did not change the consistency of their beliefs appreciably over time. This suggests that the motivation to eliminate logical inconsistencies among beliefs is a Western cultural phenomenon and may not generalize to Asian cultures. (For other evidence that Asians are less inclined than Westerners to engage in analytic thinking of the sort implied by a syllogistic model of belief organization, see Choi, Nisbett, & Norenzayan, 1999.)

Related Considerations

The formation of associations between antecedents and consequences has recently been elaborated in a conceptualization of goal structure proposed by Shah and Kruglanski (2000, 2003; Shak, Kruglanski & Friedman, 2003). This conceptualization has many features in common with that of McGuire and McGuire (1991). They propose that calling people's attention to a goal activates thoughts about the means of attaining it. Correspondingly, calling attention to means can activate thoughts about the goals that may result from it. In support of this possibility, activating a goal increased the ease of identifying means-related concepts in a word-recognition task (Shah & Kruglanski, 2000), whereas activating a means to an end increased the ease of identifying words that exemplified the end (Shah & Kruglanski, 2003).

The Construction of Implicit Theories

General knowledge about the causes and consequences of events can function as *implicit theories* about oneself, other persons, or the world in general. As noted earlier in this chapter, an implicit theory consists of two or more temporally or causally related propositions. The simplest form of such a theory might be an *implicational molecule* similar to that postulated by Abelson and Reich (1969; see also Wyer, 2004; Wyer & Carlston, 1979) (e.g., the theory that people make about themselves, others, or real-world events). For example, the generalization that people get what they deserve might be captured by a molecule of the form

$$[\text{P is good (bad). Good (bad) things befall P}] \quad (2)$$

The theory that people who share interests and values like one another might be conveyed in a "similarity-attraction" molecule:

$$[\text{P likes (dislikes) X; O likes (dislikes) X; P likes O}] \quad (3)$$

Molecules about the world in general can also exist. For example, the theory that things that occur frequently are easy to remember might be represented by an "ease-of-retrieval" molecule of the form

$$[\text{Instances of X occur frequently. Instances of X are easy to recall}] \quad (4)$$

Implicit theories may be formed in the course of understanding the causal relations among the events that one encounters in daily life. With frequent repetitions, however, the propositions that compose the representation may become so strongly linked that thoughts about one of them spontaneously activate the others. To this extent, the set of propositions acquires a schematic quality, being used to interpret information that exemplifies them in much the same way as the schema of a human face or a situation model.

The evidence of this possibility, although limited, is compelling. A study by Sentis and Burnstein (1979), in the context of research on cognitive balance (Heider, 1958), is illustrative. Participants were asked to learn liking relations among sets of three persons that were either consistent with the similarity–attraction molecule (or, in Heider's terms, were balanced) or were inconstant with this molecule (imbalanced). Later, they were asked to verify sets composed of one, two, or three of the relations they had seen. The time to verify the relations contained in molecule-inconsistent sets increased with the number to be verified. This suggests that the relations were stored separately from one another and that each had to be verified individually. When the relations were molecule consistent, however, participants took *less* time to verify three relations in combination than to verify only one. Participants apparently formed a schematic representation of molecule-consistent sets of relations at the time they encountered them. Therefore, they found it easier to verify information that matched the configuration as a whole, whereas they were required to unpack the representation to verify its individual features.

Implicit theories are widely applied in explaining and predicting events in one's social and physical world. We return to this possibility later in this chapter.

Person Impression Formation

Preliminary Considerations

Applications of principle 11 are particularly evident in research on person impression formation (Hastie et al., 1980; Srull & Wyer, 1989). In this research, people are typically asked to form an impression of a hypothetical

person on the basis of a set of favorable or unfavorable behaviors. The behaviors are sometimes preceded by favorable or unfavorable trait descriptions. By applying principle 11 to the content, type, and order in which the behaviors are later recalled in this paradigm, Srull and Wyer (1989) drew the following conclusions:

1. People with an impression formation objective interpret the behaviors in terms of traits, thus forming associations between the trait concepts and the behaviors they exemplify (Gordon & Wyer, 1987; Hamilton et al., 1980; but see Klein & Loftus, 1990).
2. People extract an evaluative concept of the person as likeable or dislikeable on the basis of the initial information they receive.
3. Once this concept is formed, they encode the behaviors of the person as favorable or unfavorable and think about them with reference to the person concept, thereby forming associations between the behaviors and the concept.
4. When people encounter a behavior that is eval-

uatively inconsistent with the general concept of the person, they respond in two ways.
a. First, they think about the behavior in relation to others in an attempt to understand why it might have occurred (e.g., why a good person might do a bad thing, or why a bad person might do something admirable). This activity leads associations to be formed between the inconsistent behavior and others.
b. Second, they review the behaviors that are consistent with the central person concept in an attempt to confirm the validity of this concept. This strengthens the behaviors' associations with the concept.

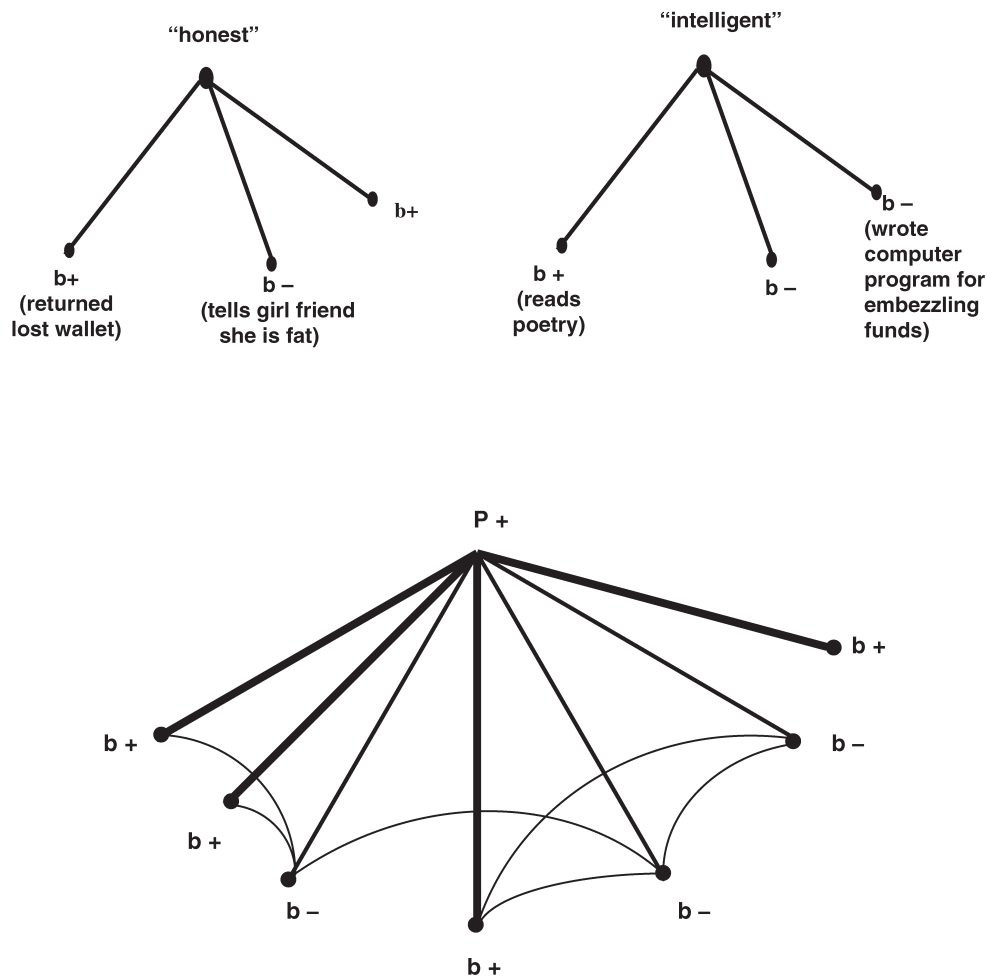
Thus, applying an associative network metaphor, the top half of Figure 12.1 shows the trait-based representations that might be formed from information that a person has engaged in three honest and three intelligent behaviors. If prior information about the person has led a favorable evaluative concept to be formed of him, and if


FIGURE 12.1. Metaphorical trait-based and person-based representations of a person characterized by a favorable person concept (P+) and by favorable (b+) and unfavorable (b–) behaviors pertaining to honesty and intelligence. Behaviors that are inconsistent with the person concept are assumed to be thought about in relation to the two behaviors that precede them.

these behaviors are interpreted as favorable (e.g., "returned a lost wallet" or "reads poetry") and unfavorable ("tells his girl friend she is fat" or "developed a computer-based system for embezzling funds from his employer"), the person-based representation might be constructed of the form shown at the bottom of Figure 12.1.

However, it is important to note that the content and structure of the mental representation assumed by the model is closely tied to the *processes* that theoretically underlie impression formation under the conditions of concern. If the processes do not occur, the associations of the sort described in Figure 12.1 would not be formed.

Other qualifications on the processes assumed by Srull and Wyer (1989) to underlie person impressions come from investigations of (1) the formation of impressions of groups, (2) the formation of impressions based on belief and opinions of social relevance, and (3) the impressions formed from behaviors described in a social context (e.g., a conversation). The mental representations that are formed are qualified correspondingly.

Forming Impressions of Groups

Suppose people are asked to form impressions of a group of individuals, each described by a different behavior. Some members' behaviors may be evaluatively inconsistent with their concept of the group as a whole. If the group is cohesive and its members are likely to interact, an understanding of other members' behavior might be thought about in an attempt to explain these inconsistencies. In many cases, however, the group may simply be a collective (African Americans, Nazis, etc.), whose members may not even know one another. Then, this cognitive activity is unlikely to occur, and so the interbehavior associations that facilitate the recall of expectancy-inconsistent behaviors of individual persons may not be formed. Consequently, persons in these conditions often recall expectancy-consistent behaviors better than inconsistent ones (Hamilton & Sherman, 1996; Srull, 1981; Wyer & Srull, 1989). (But see Hamilton & Gifford, 1976, for a qualification on the latter conclusion.)

These considerations have implications for the effects of stereotyping on memory. If people have formed a stereotype-based impression of an ethnic group on the basis of behaviors of several different members, they may have better recall of a person whose behavior confirms their stereotype than of a person whose behavior disconfirms it. At the same time, if people encounter several behaviors of a particular group member, they are more likely to recall those behaviors that conflict with their stereotype-based expectations than behaviors that confirm these expectations.

Impressions Based on Beliefs and Opinions

In much research on person impression formation, people are asked to form impressions of someone on the basis of behaviors that are of little personal or social relevance ("got confused by television sitcoms," "shouted and honked at slow drivers," etc.). Outside the laboratory, however, impressions are often based on expres-

sions of opinions about social issues. In this case, people may not think about the consistency of these opinions with a concept of the actor. Rather, they may compare the opinions to their *own* positions on the issues. In doing so, they are likely to expend more cognitive effort on expressions of opinion with which they disagree. As a result of this cognitive activity, they may have better recall of these behaviors and opinion statements than of those with which they agree, independently of their consistency with the general attitudes and orientation of the person who expressed them (Wänke & Wyer, 1996; Wyer, Lambert, Budesheim, & Gruenfeld, 1992).

Impression Formation in Social Contexts

Outside the laboratory, we rarely encounter a listing of someone's behavior out of the context in which the behaviors occur. Rather, we hear stories about the person, or anecdotes about his or her activities in specific situations. Moreover, the information is itself conveyed in a social context (e.g., a conversation in which the individual is a topic of discussion. In these conditions, the impression formation processes may differ in several ways from those that Srull and Wyer (1989) assumed.

First, when trait and behavior descriptions of a person are conveyed in a conversation, speakers' trait descriptions of the target appear to influence participants' impressions of the speakers rather than the person the speakers are discussing (Wyer, Budesheim, & Lambert, 1990). Furthermore, listeners use the behaviors mentioned by one speaker as a basis for confirming the validity of their impression of the other speaker. (Thus, for example, if Arthur mentions a favorable behavior of a target that is inconsistent with Bob's unfavorable trait description of the individual, it confirms the suspicion that Bob is simply being nasty rather than conveying a true description of the target's personality.) Consequently, one speaker's behaviors become associated with the other speaker as well and are better recalled for this reason (Wyer et al., 1990).

Second, when participants overhear a conversation about one of the speakers, their reactions to the behaviors described are guided by normative expectations for speakers to be both polite and modest. Thus, they think more extensively about behaviors that deviate from these expectations. For example, they think more about a speaker's unfavorable descriptions of the person to whom they are speaking (which violate a norm to be polite) but think more about favorable descriptions that speakers provide about themselves (which violate a norm to be modest). Thus, these behaviors become more strongly associated with the speaker and are better recalled later (Wyer, Budesheim, Lambert, & Swan, 1994).

These contingencies exemplify a general point. That is, the impression-related mental representations that result from the associative processes implied by principle 11 depend substantially on the social context in which the information is presented as well as on the information itself. Conclusions about the content and structure of the representations cannot be divorced from these processes.

Spontaneous Construction of Generalized Representations

In the absence of a specific goal that requires it, the spontaneous abstraction of a generalized representation from specific instances occurs less often than one might intuitively expect. This is particularly true of event representations. Gick and Holyoak (1983; see also Holyoak & Koh, 1987) found that participants' solutions to a problem were typically unaffected by their exposure to analogous problems that could be solved using the same general principle. In fact, several specific instances of the problem were required before the principle was recognized. Colcombe and Wyer (2002; Wyer et al., 2002) drew similar conclusions in a different research paradigm.

The formation of generalized entity representations may also not be spontaneous. Klein and his colleagues (Klein & Loftus, 1993b; Klein, Loftus, Trafton, & Fuhrman, 1992; Sherman & Klein, 1994) showed that participants' trait judgments of a person was independent of their knowledge about the person's behaviors when they had had substantial past experience with the person being judged. Although this suggests that trait representations of well-known persons exist in memory independently of behaviors, this does not necessarily mean that the representations were formed spontaneously. In some studies (Sherman & Klein, 1994), participants' experience with the target person was experimentally manipulated. In these studies, however, participants were given an implicit impression formation objective. Therefore, these results also do not indicate that new generalized entity representations are constructed in the absence of specific goals that require them.

THE MENTAL REPRESENTATION OF SELF-KNOWLEDGE

Virtually all the knowledge we acquire implicates ourselves as either an actor, an observer, or an experiencing agent. Even when the information we receive pertains to matters of little personal concern, we are often aware of the act of acquiring it and the situation in which it occurs. To this extent, self is part of the knowledge representation we form.

On the other hand, many features of a mental representation decay over time. Furthermore, not all features of an existing representation are included in the new representation that we construct in the course of goal-directed activity. For these reasons, the knowledge we acquire often becomes dissociated from the experience of acquiring it. Thus, for example, we may have been aware of the experience of hearing George W. Bush make assertions about Iraq's stockpiling of nuclear weapons at the time we first encountered them in a speech and may have thoughts that his assertions were false and irresponsible. After a period of time, however, we may still recall his statements but be unable to remember the particular time and place in which the statements were uttered. A detailed discussion of self-knowledge and its impact on memory and judgments is beyond the scope of this chapter (for reviews, see Greenwald & Pratkanis, 1984; Kihlstrom & Klein, 1994; Markus & Nurius, 1986). Certain observations are nevertheless worth mention.

The content and structure of knowledge about oneself are presumably similar to that of knowledge about others. Procedural knowledge concerns one's own behavioral reactions to the stimuli we encounter in a situation. Declarative knowledge can be of any or all of the forms mentioned earlier in this chapter. For example, it can consist of both situation models of one's experiences in specific situations and generalized event representations that have been formed in the course of thinking about an experiences or communicating about it to others. One might also form generalized entity representations of oneself, consisting of traits and prototypical behaviors.

In this regard, many theories assume that people construct a *self-concept*, or self-schema, that is evaluative in nature, and to which more specific trait and behavioral descriptions are attached. In fact, several independent self-representations could exist that are domain and situation specific (Markus & Nurius, 1986; Markus & Wurf, 1987). Other distinctions are implicit in Higgins's (1987, 1996b, 1998) theory of self-regulatory processes. Higgins (1996b) distinguishes between "instrumental" self-representations (analogous to procedural self-knowledge, as noted earlier in this chapter) and "dispositional" self-representations (composed of traits and competencies). These latter representations can be subdivided into "actual" selves, "ideal" selves, and "ought" selves (characteristics of oneself that significant others consider desirable). Calling attention to differences in the content of these latter self-representations can have important emotional and behavioral consequences (Higgins, 1996b, 1998).

The different self-representations postulated by Markus, Higgins, and their colleagues might be structurally similar to an associative network of the sort described earlier. On the other hand, Klein and his colleagues (for a review, see Klein & Loftus, 1993b) have reported evidence that trait self-descriptions and behaviors that exemplify them are stored separately in memory. In a typical study (Klein & Loftus, 1993a), participants were asked, in counterbalanced order, both (1) to verify that they had a particular trait and (2) to generate a behavior they had performed that exemplified the trait. Asking participants to recall a trait-related behavior had little effect on the time they took to verify that they possessed the trait it exemplified. Correspondingly, making a trait judgment did not influence the time required to generate a trait-related behavior. These and other findings suggest that people's trait representations of themselves are stored separately from the representation of behaviors they perform that exemplify them. Consequently, neither is typically used as a basis for judgments of the other.

An important component of self-knowledge could concern one's subjective reactions to the objects and events that one encounters. These feelings are often used as bases for judgments and decisions about their referents (Schwarz, 2004; Schwarz & Clore, 1983, 1996; Strack & Deutsch, 2004). However, these feelings are not them-

selves part of the self-knowledge that is stored in memory. Rather, they may be conditioned *responses* to descriptive concepts and knowledge that occur when this knowledge is activated (Wyer, Clore, & Isbell, 1999).

THE USE OF MENTAL REPRESENTATIONS AS BASES FOR JUDGMENT

As noted earlier, the nature of mental representations is of limited interest in the absence of how these representations come into play in judgment and behavioral decision making. That is, one must ultimately be able to specify both *when* one or another representation is likely to be applied and *how* the representation is used, once it is called into play. This chapter concludes with a brief discussion of each question.

Which Representations Are Used?

More than one mental representation can have implications for a judgment or decision, and these implications can differ. In such cases, people are unlikely to conduct an exhaustive review and analysis of the alternative criteria they might potentially apply. Rather, they may use the first knowledge representation that comes to mind, provided it is deemed applicable for attaining the goal one is pursuing. The factors that influence the activation and use of previously acquired knowledge have been reviewed in detail elsewhere (Higgins, 1996a) and need not be reiterated in detail. Two factors, recency and frequency, are particularly important.

Recency Effects on Memory and Judgment

The more recently a unit of knowledge has been formed and/or used, the more accessible it is in memory. Therefore, the more likely it is to be brought to bear on judgments and decisions to which it is potentially applicable. This gives rise to the following principle:

> **Principle 12.** Once a new mental representation has been formed, it is likely to be used as a basis for judgments and decisions to which it applies independently of the information that led to its construction.

Numerous studies confirm this principle (for reviews, see Higgins, 1996a; Wyer, 2004). Impression formation research, for example, shows that once people form an initial trait concept of a person on the basis of a subset of his or her behaviors, this concept is later used as a basis for later judgments of the person without consulting the behavior that led the concept to be formed (Carlston, 1980; Carlston & Skowronski, 1986; Lingle & Ostrom, 1979; Srull & Wyer, 1989). The verbal descriptions that are assigned to stimuli can be influenced by the context in which the stimuli are encountered. However, these descriptions are later recalled out of their original context and used as bases for judgments and decisions without considering the conditions that gave rise to their construction (Higgins & Lurie, 1983; Sherman, Ahlm, Berman, & Lynn, 1978).

Similar effects can occur in memory. People who have formed a mental representation of an experience at the time the experience occurred might later recall and use the representation for a purpose they did not anticipate. In the course of pursuing this objective, they may form a new representation, the content and structure of which differ from the one they had formed earlier, and may store this representation in memory independently of the original. When they are later asked to reconstruct the experience, they may use this more recently formed representation rather than the original as a basis for their reconstruction. In this case, memory errors are likely to occur.

This phenomenon may be particularly evident when the original representation is coded nonverbally. In a study by Schooler and Engstler-Schooler (1990), for example, participants were shown a number of faces and asked to describe one of them verbally. They were later less able to recognize this face than faces that had not been described. Thus, the verbally coded representation they had constructed, which was less detailed than the nonverbal representation they had formed, was used as a basis for recognition, decreasing accuracy.

This may only occur if the verbally coded representation that is accessible in memory is assumed to be a sufficient basis for judgment (Chaiken et al., 1989). If the representation is deemed irrelevant, participants may revert to a previously formed representation that they believe to be more appropriate. A study by Adaval and Wyer (2004) provides evidence of this contingency. Participants watched a 10-minute segment of a movie depicting the interaction between a husband and wife. The protagonists' verbal exchanges during the interaction were particularly relevant to impressions of their personalities, whereas their nonverbal behaviors were not. Participants were assumed to construct a situation model of the events they observed in the course of watching them. After observing the interaction, some participants wrote down their impressions of the protagonists whereas others described the sequence of events that occurred. Participants in the course of communicating their impressions were expected to construct a new representation of the protagonists on the basis of things the protagonists had said to one another. However, participants who communicated the sequence of events that occurred were expected to include the protagonists' nonverbal behaviors in their representation as well.

After performing the writing task, participants were given a recognition memory test. We expected that participants would use the representation they had formed in performing the writing task as a basis for identifying recognition items to which it was potentially relevant, and that their use of this representation would decrease accuracy. However, they should use their more detailed situation model to verify events to which the abstract representation was irrelevant, and so their recognition accuracy should not be affected. Consistent with expectations, describing the sequence of events that occurred

decreased participants' recognition of both statements and nonverbal behaviors relative to control conditions. In contrast, communicating impressions of the protagonists decreased recognition of protagonists' statements but *not* their nonverbal behaviors. In other words, the abstract representations that participants constructed decreased recognition of only those events to which the representations were relevant.

The construction of a new representation can influence not only what is remembered but also how it is remembered. In a study by Higgins and Rholes (1978), participants who had received information about a target person's behavior were asked to communicate a description of the individual to someone who either liked the person or disliked the person. Participants' written communications were biased toward the ostensible attitudes of the intended recipient. However, their later recall of the original information was similarly biased. This memory difference was not evident, however, when participants expected to prepare a message but did not actually do so. Thus, participants presumably constructed a new representation of the target in the course of preparing their written communication and used this representation, once constructed, as a basis for recalling the information on which it was based.

The influence of communicating about an experience or memory for the original experience has important implications. In an early study by Loftus and Palmer (1974), participants who had seen a picture of an automobile accident were asked either how fast the car had been going when it "smashed into" the tree or how fast it had been going when it "hit" the tree. Not surprisingly, participants' estimates were greater in the first condition than the second. When later describing the scene of the accident, however, the former participants were more likely to report seeing broken glass, although this was not actually shown in the picture. Participants when answering the first question apparently constructed a mental image of the accident that was consistent with implications of the question, and features of this image provided the basis for their memory of what they had seen.

It is easy to imagine how similar effects could occur in actual situations. For example, the prior questioning of witnesses before they appear on the stand could influence their reconstructive memory for the events they had witnessed, thus potentially invalidating their "eyewitness" testimony (Loftus, 1995). Adults' post hoc "memories" of the sexual abuse they experienced as a child could be similarly affected (Loftus, 2000). In this regard, Loftus and Palmer (1974) suggest that new representations can actually replace the originals rather than simply being more easily accessible. However, the two possibilities have not been distinguished empirically.

Frequency Effects

The relative accessibility of a representation in memory, and, therefore, the likelihood of using it, is also a function of the frequency with which it has been applied in the past. When an abstract representation has been fre-

quently applied, it may acquire the status of an implicit theory that is brought to bear on not only judgments of future events but memory for past ones. Furthermore, these theories, if applied frequently, can become chronically accessible in memory (Bargh, Bond, Lombardi, & Tota, 1986; Higgins, King, & Mavin, 1982). Consequently, these theories not only can influence what aspects of new information are retained in memory (Higgins et al., 1982) but also can be used as a basis for judgment in their own right. Ross (1989) cites several examples of these effects in conceptualizing the role of implicit theories in reconstruction of the past. For example, women's retrospective accounts of their emotional states during their most recent menstrual period are more similar to their implicit theories about their typical reactions during their menstrual cycle than to the actual emotions they experienced, as indicated by a daily diary they kept during the period in question (Ross, 1989). Similarly, persons who had an implicit theory that a training program would improve their study skills tended to recall their pretraining performance level as less than their posttraining level regardless of whether they had actually improved or not (Conway & Ross, 1984).

How Are Mental Representations Used?

Research on the use of different types of representations are limited. Three types of mental representation described in this chapter—entity (e.g., person) representations, event representations, and implicit theories (implicational molecules)—are particularly worth considering.

The Use of Entity Representations

The most common type of entity representation of concern in social psychological research pertains to persons (e.g., a specific individual, a prototypical person, or a group). The representation is typically categorical, consisting of a central concept with which a number of specific features are attached (see Figure 12.1). Once such a representation is formed, participants typically use its central concept as a basis for judgment without performing an extensive review and analysis of its contents (principle 12). This is true even if the behaviors associated with the concept have different implications. Thus, for example, if a favorable or unfavorable concept of someone has been constructed, this concept is used as a basis for evaluating the person despite the fact that behaviors that are inconsistent with this concept are better recalled (Srull, Lichtenstein, & Rothbart, 1985). This is true even when subsequent information reveals that the basis for forming the central concept is invalid (Lingle & Ostrom, 1979; Wyer & Budesheim, 1987; Wyer & Unverzagt, 1985).

Similar considerations surround the use of categorical representations as bases for judgment. Fiske and Pavelchak (1986; see also Fiske & Neuberg, 1990) postulate that when people receive a trait or behavioral description of a person who belongs to a specified social

category, they first decide whether the person is a typical member of the category, based on a global (schematic) comparison of the individual's features to those that characterize the category in general. If the individual is judged to be typical, the favorableness of the category as a whole is used as a basis for their evaluation. Only if the individual is judged to be atypical do people perform a detailed, "piecemeal" analysis of the individual's specific features.

To the extent individual features of an entity representation are considered, the question arises as to how they are used to compute a judgment. This could be done using mechanistic procedures similar to those produced by Fishbein (1963; Fishbein & Hunter, 1964) or Anderson (1971, 1981). To this extent, the diagnosticity and extremity of the individual features are likely to be important. This may not be the case, however, when other computational procedures are used, as suggested in the next section.

The Use of Event Representations

Event representations are composed of a sequence of causally and temporally related events that are conceptualized as a single unit. Evaluations that are made on the basis of these representations are unlikely to involve a piecemeal computation of specific features. Rather, they may be based on a more global assessment of the implications of the event sequence as a whole.

Pennington and Hastie (1986, 1988, 1992) first identified the effects of these representations in research on jury decision making. Their studies suggest that the sort of representation that is formed from information depends on the format in which it is presented, and that the judgments that are made depend on the type of representation that is formed. In a typical study (Pennington & Hastie, 1988), participants received courtroom testimony about a crime in which the evidence was conveyed in one of two ways. In *witness-order* conditions, the testimony was organized according to the witness who presented it. In *story-order* conditions, it was presented in the order it became relevant in constructing a narrative of the events that led up to the crime, the crime itself, and its aftermath. When the prosecution testimony and the defense testimony were conveyed in different orders, 70% of the participants favored the side whose evidence was conveyed in story order. When the evidence for both sides was conveyed in the same order, participants were equally likely to favor each side, but they were more confident of their decision in story-order conditions.

In Pennington and Hastie's studies, an understanding of the temporal order of the events was particularly important in assessing the circumstances of the crime and the likelihood of the defendant's guilt. When this is not the case, the representation that is formed, and the strategy that is employed, can depend on the format in which the information is presented. This possibility was examined in a series of studies by Adaval and her colleagues. In some experiments (Adaval & Wyer, 1998), participants evaluated a vacation trip on the basis of information about the events that would occur. In others

(Adaval, Isbell, & Wyer, in press), they evaluated a politician on basis of events that took place in the course of his career. In *narrative-format* conditions, the events described in both sets of studies were conveyed in a narrative that indicated the order they occurred. In *list-format* conditions, they were conveyed in a bullet-point format and no indication was given of their temporal order. The results of the studies were quite consistent. When all the information was evaluatively similar (all favorable or all unfavorable), evaluations of the target (the vacation or the politician) were nonsignificantly more extreme when the information was conveyed in a list, suggesting that a holistic processing strategy was not inherently any more effective than a piecemeal strategy.

However, accompanying the verbal information with pictures increased the evaluations of the target when the information was conveyed in a narrative but decreased the extremity of these evaluations when the same information was conveyed in a list. As noted earlier, visual images are likely to be components of an event representation, and pictures may facilitate the construction of these images. Consequently, they increase the impact of a narrative representation of the sequence of events as a whole. On the other hand, pictures may interfere with the piecemeal integration of the evaluations of individual events, which is primarily a semantic process. In short, the effects of pictures on evaluations depend on the computational strategy that participants employed, and this strategy, in turn, depends on the sort of representation that participants formed from the information they receive.

Implicit Theories and Implicational Molecules

The influence of implicit theories is evident in virtually all domains of social judgment and decision making. For example, they can guide reactions to success and failure (Dweck, 1991; Dweck & Leggett, 1988), perceptions of social support (Mankowski & Wyer, 1996), perceptions of social reality (Shrum, 2002), person perception (Hong, Chiu, Dweck, & Sacks, 1997), and hindsight bias (Fischoff, 1982; Sanna & Schwarz, 2003). Cultural differences in judgments and behavior can also be traced to differences in the implicit theories that are applied (cf. Hong & Chiu, 2001; Hong, Morris, Chiu, & Benet-Martinez, 2000). A review of research on the use of implicit theories is beyond the scope of this chapter (see Wyer, 2004). A general conceptualization of the rules that govern the use of implicit theories is worth noting briefly.

The simplest implicit theories can be conceptualized as implicational molecules of the form described earlier in this chapter. The use of these molecules in explanation and prediction is postulated by Abelson and Reich (1969) to be governed by a *completion principle*:

> **Principle 13.** If a specific experience or set of experiences instantiates all but one proposition in an implicational molecule, an instantiation of the remaining proposition is inferred to be true as well.

The power of this molecule derives from the assumption that its validity does not depend on which components of a molecule are instantiated by the information available and which are to be inferred. For example, reconsider the "just deserts" molecule noted earlier in this chapter; that is, [P is good (bad). Good (bad) things befall P]. To the extent this molecule is applied, people are likely to infer that a particular person will get what he or she deserves (e.g., that if the person is bad, he or she will be punished or will otherwise come to harm). However, they are also likely to infer that a person deserves what he or she gets (e.g., if the person has experienced misfortune, he or she is likely to be bad or to have done a bad thing). The tendency for persons to make this latter inference has been demonstrated in numerous studies on the disposition to maintain beliefs in a just world (Lerner, Miller, & Holmes, 1976; Lerner & Simmons, 1966; Walster, 1966; Wyer, Bodenhausen, & Gorman, 1985).

The use of numerous cognitive heuristics can also be conceptualized as applications of implicational molecules (Wyer, 2004). For example, consider the molecules [Instances of X occur frequently. Instances of X come to mind easily] and [P is a member of category X. P has attributes x, y, z . . .]. These molecules have implications similar to the availability and representativeness heuristics identified by Tversky and Kahneman (1973, 1982). That is, people not only infer that things come to mind easily if they occur frequently but also infer that things occur frequently if they come easily to mind. (For numerous examples of the impact of ease of retrieval on judgments, see Schwarz, 1998, 2004.) Similarly, people may infer not only that someone who is a Chinese studies professor is likely to be short, have dark hair, and read poetry but also that a person who is short, has dark hair, and reads poetry is likely to be a Chinese studies professor (Kahneman & Tversky, 1971).

Other molecules can be specific to certain types of persons, objects and events. For example, "liking" and "loving" reflect similar affective relations. Yet, [P likes X. O likes X. P likes O] and [P loves X. O loves X. P dislikes O] may coexist and may be applied in different situations, depending on the nature of X. (For example, the first molecule may be applied when X is an inanimate object, a personal interest, or a basic value. The second may be applied when X is a specific job to which both P and O aspire, or a woman whom both would like to marry.) However, the use of the molecules can also vary with their relative accessibility in memory, as noted in the previous section.

CONCLUDING REMARKS

This chapter has attempted to review the general principles that govern the representation of social knowledge and to provide examples of their application. Although the research cited has generally been conducted in the laboratory, I have tried to focus on the representation of knowledge of the sort people acquire in every day life, from conversation, movies, and television or from direct experience. Although the research I have covered is

broad, it is by no means complete. Several areas, including the mental representation of affect and emotion (Ortony, Clore, & Collins, 1988) and the motivational determinants of mental representation (cf. Kunda, 1987, 1990), have barely been covered at all. Nevertheless, this chapter ideally provides a general indication of the state of existing knowledge on the determinants and consequences of mental representations and, in doing so, suggests directions for future research and theorizing.

NOTES

1. A distinction should be made between the mental image that is formed of a verbally described event and a picture. For one thing, many features that might be conveyed in a picture may be absent. (For example, the image of "a boy kicked the football" may not contain an indication of his hair color.) At the same time, features in other sense modalities (e.g., an acoustic representations of a speaker's tone of voice) may be part of the image as well.
2. We will not enter into the debate as to whether visual images are actually formed (cf. Anderson, 1983; Pylyshyn, 1973). However, research by Kosslyn (1980) and others (cf. Shepard & Metzler, 1971) testifies to the utility of a visual image metaphor in conceptualizing information processing and the representations that result from it. Its utility is further demonstrated in the discussion to follow.

CHAPTER 13

Standards

MONICA BIERNAT
SCOTT EIDELMAN

Standards are relevant to nearly every field of inquiry, to every domain of life. There are standards for admission to schools and to professions, for promotions and other evaluations in schools and the workplace, for diagnosing illnesses and assessing recovery, and for determining guilt in the legal system and progress in society. Indeed, it seems difficult—if not impossible—to imagine a world without points of reference against which we might judge and evaluate. In this chapter we focus our attention on *social* standards—individual people or groups—as they affect judgments or evaluations of others and the self. Despite this restricted focus, we hope to highlight general principles by which standards exert influence on judgment and behavior.

Higgins (1990) provides a useful definition of the key construct with which we are concerned: "a standard is a criterion or rule established by experience, desires, or authority for the measure of quantity and extent, or quality and value" (p. 302). A *social standard* in particular may be thought of as "any attribute of a person or of a collection of people that serves as a point of comparison for an individual" (Miller & Prentice, 1996, p. 800). This chapter briefly examines how standards are selected but primarily considers the consequences of the comparison process—that is, the judgment outcome of comparison to some standard. This focus on comparison means that we are concerned with the *relativity* of judgment. Beginning with research on such diverse areas as psychophysics (Helson, 1947, 1964; Parducci, 1956; Postman & Miller, 1945; Stevens, 1957; Volkman, 1951; Wever & Zener,

1928) and the self (James, 1890/1948), psychologists have long emphasized the relativity of intra- and interpersonal experience. That judgment is relative or comparative appears in research on attitudes (Sherif & Hovland, 1961) and decision making (Houston & Sherman, 1995; Kahneman & Miller, 1986), as well as in two domains that are given attention in this chapter: person perception (e.g., Higgins, Rholes, & Jones, 1977) and self-evaluation (Festinger, 1954a, 1954b).

One central theme pervades this chapter: that the outcome of a comparative process can be conceptualized in terms of either *assimilation* or *contrast*. Assimilation occurs when the target of evaluation (e.g., another person or the self) is pulled toward or judged consistently with the standard or expectation, and contrast occurs when the target is differentiated from (judged in a direction opposite) the comparative frame. By "judgment," we typically refer to a connotative evaluation (e.g., a rating on some trait dimension) but also to outcomes that are affective (such as mood or self-esteem) or behavioral (e.g., task performance) in nature as well. Delineating when assimilation versus contrast occurs represents an important goal of this review.

We begin with a brief overview of how standards might be selected in a given judgment situation or, alternatively, thrust on the perceiver. We then review some recent models of standard use and its consequences, and finally we turn to illustrations of how standards are used in self- and other judgment. Here we consider the role of self as standard in judging others, the role of stereotypes

as standards in judging others, and the role of internalized guides and other people to judge the self. Though selective, we hope this review illustrates some basic principles about how standards influence judgment in everyday life.

SELECTION OF STANDARDS

Though the use of standards is ubiquitous, relatively little research attention has been paid to how standards are selected from among the myriad possibilities that exist (cf. Miller & Prentice, 1996). One reason for this lack of attention is simple: Standards are often encountered rather than chosen (Wood, 1989). For example, hopeful undergraduates are not afforded the luxury of choosing what criteria will determine admission into graduate school. And social standards may be imposed (or impose themselves) on individuals. The job candidates who caught a glimpse of the competition ("Mr. Clean" or "Mr. Dirty") in Morse and Gergen's (1970) classic study did not ask to do so, nor did they postpone drawing inferences about their own likelihood of success as a result of this encounter.

As this last example suggests, comparison to standards is often a relatively automatic process (Dunning & Hayes, 1996; Gilbert, Giesler, & Morris, 1995; Stapel & Blanton, 2004), which is to say that standards are often used without intent or awareness (Bargh, 1994). For example, Herr (1986) found that presentation of stimuli outside participants' awareness affected their judgments of an ambiguous target: Moderate stimuli produced assimilation to the standard, and extreme stimuli produced contrast. Mussweiler, Rüter, and Epstude (2004) found similar results in the domain of self-judgment, with participants rating themselves as more or less athletic when subliminally exposed to moderate and extreme standards, respectively. Research by Stapel and Blanton (2004) went even further by showing that subliminal exposure to standards affected *implicit* self-evaluation. When primed with a low standard, the size of participants' signatures (an implicit measure of self-evaluation) became larger; a high standard prompted smaller signatures. In other words, standards—in this research, Albert Einstein or a clown—affected self-evaluation in the absence of any intent to form a judgment. Even when judgment is deliberate, standards used may be unknown or inaccessible (cf. Nisbett & Wilson, 1977; see Parducci, 1983, for a discussion in the realm of psychophysics).

Which standards are used in judgment is often based on the preceding and current contexts in which we find ourselves. Helson's (1964) adaptation-level theory is a case in point. According to Helson, judgment is made with reference to a psychological neutral point (the adaptation level), essentially the average of one's past experiences along the dimension in question. Of course, not all past experience carries equal weight. Factors such as recency and frequency may determine the impact of particular standards on judgment (Avant & Helson, 1973), and judgments may be based on some combination of both the most recent context and the normative standard established by the average of one's past experiences (e.g., see Higgins & Lurie, 1983; Higgins & Stangor, 1988). Judgments may also be influenced by some combination of both local and general norms (Giladi & Klar, 2002; Klar & Giladi, 1997).

Not all perspectives, however, emphasize precomputed points of reference. Norm theory (Kahneman & Miller, 1986), for example, emphasizes the construction of standards *after* events have occurred (see also Goethals, Messick, & Allison, 1991; Taylor, Wood, & Lichtman, 1983). According to norm theory, stimuli evoke their own frame of reference by either recruiting specific exemplars from memory or constraining mental simulation. In each case, counterfactual alternatives are evoked in response to instigating stimuli, and the stimuli are then compared against these postcomputed alternatives.

To this point, we have considered the selection of standards to be a fairly passive process. Yet people have goals, and standards are often chosen with these goals in mind. For example, when selecting one of two possible partners for an upcoming problem-solving task, participants in a study by Ditto and Lopez (1992, study 1) required more evidence of intelligence when an unlikable target was the obvious candidate compared to when the obvious candidate was likable. Because the two possible partners differed in their desirability (irrespective of their intelligence), differential standards were set based on preferred outcomes (see also Sanitioso & Kunda, 1991). Similarly, when deciphering the results of a self-administered medical test, participants allowed more time to pass (i.e., used a higher standard) when led to believe that no change in the color of a test strip indicated the presence of an enzyme deficiency than when led to believe this lack of color change indicated normal enzyme presence (Ditto & Lopez, 1992, study 2). Standards for judging others have also been linked to current needs. Esteem threats, for example, prompt egocentric contrast; Beauregard and Dunning (1998) found that participants' scores on an aptitude test were negatively related to their judgments of a target's intelligence, but only when self-esteem first was challenged. By setting more stringent intelligence standards, high-scoring participants protected their accomplishments by making their performance more unique and harder to obtain. In contrast, the less stringent standards set by low-scoring participants meant that they could also "qualify" for the label "intelligent."

These examples point to *quantitative* differences in standard setting based on particular goals. These same goals may also be reflected in *qualitative* differences in the selection of standards. The vast literature on social comparison theory offers a number of examples. It is widely known that Festinger (1954a, 1954b) posited a basic drive to assess one's abilities and opinions, and that in the absence of objective standards such needs would be best met by comparison with similar others. Thus, social standards were thought to be chosen based on their diagnosticity (see also Wheeler, Martin, & Suls, 1997).

Though Festinger was somewhat vague as to what constituted similarity, others specified that people should select for comparison those who are similar along attributes related to the dimension being judged (Goethals & Darley, 1977). This "related attributes" hypothesis has received empirical support (e.g., Gastorf & Suls, 1978; Miller, 1982; Wheeler, Koestner, & Driver, 1982; Zanna, Goethals, & Hill, 1975).[1]

Motives besides self-assessment have also been shown to drive social comparison (Helgeson & Mickelson, 1995; Taylor & Lobel, 1989), with selection of relevant standards following suit. For example, needs for self-enhancement may motivate comparison with those less well off (Hakmiller, 1966; Wills, 1981; Wood, Taylor, & Lichtman, 1985). Perhaps counterintuitively, comparison with superior others may also foster self-enhancement, provided that we see ourselves as similar to these outperforming others (Collins, 1996; Thornton & Arrowood, 1966; Wheeler, 1966). Self-improvement goals are also associated with the selection of upward comparison targets (Lockwood & Kunda, 1997; Taylor & Lobel, 1989; Wood, 1989).

With so many standards available, one frequent motive may be efficiency, such that standards routinely used in judgment continue to be selected. When evaluating others, participants seem to consistently invoke one well-known and well-used standard; specifically, the self (Dunning & Hayes, 1996; Holyoak & Gordon, 1983). Close friends also become more accessible following self-evaluation, implying their role as a frequent source of comparison (Mussweiler & Rüter, 2003, study 1). Interestingly, routine standards may even be used in spite of the fact that they are often uninformative (e.g., when they are dissimilar along the critical judgment dimension) (Mussweiler & Ruter, 2003, study 3; cf. Festinger, 1954a, 1954b).

People also seem inclined to choose specific *dimensions* on which to be judged (Wood, 1989), as well as contexts in which particular standards may be more or less relevant. For example, participants often express favor for dimensions on which they excel (Tesser & Campbell, 1980; Van Knippenberg, Wilke, & de Vries, 1981; see also Van Knippenberg, 1978). Consider research by Lemaine (1974), who asked two groups of boys at a summer camp to build huts. One group was intentionally disadvantaged with inadequate building supplies. Not to be outdone, these boys fought to gain recognition along a new dimension—the garden they grew next to their second-rate hut. Research with women suffering from breast cancer also indicates intent to change or narrow dimensions of comparison so that negative mood or self-assessment can be deflected (Taylor et al., 1983). Because local contexts instantiate standards, these too may be strategically chosen (Crocker & Major, 1989; Davis, 1966; Frank, 1985). As Gilbert and colleagues (1995) note, though comparisons often arise spontaneously, people often have the choice over which standards they encounter via the contexts they enter. In short, though standards may often be thrust on us, we also play an active role in selecting and construing those standards.

MODELS OF STANDARD USE AND CONSEQUENCES

In this section, we highlight relatively recent models of standard use that have been developed in the literature on social judgment. But first, a quick mention of some major contributions to understanding *psychophysical* and *attitudinal* judgments is warranted. Helson's (1947, 1964) notion of adaptation level, described earlier, notes that the standard in a judgment setting is the "point of perceived neutrality" or, technically, the weighted logarithmic mean of previous stimulation on some dimension. In other words, the context (past experience) provides the standard. Essentially Helson's model is about *contrast*– that is, judgment (and perception) shifts away from the adaptation level, as when a "moderately bright" room appears *very bright* to one who has been adapted to the dark, and *very dim* to one adapted to the bright sunlight.

Volkmann's (1951) "rubberband model" introduced the notion of a frame of reference: Judges set endpoints of response scales to capture the stimulus range they expect to encounter. Anchoring and reanchoring is done as the stimulus range extends and restricts (see Parducci, 1956; Postman & Miller, 1945). The context again provides the standard, but not in the perceptual manner described by Helson. Instead, *cognitions* determine the range of stimuli perceivers *expect* to encounter, and these are translated into judgmental frames of reference. Parducci (1963) incorporated much of the rubberband model in the "range" principle of his model but also invoked a "frequency" principle as well, which suggested that judges use judgments to reflect the frequency—the rank-order position—of items in the stimulus range. For both Volkmann and Parducci, judgments of stimuli are generally contrasted from extreme anchors: With the extension of a range in one direction, judgments move toward the other.

In attitudinal judgment, the idea of own attitude as an anchor was introduced by Hovland and Sherif (1952). That is, one's own position on an issue serves as an anchor so that all other attitudinal positions are judged relative to it. This ultimately led to the development of the social judgment or "assimilation-contrast" model (Sherif & Hovland, 1961), which posited that stimuli *close to* the anchor (i.e., within the "latitude of acceptance") are assimilated, whereas those further away from the anchor (within the "latitude of rejection") are contrasted.[2] Upshaw's (1962, 1969) variable perspective model also took some of Volkmann's ideas and extended them to the domain of attitudinal judgment. Response scales are anchored to the expected range of stimuli on a dimension; this is the judge's "perspective." But if the judge's own position on the dimension is outside the range, the perspective gets extended to encompass his or her position, and the result is enhanced contrast effects.

These early models—along with work by Fechner (1860), Stevens (1957), Thurstone (1928), and Anderson (1974), among others—set the stage for a number of the modern judgment perspectives reviewed below (see Eiser, 1990, for more detail on early judgment

models). These modern models again ask the central question—when assimilation and when contrast?—and they focus on social judgment—judgments of others and the self.

The Set–Reset Model

The set–reset model (Martin, 1986; Martin & Achee, 1992; Martin, Seta, & Crelia, 1990), like many to be reviewed in this section, focuses on context as standard and considers the overlap that exists between an ambiguous target and this context. In a process termed "setting," a judge's representation of an ambiguous target can be pulled toward that overlapping context. In essence, assimilation occurs because reactions to the context can be mistaken for reactions to the target. But if the judge realizes he or she is affected by context, an attempt may be made to avoid using the context—to partial out or subtract its effects. However, because of the overlap between the context and target, this correction may involve subtracting out some of the "true" reaction to the target. The result of this resetting process is reduced assimilation or *contrast* from the context. Contrast effects based on resetting are posited to require more cognitive effort than assimilation effects (Martin et al., 1990).

This model suggests several features that determine the use of context for setting versus resetting. For setting to happen, the target must be ambiguous and the context must be relatively broad and indistinct, such that overlap between context and target can occur. Resetting requires some sort of cue that the effects of the context should be partialed out of the evaluation of the target. For example, Martin (1986) found that an ambiguous target was assimilated to valenced primes, but only when participants were led to believe the priming procedure was interrupted—that is, the effect of the prime was maintained over the interruption and continued to "set" the target. But when the task was completed—signaling separation of prime and target—resetting was triggered, resulting in more favorable ratings in the negative prime condition and less favorable ratings in the positive prime condition (contrast). Other cues to reset include heightened awareness of the context and its influence (Lombardi, Higgins, & Bargh, 1987; Strack, Schwarz, Bless, Kübler, & Wänke, 1993) as well as direct instruction or conversational norms (e.g., "Don't let today's weather affect your mood estimate"; Schwarz & Clore, 1983).

The Inclusion–Exclusion Model

The basic prediction of the inclusion–exclusion model (Schwarz & Bless, 1992a, 1992b) is simple: that "assimilation effects are likely to emerge when the target stimulus and the context stimuli are assigned to the same category, whereas contrast effects may emerge when they are assigned to different categories" (Schwarz & Bless, 1992a, p. 218). The former process—jointly categorizing context and target—reflects *inclusion*, and the latter reflects *exclusion*. In this model, inclusion is the default

mode, as long as the context includes information that is potentially relevant to the representation of the target (obviously irrelevant information is ignored). But if features of the task or situation at hand suggest that contextual information should not be used, "exclusion" or subtraction occurs, resulting in contrast. Inclusion–exclusion is highly similar to setting–resetting (Martin, 1986), and indeed both of these models can be thought of as partialing models, which involve a relatively automatic assimilation mode and a more effortful correction process.

Schwarz and Bless's model is more specific, however, in its emphasis on categorization processes as the key contributor to assimilation and contrast effects (see also Tajfel & Wilkes, 1963). It also offers the elegant organizing principle that inclusion = assimilation and exclusion = contrast. Factors that contribute to exclusion (vs. inclusion) include *extreme*, *distinct*, and *narrow* contexts. The inclusion–exclusion model also adds the proposition that excluded information can serve as a standard of comparison. And because excluded information is likely to constitute an *extreme* standard, this use of the context as standard can contribute to a contrast effect. Thus, two forms of contrast are posited: *exclusion* (correction) or *comparison*, and which occurs, depends on whether the context stimulus is directly *linked* to the dimension of judgment. If so, it will serve as a standard of comparison. If not, it is merely subtracted from the representation but is unlikely to be used as a standard (Schwarz, Münkel, & Hippler, 1990).

The Flexible Correction Model

The previous two models assume that assimilation is the default judgment outcome, and that it reflects a less effortful mode of processing. In contrast, the flexible correction model (Petty & Wegener, 1993; Wegener & Petty, 1995, 1997) suggests that *either* assimilation or contrast may be the default; one is not more effortful or more likely than the other. This approach suggests that perceivers have naive theories about how contexts might affect their subsequent judgments and that they then engage in steps to correct these biases (preemptively, online, or after the fact). If a theory suggests that a context may produce assimilation, those who are motivated and able to do so will correct their judgments away from this assimilative bias. But if a theory suggests a context will produce contrast, correction will occur away from this contrastive bias. For example, most people assume that first considering a dream vacation spot will likely bias judgments of "average" locations in a contrastive fashion (Indianapolis seems less appealing after thoughts of Paris), and indeed judgments show this pattern (Wegener & Petty, 1995). But when cued to *not* let prior judgments affect later judgments, the contrastive tendency is reduced and slightly reversed. This model, then, argues for either assimilation or comparison contrast as a basic outcome of judgment, and for *corrective* contrast or assimilation when motivation and ability to correct are high.

The Interpretation–Comparison Model

Stapel and colleagues have conducted an array of studies pointing to features that contribute to assimilation versus contrast effects, and their general approach can be characterized in terms of an interpretation–comparison model (ICM; Stapel & Koomen, 1998, 2000; Stapel & Winkielman, 1998). According to their model, accessible and applicable contextual cues are likely to be used as an interpretation frame and produce assimilation effects, whereas distinct contextual cues function as comparison standards and produce contrast. Thus, interpretation = assimilation, comparison = contrast (see Higgins, 1996; Stapel & Koomen, 1998).

In general, this model requires some kind of similarity between the target and the context or standard for any type of context effect to emerge. This idea in itself is not novel—in Brown's (1953) classic study of weight estimates, judges showed contrast from extreme weight anchors of the same type as the targets, but not from an equally heavy *tray* that was also lifted. Brown (1953) stated: "The anchor, to be effective, must be perceived as a member of the same class" as the target (p. 210; see also Parducci, Knobel, & Thomas, 1976; Suls & Wills, 1991; Upshaw & Ostrom, 1984). Stapel and colleagues note that given similarity, another feature that determines whether interpretation (assimilation) or comparison (contrast) occurs is the *distinctness* of the standard or context (Stapel, Koomen, & van der Plight, 1996, 1997; see also Helson, 1964). *Distinct* contexts serve as comparison standards, as do *extreme* contexts (e.g., Herr, 1986). On the other hand, the use of primed/contextual information as an interpretation frame is enhanced by *nondistinct*, *moderate*, and/or *broad* contextual cues.

Research examining the impact of *distinctness* versus *breadth* has typically involved manipulations in which either broad, abstract behavior labels are primed or specific actor–trait links or *exemplars* are primed. In general, exemplar primes produce *contrast*, whereas broad or abstract primes produce assimilation (e.g., Stapel & Koomen, 1996; Stapel & Schwarz, 1998). Comparable effects have also emerged in research examining behavioral responses to primes or context. In a study that might be called a modern classic, researchers found that priming of an elderly stereotype (through exposure to broad terms associated with that category) led individuals to walk more slowly as they left an experiment—a behavioral assimilation effect (Bargh, Chen, & Burrows, 1996). In follow-up research, however, others found that priming of *exemplars* (e.g., Albert Einstein) rather than broad categories (professor) produced behavioral contrast effects (Dijksterhuis et al., 1998; see also Dijksterhuis, Spears, & Lépinasse, 2001).

Central to the ICM is the fact that narrow primes are more likely to be used as comparative standards of judgment that exclude the target, whereas wide or abstract primes serve as interpretive frames in which the target can be included (Schwarz & Bless, 1992a; Stapel & Koomen, 1996, 1997). Indeed, it is worth noting that the concept of an interpretation frame is quite similar to the inclusion principle in Schwarz and Bless's (1992a)

inclusion–exclusion model. That is, the same principles that lead a context to serve as an interpretation frame also lead the target to be included in the context, with assimilation as the likely result. However, the comparison standard portion of the ICM is *not* analogous to Schwarz and Bless's exclusion principle (which implies more active correction) but does resemble the separate comparison process posited by Schwarz and Bless (see above). The ICM also does not make any claims about the default context effect, or the relative ease/effort involved in these outcomes. The key contribution of the ICM is its broad characterization of two functions that context can serve—the interpretation/framing function versus the comparison function.

The Selective Accessibility Model

The selective accessibility model (SAM), recently formalized by Mussweiler (2003a, 2003b), highlights how knowledge made accessible through comparison processes influences judgments of targets. Specifically, the model suggests that there are three phases involved in rendering a comparative judgment. First, a standard must be selected; second, the comparison must occur—one assesses the similarity/dissimilarity of the target object to the standard—and third, knowledge made accessible by the earlier phases must be integrated to produce an evaluation of the target.

Although the standard selection phase is important, the key contribution of the SAM lies in its articulation of what occurs in subsequent steps. The comparison step involves an initial, holistic assessment of similarity between the target and the standard, and based on that decision, the judge then engages in either similarity or dissimilarity testing. This testing then leads to the selective accessibility of evidence consistent with the hypothesis. That is, if one is testing the hypothesis that the target = the standard, standard-consistent knowledge of the target will become accessible. And conversely, when one tests the hypothesis that the target ≠ the standard, standard-*in*consistent knowledge about the target becomes accessible.

In the final judgment stage, the SAM predicts that similarity testing and the resultant accessibility of standard-consistent knowledge about the target leads to *assimilation*, whereas dissimilarity testing and the resultant accessibility of standard-inconsistent knowledge leads to *contrast*. In the SAM, then, the direction of context effects depend on whether accessible information makes the target seem like or unlike the standard.

Mussweiler's model also acknowledges that the comparison process, in addition to producing selective accessibility effects, provides a reference point—a standard—against which the accessible knowledge can be compared. Thus, considering whether one is adjusting well to college compared to a very well-adjusted student might activate knowledge of one's own good adjustment (and therefore prompt assimilation) at the same time that a high standard is invoked (facilitating contrast). Mussweiler (2003b) notes that "reference point use may well constitute an additional mechanism that influences

the evaluative consequences of comparison independently of selective accessibility . . . the same comparison may involve both the assimilative tendencies of selective accessibility and the contrastive tendencies of reference point use" (p. 483). This theme will be taken up in the next judgment model to be considered.

The Expectation and Contrast Model

A number of social judgment models suggest that assimilation is a relatively effortless process, whereas contrast requires both motivation and capacity to proceed (e.g., Martin et al., 1990; see similar themes in Gilbert, Pelham, & Krull's, 1988, stage model of attributional judgment). In the flexible correction model, *either* assimilation or contrast is the default, depending on naive theories about the impact of context. In contrast to these perspectives, Manis and Paskewitz (1984a, 1984b) suggest that contrast and assimilation operate in parallel, with no exclusive processing advantage for either: Judgments are affected by both *expectational* influences and *comparison* strategies. For example, a priming experience or past exposure to relevant stimuli can create an expectation about what future experiences will be like, promoting assimilation; at the same time, the prime creates an anchor against which subsequent stimuli are judged, promoting contrast (see Manis, Biernat, & Nelson, 1991). The net judgment result depends on which tendency is strongest.

In an illustrative study, participants were first exposed to a series of word definitions that indicated either high or low pathology and were asked to indicate which had been produced by schizophrenic patients (Manis & Paskewitz, 1984a). This induction series was designed to create *expectations* about the kinds of definitions likely to be seen later in the study, and indeed, measures indicated that those in the high pathological induction condition expected more psychopathology in a subsequent group of targets. When participants then judged a test series of moderately psychopathological definitions, a marked contrast effect emerged, with the moderate definitions judged more pathological by those originally exposed to the nonpathological induction set. Furthermore, expectations were positively correlated with judgments. Thus, the induction phase produced corresponding expectations that positively predicted judgments, at the same time these judgments were *contrasted* from that initial context.

The expectation and contrast model does not speak directly to specific factors that affect assimilation and contrast effects. However, implicit in the model is that context effects in general require that an unambiguous—perhaps *extreme*–expectation be induced, and contrast effects require that the target be *ambiguous or moderate* on the dimension of interest, or discrepant from the context. In addition, Manis and Paskewitz (1984a) propose that the time course of the expectation and contrast paths operate differently; namely, the contrastive tendency may decline more rapidly than the assimilative one. Indeed, with a time delay introduced between a contextual induction of expectations and target judgments, assimilation rather than contrast is a typical result (Manis

& Blake, 1963; Manis & Moore, 1978). Perhaps the most significant aspect of this model is its premise that assimilative and contrastive tendencies work in tandem; that they may "derive from the same eliciting experience" (Manis et al., 1991, p. 210).

The Reflection and Evaluation Model

Another general model of comparative thinking, the reflection and evaluation model (REM), was recently proposed by Markman and McMullen (2003). We describe this model last because it shares much in common with the inclusion–exclusion model (Schwarz & Bless, 1992a) and Mussweiler's (2003b) SAM. It also picks up the theme of simultaneity in comparative processes articulated by Manis and Paskewitz (1984a, 1984b). However, the heart of this model is the notion of *mental simulation*— "the consideration of alternatives to present reality" (p. 244; see Kahneman & Miller, 1986), and the theory is concerned primarily with *self*-judgments (counterfactual comparison research providing the main empirical base). In general, the model proposes two modes of mental simulation that operate in parallel. The *reflection* mode involves "as if" thinking, in which one "simulates that information about the comparison standard is true of, or part of, the self" (Markman & McMullen, 2003, p. 245). Note that this mode is quite similar to Mussweiler's notion of similarity testing, and that the likely outcome of this process is also *assimilation*. The second mode of simulation is *evaluation*, in which the standard operates as a point of reference against which the self is evaluated, likely leading to *contrast*. Markman and McMullen note that "reflection occurs when information about the standard is included in one's self-construal, and evaluation occurs when such information is excluded" (p. 245), a statement that highlights the strong connection to Schwarz and Bless's (1992a) inclusion–exclusion model.

One distinction between "reflection" in the REM and "selective accessibility" in the SAM is that the information one comes up with in reflection may be *imaginary* rather than selected from an assortment of facts about the self. Nonetheless, imagination brings standard-consistent cognitions to the fore of thought. And rather than the biased hypothesis-testing mechanism posited by Mussweiler, the imagination effect is similar to findings in the imagination–explanation literature, whereby coming up with explanations for possible future events increases estimates of the probability those events will occur (Koehler, 1991; Ross, Lepper, Strack, & Steinmetz, 1977).

Also distinguishing the REM from most other models is the notion of parallel yet independent processes of reflection and evaluation. The ultimate outcome of these processes (i.e., whether assimilation or contrast occurs) depends on the relative strength of these processes, which, in turn, is based on "the extent to which contextual features encourage one to think about the self and the standard together, as a single unit or entity (i.e., inclusion), or the extent to which one thinks about the self and the standard separately, as two distinct entities (i.e., exclusion)" (Markman & McMullen, 2003, p. 249). That is,

context will determine whether a mode of inclusion or exclusion operates. What are the contextual features that matter here? Many of the features described earlier: Similarity between standard and target or temporal closeness will prompt the reflection process and assimilation; distinctness of the standard or immutability of the self will prompt evaluation and contrast. Markman and McMullen (2003) also note that attentional focus is key: To the extent that context focuses one on the standard itself, reflection is likely, but to the extent the focus is on the *comparison* between the self and standard, evaluation is likely (see McMullen, 1997).

In general, then, the REM can be thought of as a hybrid of the inclusion–exclusion model (Schwarz & Bless, 1992a), the ICM (Stapel & Koomen, 1998, 2000), and the SAM (Mussweiler, 2003a, 2003b), with a hint of expectation–contrast thrown in (Manis & Paskewitz, 1984a, 1984b). The authors suggest that contextual factors affecting inclusion–exclusion set the processes of reflection and evaluation in motion. These processes make different kinds of information accessible and result in assimilation or contrast, in judgment and behavior.

Summary

The models reviewed above have in common the idea that a contextual cue can function as either an interpretive framework or a reference point. Factors that make the context less distinct from the target (i.e., allow for inclusion of the target in the context) facilitate the *interpretation* framework, whereas those that make the context distinct (allow for exclusion) generally facilitate the use of context as a *reference point* that prompts contrast. The models are largely cognitive in nature and largely silent on the issue of how motivational variables may contribute to judgment outcomes (cf. Higgins, Chapter 19, this volume). They also differ in important ways; in terms of the assumed default process (assimilation or contrast), the sequential versus simultaneous nature of the process, the assumed effort involved in contrast (i.e., is it a basic perceptual effect or part of an effortful correction process?), and the extent to which process variables are articulated (e.g., similarity–dissimilarity testing in the SAM; as-if thinking in the REM). Assimilation and contrast effects both occur under different conditions, and the models described here have been able to predict and explain a large array of findings. Integrating the models fully would be an arduous task, and no doubt each model may have its own special sphere of relevance. What seems more important is that these models offer a general framework for predicting and understanding the when and why of assimilation and contrast.

ILLUSTRATIONS OF STANDARD USE IN SELF- AND OTHER JUDGMENT

The previous section reviewed general models of social judgment. But precisely how is standard use reflected in everyday evaluation of self and others? In this section, we provide a selective sampling of specific ways in which standard use affects judgments of others and the self. We consider the *self* and *stereotypes* as standards for judging others and a variety of standards used to judge the self.

The Self As a Standard in Judging Others

Psychologists have long accorded the self a prominent role in the judgment of others (e.g., Freud, 1924/1956; James, 1890/1948), often specifying that the self can serve as a standard to judge others (Combs, 1959; Heider, 1958; Krech & Crutchfield, 1948). For example, attitude theorists have argued that one's own attitudes serve as anchors in the evaluation and perception of other attitude stances (Eiser & Stroebe, 1972; Hovland, Harvey, & Sherif, 1957; Judd & Harackiewicz, 1980; Sherif & Hovland, 1961; Upshaw, 1962). Even Helson (1964), whose work emphasized sensory contributions to judgment, suggested that an individual's attitudes and beliefs can be included in his or her general "adaptation level," affecting subsequent experience and judgment. In this section, we review findings from two literatures, each indicating that the self is influential as a standard for judging others. However, as we will see, the form this judgment takes—either assimilation to or contrast from the self—depends on a host of variables, many reviewed in the models described earlier.

Using Our Own Attributes in Judgments of Other Individuals

In this section, we consider how the self's attributes may be used to judge others in situations in which there is no explicit call to compare. Research on attributive projection indicates a positive relationship between one's standing on a given trait and judgment of that trait in others (Dunning, 2003; Holmes, 1968). For example, self-relevant attributes appear in the free descriptions of others more often than do non-self-relevant attributes (e.g., Dornbush, Hastrof, Richardson, Muzzy, & Vreeland, 1965; Lemon & Warren, 1976; Shrauger & Patterson, 1976), and individuals who judge themselves extremely on attributes tend to rate ambiguous or attribute-consistent targets more highly on those traits than do individuals for whom the attribute is less relevant (e.g., Carpenter, 1988; Catrambone & Markus, 1987; Lewicki, 1983; Markus, Crane, Bernstein, & Siladi, 1982; Markus & Smith, 1981; Markus, Smith, & Moreland, 1985). Recently, it has been shown that we may also assume that others have goals similar to our own (Kawada, Oettingen, Gollwitzer, & Bargh, 2004).

Lambert and Wedell (1991) documented that this positive relationship between own and ambiguous other's standing on a trait holds even after controlling for dimension importance and affective response to the target. For example, self-described "sociable" participants judged an ambiguously sociable actor (who "installed a telephone answering machine" and "decided to join the Peace Corps") to be more sociable than did nonsociable participants, even when the importance of sociability and affective extremity in reactions to the target behaviors were controlled (Lambert & Weddel, 1991, study 1).

These findings demonstrate assimilation: Judgments of others are drawn toward the self. As suggested previously, this assimilative pattern is most pronounced when targets are ambiguous with respect to the trait in question (Green & Sedikides, 2001). Similarly, the type of judgment task also may affect the propensity to assimilate targets to the self. Factual tasks leave little room for the self to influence judgment of others. In contrast, more "conjectural tasks"—those that require inferential judgment—allow perceivers to go "beyond the information given" (Catrambone & Markus, 1987). Both target ambiguity and judgment tasks that are open to construal will reappear in this chapter as factors that make judgmental assimilation more likely.

However, some of this same literature points to circumstances under which differentiation or contrast of others from the self is more likely to occur. One condition seems to be that the target other is unambiguously low on the self-relevant trait. For example, Markus and Fong (1979, cited in Markus & Smith, 1981) reported that "independent schematics" judged an actor who never behaved independently as more dependent than did aschematic participants. Somewhat different interpretations have been advanced for these sorts of contrast effects. Markus and Smith (1981) interpret them in social judgment theory terms (Sherif & Hovland, 1961). To the extent that a target's actions fall outside an individual's latitude of acceptance (as do very dependent actions when one is an independent person), those actions are seen as distinctive and therefore contrasted from one's own position. However, Lambert and Wedell (1991) suggest that participants' judgments of such *un*ambiguous behaviors are not directly mediated by self-standing on the trait in question but by the extremity in one's evaluative reactions to the target behaviors. This explanation is more consistent with accentuation theory, which posits that reactions to stimuli (in this case, targets who behave dependently vs. not) are polarized in accordance with value connotations of those behaviors (Eiser, 1990; Eiser & Stroebe, 1972; Judd & Harackiewicz, 1980; Tajfel, 1957).

A somewhat different form of contrast effect is also evident in research on "egocentric definitions" of trait concepts (Dunning, 1993; Dunning & Cohen, 1992; Dunning, Meyerowitz, & Holzberg, 1989). In a series of studies, Dunning and his colleagues have consistently reported *negative* relationships between participants' objective standing on an attribute (e.g., SAT scores) and their subjective judgments of a target person (whose SAT scores are known) on that same attribute (e.g., intelligence; Beauregard & Dunning, 1998; Dunning & Cohen, 1992; Dunning & Hayes, 1996; Dunning & McElwee, 1995; Dunning et al., 1989; Dunning, Perie, & Story, 1991; see also Felson, 1990). For example, Dunning and Cohen (1992, study 4) found that the more hours of athletic activity participants engaged in per week, the less athletic they judged targets described as engaging in various hours of athletic activity themselves. This general contrast effect was strongest for low-athletic targets (those who spent just 1 hour per week in athletic pursuits). That is, low-athletic participants tended to judge these targets favorably on the athletic dimension, whereas high-athletic participants judged them unfavorably.

The type of contrast effect demonstrated by Dunning and his colleagues appears to be self-serving in nature: "Individuals will define traits in ways that reflect back favorably on themselves" (Beauregard & Dunning, 1998, p. 608). The high-performing individual—for example, one who scores 780 on the math SAT—will set high standards for math performance, thereby distinguishing among targets with lower scores and successively denigrating these targets as their scores decrease. The result is that one's own performance and underlying ability are favorably distinguished from others, presumably increasing one's sense of self-worth. The low-performing individual (e.g., one who scores 500 on the math SAT) will set lower standards for math performance such that he or she can be included among those "qualifying" for the trait (i.e., having math ability), with some regard for "reality constraints" (Kunda, 1990). Additional research has demonstrated that this "egocentric effect" is strongest among those participants who explicitly mention comparing the target to themselves (Dunning & Hayes, 1996), among those dispositionally high in self-esteem (who presumably have a positive self-image to protect; Dunning & Beauregard, 2001), and under conditions when self-esteem is threatened (e.g., as a result of failure on a task; Beauregard & Dunning, 1998).

It is worth noting an important distinction between the work of Dunning and his colleagues and that of Markus, Lambert, and Wedell and others. As indicated earlier, these latter researchers have primarily documented assimilative effects of self on judgments of others, whereas Dunning and his colleagues report contrastive results. A key difference seems to be that the self-attributes Dunning assesses are participants' specific performances or behaviors on the dimension of interest (e.g., SAT scores, hours of athletic activity, and times per week being late to class) rather than the more typically used global trait ratings (e.g., intelligence, athleticism, and punctuality). Consistent with the notion that *distinct* contexts trigger contrast, others may more easily be contrasted from *specific* self-referential standards but assimilated to *abstract* self-views. Indeed, in one study from Dunning's lab that relied on less distinct self-ratings (e.g., to what extent do you "make friends easily"?), judgments of others on the related trait (e.g., sociability) were assimilated to self-ratings (Beauregard & Dunning, 2001).

False Consensus and False Uniqueness

This discussion of self-as-standard for judging others has thus far skirted around two other relevant literatures: One on the false consensus effect—the tendency to overestimate the likelihood that others will act or feel as we do (e.g., Marks & Miller, 1987; Mullen et al., 1985; Ross, Greene, & House, 1977; Sherman, Pressin, & Chassin, 1984)—and one on the false uniqueness effect—the tendency to underestimate the commonality of our self-attributes (Campbell, 1986; Goethals et al., 1991; Marks, 1984; Suls & Wan, 1987). In general terms, these two

phenomena represent assimilation and contrast effects, respectively. Although clearly relevant to our previous discussion of the role of self in judging others, they have one distinction: False consensus and false uniqueness effects involve making predictions regarding the attitudes and behaviors of a target population or group rather than judging a specific individual about whom some descriptive information has been provided. Thus, these effects are more predictive than evaluative, and more general (group-related) than particular (person-related).

Operationally, the false consensus effect is said to have occurred "when a person engaging in a given behavior estimates that behavior to be shared by a larger proportion of some reference group than would be estimated by a person engaging in an alternative behavior" (Mullen, Driskell, & Smith, 1989, p. 84). In other words, false consensus is not about deviations from *actual* consensus (see Gross & Miller, 1997, for some discussion of this type of error) but, rather, about deviations between individuals who differ in their self-reported attributes in terms of their predictions and expectations regarding others' standing on those attributes. The effect has been reported in such domains as behaviors, traits, preferences, beliefs, and personal problems (see Marks & Miller, 1987; see Wallen, 1943, for an earlier attitudinal example). For example, people who indicate that they would wear a sandwich board sign saying "Eat at Joe's" assume that 65% of others would do the same (compared to a 31% estimate among those who would not wear the sign themselves; Ross et al., 1977); similarly, people who take showers during a shower ban assume that 63% of others do as well (compared to a 39% estimate by nonbathers; Monin & Norton, 2003). The false consensus effect—again, an assimilative tendency—is conceptually linked to the phenomena of social projection (Allport, 1924), attributive or assimilative projection (Berkowitz, 1960; Holmes, 1968, 1978; Murstein & Pryer, 1959), and assumed similarity (Cronbach, 1955). One meta-analysis based on 23 studies indicated a reliable, moderate false consensus effect size ($r = .31$; Mullen et al., 1985; see also Krueger, 2000).

As is true of other self-as-standard phenomena, explanations for the false consensus effect have focused on both cognitive and motivational factors. The most common cognitive accounts emphasize selective exposure and/or cognitive availability and accessibility—people normally associate with (and therefore have available in memory) others who are similar to themselves (Bosveld, Koomen, & van der Pligt, 1994; Goethals, Allison, & Frost, 1979; Manstead, 1982; Mullen et al., 1985; Ross et al., 1977; Sherman, Presson, Chassin, Corty, & Olshavsky, 1983). The fact that false consensus effects are stronger when projecting to ingroups than outgroups also supports the "assumption of similarity" account (Mullen, Dovidio, Johnson, & Copper, 1992; Spears & Manstead, 1990). Dawes's (1989) cognitive/statistical induction account further suggests that one's own behavior may be the only available information regarding prevalence; if the self is akin to a randomly drawn individual from the population of interest, it may be reasonable to assume that own behavior is the majority position.[3]

In addition to these cognitive factors, false consensus may also be motivated by the need to validate the correctness of a position, maintain or protect self-esteem, promote smooth interaction, and so on (Agostinelli, Sherman, Presson, & Chassin, 1992; Sherman et al., 1984; for reviews, see also Dunning, 2003; Marks & Miller, 1987). In one set of studies, participants given failure feedback (about their ability to discriminate among fake and real suicide notes) showed a strong false consensus effect in their estimates of the performance of other undergraduates on the same task (Sherman et al., 1984). Importantly, in the success conditions, participants were just as likely to "project" from their own behavior as from an available other individual's behavior in their estimates of group performance, but in the failure condition, projection was greatest when the self rather than another available individual was involved. The authors write, "when self is threatened, perceptions of consensus may be increased by a motivation to seek normalization and support for one's own behavior" (Sherman et al., 1984, p. 127).

The false uniqueness effect is a complementary pattern indicating contrast of others from the self. With false uniqueness, the prevalence of one's own attributes in a given population is underestimated. This result tends to appear in judgments of talent, ability, or other desirable characteristics (or internal traits; see McFarland & Miller, 1990), such that one's virtues are perceived as rare (Suls, Wan, Barlow, & Heimberg, 1990). In general, false uniqueness effects are less commonly reported than false consensus effects, as a count of relevant published articles attests (at this writing, PsycInfo retrieves 154 "false consensus" hits and only 17 on "false uniqueness"). Researchers creating situations favorable to both phenomena seem more likely to find evidence for consensus (e.g., Agostinelli et al., 1992; Campbell, 1986; Sherman et al., 1984). Perhaps this indicates the cumulative effect of cognitive and motivational forces in the false consensus effect.[4] That is, the dominant cognitive account of false consensus effects—self-standing as highly accessible—cannot explain false uniqueness effects, leaving self-enhancement as the primary contributor to false uniqueness.

Still, a number of factors have been proposed as determinants of whether assimilation (false consensus) or contrast (false uniqueness) occurs. For example, studies have documented assimilative effects on some dimensions (e.g., attitudes) and contrast on others (e.g., abilities; Marks, 1984). Valence of the dimension may play a role, such that we underestimate the percentage of others who perform "moral" acts such as giving blood, but overestimate the prevalence of "selfish" acts (Allison, Messick, & Goethals, 1989; Goethals, 1986; Mullen & Goethals, 1990). Furthermore, a meta-analysis indicated that independent of this valence effect, false consensus reduces as the *actual* consensus regarding an attribute increases. That is, when perceivers are actually in the majority, the tendency to overestimate this consensus is reduced (Mullen & Goethals, 1990; see also Krueger, 1998).

Additional studies have demonstrated that which effect is observed depends on an individual's standing

on the dimension (Campbell, 1986; Goethals, 1986; Sigelman, 1991). For example, Campbell (1986) found that those low in self-rated ability showed stronger false consensus effects (especially when the abilities were self-relevant) than those *high* in ability (though the latter did not show reliable false uniqueness effects). And in a study focusing on own attitudes toward stigmatized groups and perceptions of the attitudes of others, those *low in tolerance* showed false consensus effects, whereas those *high in tolerance* showed strong false uniqueness effects (Sigelman, 1991).

Still others have found evidence for both effects in a single judgment context, but on different sets or types of questions. For example, in one study, false consensus was found on measure of choice between two unpleasant situations, whereas false uniqueness was found on a measure of emotional reactions in the least preferred choice situation (McFarland & Miller, 1990). Biernat, Manis, and Kobrynowicz (1997) further suggested that the form of measurement (objective or subjective) as well as judgment order determines whether others are contrasted from or assimilated to the self.

False consensus and false uniqueness effects may also depend on the extent to which one's construal of an attribute being judged (e.g., in positive or negative terms, or in broad or narrow terms) matches beliefs about the construal of the population whose opinions are being estimated (Bosveld, Koomen, & van der Plight, 1996; Bosveld, Koomen, van der Pligt, & Plaisier, 1995). For example, in one study, highly involved Christians (compared to less involved Christians and "nonbelievers") showed a false uniqueness effect when estimating the percentage of Christians in the Netherlands, and this effect was based in part on their construal of the category "Christian" in narrow terms (Bosveld et al., 1996). Gilovich (1990) has argued that false consensus effects are stronger on items or issues that are open to "subjective construal." For example, false consensus is greater when individuals make self–other judgments of "competitiveness" (a highly subjective attribute) compared to self–other judgments of being a "first-born child" (an objective attribute, not open to differential construal).

In general, this literature points to assimilation as the more likely outcome in projections from the self to other groups. However, motivational goals of self-enhancement, as well as narrow construals of self-relevant categories, may prompt differentiation of self from others—or contrast. Interestingly, Karniol (2003) has recently pointed out an apparent paradox in the false consensus literature: False consensus effects are *weaker* (though not indicative of false uniqueness) when self-standing is salient (e.g., when participants first indicate their choices or attitudes and then estimate those of others; see meta-analyses by Fabrigar & Krosnick, 1995; Mullen et al., 1985; Mullen & Hu, 1988). This suggests that individuals do not assume similarity between self and other; in fact, the self is typically viewed as fairly distinct from others (Holyoak & Gordon, 1983; Kihlstrom et al., 1988), a feature that typically gives rise to *contrast* (Stapel & Koomen, 1998). Karniol (2003) suggests a "protocentric" alternative to the "egocentric" view re-viewed in this section: Predictions about others (typically, assimilative predictions) are made relative to generic representations of prototypical others. The next section considers a particular type of social representation—stereotypes—as they affect other judgments.

Stereotypes as Standards in Judging Others

Most prominent models and studies of stereotyping highlight *assimilation* effects. Indeed, the very definition of a "stereotyping effect" invokes assimilation—an individual member of a group is judged in line with a group stereotype (see Brewer, 1996). From this perspective, a stereotype serves as an interpretive framework that guides encoding of an individual target's behavior (von Hippel, Sekaquaptewa, & Vargas, 1995) and judgment of that target in a manner consistent with the stereotype (Bodenhausen & Macrae, 1998; Brewer, 1988; Fiske & Neuberg, 1990). Hundreds of studies suggest that stereotypes often operate in this fashion (for a review, see Schneider, 2004).

Another view suggests that in addition to serving as interpretive frameworks, stereotypes also function as *comparison standards* for judging individual group members on stereotype-relevant dimensions (Biernat & Kobrynowicz, 1997; Biernat & Manis, 1994; Biernat, Manis, & Nelson, 1991). For example, the stereotype that women are more verbally able than men may not only lead perceivers to expect that a given woman will have higher verbal skill than a given man but may also prompt them to compare the woman's skill to the expected (high) skill level of women, and the man's skill to the expected (lower) skill level of men. Because women are compared to women and men to men, standards "shift" with category membership. The result in this example is that women are held to a higher standard than men, with the potentially paradoxical consequence that a given woman may be judged *less* verbally skilled than a comparable man—a contrast effect (see Biernat & Kobrynowicz, 1997; Biernat & Manis, 1994).

Biernat and colleagues have noted, however, that such contrastive patterns are more likely when judges use *subjective* evaluative language (labels such as "high" or "low," "good" or "bad") rather than "objective" or common-rule assessments (e.g., estimates of verbal SAT scores). This is the case because subjective language is slippery—there is no inherent, stable, agreed-on meaning of the label "good"—and therefore it can be used and interpreted in a within-category fashion. "Good verbal skill" for a woman may mean something quite different (objectively better) than "good verbal skill" for a man. By definition, common-rule judgments cannot shift in meaning in this way (e.g., an SAT score means the same thing regardless of the target's category membership). Thus, for example, objective estimates of verbal skill (SAT scores, grades) tend to be higher for female than male targets, even when subjective evaluations for the sexes are identical (Biernat & Manis, 1994). Indeed, the signature "shifting standards" finding is that stereotype-assimilative findings tend to emerge when target judgments are made in objective units, but reductions or reversals (contrast) ap-

pear when subjective evaluations are rendered (for reviews, see Biernat, 2003; Biernat, Vescio, & Manis, 1998).

Stereotype-contrastive judgment patterns are also described in the literature on expectancy violation theory (Bettencourt, Dill, Greathouse, Charlton, & Mulholland, 1997; Biernat, Vescio, & Billings, 1999; Jackson, Sullivan, & Hodge, 1993; Jussim, Coleman, & Lerch, 1987). According to this perspective, when information about a target violates stereotype-based expectations, evaluations are extremitized in the direction of that violation. Thus, Blacks with strong academic credentials may be judged more competent than Whites with comparable credentials (Jackson et al., 1993; Linville & Jones, 1980), Whites who speak nonstandard English may be viewed more negatively than Blacks who do the same (Jussim et al., 1987), and baby-faced children who commit serious misbehavior may receive harsher punishment than their mature-faced peers (Zebrowitz, Kendall-Tackett, & Fafel, 1991; see also Zebrowitz & Lee, 1999).

An important distinguishing characteristic of the shifting standards model, however, is its contention that these contrastive patterns may be more apparent than real, in that they tend to diminish when targets are judged along a common continuum (i.e., in objective units). Research bears this prediction out. In an applicant evaluation study, Biernat and Kobrynowicz (1997) found relatively high subjective evaluations of women relative to men. However, the same study revealed that when other judgments and decisions were made about the applicants (e.g., objective performance estimates and decision rules to be certain of the applicant's ability) women were judged more negatively than men (lower objective performance appraisals were given; harsher decision rules for diagnosing ability were applied). In other words, assimilation to stereotypes persisted (see also Foddy & Smithson, 1989; Foschi, 1992, 1998). A very similar pattern emerged in a study of expectations and stereotypes based on baby-facedness. Berry and Zebrowitz-McArthur (1988) found that baby-faced defendants who committed intentional offenses were sentenced more severely than analogous mature-faced defendants. However, this contrast effect appeared only on the subjective sentencing decision (rated from "minimum" to "maximum"). In forced-choice judgments of *guilt* (yes or no), baby-faced defendants received the benefits of the benign stereotype associated with their group; they were less likely than mature-faced defendants to be found guilty of intentional crimes.

More generally, research on expectancy violation highlights the dual role that stereotypes and expectations may play in social judgment: They tell us what we are likely to see (and thereby influence our perceptions in the process), and they serve as benchmarks against which deviations from expectation can be noted. This echoes themes introduced in the expectation–contrast model of Manis and Paskewitz (1984a, 1984b). The outcomes of these two processes seem to depend, in part, on whether judgments are rendered in subjective or objective units.

Abele and Petzold (1998) also considered the role of stereotypes as expectations versus reference points or "perspectives." Expectations produce assimilation effects, in that assumptions about the "typical case" are integrated into judgments of the target (Anderson, 1981), whereas reference points or "perspectives" produce contrast in that the target is judged relative to the category range or boundaries (Eiser & van der Pligt, 1982; Ostrom & Upshaw, 1968; Parducci, 1965; Upshaw, 1962). The consequence of using stereotypes as expectations is that the distinction *between* categories is enhanced, and differentiation within categories is reduced (Tajfel, 1969; Tajfel & Wilkes, 1963). When stereotypes are used as reference points, however, greater within-category distinction relative to between-category differentiation results. Thus, this perspective suggests that stereotype-assimilative effects will be observed whenever conditions are present that emphasize the need for between-category differentiation. These may include motivational factors such as social identity concerns (Hogg & Abrams, 1988; Tajfel, 1957; Turner, Oakes, Haslam, & McGarty, 1994) or position in a high-power role (Fiske, 1993), as well as explicitly stated task purposes or "metainformational cues" (Leyens, Yzerbyt, & Schadron, 1994; Yzerbyt, Schadron, Leyens, & Rocher, 1994).

In their own research, Abele and Petzold (1998) documented that when judges evaluated the helpfulness of both nurses and stockbrokers in an intermixed format, this cued them that differentiation between categories was important, and assimilation to stereotypes occurred (nurses were judged more helpful than stockbrokers; see also Manis, Paskewitz, & Cotler, 1986; Martin & Seta, 1983; Seta, Martin, & Capehart, 1979; Tajfel & Wilkes, 1963). When targets were presented in blocks (nurses separated from stockbrokers), this apparently cued perceivers that within-category differentiation was critical—in blocked conditions, stockbrokers were judged more helpful than nurses (a contrast effect).

When assimilation to and when contrast from stereotypes? Few would deny that stereotypes play an important role in the judgments we make about other people. And most of the literature on stereotyping concerns itself with *assimilation* effects—the tendency for individual members of stereotyped groups to be judged consistently with group stereotypes. However, assimilation is less likely to occur when target attributes are *in*consistent with the category label, and more generally when clearly diagnostic individuating information is available (see Kunda & Thagard, 1996, for a review). As noted previously, assimilation to stereotypes is also less likely when judgments are assessed in subjective as opposed to common rule units (Biernat et al., 1991)

A number of these features have been discussed elsewhere in this chapter as factors affecting assimilation and contrast. For example, ambiguous features of targets are likely to prompt assimilation, as the information can readily be drawn to and interpreted in light of the stereotype (an "inclusion" or "interpretation" effect; Schwarz & Bless, 1992a; Stapel & Koomen, 1998). But extreme targets will not be assimilated and may in fact be contrasted from the stereotype (an "exclusion" effect). Furthermore, "fit" between category and individuating informa-

tion is important—when fit occurs, judgments of others are likely to be category based (assimilated).

It is also worth noting that to the extent that stereotypes provide a context for interpreting or evaluating a target, they can be conceptualized as *wide* or *indistinct*, as well as *entitative*—all features that promote assimilation. And major models of stereotyping, such as Fiske and Neuberg's (1990) continuum model, Brewer's (1988) dual-process model, and Bodenhausen and Macrae's (1998) model of facilitation and inhibition, highlight the importance of *processing goals*: Motivational factors such as accuracy and interdependence, or the desire not to use stereotypes, may make assimilation to stereotypes *less* likely.

Standards Used to Judge the Self

In judging others, standards and expectancies tend to function as reference points, providing information useful for interpreting and evaluating data about a given target. In judging the *self*, this informational function is also relevant, but standards can additionally serve as regulatory criteria (see Carver & Scheier, 1981, 2002; Duval & Wicklund, 1972). That is, standards provide information about "valued end states" according to which we appraise ourselves and our progress toward goals (Higgins, 1990, 1996; Higgins, Strauman, & Klein, 1986). In this section, we focus on two general sources of standards according to which we evaluate, appraise, and regulate the self: (1) internally represented "guides" and (2) other people.

Internalized Guides as Standards

That we evaluate ourselves relative to personal standards is clear in much theoretical work on the self (e.g., Cooley, 1902/1964; Kelley, 1952; Lewin, 1935). For example, Lewin (1951) noted that the experience and judgments of success and failure are based on some frame of reference, such as internalized norms and values of the culture or one's own level of aspiration (see also Sherif, 1936). That such standards are important for self-evaluation can be seen in the case of an objectively "successful" person who, by virtue of setting high standards for performance, may have a relatively lower self-appraisal than someone with low standards or with worse objective performance (see Felson, 1993). The use of internal evaluative standards may "increase the number of failures who are happy with themselves and successful people who are unhappy" (Felson, 1993, p. 16; see Brickman, Coates, & Janoff-Bulman, 1978).

OBJECTIVE SELF-AWARENESS

One theoretical perspective that has highlighted the tendency to compare the self to these internal standards is objective self-awareness (OSA) theory (Duval & Wicklund, 1972). OSA occurs "when attention is directed inward and the individual . . . is the object of his (sic) own consciousness" (p. 2). OSA is hypothesized to initiate, automatically or spontaneously, a comparison of the self against standards, where standards are defined as

"mental representations of correct behavior, attitudes and traits" (Duval & Wicklund, 1972, p. 3). To the extent that comparison to standards reveals discrepancies, negative affect should result, along with motivation to restore consistency—either by *changing* the discrepant attribute (typically, the behavior, attitude or trait, or perhaps even the standard; Batson, Thompson, Seuferling, Whitney, & Strongman, 1999; Duval & Lalwani, 1999) or by *avoiding* self-focus—getting out of the business of comparison to standards altogether (Greenberg & Musham, 1981).

In general, OSA theory suggests that comparison to standards will produce *contrast* effects when discrepancies are noted—typically negative self-evaluation relative to a (positive) standard. But assimilation (favorable self-views, consistent with the standard) can also result when the standard is met (and relative to conditions when the comparison did not occur; e.g., when one was not self-aware). Furthermore, extensions of the theory have suggested that *behaviorally*, self-awareness may prompt movement toward the standard, another kind of assimilation effect. In their test-operate-test-exit (TOTE) feedback model of OSA, Carver, Blaney, and Scheier (1979) posited that self-standard discrepancies also produce an implicit appraisal of the likelihood of reducing the discrepancy. To the extent that expectations of reducing the discrepancy are high, individuals work to meet the standard. But if expectations of meeting the standard are low, avoidance of self-focus is the result. Others have suggested that it is not expectations per se that are key but, rather, the individual's sense that his or her rate of progress in meeting the standard is sufficient relative to the size of the discrepancy (Duval, Duval, & Mulilis, 1992; Silvia & Duval, 2001). In any case, movement toward the standard reflects an assimilative process. Interestingly, the *assimilative* behavioral tendency may be prompted by the initial *contrastive* emotional reaction. That is, the negative affect produced by becoming aware of a self-standard discrepancy has a motivational quality geared toward assimilative change—typically, moving the self toward the standard (see Silvia & Duval, 2001).

SELF-DISCREPANCY

The phenomenon of self-evaluation and -regulation relative to internalized standards can also be seen in theoretical work by Higgins (1987, 1990, 1996). In his perspective on the "self as digest," an important component of self-knowledge is the *monitored self*—a representation of "how a person is doing in relation to some desired (or undesired) end state" (Higgins, 1996, p. 1070). According to this model, the self is monitored and therefore regulated by means of comparison between various *domains* of and *standpoints* on the self. It is by virtue of comparing these various selves (e.g., comparing the actual/own self to the ought/own self) and noting discrepancies between them that we experience affect (e.g., sadness in the case of actual/ideal discrepancies or guilt in the case of actual/ought discrepancies) and, potentially, engage or redirect our behavioral efforts. Higgins (1999) outlined four factors that enhance self-discrepancy effects: (1) magni-

tude/extremity of discrepancies, (2) accessibility of discrepancies, (3) applicability/relevance, and (4) importance.

Most of these moderators will sound similar to those mentioned elsewhere in this chapter. In various judgment models, extremity, applicability, and accessibility are described as factors determining whether assimilation or contrast effects emerge in social judgment. To what extent, then, can self-discrepancy effects be conceptualized in assimilation-contrast terms? As was the case with objective self-awareness theory, the emotion patterns described above reflect a type of *contrast* effect: By comparing the actual self to ideal or ought standards, we may accentuate our differences from the desired state and feel worse than we would had the comparison not occurred. Extreme, accessible, and applicable discrepancies prompt the most emotional contrast.[5]

STANDARDS OF NONPREJUDICE

Research on prejudice and prejudice expression represents an important area in which the issue of self-guides and regulation has been considered (Devine, Monteith, Zuwerink, & Elliot, 1991; Monteith, 1996; Monteith, Devine, & Zuwerink, 1993; Plant & Devine, 2001). In general, this research focuses on the likelihood that intergroup settings will reveal to individuals that they fail meet their internalized standards of nonprejudice. For example, when Whites are asked to consider the scenario "a Black person sits next to you on the bus," they may notice discrepancies between how they "would" react, and how they "should" react. As might be expected, those high in prejudice report both more prejudiced "would" reactions in these settings and more lenient standards (for how they "should" react). Furthermore, should–would discrepancies are associated with self-dissatisfaction, guilt, and discomfort among low-prejudice individuals more so than among high-prejudice individuals, though guilt can be intensified for both groups if standards are initially made salient (Monteith, 1996). As noted earlier, this general pattern can be viewed as a type of contrast effect—comparison to standards typically reveals discrepancies, and these prompt more extreme emotional reactions than occur in the absence of the comparison.

And again, comparison to prejudice-relevant internalized standards may produce a kind of *behavioral* assimilation effect—moving toward the standard—similar to that posited in the theory of objective self-awareness. For example, Monteith (1993) found that among low-prejudiced individuals, should–would discrepancies activated self-regulatory processes (such as slowing down and self-focusing) that could lead to increased control of prejudicial responses in the future (Monteith, Ashburn-Nardo, Voils, & Czopp, 2002). These responses are ultimately geared toward establishing "cues for control" that can aid the individual in inhibiting prejudiced responses. Again, the consequence of noticing a discrepancy (and experiencing negative affect as a result) prompts behavior designed to move the individual toward the (nonprejudiced) standard.

POSSIBLE SELVES

The notion of "possible selves" as goal states further suggests that by comparing the current self to a desired future self, activity directed toward that state becomes more energized and organized, with resulting positive effects on performance (Markus & Nurius, 1986; Markus & Wurf, 1987; Ruvolo & Markus, 1992; see also James's 1890/1948, notion of "potential" selves). Possible selves are "the cognitive manifestation of enduring goals, aspirations, motives, fears, and threats" and they "provide the essential link between the self-concept and motivation" (Markus & Nurius, 1986, p. 954).

Affectively, positive possible selves may create optimism and belief in the mutability of the current self (Markus & Nurius, 1986), thus fulfilling basic needs for self-enhancement. On the behavioral side, possible selves have been predicted to improve self-regulation and enhance performance precisely because they focus attention on goal-related activity and strategies necessary to achieve goals (Gollwitzer, 1996; Oyserman, 2001). In the absence of these strategies, possible selves may not produce positive outcomes. For example, in a study of low-income eighth graders, academic possible selves predicted improved grades, more time doing homework, more class participation, and less referral to remedial summer school, but only when they were accompanied by "roadmaps" or strategies for achieving positive outcomes (Oyserman, Bybee, Terry, & Hart-Johnson, 2004). Thus, a moderator of the behavioral assimilative tendencies produced by possible selves is the extent to which concrete strategies are made accessible by those future selves.

SELF-REGULATION

All the concepts described previously are ultimately about self-regulation. As the foregoing descriptions attest, standards (such as goal states) prompt positive self-evaluation when met and negative self-evaluation when not met (e.g., Bandura, 1997). Effortful action to meet standards or goals is prompted when one notices a discrepancy between reality and the standard. Again, this suggests that affective *contrast* is geared toward behavioral *assimilation*. For Bandura (1997), the behavioral movement toward the goal will only occur, however, if the individual feels self-efficacious with respect to the action required for goal attainment.

In their model of cybernetic feedback control, Carver and Scheier (2002) also posit that a goal is a standard toward which the individual is oriented. Moving toward the goal requires "identifying one's location on the relevant variable . . . , determining where that location is with respect to the goal (by means of a comparison between input and goal), and making changes to diminish the gap between present location and goal" (p. 305). This "discrepancy-reducing feedback loop" operates in an assimilative fashion. That is, discovering the discrepancy ultimately moves the individual toward the goal.

Interestingly, these researchers have also discussed *antigoals* such as feared possible selves that garner self-

regulation geared toward *enhancing* discrepancies or creating behavioral contrast (Carver, 2001; Carver, Lawrence, & Scheier, 1999; Carver & Scheier, 1998). For example, a teenager may want to avoid being like his parents (see Carver, 2001). But, such "discrepancy-enlarging" loops often get taken up in the "orbit" of a discrepancy-reducing loop. Carver (2001) writes, "the rebellious adolescent, trying to be different from his parents, soon finds a group of other adolescents to conform to, all of whom are remaining different from their parents" (p. 310). Thus, the contrastive inclination may be subsumed by an assimilative or discrepancy-reducing mechanism.

A second *affective* loop also operates and "checks on how well the behavior loop is reducing its discrepancies" (Carver, 2001, p. 311). If a discrepancy is noted (such that progress is too slow), negative affect results (e.g., depression) *and* the behavioral response is to change something—go faster, work harder, choose a different course of action. If no discrepancy is noted (progress is as expected or better than expected), affect is positive (e.g., elation or joy is experienced) and resources may be pulled back. Again, this affective system is ultimately in service of *behavioral* assimilation toward goals. However, as was briefly discussed in the context of self-awareness theory, one can also decide to change one's standards, either downward, such that progress toward goals seems better and positive affect results, or upward, such that a greater challenge is experienced (though negative affect may also result). That is, the standard may assimilate toward the behavior (Carver, 2001).

In a related vein, and building on his theory of self-discrepancy, Higgins (1997, 1998) posited two broad types of self-regulatory goals designed to meet needs for nurturance and accomplishment on the one hand and for security and safety on the other: *promotion* and *prevention*. A promotion orientation is focused on advancement or accomplishment—meeting one's goals, becoming one's "ideal self." This is an "eager *approach* strategy," in which one aims for desirable outcomes. Prevention orientation, on the other hand, is strategically failure avoidant. The individual is focused on "ought selves" and pursues strategies designed to avoid undesirable outcomes. How is this relevant to assimilation and contrast? At a very general level, promotion goals can be conceptualized in terms of assimilation: One wants to become the hoped-for self, and this organizes action in pursuit of that goal. When the goal is reached, happiness is the result, a kind of affective assimilation (Higgins, Shah, & Friedman, 1997; Idson, Liberman, & Higgins, 2000). Prevention focus, on the other hand, can be conceptualized in terms of contrast: One hopes to remain distant from the undesired self, and thus behavior is geared toward contrasting the self from that undesired outcome. When the outcome is successfully avoided, quiescent emotions result, perhaps also a contrast from the to-be-avoided state.

SUMMARY

A desired self (whether in "ought," "ideal," or "possible" form) "functions as both a goal to be attained and a standard for self-evaluation" (Higgins, 1996, p. 1071). Thus, the more important a desired self, the greater its goal strength, and the greater motivation, effort, and energy the individual is likely to direct toward the goal. The result is an increased likelihood that the goal will actually be achieved (assimilation to the standard). At the same time, the more important a desired self, the more significant it is as a standard for self-evaluation, and the more likely that standing relative to the standard will be closely monitored. The result is enhanced attention to discrepancies and intensified distress reactions when discrepancies are noted (a type of contrast; see Newman, Higgins, & Vookles, 1992). In this sense, internalized standards are like many other constructs discussed in this chapter, in that they both draw in and push away the target of evaluation under different circumstances and on different outcomes.

Others as Standards for Judging the Self: Social Comparison

One major source of standards according to which we evaluate, appraise, and regulate the self is other people. Early theorists in psychology described the importance of *reference groups* for self-definition (Hyman, 1942; Kelley, 1952; Merton & Kitt, 1950; Newcomb, 1942; Sherif, 1948). For example, Hyman (1942) noted that one's status on relevant dimensions may be determined by an understanding of oneself within the context of one's reference group. In his well-known Bennington study, Newcomb (1943) described how conservative first-year college students adopted the liberal senior class as their frame of reference and attitudinally moved toward (assimilated to) this reference group.

And, of course, social comparison theory (Festinger, 1954a, 1954b) suggests that an important source of self-assessment or -evaluation is comparisons with other people, particularly when objective information is lacking (cf. Klein, 1997). That is, others may serve as standards for evaluating the self. As discussed earlier, motives besides accuracy may drive social comparison (e.g., self-enhancement and self-improvement; Wood, 1989), leading to different *choices* of comparison targets and different *outcomes* of the comparison process.

Perhaps the most common outcomes examined in social comparison research are affective (as in measures of mood or self-esteem) or cognitive/evaluative (as in evaluative trait ratings, particularly on the dimension of the comparison) in nature. Earlier we mentioned Morse and Gergen's (1970) "Mr. Clean/Mr. Dirty" study. In this study, prospective job candidates' self-esteem was harmed by upward comparison to the well-dressed competitor, Mr. Clean, but improved by downward comparison to the sloppy competitor, Mr. Dirty. This basic pattern—downward comparisons feel good, upward comparisons feel bad—has been noted in many studies (for reviews, see Buunk, Collins, Taylor, VanYperen, & Dakof, 1990; Lockwood, 2002; Major, Testa, & Bylsma, 1991; Smith, 2000). These are *contrast* effects, and they reflect the basic notion of social comparison standards as points of reference against which the self is evaluated.

However, contrast is not an inevitable outcome of social comparison. Assimilation to an *upward* target was demonstrated very early in the history of social comparison research (Wheeler, 1966). Noting that people are often motivated to compare upward even though such comparisons may lead to negative affect, Wheeler (1966) suggested that the comparer, in such situations, assumes *similarity* with the superior other and will experience negative comparison consequences only to the extent that he or she is *not* as similar to the target as expected. Wheeler's results were consistent with this prediction: In his research, a majority (75%) of the participants who compared upward perceived themselves as similar to the comparison target, but only a minority (36%) of those who compared downward assumed they were similar to the upward targets.

More recently, Collins (1996, 2000) directly invoked the processes of assimilation and contrast to explain the consequences of comparing upward. She suggests that if perceivers expect to be different from an upward target, they will pay particular attention to these differences and contrast the self from the target. This could produce a perception of the self as even more different from (worse than) the target than is actually the case. On the other hand, an expectation that one is *similar* to an upward target results in the perceptual "blurring" of actual differences between self and target (inclusion), leading the comparer to assimilate the self to the target. It is through this assimilative process that an upward comparison target may actually be used to self-enhance.

These ideas are similar to those articulated in Mussweiler's (2003a, 2003b) SAM and Markman and McMullen's (2003) REM. Both suggest that the outcome of a comparison process depends on the information that is accessible when the comparison is made. Assimilation will result if similarity testing has made information about target–self similarity accessible (Mussweiler, 2003a), or if a reflection process invokes mental simulation of the self as like the target (Markman & McMullen, 2003a). Contrast results from dissimilarity testing for Mussweiler (2003), and from an evaluation process—in which self is distinguished from the target—for Markman and McMullen (2003).

Evidence does suggest that upward comparisons can be self-enhancing and inspiring, and that similarity between self and the upward target is important to this process (Wood, 1989; Wood & van der Zee, 1997; see also Lockwood & Kunda, 1999). For example, Lockwood and Kunda's (1997) research on comparison with "superstars" found that role models whose success was perceived as attainable produced assimilation effects, whereas dissimilar upward comparison targets—those whose accomplishments could not possibly be attained by the self—produced a contrast effect (negative self-evaluations on traits related to career success). Wood (1989) argued that upward comparisons can have *negative* consequences if the comparison target is perceived as a competitor—again, someone *dissimilar* from the self. In another clever study, women's self-assessments of attractiveness were generally *contrasted* from highly attractive standards (a photograph of a very attractive woman).

However, when the attractive other was similar to the self (because she shared one's attitudes or one's birthday), *assimilation* occurred (Brown, Novick, Lord, & Richards, 1992). Mussweiler and Bodenhausen (2002) focused on ingroup–outgroup status as an important similarity factor. They found that comparison to ingroup members prompted similarity testing and judgmental assimilation. For example, when men compared themselves with a "highly caring" male standard, self-assessments of caringness were high—an assimilation effect. But a comparison with a highly caring *female* standard—an outgroup target—prompted dissimilarity testing and contrast (see also Blanton, Crocker, & Miller, 2000; Brewer & Weber, 1994; Buunk, Ybema, van der Zee, Schaufeli, & Gibbons, 2001; McFarland, Buehler, & MacKay, 2001).

Also relevant to this discussion of the consequences of upward comparison is Tesser's self-evaluation maintenance model (SEM; Tesser, 1988; Tesser & Campbell, 1980, 1983). The SEM proposes that two processes—reflection and comparison—affect self-evaluation with close others who perform well. If a close other performs well on a dimension that is *not* central to one's self-definition, one benefits by being able to reflect in the success of the other (affective assimilation). But if the close other performs well on a dimension important to the self, negative affect and self-esteem result (contrast). Interestingly, closeness as conceptualized in the SEM should enhance *similarity* testing—the factor in Mussweiler's (2003a) SAM model that moves one toward *assimilation*. But in the case of clear outperformance by the close other, the *difference* in self- and other attainment may be highlighted and made highly accessible. Specifically, such a comparison may activate the *distinctive* aspects of the self (i.e., as a worse performer) producing contrast (see Broemer & Diehl, 2004). However, closeness may also incline one toward assimilation to the extent that one construes the upward target as part of the self. Specifically, the general pattern of contrast predicted by SEM when one is outperformed by a close other can be reversed following manipulations designed to "expand" the notion of self (Gardner, Gabriel, & Hochschild, 2002).

Similarity has also been implicated in understanding the outcomes of *downward* comparisons. To the extent that one views a downward outcome as possible for the self—particularly if one actively simulates this outcome—*assimilation* results (Lockwood, 2002). In three studies, Lockwood (2002) found that if participants felt as though they could be like the downward target (as when college undergraduates compared to a recent graduate who was having trouble on the job market), negative self-evaluation resulted (assimilation to the downward target). But when this vulnerability was reduced—when the comparison was to a fellow undergraduate doing much worse than the self in the immediate college context—self-evaluations were favorable (contrast). More generally, comparing with a worse-off other may be threatening only if the target's outcome is perceived to be uncontrollable, in that uncontrollability implies "it could happen to me" (Major et al., 1991). In Taylor and Lobel's (1989) review of their work with cancer patients, they

suggest that comparing downwardly, for instance, to a patient who is coping more poorly, may remind one of what the future may hold. Here, uncontrollability implies (potential) similarity.

Similarity ultimately boils down to the notion of *inclusion* in Schwarz and Bless's (1992a) inclusion–exclusion model. That is, if one can claim or envision oneself as *included* in the category of a comparison target (upward or downward), assimilation rather than contrast will occur.

Recently, Locke (2003) touched on this central notion of inclusion when he described "connections" or "solidarity" with the target of comparison. Features such as shared group membership (Mussweiler & Bodenhausen, 2002) or shared birthdays (Brown et al., 1992), or vulnerability to another's negative outcomes (Lockwood, 2002), or a primed sense of the self as socially integrated or "expanded" (Gardner et al., 2002; Stapel & Koomen, 2001) increase inclusion and assimilation.

BEHAVIORAL CONSEQUENCES

Relative to affect and cognition, behavioral reactions to social comparison have been studied rarely. Nevertheless, some research on upward comparisons does point to an important positive behavioral outcome: Making upward comparisons may generate negative affect but also feelings of inspiration that can sometimes lead to behavioral improvement (Blanton, Buunk, Gibbons, & Kuyper, 1999; Gibbons, Blanton, Gerrard, Buunk, & Eggleston, 2000; Major et al., 1991; Seta, 1982; Seta, Seta, & Donaldson, 1991; cf. Markman & McMullen, 2003). In one study, smokers who preferred upward comparisons—comparisons to those who were more successful at quitting—were more likely to have succeeded in their cessation attempts 6 months later (Gerrard, Gibbons, Lane, & Reis-Bergan, 2002, cited in Gibbons et al., 2002).

Markman and McMullen's (2003) REM, described earlier in this chapter, offers predictions about the motivational–behavioral outcomes of comparative thinking. In this model, all behavioral consequences are mediated by affect, but positive and negative affect are posited to produce different levels of behavioral *persistence*, depending on the type of task. Specifically, through "mood as information" processes, positive affect should produce less persistence on *achievement tasks* but more persistence on *enjoyment tasks* (see Markman & McMullen, 2003; Martin, Ward, Achee, & Wyer, 1993; Schwarz, 1990).

This leads to the interesting prediction that in social comparison situations that prompt positive affect—say, in upward comparison to a target whose accomplishments seem attainable—behavioral perseverance may *not* result. Instead, those inspired by the other may find themselves lacking the motivation to persist on tasks relevant to achieving the high standard. Although we are not aware of research directly testing this prediction, Markman and McMullen (2003) cite recent work by Oettingen and colleagues on the role of fantasy and expectations in motivation (Oettingen, 1996; Oettingen & Mayer, 2002). In this work, positive fantasy—"mentally enjoying future outcomes" (Oettingen & Mayer, 2002, p. 1199)—has been shown to undermine motivation and success because it takes energy away from activity that would otherwise be directed toward achieving the goal. Thus, upward comparison targets may create high expectations for own future success, which are inspiring and motivating. But at the same time, those who compare upward may find themselves fantasizing rather than exerting effort toward meeting the high standard. Apparently, this can be overcome, however, if perceivers are led to explicitly contrast their positive fantasies with *reality*. This makes both present and future accessible and seems to produce enhanced motivation and success (Oettingen, Pak, & Schnetter, 2001).
