PLEASE READ—IMPORTANT INFORMATION

The *Gale Encyclopedia of Mental Disorders* is a medical reference product designed to inform and educate readers about a wide variety of mental disorders, diagnostic techniques and tests, therapies, and psychiatric medications. The Gale Group believes the product to be comprehensive, but not necessarily definitive. It is intended to supplement, not replace, consultation with a physician or other health care practitioner. While the Gale Group has made substantial efforts to provide information that is accurate, comprehensive, and up-to-date, the Gale Group makes no representations or warranties of any kind, including without limitation, warranties of merchantability or fitness for a particular purpose, nor does it guarantee the accuracy, comprehensiveness, or timeliness of the information contained in this product. Readers should be aware that the universe of medical knowledge is constantly growing and changing, and that differences of medical opinion exist among authorities. Readers are also advised to seek professional diagnosis and treatment of any medical condition, and to discuss information obtained from this book with their health care provider.

INTRODUCTION

The *Gale Encyclopedia of Mental Disorders* is a valuable source of information for anyone who wants to learn more about mental disorders and their treatments. This collection of approximately 400 entries provides in-depth coverage of specific disorders recognized by the American Psychiatric Association (as well as some disorders not formally recognized as distinct disorders), diagnostic procedures and techniques, therapies, and psychiatric medications. In addition, entries have been included to facilitate understanding of related topics, such as Advance directives, Crisis housing, and Neurotransmitters.

This encyclopedia minimizes medical jargon and uses language that laypersons can understand, while still providing thorough coverage that will benefit health science students as well.

Entries follow a standardized format that provides information at a glance. Rubrics include:

Disorders	**Medications**
Definition	Definition
Description	Purpose
Causes and symptoms	Description
Demographics	Recommended dosage
Diagnosis	Precautions
Treatments	Side effects
Prognosis	Interactions
Prevention	Resources
Resources	

INCLUSION CRITERIA

A preliminary list of mental disorders and related topics was compiled from a wide variety of sources, including professional medical guides and textbooks, as well as consumer guides and encyclopedias. The advisory board, made up of professionals from a variety of health care fields including psychology, psychiatry, pharmacy, and social work, evaluated the topics and made suggestions for inclusion. Final selection of topics to include was made by the advisory board in conjunction with the Gale editor.

ABOUT THE CONTRIBUTORS

The essays were compiled by experienced medical writers, including physicians, pharmacists, and psychologists. The advisors reviewed the completed essays to ensure that they are appropriate, up-to-date, and accurate.

HOW TO USE THIS BOOK

The *Gale Encyclopedia of Mental Disorders* has been designed with ready reference in mind.

- Straight **alphabetical arrangement** of topics allows users to locate information quickly.
- **Bold-faced terms** within entries direct the reader to related articles.
- **Cross-references** placed throughout the encyclopedia direct readers from alternate names, drug brand names, and related topics to entries.
- A list of **key terms** is provided where appropriate to define unfamiliar terms or concepts. A **glossary** of key terms is also included at the back of Volume II.
- The **Resources** sections direct readers to additional sources of information on a topic.
- Valuable **contact information** for organizations and support groups is included with many of the disorder entries.
- A leaf graphic () inserted next to the entry title denotes entries about herbals (such as Ginkgo biloba) or dietary supplements (such as SAMe). These entries have the same rubrics as the medication entries; however, the graphic is to draw attention to the fact that these entries are not about prescription medications.
- A **Symptoms list** at the back of Volume II has been included *not* for diagnosis but to reveal patterns in

symptoms and disorders and to provide a starting point for research or discussion with a health care provider.

- A comprehensive **general index** guides readers to all topics mentioned in the text.

GRAPHICS

The *Gale Encyclopedia of Mental Disorders* contains 100 illustrations, photos, and tables. A color insert in each volume has been included to enhance certain photos shown in the text in black and white.

ADVISORY BOARD

A number of experts in medicine, psychology, psychiatry, and pharmacy provided invaluable assistance in the formulation of this encyclopedia. The members of the advisory board performed a myriad of duties, from defining the scope of coverage to reviewing individual entries for accuracy and accessibility. The editor would like to express appreciation to them for their time and for their contributions.

Abnormal Involuntary Movement Scale

Definition

The Abnormal Involuntary Movement Scale (AIMS) is a rating scale that was designed in the 1970s to measure involuntary movements known as **tardive dyskinesia** (TD). TD is a disorder that sometimes develops as a side effect of long-term treatment with neuroleptic (antipsychotic) medications.

Purpose

Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements of the patient's face, mouth, trunk, or limbs, which affects 20%–30% of patients who have been treated for months or years with neuroleptic medications. Patients who are older, are heavy smokers, or have diabetes mellitus are at higher risk of developing TD. The movements of the patient's limbs and trunk are sometimes called choreathetoid, which means a dance-like movement that repeats itself and has no rhythm. The AIMS test is used not only to detect tardive dyskinesia but also to follow the severity of a patient's TD over time. It is a valuable tool for clinicians who are monitoring the effects of long-term treatment with neuroleptic medications and also for researchers studying the effects of these drugs. The AIMS test is given every three to six months to monitor the patient for the development of TD. For most patients, TD develops three months after the initiation of neuroleptic therapy; in elderly patients, however, TD can develop after as little as one month.

Precautions

The AIMS test was originally developed for administration by trained clinicians. People who are not health care professionals, however, can also be taught to administer the test by completing a training seminar.

Description

The entire test can be completed in about 10 minutes. The AIMS test has a total of twelve items rating involuntary movements of various areas of the patient's body. These items are rated on a five-point scale of severity from 0–4. The scale is rated from 0 (none), 1 (minimal), 2 (mild), 3 (moderate), 4 (severe). Two of the 12 items refer to dental care. The patient must be calm and sitting in a firm chair that doesn't have arms, and the patient cannot have anything in his or her mouth. The clinician asks the patient about the condition of his or her teeth and dentures, or if he or she is having any pain or discomfort from dentures.

The remaining 10 items refer to body movements themselves. In this section of the test, the clinician or rater asks the patient about body movements. The rater also looks at the patient in order to note any unusual movements first-hand. The patient is asked if he or she has noticed any unusual movements of the mouth, face, hands or feet. If the patient says yes, the clinician then asks if the movements annoy the patient or interfere with daily activities. Next, the patient is observed for any movements while sitting in the chair with feet flat on the floor, knees separated slightly with the hands on the knees. The patient is asked to open his or her mouth and stick out the tongue twice while the rater watches. The patient is then asked to tap his or her thumb with each finger very rapidly for 10–15 seconds, the right hand first and then the left hand. Again the rater observes the patient's face and legs for any abnormal movements.

After the face and hands have been tested, the patient is then asked to flex (bend) and extend one arm at a time. The patient is then asked to stand up so that the rater can observe the entire body for movements. Next, the patient is asked to extend both arms in front of the body with the palms facing downward. The trunk, legs and mouth are again observed for signs of TD. The patient then walks a few paces, while his or her gait and hands are observed by the rater twice.

KEY TERMS

Choreathetoid movements—Repetitive dance-like movements that have no rhythm.

Clozapine—A newer antipsychotic medication that is often given to patients who are developing signs of tardive dyskinesia.

Neuroleptic—Another name for the older antipsychotic medications, such as haloperidol (Haldol) and chlorpromazine (Thorazine).

Syndrome—A group of symptoms that together characterize a disease or disorder.

Tardive dyskinesia—A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs either late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

Results

The total score on the AIMS test is not reported to the patient. A rating of 2 or higher on the AIMS scale, however, is evidence of tardive dyskinesia. If the patient has mild TD in two areas or moderate movements in one area, then he or she should be given a **diagnosis** of TD. The AIMS test is considered extremely reliable when it is given by experienced raters.

If the patient's score on the AIMS test suggests the diagnosis of TD, the clinician must consider whether the patient still needs to be on an antipsychotic medication. This question should be discussed with the patient and his or her family. If the patient requires ongoing treatment with antipsychotic drugs, the dose can often be lowered. A lower dosage should result in a lower level of TD symptoms. Another option is to place the patient on a trial dosage of **clozapine** (Clozaril), a newer antipsychotic medication that has fewer side effects than the older neuroleptics.

Abuse

Definitions

Abuse is a complex psychosocial problem that affects large numbers of adults as well as children throughout the world. It is listed in the *Diagnostic and Statistic Manual of Mental Disorders* (*DSM-IV-TR*) under the heading of "Other Conditions That May Be a Focus of Clinical Attention." Although abuse was first defined with regard to children when it first received sustained attention in the 1950s, clinicians and researchers now recognize that adults can suffer abuse in a number of different circumstances. Abuse refers to harmful or injurious treatment of another human being that may include physical, sexual, verbal, psychological/emotional, intellectual, or spiritual maltreatment. Abuse may coexist

with **neglect**, which is defined as failure to meet a dependent person's basic physical and medical needs, emotional deprivation, and/or desertion. Neglect is sometimes described as passive abuse.

The costs of abuse to society run into billions of dollars annually in the United States alone. They include not only the direct costs of immediate medical and psychiatric treatment of abused people but also the indirect costs of learning difficulties, interrupted education, workplace absenteeism, and long-term health problems of abuse survivors.

Types of abuse

Physical

Physical abuse refers to striking or beating another person with the hands or an object, but may include assault with a knife, gun, or other weapon. Physical abuse also includes such behaviors as locking someone in a closet or other small space, depriving someone of sleep, burning, gagging, or tying them up, etc. Physical abuse of infants may include shaking them, dropping them on the floor, or throwing them against the wall or other hard object.

Sexual

Sexual abuse refers to inappropriate sexual contact between a child or an adult and someone who has some kind of family or professional authority over them. Sexual abuse may include verbal remarks, fondling or kissing, or attempted or completed intercourse. Sexual contact between a child and a biological relative is known as incest, although some therapists extend the term to cover sexual contact between a child and any trusted caregiver, including relatives by marriage. Girls are more likely than boys to be abused sexually; according to a conservative estimate, 38% of girls and 16% of boys are sexually abused before their eighteenth birthday.

Verbal

Verbal abuse refers to regular and consistent belittling, name-calling, labeling, or ridicule of a person; but it may also include spoken threats. It is one of the most difficult forms of abuse to prove because it does not leave physical scars or other evidence, but it is nonetheless hurtful. Verbal abuse may occur in schools or workplaces as well as in families.

Emotional/psychological

Emotional/psychological abuse covers a variety of behaviors that hurt or injure others even though no physical contact may be involved. In fact, emotional abuse is a stronger predictor than physical abuse of the likelihood of **suicide** attempts in later life. One form of emotional abuse involves the destruction of someone's pet or valued possession in order to cause pain. Another abusive behavior is emotional blackmail, such as threatening to commit suicide unless the other person does what is wanted. Other behaviors in this category include the silent treatment, shaming or humiliating someone in front of others, or punishing them for receiving an award or honor.

Intellectual/spiritual

Intellectual/spiritual abuse refers to such behaviors as punishing someone for having different intellectual interests or religious beliefs from others in the family, preventing them from attending worship services, ridiculing their opinions, and the like.

KEY TERMS

Cognitive restructuring—An approach to psychotherapy that focuses on helping the patient examine distorted patterns of perceiving and thinking in order to change their emotional responses to people and situations.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Flashback—The re-emergence of a traumatic memory as a vivid recollection of sounds, images, and sensations associated with the trauma. The person having the flashback typically feels as if he or she is reliving the event.

Incest—Unlawful sexual contact between persons who are biologically related. Many therapists, however, use the term to refer to inappropriate sexual contact between any members of a family, including stepparents and stepsiblings.

Stalking—The intentional pursuit or surveillance of another person, usually with the intent of forcing that person into a dating or marriage relationship. Stalking is now punishable as a crime in all 50 states.

Child abuse

Child abuse first attracted national attention in the United States in the 1950s, when a Denver pediatrician named C. Henry Kempe began publishing his findings regarding x-ray evidence of intentional injuries to small children. Kempe's research was followed by numerous investigations of other signs of child abuse and neglect, including **learning disorders**, malnutrition, failure to thrive, conduct disorders, emotional retardation, and sexually transmitted diseases in very young children.

Statistics from the mid-1990s indicate that although child abuse is found at all levels of income and educational achievement in the United States, children born into poor families are 12 times as likely to be abused as the children of middle-class or wealthy families, without regard to race or ethnic background. About 25% of children who are abused or neglected are younger than two years of age. Both sexes are equally affected. As of 2000, between 1,000 and 1,200 children die each year in the United States as the result of physical abuse. Of those who survive, 20% suffer permanent physical injury. Children who suffer from birth defects, developmental delays, or chronic illnesses have a higher risk of being abused by parents or other caregivers.

Abused adults

The women's movement of the 1970s led not only to greater recognition of domestic violence and other forms of abuse of adults, but also to research into the factors in the wider society that perpetuate abusive attitudes and behaviors. As of 2002, women are still more likely than men to be the targets of abuse in adult life.

Domestic violence

Domestic violence refers to the physical, emotional, and sexual abuse of a spouse or domestic partner. Early research into the problem of wife battering focused on middle-class couples, but it has since been recognized that spouse abuse occurs among wealthy professional couples as well. In addition, studies done in the late 1980s and 1990s indicate that domestic violence also occurs among gay and lesbian couples. It is estimated that four million women in the United States are involved in abusive marriages or relationships; moreover, most female murder victims are killed by their spouse or partner rather than by strangers.

Domestic violence illustrates the tendency of abusive people to attack anyone they perceive as vulnerable; most men who batter women also abuse their children; some battered women abuse their children; and abusive humans are frequently cruel to animals.

Elder abuse

Elder abuse has also become a subject of national concern in the last two decades. As older adults are living longer, many become dependent for years on adult caregivers, who may be either their own adult children or nursing home personnel. Care of the elderly can be extremely stressful, especially if the older adult is suffering from **dementia**. Elder abuse may include physical hitting or slapping; withholding their food or medications; tying them to their chair or bed; neglecting to bathe them or help them to the toilet; taking their personal possessions, including money or property; and restricting or cutting off their contacts with friends and relatives.

Abusive professional relationships

Adults can also be abused by sexually exploitative doctors, therapists, clergy, and other helping professionals. Although instances of this type of abuse were dismissed prior to the 1980s as consensual participation in sexual activity, most professionals now recognize that these cases actually reflect the practitioner's abuse of social and educational power. About 85% of sexual abuse cases in the professions involve male practitioners and female clients; another 12% involve male practitioners and male clients; and the remaining 3% involve female practitioners and either male or female clients. Ironically, many of these abusive relationships hurt women who sought professional help in order to deal with the effects of childhood abuse.

Stalking

Stalking, or the repeated pursuit or surveillance of another person by physical or electronic means, is now defined as a crime in all 50 states. Many cases of stalking are extensions of domestic violence, in that the stalker (usually a male) is attempting to track down a wife or girlfriend who left him. However, stalkers may also be casual acquaintances, workplace colleagues, or even total strangers. Stalking may include a number of abusive behaviors, including forced entry to the person's home, destruction of cars or other personal property, anonymous letters to the person's friends or employer, or repeated phone calls, letters, or e-mails. About 80% of stalking cases reported to police involve men stalking women.

Workplace bullying

Workplace bullying is, like stalking, increasingly recognized as interpersonal abuse. It should not be confused with sexual harassment or racial discrimination. Workplace bullying refers to verbal abuse of other workers, interfering with their work, withholding the equipment or other resources they need to do their job, or

This woman's husband had just beaten her. She took her children and left the house, and called police from a phone booth. She was afraid to return home. *(Nubar Alexanian/ CORBIS. Photo reproduced by permission.)*

invading their personal space, including touching them in a controlling manner. Half of all workplace bullies are women, and the majority (81%) are bosses or supervisors.

Causes of abuse

The causes of interpersonal abuse are complex and overlapping. Some of the most important factors are:

- Early learning experiences: This factor is sometimes described as the "life cycle" of abuse. Many abusive parents were themselves abused as children and have learned to see hurtful behavior as normal childrearing. At the other end of the life cycle, some adults who abuse their elderly parent are paying back the parent for abusing them in their early years.
- Ignorance of developmental timetables: Some parents have unrealistic expectations of children in terms of the appropriate age for toilet training, feeding themselves, and similar milestones, and attack their children for not meeting these expectations.
- Economic stress: Many caregivers cannot afford part-time day care for children or dependent elderly parents, which would relieve some of their emotional strain. Even middle-class families can be financially stressed if they find themselves responsible for the costs of caring for elderly parents before their own children are financially independent.
- Lack of social support or social resources: Caregivers who have the support of an extended family, religious group, or close friends and neighbors are less likely to lose their self-control under stress.
- Substance abuse: Alcohol and mood-altering drugs do not cause abuse directly, but they weaken or remove a person's inhibitions against violence toward others. In addition, the cost of a drug habit often gives a substance addict another reason for resenting the needs of the dependent person. A majority of workplace bullies are substance addicts.
- Mental disorders: Depression, **personality disorders**, dissociative disorders, and anxiety disorders can all affect parents' ability to care for their children appropriately. A small percentage of abusive parents or spouses are psychotic.
- Belief systems: Many men still think that they have a "right" to a relationship with a woman; and many people regard parents' rights over children as absolute.

- The role of bystanders: Research in the social sciences has shown that one factor that encourages abusers to continue their hurtful behavior is discovering that people who know about or suspect the abuse are reluctant to get involved. In most cases, bystanders are afraid of possible physical, social, or legal consequences for reporting abuse. The result, however, is that many abusers come to see themselves as invulnerable.

Aftereffects

Abuse affects all dimensions of human development and existence.

Physical and neurobiological

In addition to such direct results of trauma as broken bones or ruptured internal organs, physically abused children often display retarded physical growth and poor coordination. Malnutrition may slow the development of the **brain** as well as produce such dietary deficiency diseases as rickets. In both children and adults, repeated trauma produces changes in the neurochemistry of the brain that affect memory formation. Instead of memories being formed in the normal way, which allows them to be modified by later experiences and integrated into the person's ongoing life, traumatic memories are stored as chaotic fragments of emotion and sensation that are sealed off from ordinary consciousness. These traumatic memories may then erupt from time to time in the form of flashbacks.

Cognitive and emotional

Abused children develop distorted patterns of cognition (knowing) because they are stressed emotionally by abuse. As adults, they may suffer from cognitive distortions that make it hard for them to distinguish between normal occurrences and abnormal ones, or between important matters and relatively trivial ones. They often misinterpret other people's behavior and refuse to trust them. Emotional distortions include such patterns as being unable to handle strong feelings, or being unusually tolerant of behavior from others that most people would protest.

Social and educational

The cognitive and emotional aftereffects of abuse have a powerful impact on adult educational, social, and occupational functioning. Children who are abused are often in physical and emotional pain at school; they cannot concentrate on schoolwork, and consequently fall behind in their grades. They often find it hard to make or keep friends, and may be victimized by bullies or become bullies themselves. In adult life, abuse survivors are at risk of repeating childhood patterns through forming relationships with abusive spouses, employers, or professionals. Even though a survivor may consciously want to avoid re-abuse, the individual is often unconsciously attracted to people who remind him or her of the family of origin. Abused adults are also likely to fail to complete their education, or they accept employment that is significantly below their actual level of ability.

Treatment

Treatment of the aftereffects of abuse must be tailored to the needs of the specific individual, but usually involves a variety of long-term considerations that may include legal concerns, geographical relocation, and housing or employment as well as immediate medical or psychiatric care.

Medical and psychiatric

In addition to requiring immediate treatment for physical injuries, abused children and adults often need long-term **psychotherapy** in order to recover from specific mental disorders and to learn new ways of dealing with distorted thoughts and feelings. This approach to therapy is known as cognitive restructuring. Specific mental disorders that have been linked to childhood abuse include major depression, **bulimia nervosa**, **social phobia**, Munchausen syndrome by proxy, **generalized anxiety disorder**, **post-traumatic stress disorder**, **borderline personality disorder**, **dissociative amnesia**, and **dissociative identity disorder**. Abused adults may develop post-traumatic stress disorder, major depression, or substance abuse disorders. At present, researchers are focusing on genetic factors as a partial explanation of the fact that some people appear to react more intensely than others to being abused.

Legal considerations

Medical professionals and, increasingly, religious professionals as well, are required by law to report child abuse to law enforcement officials, usually a child protection agency. Physicians are granted immunity from lawsuits for making such reports.

Adults in abusive situations may encounter a variety of responses from law enforcement or the criminal justice system. In general, cases of spouse abuse, stalking, and sexual abuse by professionals are taken more seriously than they were two or three decades ago. Many communities now require police officers to arrest the aggressor in domestic violence situations, and a growing number of small towns as well as cities have shelters for family

members fleeing violent households. All major medical, educational, and legal professional societies, as well as mainstream religious bodies, have adopted strict codes of ethics, and have procedures in place for reporting cases of abuse by their members. Abuse in the workplace, however, is still a relatively new area of concern, and people affected by it have relatively few legal protections or resources as of 2002.

Prevention

Prevention of abuse requires long-term social changes in attitudes toward violence, gender roles, and the relationship of the family to other institutions. Research in the structure and function of the brain may help to develop more effective treatments for the aftereffects of abuse and possibly new appoaches to help break the intergenerational cycle of abuse. At present, preventive measures include protective removal of children or elders from abusive households; legal penalties for abusive spouses and professionals; and educating the public about the nature and causes of abuse.

Acupuncture

Definition

Acupuncture, one of the main forms of therapy in traditional Chinese medicine (TCM), has been practiced for at least 2,500 years. In acupuncture, certain points on the body associated with energy channels or meridians are stimulated by the insertion of fine needles. Unlike the hollow hypodermic needles used in mainstream medicine to give injections or draw blood, acupuncture needles are solid. The points can be needled between 15 and 90 degrees in range relative to the skin's surface, depending on treatment.

Acupuncture is thought to restore health by removing energy imbalances and blockages in the body. Practitioners of TCM believe that there is a vital force or energy called *qi* (pronounced "chee") that flows through the body, and between the skin surface and the internal organs, along channels or pathways called meridians. There are 12 major and 8 minor meridians. Qi regulates the spiritual, emotional, mental, and physical harmony of the body by keeping the forces of yin and yang in balance. Yang is a principle of heat, activity, brightness, outwardness, while yin represents coldness, passivity, darkness, interiority, etc. TCM does not try to eliminate either yin or yang, but to keep them in harmonious balance. Acupuncture may be used to raise or lower the level of yin or yang in a specific part of the body in order to restore the energy balance.

Acupuncture was virtually unknown in the United States prior to President Nixon's trip to China in 1972. A reporter for the *New York Times* named James Reston wrote a story for the newspaper about the doctors in Beijing who used acupuncture to relieve his pain following abdominal surgery. By 1993, Americans were making 12 million visits per year to acupuncturists, and spending $500 million annually on acupuncture treatments. By 1995, there were an estimated 10,000 certified acupuncturists practicing in the United States; as of 2000, there were 20,000. About a third of the credentialed acupuncturists in the United States as of 2002 are MDs.

Acupuncture's record of success has been sufficiently impressive to stimulate a number of research projects investigating its mechanisms as well as its efficacy. Research has been funded not only by the National Center for Complementary and Alternative Medicine (NCCAM), but also by the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the National Institute of Dental Research, the National Institute of Neurological Disorders and Stroke (NINDS), and the National Institute on Drug Abuse. In 1997 a consensus panel of the National Institutes of Health (NIH) presented a landmark report in which it described acupuncture as

KEY TERMS

Cardiac tamponade—A condition in which blood leaking into the membrane surrounding the heart puts pressure on the heart muscle, preventing complete filling of the heart's chambers and normal heartbeat.

Electroacupuncture—A variation of acupuncture in which the practitioner stimulates the traditional acupuncture points electronically.

Endorphins—A group of peptide compounds released by the body in response to stress or traumatic injury. Endorphins react with opiate receptors in the brain to reduce or relieve pain.

Hyperemesis gravidarum—Uncontrollable nausea and vomiting associated with pregnancy. Acupuncture appears to be an effective treatment for women with this condition.

Meridians—In traditional Chinese medicine, a network of pathways or channels that convey qi (also sometimes spelled "ki"), or vital energy, through the body.

Moxibustion—A technique in traditional Chinese medicine that involves burning a *Moxa,* or cone of dried wormwood leaves, close to the skin to relieve pain. When used with acupuncture, the cone is placed on top of the needle at an acupuncture point and burned

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Opioids—Substances that reduce pain and may induce sleep. Some opioids are endogenous, which means that they are produced within the human body. Other opioids are produced by plants or formulated synthetically in the laboratory.

Pneumothorax—A condition in which air or gas is present in the chest cavity.

Qi—The Chinese term for energy, life force, or vital force.

Yin and yang—In traditional Chinese medicine and philosophy, a pair of opposing forces whose harmonious balance in the body is necessary to good health.

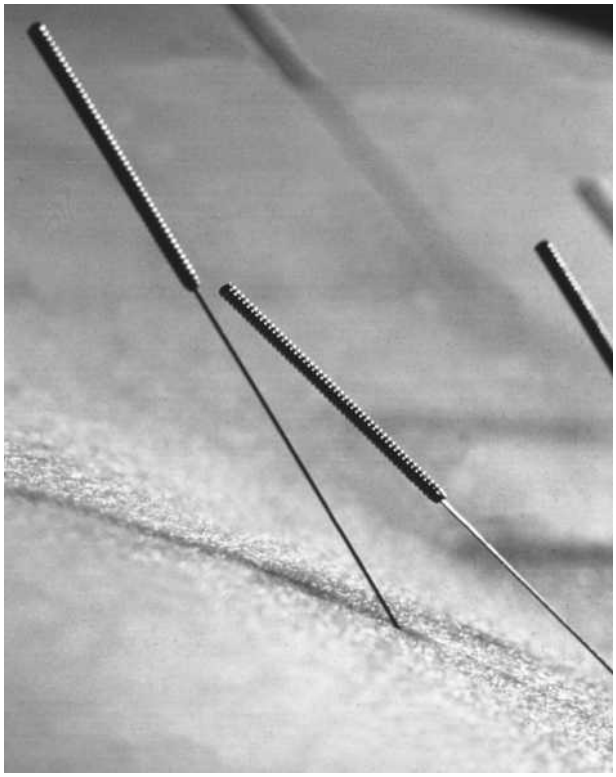
a sufficiently promising form of treatment to merit further study. In 2000, the British Medical Association (BMA) recommended that acupuncture should be made more readily available through the National Health Service (NHS), and that family doctors should be trained in some of its techniques.

Purpose

As already noted, the purpose of acupuncture in TCM is the rebalancing of opposing energy forces in different parts of the body. In Western terms, acupuncture is used most commonly as an adjunctive treatment for the relief of chronic or acute pain. In the United States, acupuncture is most widely used to treat pain associated with musculoskeletal disorders, but it has also been used in the treatment of substance abuse, and to relieve nausea and vomiting. A study done in 2001 showed that acupuncture was highly effective in stopping the intense vomiting associated with a condition in pregnant women known as hyperemesis gravidarum. In the past several years, acupuncture has been tried with a new patient population, namely children with chronic pain syndromes. One study of 30 young patients with disorders ranging from migraine headaches to endometriosis found that 70% felt that their symptoms had been relieved by acupuncture, and described themselves as "pleased" by the results of treatment. In addition to these disorders, acupuncture has been used in the United States to treat asthma, infertility, depression, anxiety, HIV infection, fibromyalgia, menstrual cramps, carpal tunnel syndrome, tennis elbow, pitcher's shoulder, chronic fatigue syndrome, and postoperative pain. It has even been used in veterinary medicine to treat chronic pain and prevent epileptic convulsions in animals. As of 2002, NCCAM is sponsoring research regarding the effectiveness of acupuncture in the rehabilitation of stroke patients.

The exact Western medicine mechanism by which acupuncture works is not known. Western researchers have suggested three basic explanations of acupuncture's efficacy in pain relief:

- Western studies have found evidence that the traditional acupuncture points conduct electromagnetic signals. Stimulating the acupuncture points causes these signals to be relayed to the **brain** at a higher than normal rate. These signals in turn cause the brain to release pain-relieving chemicals known as endorphins, and immune system cells to weak or injured parts of the body.
- Other studies have shown that acupuncture activates the release of opioids into the central nervous system. Opioids are also analgesic, or pain-relieving compounds.

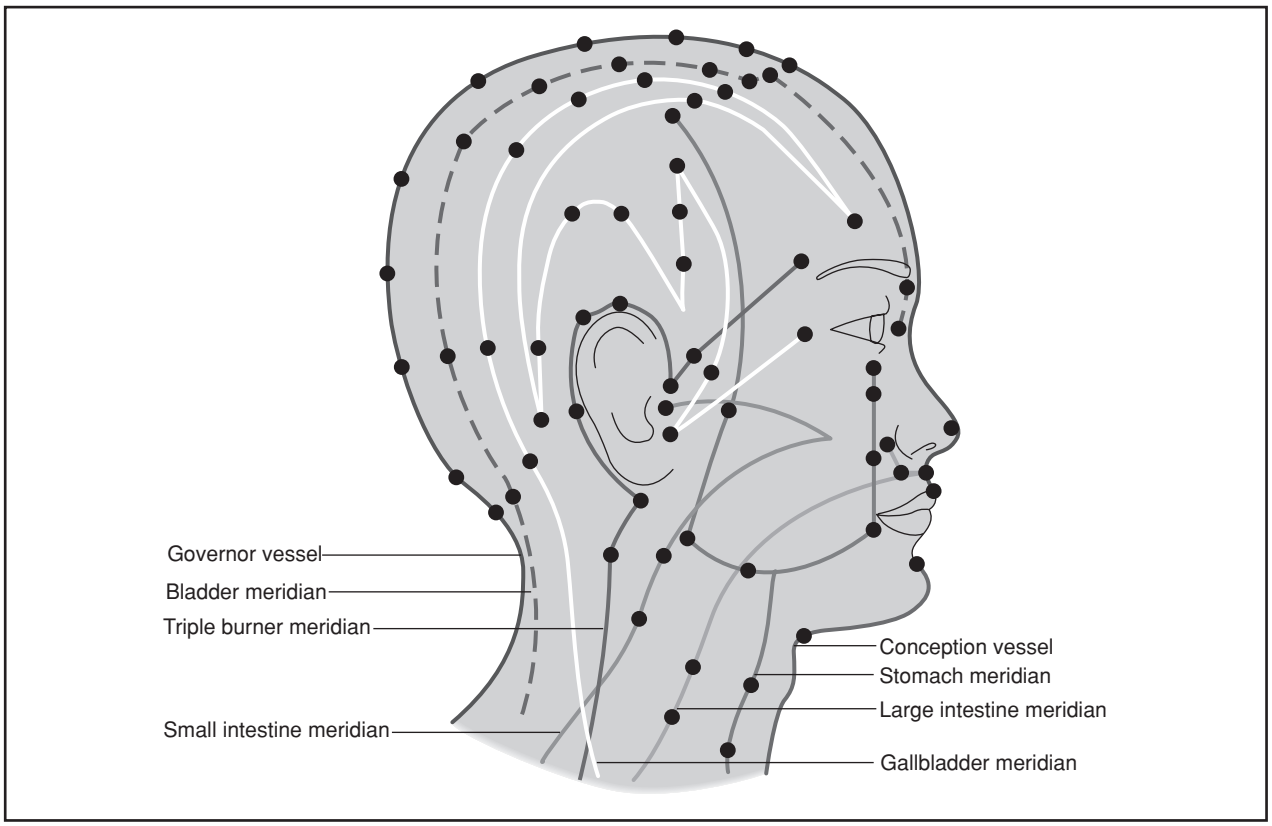


The purpose of acupuncture is to rebalance opposing energy forces in different parts of the body. In the United States, acupuncture is most widely used to treat pain associated with musculoskeletal disorders, but it has also been used in the treatment of substance abuse, and to relieve nausea and vomiting. *(Photo Researchers, Inc. Reproduced by permission.)*

- Acupuncture appears to alter the chemical balance of the brain itself by modifying the production and release of **neurotransmitters** and neurohormones. Acupuncture has been documented to affect certain involuntary body functions, including immune reactions, blood pressure, and body temperature.

In addition to its efficacy in relieving pain and other chronic conditions, acupuncture has gained in popularity because of several additional advantages:

- It lacks the side effects associated with many medications and surgical treatments in Western medicine.
- It is highly cost-effective; it may be used early in the course of a disease, potentially saving the patient the cost of hospitalizations, laboratory tests, and high-priced drugs.
- It can easily be combined with other forms of therapy, including psychotherapy.
- It is noninvasive.
- It carries relatively few risks.



Acupuncture sites and meridians on the face and neck. *(Illustration by Hans & Cassady, Inc.)*

Precautions

Although the risk of infection in acupuncture is minimal, patients should make sure that the acupuncturist uses sterile disposable needles. In the United States, the Food and Drug Administration (FDA) mandates the use of sterilized needles made from nontoxic materials. The needles must be clearly labeled as having their use restricted to qualified practitioners.

Patients should also inquire about the practitioner's credentials. Since acupuncture is now taught in over forty accredited medical schools and osteopathic colleges in the United States, patients who would prefer to be treated by an MD or an osteopath can obtain a list of licensed physicians who practice acupuncture in their area from the American Academy of Medical Acupuncture. With regard to nonphysician acupuncturists, 31 states have established training standards that acupuncturists must meet in order to be licensed in those states. In Great Britain, practitioners must qualify by passing a course offered by the British Acupuncture Accreditation Board.

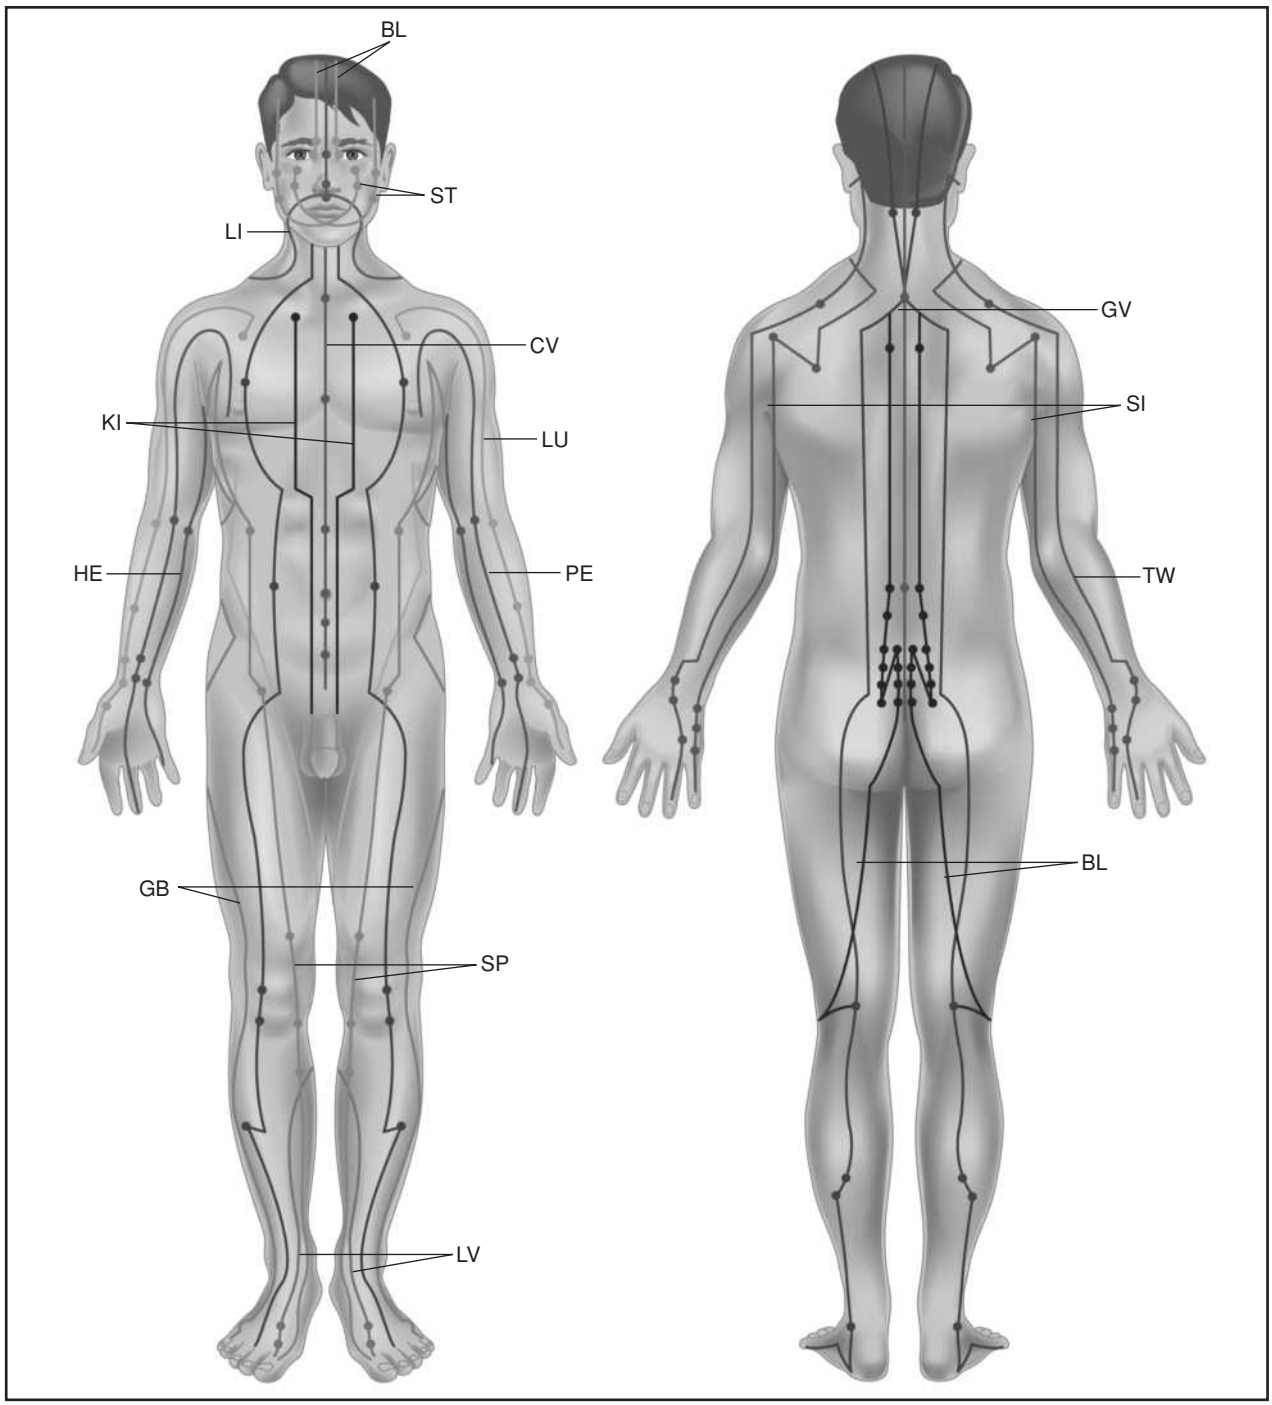
Patients seeking acupuncture treatment should provide the practitioner with the same information about their health conditions and other forms of treatment that they would give their primary care doctor. This information should include other alternative and complementary therapies, especially herbal remedies.

Acupuncture should not be used to treat severe traumatic injuries and other emergency conditions requiring immediate surgery. In addition, it does not appear to be useful in smoking cessation programs.

As is true with other forms of medical treatment, a minority of patients do not respond to acupuncture. The reasons for nonresponsiveness are not known at the present stage of research.

Description

In traditional Chinese medicine, acupuncture treatment begins with a thorough physical examination in which the practitioner evaluates the patient's skin color, vocal tone, and tongue color and coating. The practitioner then takes the patient's pulse at six locations and three depth levels on each wrist. These thirty-six pulse measurements will tell the practitioner where the qi in the patient's body might be blocked or unbalanced. After collecting this information, the acupuncturist will then identify the patterns of energy disturbance and the acupunc-



Traditional Chinese medicine teachings state that channels of energy flow throughout the body, and that disease is caused by too much or too little flow of energy along these channels. Points along the channels, called meridians, are manipulated in acupuncture. In the illustration, points are shown on the bladder (BL), conception vessel (CV), gall bladder (GB), governing vessel (GV), heart (HE), kidney (KI), large intestine (LI), liver (LV), lung (LU), pericardium (PE), small intestine (SI), spleen (SP), stomach (ST), and triple warmer (TW) meridians. *(Illustration by Electronic Illustrators Group.)*

ture points that should be stimulated to unblock the qi or restore harmony. Up to ten or twelve acupuncture needles will be inserted at strategic points along the relevant meridians. In traditional Chinese practice, the needles are twirled or rotated as they are inserted. Many patients feel nothing at all during this procedure, although others experience a prickling or mild aching sensation, and still others a feeling of warmth or heaviness.

The practitioner may combine acupuncture with moxibustion to increase the effectiveness of the treatment. Moxibustion is a technique in which the acupuncturist lights a small piece of wormwood, called a moxa, above the acupuncture point above the skin. When the patient begins to feel the warmth from the burning herb, it is removed. Cupping is another technique that is a method of stimulation of acupuncture points by applying suction through a metal, wood, or glass jar, and in which a partial vacuum has been created. Producing blood congestion at the site, the site is thus stimulated. The method is used for lower back pain, sprains, soft tissue injuries, as well as relieving fluid from the lungs in chronic bronchitis.

In addition to the traditional Chinese techniques of acupuncture, the following are also used in the United States:

- Electroacupuncture. In this form of acupuncture, the traditional acupuncture points are stimulated by an electronic device instead of a needle.
- Japanese meridian acupuncture. Japanese acupuncture uses thinner, smaller needles, and focuses on the meridians rather than on specific points along their course.
- Korean hand acupuncture. Traditional Korean medicine regards the hand as a "map" of the entire body, such that any part of the body can be treated by stimulating the corresponding point on the hand.
- Western medical acupuncture. Western physicians trained in this style of acupuncture insert needles into so-called trigger points in sore muscles, as well as into the traditional points used in Chinese medicine.
- Ear acupuncture. This technique regards the ear as having acupuncture points that correspond to other parts of the body. Ear acupuncture is often used to treat substance abuse and chronic pain syndromes.

A standard acupuncture treatment takes between 45 minutes to an hour and costs between $40 and $100, although initial appointments often cost more. Chronic conditions usually require 10 treatment sessions, but acute conditions or minor illnesses may require only one or two visits. Follow-up visits are often scheduled for patients with chronic pain. As of 2000, about 70%–80% of health insurers in the United States reimbursed patients for acupuncture treatments.

Preparation

Apart from a medical history and physical examination, no specific preparation is required for an acupuncture treatment. In addition to using sterile needles, licensed acupuncturists will wipe the skin over each acupuncture point with an antiseptic solution before inserting the needle.

Aftercare

No particular aftercare is required, as the needles should not draw blood when properly inserted. Many patients experience a feeling of relaxation or even a pleasant drowsiness after the treatment. Some patients report feeling energized.

Risks

Several American and British reports have concluded that the risks to the patient from an acupuncture treatment are minimal. Most complications from acupuncture fall into one of three categories: infections, most often from improperly sterilized needles; bruising or minor soft tissue injury; and injuries to muscle tissue. Serious side effects with sterilized needles are rare, although cases of pneumothorax and cardiac tamponade have been reported in the European literature. One American pediatrician estimates that the risk of serious injury from acupuncture performed by a licensed practitioner ranges between 1:10,000 and 1:100,000— or about the same degree of risk as a negative reaction to penicillin.

Normal results

Normal results from acupuncture are relief of pain and/or improvement of the condition being treated.

Abnormal results

Abnormal results from acupuncture include infection, a severe side effect, or worsening of the condition being treated.

Acute stress disorder

Definition

Acute stress disorder (ASD) is an anxiety disorder characterized by a cluster of dissociative and anxiety symptoms that occur within a month of a traumatic stressor. It is a relatively new diagnostic category and was added to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* in 1994 to distinguish time-limited reactions to trauma from the farther-reaching and longer-lasting **post-traumatic stress disorder** (PTSD). Published by the American Psychiatric Association, the *DSM* contains diagnostic criteria, research findings, and treatment information for mental disorders. It is the primary reference for mental health professionals in the United States.

Description

ASD, like PTSD, begins with exposure to an extremely traumatic, horrifying, or terrifying event. Unlike PTSD, however, ASD emerges sooner and abates more quickly; it is also marked by more dissociative symptoms. If left untreated, however, ASD is likely to progress to PTSD. Because the two share many symptoms, some researchers and clinicians question the validity of maintaining separate diagnostic categories. Others explain them as two phases of an extended reaction to traumatic stress.

Causes and symptoms

Causes

The immediate cause of ASD is exposure to trauma—an extreme stressor involving a threat to life or the prospect of serious injury; witnessing an event that involves the death or serious injury of another person; or learning of the violent death or serious injury of a family member or close friend. The trauma's impact is determined by its cause, scope, and extent. Natural disasters (floods, earthquakes, hurricanes, etc.) or accidents (plane crashes, workplace explosions) are less traumatic than human acts of intentional cruelty or terrorism. Terrorist-inflicted trauma appears to produce particularly high rates of ASD and PTSD in survivors and bystanders.

Although most people define trauma in terms of events such as war, terrorist attacks, and other events that result in vast loss of life, the leading cause of stress-related mental disorders in the United States is motor vehicle accidents. Most Americans will be involved in a traffic accident at some point in their lives, and 25% of the population will be involved in accidents resulting in serious injuries. The National Comorbidity Survey of 1995 found that 9% of survivors of serious motor vehicle accidents developed ASD or PTSD.

Several factors influence a person's risk of developing ASD after trauma:

- Age—Older adults are less likely to develop ASD, possibly because they have had more experience coping with painful or stressful events.
- Previous exposure—People who were abused or experienced trauma as children are more likely to develop ASD (or PTSD) as adults, because these may produce long-lasting biochemical changes in the central nervous system.
- Biological vulnerability—Twin studies indicate that certain abnormalities in **brain** hormone levels and brain structure are inherited, and that these increase a person's susceptibility to ASD following exposure to trauma.
- Support networks—People who have a network of close friends and relatives are less likely to develop ASD.
- Perception and interpretation—People who feel inappropriate responsibility for the trauma, regard the event

KEY TERMS

Adjustment disorder—A disorder defined by the development of significant emotional or behavioral symptoms in response to a stressful event or series of events. Symptoms may include depressed mood, anxiety, and impairment of social and occupational functioning.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, changing, or dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal or dreamlike.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Dissociative amnesia—A dissociative disorder characterized by loss of memory for a period or periods of time in the patient's life. May occur as a result of a traumatic event.

Exposure therapy—A form of cognitive-behavioral therapy in which patients suffering from phobias are exposed to their feared objects or situations while accompanied by the therapist. The length of exposure is gradually increased until the association between the feared situation and the patient's experienced panic symptoms is no longer present.

Flashback—The re-emergence of a traumatic memory as a vivid recollection of sounds, images, and sensations associated with the trauma. The person having the flashback typically feels as if he or she is reliving the event.

Hyperarousal—A symptom of traumatic stress characterized by abnormally intense reactions to stimuli. A heightened startle response is one sign of hyperarousal.

Hypervigilance—A state of abnormally intense wariness or watchfulness that is found in survivors of trauma or long-term abuse. Hypervigilance is sometimes described as "being on red alert all the time."

Personalization—The tendency to refer large-scale events or general patterns of events to the self in inappropriate ways. For example, a person who regards the loss of a friend or relative in an accident as punishment for having quarreled with them before the accident is said to be personalizing the event. Personalization increases a person's risk of developing ASD or PTSD after a traumatic event.

Psychic numbing—An inability to respond emotionally with normal intensity to people or situations; this affects positive emotions as well as fear or anger.

Sequela (plural, sequelae)—An abnormal condition resulting from a previous disease or disorder. An episode of depression is a common sequela of acute stress disorder.

Supportive—An approach to psychotherapy that seeks to encourage the patient or offer emotional support to him or her, as distinct from insight-oriented or educational approaches to treatment.

Survivor's guilt—A psychological reaction in trauma survivors that takes the form of guilt feelings for having survived or escaped a trauma without serious injury when others did not.

Therapeutic writing—A treatment technique in which patients are asked to set down in writing an account of the traumatic event and their emotional responses to it.

as punishment for personal wrongdoing, or have generally negative or pessimistic worldviews are more likely to develop ASD than those who do not personalize the trauma or are able to maintain a balanced view of life.

Symptoms

Acute stress disorder may be diagnosed in patients who (A) lived through or witnessed a traumatic event to which they (B) responded with intense fear, horror, or helplessness, and are (C) currently experiencing three or more of the following dissociative symptoms:

- psychic numbing
- being dazed or less aware of surroundings
- derealization
- depersonalization
- dissociative amnesia

Other symptoms that indicate ASD are:

- Reexperiencing the trauma in recurrent dreams, images, thoughts, illusions, or flashbacks; or intense distress when exposed to reminders of the trauma.

- A marked tendency to avoid people, places, objects, conversations, and other stimuli reminiscent of the trauma (many people who develop ASD after a traffic accident, for example, refuse to drive a car for a period of time).
- Hyperarousal or anxiety, including sleep problems, irritability, inability to concentrate, an unusually intense startle response, hypervigilance, and physical restlessness (pacing the floor, fidgeting, etc.).
- Significantly impaired social functions and/or the inability to do necessary tasks, including seeking help.
- Symptoms last for a minimum of two days and a maximum of four weeks, and occur within four weeks of the traumatic event.
- The symptoms are not caused by a substance (medication or drug of abuse) or by a general medical condition; do not meet the criteria of a **brief psychotic disorder**; and do not represent the worsening of a mental disorder that the person had before the traumatic event.

People with ASD may also show symptoms of depression including difficulty enjoying activities that they previously found pleasurable; difficulty in concentrating; and survivor's guilt at having survived an accident or escaping serious injury when others did not. The *DSM-IV-TR* (revised edition published in 2000) notes that people diagnosed with ASD "often perceive themselves to have greater responsibility for the consequences of the trauma than is warranted," and may feel that they will not live out their normal lifespans. Many symptoms of ASD are also found in patients with PTSD.

Demographics

Acute responses to traumatic stressors are far more widespread in the general United States population than was first thought in 1980, when PTSD was introduced as a diagnostic category in the *DSM-III*. The National Comorbidity Survey, a major epidemiological study conducted between 1990 and 1992, estimated that the lifetime prevalence among adult Americans is 7.8%, with women (10.4%) twice as likely as men (5%) to be diagnosed with trauma-related stress disorders at some point in their lives. These figures represent only a small proportion of adults who have experienced at least one traumatic event—60.7% of men and 51.2% of women respectively. More than 10% of the men and 6% of the women reported experiencing *four or more* types of trauma in their lives.

The prevalence of ASD by itself in the general United States population is not known. A few studies of people exposed to traumatic events found rates of ASD between 14% and 33%. Some groups are at greater risk of developing ASD or PTSD, including people living in depressed urban areas or on Native American reservations (23%) and victims of violent crimes (58%).

Diagnosis

ASD symptoms develop within a month after the traumatic event; it is still unknown, however, why some trauma survivors develop symptoms more rapidly than others. Delayed symptoms are often triggered by a situation that resembles the original trauma.

ASD is usually diagnosed by matching the patient's symptoms to the *DSM-IV-TR* criteria. The patient may also meet the criteria for a major depressive episode or **major depressive disorder**. A person who has been exposed to a traumatic stressor and has developed symptoms that do not meet the criteria for ASD may be diagnosed as having an **adjustment disorder**.

As of 2002, there are no diagnostic interviews or questionnaires in widespread use for diagnosing ASD, although screening instruments specific to the disorder are being developed. A group of Australian clinicians has developed a 19-item Acute Stress Disorder Scale, which appears to be effective in diagnosing ASD but frequently makes false-positive predictions of PTSD. The authors of the scale recommend that its use should be followed by a careful clinical evaluation.

Treatments

Therapy for ASD requires the use of several treatment modalities because the disorder affects systems of belief and meaning, interpersonal relationships, and occupational functioning as well as physical well-being.

Medications

Medications are usually limited to those necessary for treating individual symptoms. **Clonidine** is given for hyperarousal; **propranolol**, **clonazepam**, or **alprazolam** for anxiety and panic reactions; **fluoxetine** for avoidance symptoms; and **trazodone** or topiramate for **insomnia** and nightmares. Antidepressants may be prescribed if ASD progresses to PTSD. These medications may include selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), or tricyclic antidepressants.

Psychotherapy

Cognitive-behavioral therapy, exposure therapy, therapeutic writing (journaling), and supportive therapy have been found effective in treating ASD. One variant of cognitive-behavioral therapy called psychoeducation-

Immediate crisis intervention after a tragedy or natural disaster may help victims express their feelings and fears and may help them to avoid developing acute stress disorder and post-traumatic stress disorder. Here, victims of a 1993 flood in Missouri receive counseling. *(Najlah Feanny-Hicks. Corbis/SABA. Photo reproduced by permission.)*

al therapy appears to be three to four times as effective as supportive therapy in preventing ASD from progressing to PTSD. This treatment combines cognitive restructuring of the traumatic event with exposure to disturbing images and techniques for anxiety management. In addition, it can help patients identify and reinforce positive aspects of their experience. For example, some people find new strengths or talents within themselves in times of crisis, or discover new spiritual resources.

Group and family therapies also appear to help patients with ASD reinforce effective strategies for coping with the trauma, and may reduce the risk of social isolation as a reaction to the trauma. They give patients opportunities to describe what happened and how they responded; they also let patients receive warmth and caring from their listeners, and help put memories of the event into a coherent narrative, allowing them to integrate the trauma into their overall lives.

Critical incident stress management (CISM) is a comprehensive crisis-intervention system in which a team of specially trained practitioners comes to the site of a traumatic event and provides several different forms of assistance, including one-on-one crisis support; crisis management briefing, which is a 45–75-minute **intervention** for groups of people affected by the traumatic event; and critical incident stress debriefing, which is a structured group discussion of the event. CISM appears to be particularly helpful in preventing burnout and ASD in emergency service personnel, rescue personnel, police, and other caregivers who are involved in treating survivors of a traumatic event.

Alternative and complementary treatments

Many mainstream practitioners recommend holistic or naturopathic approaches to recovery from ASD, including good nutrition with appropriate dietary supplements and regular exercise. **Yoga** and some forms of body work or massage therapy are helpful in treating the muscular soreness and stiffness that is often a side effect of the anxiety and insomnia related to ASD. Hydrotherapy is often helpful for post-traumatic muscular aches and cramps. A skilled naturopath may also recommend peppermint or other herbal preparations to calm the patient's digestive tract. In addition, prayer, **meditation**, or counseling with a spiritual advisor have been

found to be helpful in treating patients with ASD whose belief systems have been affected by the traumatic event.

Diagnosis and treatment of ASD in children

Very little is known about the prevalence of ASD or PTSD in children, and even less is known how effectively medications and **psychotherapy** treat these disorders in this age group. There are as yet no standardized screens or diagnostic interviews in widespread use for assessing either ASD or PTSD in children, although a Child Post-traumatic Stress Reaction Index was published in 1992. One preliminary study recommends the cautious use of low doses of **imipramine** for treating children with ASD, but notes that research in this area has barely begun.

Prognosis

Untreated ASD is highly likely to progress to PTSD in children as well as in adults. One team of Australian researchers found that 80% of persons diagnosed with ASD met criteria for PTSD six months later; 75% met criteria for PTSD two years after the traumatic event.

Clinicians in Norway have compiled a list of four "early response" variables that appear to be effective predictors of ASD's progressing to PTSD:

- the degree of the patient's sleep disturbance
- a strong startle reaction
- the degree of the patient's social withdrawal
- fear or phobia related to the site of the traumatic event

In addition to developing PTSD, people diagnosed with ASD are at increased risk of developing a major depressive disorder, particularly if their emotional responses to the trauma were marked by intense despair and hopelessness. Other sequelae may include neglect of personal needs for health or safety; and impulsive or needlessly risky behavior.

Prevention

Some forms of trauma, such as natural disasters and accidents, can never be completely eliminated from human life. Traumas caused by human intention would require major social changes to reduce their frequency and severity, but given the increasing prevalence of trauma-related stress disorders around the world, these long-term changes are worth the effort. In the short run, educating people—particularly those in the helping professions—about the signs of critical incident stress may prevent some cases of exposure to trauma from developing into ASD and progressing to full-blown PTSD.

Addiction

Definition

Most definitions refer to addiction as the compulsive need to use a habit-forming substance, or an irresistible urge to engage in a behavior. Two other important defining features of addiction are tolerance, the increasing need for more of the substance to obtain the same effect, and withdrawal, the unpleasant symptoms that arise when an addict is prevented from using the chosen substance.

Description

The term addiction has come to refer to a wide and complex range of behaviors. While addiction most commonly refers to compulsive use of substances, including alcohol, prescription and illegal drugs, cigarettes, and food, it is also used to describe excessive indulgence in activities such as work, exercise, shopping, sex, the Internet, and gambling.

Causes and symptoms

Causes

Some experts describe the range of behaviors designated as addictive in terms of five interrelated concepts: patterns, habits, compulsions, impulse control disorders, and physical addiction. There is ongoing controversy as to whether addictions constitute true physical disease in the same sense that diabetes and hypertension are considered physical diseases. Indeed, the most prevalent model of substance dependence today is the so-called disease model. This model, first introduced in the late 1940s by E. M. Jellinek, was adopted in 1956 by the American Medical Association. Since that time, the disease model of alcoholism and drug addiction has been well accepted throughout the world.

Other experts disagree with the analogy between substance abuse and physical disease. They believe that addictive behaviors can be better understood as problematic habits or behavior patterns that have been learned in accordance with the principles that guide all learning. To these experts, addictive behaviors are maladaptive habits and behavior patterns that can be "unlearned" and replaced with new, alternative, more healthful behaviors. According to learning theorists, one's past and present experiences, environment, family history, peer group influences, and individual beliefs and expectations, determine who will or will not become addicted to a substance or behavior.

Psychodynamic theorists believe that addicts suffer from an inability to soothe themselves or comfortably manage the emotions of day-to-day life. Feelings such as anxiety, depression, shame, discomfort in social situations, and anger are often believed to be causes of substance abuse. In this sense, many experts believe that addicts self-medicate, that is, use destructive substances to ease their painful emotions.

Disease model adherents believe that the compulsion to use is genetically and physiologically based and that, while the disease can be arrested, the disease is progressive and, if unchecked, fatal. Researchers have found the sons of alcoholics to be twice as prone to alcoholism as other people. Among pairs of identical twins, if one is alcoholic, there is a 60% chance that the other will be also. In spite of an apparent inherited tendency toward alcoholism, the fact that the majority of people with alcoholic parents do not become alcoholics themselves demonstrates the influence of psychosocial factors, including personality factors and a variety of environmental stressors, such as occupational or marital problems.

Symptoms

Both disease model and learning model adherents agree that initial positive consequences of substance abuse or addictive activities are what initially "hook," and then later keep, the addict addicted. Addicts describe feelings of euphoria when using their substance or engaging in their activity of choice. Many experts believe that these substances and activities affect **neurotransmitters** in the **brain**. Use causes an increase in endorphin levels, which is believed to be one of the chief causes of the "high" sensation experienced by addicts.

As the addict continues to use, his or her body adjusts to the substance and tolerance develops. Increasing amounts of the substance are needed to produce the same effect. Levels of substances that addicts routinely ingest would be lethal to a non-addict.

Over time, physical symptoms of dependence strengthen. Failure to use leads to withdrawal symptoms, which include flu-like aches and pains, digestive upset, and, in severe cases, **seizures**, and hallucinatory-like sensations, such as the feeling of bugs crawling on the skin. Damage to various organs of the body, including the brain and liver, can lead to serious and even fatal illness as well as mental symptoms such as **dementia**. Severe disruption of social and family relationships, and of the ability to maintain a steady job, are also symptoms of the addictive process.

Demographics

According to a 1999 national survey, about 14.8 million Americans used an illicit drug at least once in the

month prior to the survey, and the chances of receiving a **diagnosis** of substance abuse or dependence at some point in one's life is 16.7% for people over age 18. The lifetime chances of developing alcohol abuse or dependence is 13.8%; for nonalcohol substances, 6.2%. As of 1995, 6.1% of the population age 12 and older currently used illicit drugs. The most commonly used substances are alcohol and cigarettes, as well as marijuana, hashish, and cocaine. Unfortunately, substance abuse has been on the rise among children and adolescents since 1993.

According to findings of the National Institute of Drug Abuse, overall use of drugs in the United States has decreased by 50% during the past 20 years. However, drug use among adolescents has increased during the past 10 years.

Addiction is more common among men than women, and the use of drugs other than alcohol is skewed even further in that direction. Substance abuse is higher among the unemployed and the less educated. Most current illicit drug users are white. It is estimated that 9.6 million whites (75% of all users), 1.9 million African Americans (15% of users), and 1.0 million Hispanics (8% of users) were using illicit drugs in 1995.

Diagnosis

Substance abuse and dependence are among the psychological disorders categorized as major clinical syndromes (known as "Axis 1") in the American Psychiatric Association's ***Diagnostic and Statistical Manual of Mental Disorders*** (*DSM-IV-TR*). Alcohol, classified as a depressant, is the most frequently abused psychoactive substance. Alcohol abuse and dependence affect more than 20 million Americans—about 13% of the adult population. An alcoholic has been defined as a person whose drinking impairs his or her life adjustment, affecting health, personal relationships, and/or work.

When blood alcohol level reaches 0.1%, a person is considered intoxicated. Judgment and other rational processes are impaired, as are motor coordination, speech, and vision. Alcohol abuse, according to the *DSM-IV-TR*, progresses through a series of stages from social drinking to chronic alcoholism. Danger signs that indicate the probable onset of a drinking problem include frequent desire to drink, increasing alcohol consumption, memory lapses (blackouts), and morning drinking. Other symptoms include attempts to hide alcohol from family and colleagues, and attempts to drink in secret. Among the most acute reactions to alcohol are four conditions referred to as alcoholic psychoses: alcohol idiosyncratic intoxication (an acute reaction in persons with an abnormally low tolerance for alcohol); alcohol withdrawal **delirium** (delirium tremens); **hallucinations**; and Korsakoff's **psychosis**, an irreversible brain disorder involving severe memory loss.

Other substance abuse disorders are diagnosed by looking for patterns of compulsive use, frequency of use, increasing tolerance, and withdrawal symptoms when the substance is unavailable or the individual tries to stop using.

Treatments

Pharmacologic

Addictions are notoriously difficult to treat. Physical addictions alter a person's brain chemistry in ways that make it difficult to be exposed to the addictive substance again without relapsing. Some medications, such as Antabuse (**disulfiram**), have shown limited effectiveness in treating alcohol addiction. Substitute medications, such as **methadone**, a drug that blocks the euphoric effect of opiates, have also shown mixed results. When an addicted individual is using a substance to self-medicate for depression, anxiety, and other uncomfortable emotions, prescription medications can be an effective treatment.

Psychological and psychosocial

It is a commonly held belief by many professionals that people with addictive disorders cannot be treated effectively by conventional outpatient **psychotherapy**. Substance abusers are often presumed to have severe personality problems and to be very resistant to treatment, to lack the motivation to change, or to be just too much trouble in an outpatient office setting. Unfortunately, these beliefs may create a self-fulfilling prophecy. Many of the negative behaviors and personality problems associated with chronic substance use disappear when use of the substance stops. While some substance abusers do, in fact, have other mental disorders, they represent only a minority of the addicted population.

Most treatment for addictive behaviors is provided not by practicing clinicians (psychiatrists, psychologists, and **social workers**), but rather by specialized addiction treatment programs and clinics. These programs rely upon confrontational tactics and re-education as their primary approaches, often employing former or recovering addicts to treat newly admitted addicts.

Some addicts are helped by the combination of individual, group, and family treatment. In family treatment (or **family therapy**), "enabling behaviors" can be addressed and changed. Enabling behaviors are the actions of family members who assist the addict in maintaining active addiction, including providing money, food, and shelter. Residential settings may be effective in initially assisting the addicted individual to stay away

from the many "cues," including people, places, and things, that formed the setting for their substance use.

During the past several decades, alternatives to the complete abstinence model (the generally accepted model in the United States) have arisen. Controlled use programs allow addicted individuals to reduce their use without committing to complete abstinence. This alternative is highly controversial. The generally accepted position is that only by complete abstinence can an addicted individual recover. The effectiveness of addiction treatment based on behavioral and other psychotherapeutic methods, however, is well documented. Among these are motivation-enhancing strategies, relapse-prevention strategies using cognitive-behavioral approaches, solution-oriented and other brief therapy technques, and harm-reduction approaches.

Self-help groups such as Alcoholics Anonymous and Narcotics Anonymous have also developed widespread popularity. The approach of one addict helping another to stay "clean," without professional **intervention**, has had tremendous acceptance in the United States and other countries.

Prognosis

Relapse and recidivism are, unfortunately, very common. Interestingly, a classic study shows that people addicted to different substances show very similar patterns of relapse. Whatever the addictive substances, data show that about two-thirds of all relapses occur within the first 90 days following treatment. Many consider recovery to be an ongoing, lifelong process. Because the use of addictive substances alters brain chemistry, cravings can persist for many years. For this reason, the predominating belief is that recovery is only possible by commitment to complete abstinence from all substance use.

Prevention

Prevention approaches are most effectively targeted at young teenagers between the ages of 11 and 13. It is during these years that most young people are likely to experiment with drugs and alcohol. Hence, reducing experimentation during this critical period holds promise for reducing the number of adults with addictive disease. Effective prevention programs focus on addressing the concerns of young people with regard to the effects of drugs. Training older adolescents to help younger adolescents resist peer pressure has shown considerable effectiveness in preventing experimentation.

Adjustment disorder

Definition

An adjustment disorder is a type of mental disorder resulting from maladaptive, or unhealthy, responses to stressful or psychologically distressing life events. This low level of adaptation then leads to the development of emotional or behavioral symptoms.

Description

Often, a person experiences a stressful event as one that changes his or her world in some fundamental way.

An adjustment disorder represents significant difficulty in adjusting to the new reality.

The stressful events that precipitate an adjustment disorder vary widely. They may include the loss of a job; the end of a romantic relationship; a life transition such as a career change or retirement; or a serious accident or sickness. Some are acute "one-time" stressors, such as relocating to a new area, while others are chronic, such as caring for a child with **mental retardation**.

Psychiatrists have disagreed about the validity of the **diagnosis** of adjustment disorder, largely because of its lack of specificity. What qualifies as a stressful event, and what is an abnormal response to it? While adjustment disorders are more difficult to quantify than other mental disorders, many researchers consider the category a useful one for two reasons: 1) an adjustment disorder may be an early sign of a major mental disorder and allow for early treatment and **intervention**; 2) adjustment disorders are "situational" or "reactive"; they do not imply that the patient has an underlying **brain** disease.

KEY TERMS

Cognitive-behavioral therapy—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Group therapy—Group interaction designed to provide support, correction through feedback, constructive criticism, and a forum for consultation and reference.

Interpersonal therapy—An approach that includes psychoeducation about the sick role, and emphasis on the present and improving interpersonal dynamics and relationships. Interpersonal therapy is effective in treating adjustment disorders related to physical illness.

Psychosocial—A term that refers to the emotional and social aspects of psychological disorders.

Solution-focused therapy—A type of therapy that involves concrete goals and an emphasis on future direction rather than past experiences.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

Support group—A group whose primary purpose is the provision of empathy and emotional support for its members. Support groups are less formal and less goal-directed than group therapy.

Causes and symptoms

Causes

The ***Diagnostic and Statistical Manual of Mental Disorders***, which is the basic reference work consulted by mental health professionals, included an important change in its most recent version, the *DSM-IV-TR*, with regard to the criteria for adjustment disorder. In the previous edition, the identifiable stressor was described as being "psychosocial," a category that excludes physical illnesses and natural disasters. In the *DSM-IV-TR*, the word "psychosocial" was deleted in order to make the point that any stressful event can lead to an adjustment disorder. It is important to recognize, however, that while adjustment disorders are triggered by external stressors, the symptoms result from the person's interpretation of and adaptation to the stressful event or circumstances. Beliefs, perceptions, fears, and expectations influence the development of an adjustment disorder.

People with chronic physical illnesses appear to have an increased risk of developing adjustment disorders, particularly one with depressed mood. This connection has been demonstrated among cancer patients. The relationship between chronic pain (as is commonly experienced by cancer patients) and depressive symptoms is still being studied.

Symptoms

DSM-IV-TR states that the symptoms of an adjustment disorder must appear within three months of a stressor; and that they must meet at least one of the following criteria: 1) the distress is greater than what would be expected in response to that particular stressor; 2) the patient experiences significant impairment in social relationships or in occupational or academic settings. Moreover, the symptoms cannot represent bereavement, as normally experienced after the death of a loved one.

DSM-IV-TR specifies six subtypes of adjustment disorder, each with its own predominant symptoms:

- With depressed mood: The chief manifestations are feelings of sadness and depression, with a sense of accompanying hopelessness. The patient may be tearful and have uncontrollable bouts of crying.
- With anxiety: The patient is troubled by feelings of apprehension, nervousness, and worry. He or she may also feel jittery and unable to control his or her thoughts of doom. Children with this subtype may express fears of separation from parents or other significant people, and refuse to go to sleep alone or attend school.

- With mixed anxiety and depressed mood: The patient has a combination of symptoms from the previous two subtypes.
- With disturbance of conduct: This subtype involves such noticeable behavioral changes as shoplifting, truancy, reckless driving, aggressive outbursts, or sexual promiscuity. The patient disregards the rights of others or previously followed rules of conduct with little concern, guilt or remorse.
- With mixed disturbance of emotions and conduct: The patient exhibits sudden changes in behavior combined with feelings of depression or anxiety. He or she may feel or express guilt about the behavior, but then repeat it shortly thereafter.
- Unspecified: This subtype covers patients who are adjusting poorly to **stress** but who do not fit into the other categories. These patients may complain of physical illness and pull away from social contact.

Adjustment disorders may lead to **suicide** or suicidal thinking. They may also complicate the treatment of other diseases when, for instance, a sufferer loses interest in taking medication as prescribed or adhering to **diets** or exercise regimens.

An adjustment disorder can occur at any stage of life.

Demographics

Adjustment disorder appears to be fairly common in the American population; recent figures estimate that 5%–20% of adults seeking outpatient psychological treatment suffer from one of the subtypes of this disorder. As many as 70% of children in psychiatric inpatient settings may be diagnosed with an adjustment disorder. In a 1991 questionnaire that was sent to child psychiatrists, 55% admitted to giving children the diagnosis of an adjustment disorder to avoid the **stigma** associated with other disorders.

Women are diagnosed with adjustment disorder twice as often as men, while in clinical samples of children and adolescents, boys and girls were equally likely to be diagnosed with an adjustment disorder. Nolen-Hoeksema, a researcher who has conducted numerous studies on gender differences in depression, has argued that women over the age of 15 exhibit a more depressive temperament than men. She theorizes that women are more likely to respond to depression in ways that make the disorder worse and prolong it. Her findings appear to have some applicability to adjustment disorder with depressed mood.

There are no current studies of differences in the frequency of adjustment disorder in different racial or ethnic groups. There is, however, some potential for bias in diagnosis, particularly when the diagnostic criteria concern abnormal responses to stressors. *DSM-IV-TR* specifies that clinicians must take a patient's cultural background into account when evaluating his or her responses to stressors.

Diagnosis

Adjustment disorders are almost always diagnosed as the result of an interview with a **psychiatrist**. The psychiatrist will take a history, including identification of the stressor that has triggered the adjustment disorder, and evaluate the patient's responses to the stressor. The patient's primary physician may give him or her a thorough physical examination to rule out a previously undiagnosed medical illness.

The American Psychiatric Association considers adjustment disorder to be a residual category, meaning that the diagnosis is given only when an individual does not meet the criteria for a major mental disorder. For example, if a person fits the more stringent criteria for **major depressive disorder**, the diagnosis of adjustment disorder is not given. If the patient is diagnosed with an adjustment disorder but continues to have symptoms for more than six months after the stressor and its consequences have ceased, the diagnosis is changed to another mental disorder. The one exception to this time limit is situations in which the stressor itself is chronic or has enduring consequences. In that case, the adjustment disorder would be considered chronic and the diagnosis could stand beyond six months.

The diagnosis of adjustment disorder represents a particular challenge to clinicians because it has no checklist of specific and observable symptoms. The diagnosis is instead based on a broad range of emotional and behavioral symptoms that can vary widely in appearance and severity. The lack of a diagnostic checklist does in fact distinguish adjustment disorders from either **post-traumatic stress disorder** or **acute stress disorder**. All three require the presence of a stressor, but the latter two define the extreme stressor and specific patterns of symptoms. With adjustment disorder, the stressor may be any event that is significant to the patient, and the disorder may take very different forms in different patients.

Adjustment disorders must also be distinguished from **personality disorders**, which are caused by enduring personality traits that are inflexible and cause impairment. A personality disorder that has not yet surfaced may be made worse by a stressor and may mimic an adjustment disorder. A clinician must separate relatively stable traits in a patient's personality from passing disturbances. In some cases, however, the patient may be given both diagnoses. Again, it is important for psychia-

trists to be sensitive to the role of cultural factors in the presentation of the patient's symptoms.

If the stressor is a physical illness, diagnosis is further complicated. It is important to recognize the difference between an adjustment disorder and the direct physiological effects of a general medical condition (such as the usual temporary functional impairment associated with chemotherapy). This distinction can be clarified through communication with the patient's physician or by education about the medical condition and its treatment. For some individuals, however, both may occur and reinforce each other.

Treatments

There have been few research studies of significant scope to compare the efficacy of different treatments for adjustment disorder. The relative lack of outcome studies is partially due to the lack of specificity in the diagnosis itself. Because there is such variability in the types of stressors involved in adjustment disorders, it has proven difficult to design effective studies. As a result, there is no consensus regarding the most effective treatments for adjustment disorder.

Psychological and social interventions

There are, however, guidelines for effective treatment of people with adjustment disorders. Effective treatments include stress-reduction approaches; therapies that teach coping strategies for stressors that cannot be reduced or removed; and those that help patients build support networks of friends, family, and people in similar circumstances. **Psychodynamic psychotherapy** may be helpful in clarifying and interpreting the meaning of the stressor for a particular patient. For example, if the person is suffering from cancer, he or she may become more dependent on others, which may be threatening for people who place a high value on self-sufficiency. By exploring those feelings, the patient can then begin to recognize all that is not lost and regain a sense of self-worth.

Therapies that encourage the patient to express the fear, anxiety, rage, helplessness and hopelessness of dealing with the stressful situation may be helpful. These approaches include journaling, certain types of art therapy, and movement or dance therapy. **Support groups** and **group therapy** allow patients to gain perspective on the adversity and establish relationships with others who share their problem. Psychoeducation and medical crisis counseling can assist individuals and families facing stress caused by a medical illness.

Such types of brief therapy as **family therapy**, **cognitive-behavioral therapy**, solution-focused therapy, and **interpersonal therapy** have all met with some success in treating adjustment disorder.

Medications

Clinicians do not agree on the role of medications in treating adjustment disorder. Some argue that medication is not necessary for adjustment disorders because of their brief duration. In addition, they maintain that medications may be counterproductive by undercutting the patient's sense of responsibility and his or her motivation to find effective solutions. At the other end of the spectrum, other clinicians maintain that medication by itself is the best form of treatment, particularly for patients with medical conditions, those who are terminally ill, and those resistant to **psychotherapy**. Others advocate a middle ground of treatment that combines medication and psychotherapy.

Alternative therapies

Spiritual and religious counseling can be helpful, particularly for people coping with existential issues related to physical illness.

Some herbal remedies appear to be helpful to some patients with adjustment disorders. For adjustment disorder with anxiety, a randomized controlled trial found that patients receiving Euphytose (an herbal preparation containing a combination of plant extracts including Crataegus, Ballota, Passiflora, Valeriana, Cola, and Paullinia) showed significant improvement over patients taking a placebo.

Prognosis

Most adults who are diagnosed with adjustment disorder have a favorable prognosis. For most people, an adjustment disorder is temporary and will either resolve by itself or respond to treatment. For some, however, the stressor will remain chronic and the symptoms may worsen. Still other patients may develop a major depressive disorder even in the absence of an additional stressor.

Studies have been conducted to follow up on patients five years after their initial diagnosis. At that time, 71% of adults were completely well with no residual symptoms, while 21% had developed a major depressive disorder or alcoholism. For children aged 8–13, adjustment disorder did not predict future psychiatric disturbances. For adolescents, the prognosis is grimmer. After five years, 43% had developed a major psychiatric disorder, often of far greater severity. These disorders included **schizophrenia**, **schizoaffective disorder**, major depression, substance use disorders, or personality disorders. In contrast with adults, the adolescents' behav-

ioral symptoms and the type of adjustment disorder predicted future mental disorders.

Researchers have noted that once an adjustment disorder is diagnosed, psychotherapy, medication or both can prevent the development of a more serious mental disorder. Effective treatment is critical, as adjustment disorder is associated with an increased risk of suicide attempts, completed suicide, substance abuse, and various unexplained physical complaints. Patients with chronic stressors may require ongoing treatment for continued symptom management. While patients may not become symptom-free, treatment can halt the progression toward a more serious mental disorder by enhancing the patient's ability to cope.

Prevention

In many cases, there is little possibility of preventing the stressors that trigger adjustment disorders. One preventive strategy that is helpful to many patients, however, is learning to be proactive in managing ordinary life stress, and maximizing their problem-solving abilities when they are not in crisis.

Advance directives

Definition

An advance directive is a written document in which people clearly specify how medical decisions affecting them are to be made if they are unable to make them, or to authorize a specific person to make such decisions for them. These documents are sometimes called "living wills." Psychiatric advance directives serve the same purpose as general medical advance directives, but are written by mental health consumers as a set of directions for others to follow, made in advance of an injury, psychiatric illness, or crisis.

Description

Many consumers of mental health services know which treatments work best for them and, over the past several years, their opinions have become increasingly valued by those providing services. However, when a mental health consumer becomes unable to make decisions or to give **informed consent** for treatments offered, others (including family, friends, judges, or care providers) make the decisions for the individual in crisis. In these kinds of crisis situations, advance directives may be beneficial for the person receiving care, because the advance directive is a legal document that may protect him or her from unwanted treatment.

Psychiatric advance directives usually fall into two categories: instruction directives and agent-driven directives.

Instruction directives

An instruction directive is a written document that specifies which treatments an individual does and does not want, in the case that that individual becomes unable to make decisions about his or her care. These documents may indicate the affected individual's preferences about many aspects of treatment, including:

- people who should be contacted at a time of psychiatric crisis
- activities that reduce (and heighten) anxiety for the individual
- effective alternatives to restraint or seclusion for the individual
- acceptable and unacceptable medications and dosages
- other interventions that might be considered during a time of crisis (such as **electroconvulsive therapy**)

Agent-driven directives

An agent-driven directive may also be called a durable power of attorney. This directive is a signed, dated, and witnessed document that authorizes a designated person (usually a family member or close friend) to act as an agent or proxy. This empowers the proxy to make medical decisions for a person when the person is deemed unable to make these decisions him/herself. Such a power of attorney frequently includes the person's stated preferences in regard to treatment. Several states do not allow any of the following people to act as a person's proxy:

- the person's physician, or other health care provider
- the staff of health care facilities that is providing the person's care
- guardians (often called conservators) of the person's financial affairs
- employees of federal agencies financially responsible for a person's care
- any person that serves as agent or proxy for 10 people or more. The person who is to act as the proxy should be familiar with the individual's expressed wishes about care, and should understand how to work within the mental health system.

These two distinct documents may, in some cases, be combined into one form.

Special concerns

In the United States, each state has laws about general medical advance directives and how those laws apply to psychiatric advance directives; a few states exclude psychiatric advance directives from their statutes. The specific form the advance directive should take, the language it should use, and the number of witnesses required to make the document legal and binding vary from state to state. In general, according to the National Mental Health Association, physicians and other health care professionals are expected to comply with the instructions of an advance directive, as long as those instructions are within the guidelines of accepted medical practice. Currently, however, few laws require providers to comply with an advance directive. It is recommended that people speak to their attorney or physician to ensure that their wishes are communicated in a form that is legally acceptable in their state.

Affect

Definition

Affect is a psychological term for an observable expression of emotion.

Description

A person's affect is the expression of emotion or feelings displayed to others through facial expressions, hand gestures, voice tone, and other emotional signs such as laughter or tears. Individual affect fluctuates according to emotional state. What is considered a normal range of affect, called the *broad affect*, varies from culture to culture, and even within a culture. Certain individuals may gesture prolifically while talking, and display dramatic facial expressions in reaction to social situations or other

stimuli. Others may show little outward response to social environments or interactions, expressing a narrow range of emotions to the outside world.

People with psychological disorders may display variations in their affect. A *restricted* or *constricted affect* describes a mild restriction in the range or intensity of display of feelings. As the reduction in display of emotion becomes more severe, the term *blunted affect* may be applied. The absence of any exhibition of emotions is described as *flat affect* where the voice is monotone, the face expressionless, and the body immobile. *Labile affect* describes emotional instability or dramatic mood swings. When the outward display of emotion is out of context for the situation, such as laughter while describing pain or sadness, the affect is termed "inappropriate."

Agoraphobia

Definition

Agoraphobia is an anxiety disorder characterized by intense fear related to being in situations from which escape might be difficult or embarrassing (i.e., being on a bus or train), or in which help might not be available in the event of a **panic attack** or panic symptoms. Panic is defined as extreme and unreasonable fear and anxiety.

According to the handbook used by mental health professionals to diagnose mental disorders, the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revision, also known as the *DSM-IV-TR*, patients with agoraphobia are typically afraid of such symptoms as feeling dizzy, having an attack of diarrhea, fainting, or "going crazy."

The word "agoraphobia" comes from two Greek words that mean "fear" and "marketplace." The anxiety associated with agoraphobia leads to avoidance of situations that involve being outside one's home alone, being in crowds, being on a bridge, or traveling by car or public transportation. Agoraphobia may intensify to the point that it interferes with a person's ability to take a job outside the home or to carry out such ordinary errands and activities as picking up groceries or going out to a movie.

Description

The close association in agoraphobia between fear of being outside one's home and fear of having panic symptoms is reflected in *DSM-IV-TR* classification of two separate disorders: **panic disorder** (PD) with agoraphobia, and agoraphobia without PD. PD is essentially characterized by sudden attacks of fear and panic. There may be no known reason for the occurrence of panic attacks; they are frequently triggered by fear-producing events or thoughts, such as driving, or being in an elevator. PD is believed due to an abnormal activation of the body's hormonal system, causing a sudden "fight-or-flight" response.

The chief distinction between PD with agoraphobia and agoraphobia without PD is that patients who are diagnosed with PD with agoraphobia meet all criteria for PD; in agoraphobia without PD, patients are afraid of panic-like symptoms in public places, rather than full-blown panic attacks.

People with agoraphobia appear to suffer from two distinct types of anxiety— panic, and the anticipatory anxiety related to fear of future panic attacks. Patients with agoraphobia are sometimes able to endure being in the situations they fear by "gritting their teeth," or by having a friend or relative accompany them.

In the United States' diagnostic system, the symptoms of agoraphobia can be similar to those of specific phobia and **social phobia**. In agoraphobia and specific phobia, the focus is fear itself; with social phobia, the person's focus is on how others are perceiving him/her. Patients diagnosed with agoraphobia tend to be more afraid of their own internal physical sensations and similar cues than of the reactions of others per se. In cases of specific phobia, the person fears very specific situations, whereas in agoraphobia, the person generally fears a variety of situations (being outside of the home alone, or traveling on public transportation including a bus, train, or automobile, for example). An example of a patient diagnosed with a specific phobia rather than agoraphobia would be the person whose fear is triggered only by being in a bus, rather than a car or taxi. The fear of the bus is more specific than the agoraphobic's fear of traveling on public transportation in general. The *DSM-IV-TR* remarks that the differential **diagnosis** of agoraphobia "can be difficult because all of these conditions are characterized by avoidance of specific situations."

Causes and symptoms

Causes

GENETIC. As of 2002, the causes of agoraphobia are complex and not completely understood. It has been known for some years that anxiety disorders tend to run in families. Recent research has confirmed earlier hypotheses that there is a genetic component to agoraphobia, and that it can be separated from susceptibility to PD. In 2001

KEY TERMS

Associationism—A theory about human learning that explains complex psychological phenomena in terms of coincidental relationships. For example, a person with agoraphobia who is afraid of riding in a car may have had a panic attack in a car on one occasion and has learned to associate cars with the physical symptoms of a panic attack.

Ayurvedic medicine—The traditional medical system of India. Ayurvedic treatments include diet, exercises, herbal treatments, meditation, massage, breathing techniques, and exposure to sunlight.

Behavioral inhibition—A set of behaviors that appear in early infancy that are displayed when the child is confronted with a new situation or unfamiliar people. These behaviors include moving around, crying, and general irritability, followed by withdrawing, and seeking comfort from a familiar person. These behaviors are associated with an increased risk of social phobia and panic disorder in later life. Behavioral inhibition in children appears to be linked to anxiety and mood disorders in their parents.

Cognitive restructuring—An approach to psychotherapy that focuses on helping the patient examine distorted patterns of perceiving and thinking in order to change their emotional responses to people and situations.

Exposure therapy—A form of cognitive-behavioral therapy in which patients suffering from phobias are exposed to their feared objects or situations while accompanied by the therapist. The length of exposure is gradually increased until the association between the feared situation and the patient's experienced panic symptoms is no longer present.

Paresthesias—Abnormal sensations of tingling or "pins and needles." Paresthesias are a common panic-like symptom associated with agoraphobia.

Phobia—Irrational fear of places, things, or situations that lead to avoidance.

Simple phobia—An older term for specific phobia.

Specific phobia—A type of phobia in which the object or situation that arouses fear is clearly identifiable and limited. An older term for specific phobia is simple phobia.

a team of Yale geneticists reported the discovery of a genetic locus on human chomosome 3 that governs a person's risk of developing agoraphobia. PD was found to be associated with two loci: one on human chromosome 1 and the other on chromosome 11q. The researchers concluded that agoraphobia and PD are common; they are both inheritable anxiety disorders that share some, but not all, of their genetic loci for susceptibility.

INNATE TEMPERAMENT. A number of researchers have pointed to inborn temperament as a broad vulnerability factor in the development of anxiety and mood disorders. In other words, a person's natural disposition or temperament may become a factor in developing a number of mood or anxiety disorders. Some people seem more sensitive throughout their lives to events, but upbringing and life history are also important factors in determining who will develop these disorders. Children who manifest what is known as "behavioral inhibition" in early infancy are at increased risk for developing more than one anxiety disorder in adult life—particularly if the inhibition remains over time. (Behavioral inhibition refers to a group of behaviors that are displayed when the child is confronted with a new situation or unfamiliar people.) These behaviors include moving around, crying, and general irritability, followed by withdrawing, seeking comfort from a familiar person, and stopping what one is doing when one notices the new person or situation. Children of depressed or anxious parents are more likely to develop behavioral inhibition.

PHYSIOLOGICAL REACTIONS TO ILLNESS. Another factor in the development of PD and agoraphobia appears to be a history of respiratory disease. Some researchers have hypothesized that repeated episodes of respiratory disease would predispose a child to PD by making breathing difficult and lowering the threshold for feeling suffocated. It is also possible that respiratory diseases could generate fearful beliefs in the child's mind that would lead him or her to exaggerate the significance of respiratory symptoms.

LIFE EVENTS. About 42% of patients diagnosed with agoraphobia report histories of real or feared separation from their parents or other caretakers in childhood. This statistic has been interpreted to mean that agoraphobia in adults is the aftermath of unresolved childhood separation anxiety. The fact that many patients diagnosed with agoraphobia report that their first episode occurred after the death of a loved one, and the observation that other agoraphobics feel safe in going out as long as someone is

with them, have been taken as supportive evidence of the separation anxiety hypothesis.

LEARNED BEHAVIOR. There are also theories about human learning that explain agoraphobia. It is thought that a person's initial experience of panic-like symptoms in a specific situation— for example, being alone in a subway station— may lead the person to associate physical symptoms of panic with all subway stations. Avoiding all subway stations would then reduce the level of the person's discomfort. Unfortunately, the avoidance strengthens the phobia because the person is unlikely to have the opportunity to test whether subway stations actually cause uncomfortable physical sensations. One treatment modality—exposure therapy—is based on the premise that phobias can be "unlearned" by reversing the pattern of avoidance.

SOCIAL FACTORS RELATED TO GENDER. Gender role socialization has been suggested as an explanation for the fact that the majority of patients with agoraphobia are women. One form of this hypothesis maintains that some parents still teach girls to be fearful and timid about venturing out in public. Another version relates agoraphobia to the mother-daughter relationship, maintaining that mothers tend to give daughters mixed messages about becoming separate individuals. As a result, girls grow up with a more fragile sense of self, and may stay within the physical boundaries of their home because they lack a firm sense of their internal psychological boundaries.

Symptoms

The symptoms of an episode of agoraphobia may include any or all of the following:

- trembling
- breaking out in a sweat
- heart palpitations
- paresthesias (tingling or "pins and needles" sensations in the hands or feet)
- nausea
- fatigue
- rapid pulse or breathing rate
- a sense of impending doom

In most cases, the person with agoraphobia feels some relief from the symptoms after he or she has left the precipitating situation or returned home.

Demographics

In general, phobias are the most common mental disorders in the general United States population, affecting about 7% of adults, or 6.4 million Americans. Agoraphobia is one of the most common phobias, affecting between 2.7% and 5.8% of American adults. The onset of symptoms is most likely to occur between age 15 and age 35.The lifetime prevalence of agoraphobia is estimated at 5%–12%. Like most phobias, agoraphobia is two to four times more common in women than in men.

The incidence of agoraphobia appears to be similar across races and ethnic groups in the U.S.

Diagnosis

The differential diagnosis of agoraphobia is described differently in *DSM-IV-TR* and in *ICD-10,* the European diagnostic manual. The U.S. diagnostic manual specifies that agoraphobia must be defined in relation to PD, and that the diagnoses of **specific phobias** and social phobias are the next to consider. The *DSM-IV-TR* also specifies that the patient's symptoms must not be related to substance abuse; and if they are related to a general medical condition, they must have excessive symptoms usually associated with that condition. For example, a person with Crohn's disease has realistic concerns about an attack of diarrhea in a public place and should not be diagnosed with agoraphobia unless the fear of losing bowel control is clearly exaggerated. The *DSM-IV-TR* does not require a person to experience agoraphobia within a set number of circumstances in order to meet the diagnostic criteria.

In contrast, the European diagnostic manual primarily distinguishes between agoraphobia and delusional or obsessive disorders, and depressive episodes. In addition, *ICD-10* specifies that the patient's anxiety must be restricted to or occur primarily within two out of four specific situations: crowds; public places; traveling alone; or traveling away from home. The primary area of agreement between the American and European diagnostic manuals is that both specify avoidance of the feared situation as a diagnostic criterion.

Diagnosis of agoraphobia is usually made by a physician after careful exclusion of other mental disorders and physical conditions or diseases that might be related to the patient's fears. Head injury, pneumonia, and withdrawal from certain medications can produce some of the symptoms of a panic attack. In addition, the physician may ask about caffeine intake as a possible dietary factor. As of 2002, there are no laboratory tests or diagnostic **imaging studies** that can be used to diagnose agoraphobia.

Furthermore, there are no widely used diagnostic interviews or screening instruments specifically for agoraphobia. One self-report questionnaire, however, is under development by Dutch researchers who recently

reported on its validity. The test is called the Agoraphobic Self-Statements Questionnaire, or ASQ, and is intended to evaluate thinking processes in patients with agoraphobia, as distinct from their emotional responses.

Treatments

Treatment of agoraphobia usually consists of medication plus **cognitive-behavioral therapy** (CBT). The physician may also recommend an alternative form of treatment for the anxiety symptoms associated with agoraphobia. Some patients may be advised to cut down on or give up coffee or tea, as the caffeine in these beverages can be contribute to their panic symptoms.

Medications

Medications that have been used with patients diagnosed with agoraphobia include the benzodiazepine tranquilizers, the MAO inhibitors (MAOIs), tricyclic antidepressants (TCAs), and the selective serotonin uptake inhibitors, or SSRIs. In the past few years, the SSRIs have come to be regarded as the first-choice medication treatment because they have fewer side effects. The benzodiazepines have the disadvantage of increasing the symptoms of agoraphobia when they are withdrawn, as well as interfering with CBT. (Benzodiazepines can decrease mental sharpness, making it difficult for patients taking these medications to focus in therapy sessions.) The MAO inhibitors require patients to follow certain dietary guidelines. For example, they must exclude aged cheeses, red wine, and certain types of beans. TCAs may produce such side effects as blurred vision, constipation, dry mouth, and drowsiness.

Psychotherapy

CBT is regarded as the most effective psychotherapeutic treatment for agoraphobia. The specific CBT approach that seems to work best with agoraphobia is exposure therapy. Exposure therapy is based on undoing the association that the patient originally formed between the panic symptoms and the feared situation. By being repeatedly exposed to the feared location or situation, the patient gradually learns that he or she is not in danger, and the anxiety symptoms fade away. The therapist typically explains the procedure of exposure therapy to the patient and reassures him or her that the exposure can be stopped at any time that his or her limits of toleration have been reached. The patient is then exposed in the course of a number of treatment sessions to the feared situation, usually for a slightly longer period each time. A typical course of exposure therapy takes about 12 weeks.

On the other hand, one group of German researchers reported good results in treating patients with agoraphobia with individual high-density exposure therapy. The patients were exposed to their respective feared situations for an entire day for two–three weeks. One year later, the patients had maintained their improvement.

Exposure treatment for agoraphobia may be combined with cognitive restructuring. This form of cognitive behavioral therapy teaches patients to observe the thoughts that they have in the feared situation, such as, "I'll die if I have to go into that railroad station," and replace these thoughts with positive statements. In this example, the patient with agoraphobia might say to him- or herself, "I'll be just fine when I go in there to buy my ticket."

Although insight-oriented therapies have generally been considered relatively ineffective in treating agoraphobia, a recent trial of brief **psychodynamic psychotherapy** in patients with PD with agoraphobia indicates that this form of treatment may also be beneficial. Of the 21 patients who participated in the 24-session course of treatment (twice weekly for 12 weeks), 16 experienced remission of their agoraphobia. There were no relapses at six-month follow-up.

Alternative and complementary treatments

Patients diagnosed with agoraphobia have reported that alternative therapies, such as **hypnotherapy** and music therapy, were helpful in relieving symptoms of anxiety and panic. Ayurvedic medicine, **yoga**, religious practice, and guided imagery **meditation** have also been helpful.

Prognosis

The prognosis for untreated agoraphobia is considered poor by most European as well as most American physicians. The *DSM-IV-TR* remarks that little is known about the course of agoraphobia without PD, but that anecdotal evidence indicates that it may persist for years with patients becoming increasingly impaired. The *ICD-10* refers to agoraphobia as "the most incapacitating of the phobic disorders," to the point that some patients become completely housebound. With proper treatment, however, 90% of patients diagnosed with agoraphobia can recover and resume a normal life.

Prevention

As of this writing in 2002, the genetic factors that appear to be implicated in the development of agoraphobia cannot be prevented. On the other hand, recent recognition of the link between anxiety and mood disorders in parents and vulnerability to phobic disorders in their chil-

dren may help to identify children at risk and to develop appropriate preventive strategies for them.

Alcohol and related disorders

Definition

Alcoholism is defined as alcohol seeking and consumption behavior that is harmful. Long-term and uncontrollable harmful consumption can cause alcohol-related disorders that include: **antisocial personality disorder**, mood disorders (bipolar and major depression) and anxiety disorders.

Description

Alcoholism is the popular term for the disorder recognized by the American Psychiatric Association (APA) as alcohol dependence. The hallmarks of this disorder are **addiction** to alcohol, inability to stop drinking, and repeated interpersonal, school- or work-related problems

KEY TERMS

Antisocial personality disorder—Disorder characterized by behavior pattern of disregard for others' rights. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy or psychopathy.

Blackout—A period of loss of consciousness or memory.

Delirium tremens—Serious alcohol withdrawal symptoms that must be treated in a hospital and that may include shaking, delirium, and hallucinations.

Detoxification—A process in which the body is allowed to free itself of a drug while the symptoms of withdrawal are treated. It is the primary step in any treatment program for drug or alcohol abuse.

Euphoria—A feeling or state of well-being or elation.

Intoxication—Condition of being drunk.

Relapse—A person experiences a relapse when he or she re-engages in a behavior that is harmful and that he or she was trying to change or eliminate. Relapse is a common occurrence after treatment for many disorders, including addictions and eating disorders.

Thiamin—A B-vitamin that is essential to normal metabolism and nerve function, and whose absorption is affected by alcoholism.

Tolerance—Progressive decrease in the effectiveness of a drug with long-term use.

Wernicke's syndrome—A group of symptoms that appears in some people who are dependent on alcohol. Due to low levels of thiamin, the syndrome results in disordered eye movements, very poor balance and difficulty walking.

Wernicke-Korsakoff syndrome—Group of symptoms that appears in people who are dependent on alcohol. The syndrome is due to a thiamin deficiency, and severely affects one's memory, preventing new learning from taking place.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

that can be directly attributed to the use of alcohol. Alcoholism can have serious consequences, affecting an individual's health and personal life, as well as impacting society at large.

Alcohol dependence is a complex disorder that includes the social and interpersonal issues mentioned above, and also includes biological elements, as well. These elements are related to tolerance and withdrawal, cognitive (thinking) problems that include craving, and behavioral abnormalities including the impaired ability to stop drinking. Withdrawal is a term that refers to the symptoms that occur when a person dependent on a substance stops taking that substance for a period of time; withdrawal symptoms vary in type and severity depending on the substance, but alcohol withdrawal symptoms can include shaking, irritability, and nausea. Tolerance is a reduced response to the alcohol consumed and can be acute or chronic. Acute tolerance occurs during a single episode of drinking and is greater when blood alcohol concentration rises. Chronic tolerance occurs over the long term when there is greater resistance to the intoxicating effects of alcohol, and, as a result, the affected person has to drink more to achieve desired effect.

The APA also recognizes another alcohol use disorder called alcohol abuse. Alcohol abuse is similar to dependence in that the use of alcohol is impairing the affected person's ability to achieve goals and fulfill responsibilities, and his or her interpersonal relationships are affected by the alcohol abuse. However, unlike a person with dependence, a person diagnosed with alcohol abuse does not experience tolerance or, when not drinking, withdrawal symptoms. People who abuse alcohol can become dependent on the substance over time.

Alcohol-related disorders are groups of disorders that can result in persons who are long-term users of alcohol. These disorders can affect the person's metabolism, gastrointestinal tract, nervous system, bone marrow (the matter in bones that forms essential blood cells) and can cause endocrine (hormone) problems. Additionally, alcoholism can result in nutritional deficiencies. Some common alcohol-related medical disorders include vitamin deficiencies, alterations in sugar and fat levels in blood, hepatitis, fatty liver, cirrhosis, esophagitis (inflammation of the esophagus), gastritis (inflammation of the lining of the stomach), **dementia**, abnormal heart rates and rhythms, lowered platelets (cells important for forming a clot), leukopenia (decrease in the number of white

blood cells that are important for body defenses and immunity), and testicular atrophy (shrinking of the testicles). People with anxiety, depression, or **bipolar disorder** may consume alcohol for temporary relief from their symptoms. Others, such as people with antisocial personality disorder, may use alcohol as part of a **dual diagnosis** of criminality and substance dependence.

Causes and symptoms

Causes

The cause of alcoholism is related to behavioral, biological, and genetic factors.

Behaviorally, alcohol consumption is related to internal or external feedback. Internal feedback is the internal state a person experiences during and after alcohol consumption. External feedback is made up of the cues that other people send the person when he or she drinks. Internal states pertaining to alcohol can include shame or hangover. Alcohol-related external cues can include reprimands, criticism, or encouragement. People may drink to the point of dependence because of peer pressure, acceptance in a peer group, or because drinking is related to specific moods (easygoing, relaxed, calm, sociable) that are related to the formation of intimate relationships.

Biologically, repeated use of alcohol can impair the **brain** levels of a "pleasure" neurotransmitter called dopamine. **Neurotransmitters** are chemicals in the brain that pass impulses from one nerve cell to the next. When a person is dependent on alcohol, his or her brain areas that produce dopamine become depleted and the individual can no longer enjoy the pleasures of everyday life—his or her brain chemistry is rearranged to depend on alcohol for transient euphoria (state of happiness).

Genetic studies have isolated a gene that causes alcohol dependence and that is usually transmitted from affected fathers to sons. Other genetic studies have demonstrated that close relatives of an alcoholic are four times more likely to become alcoholics themselves. Furthermore, this risk holds true even for children who were adopted away from their biological families at birth and raised in a non-alcoholic adoptive family, with no knowledge of their biological family's difficulties with alcohol.

Symptoms

ALCOHOL DEPENDENCE. Individuals who are alcohol-dependent compulsively drink ethanol (the chemical name for alcohol) to the level of intoxication. Intoxication occurs at blood alcohol levels of 50 to 150 mg/dl and is characterized by euphoria at first, and then if blood concentrations of alcohol continue to rise, a person can become explosively combative. Neurologically, acute intoxication causes impaired thinking, incoordination, slow or irregular eye movements, and impaired vision. As the person repeatedly drinks, the body develops a reduced response to ethanol called tolerance.

People with chronic tolerance may apparently be sober (not intoxicated) even after consumption of alcohol that could cause death in non-drinkers. People with alcohol dependence may also develop alcoholic blackouts after large amounts of ethanol consumption. These blackouts are typically characterized by **amnesia** (loss of memory) lasting several hours without impaired consciousness. In other words, people experiencing blackouts appear to be conscious, but will not remember their actions during the blackouts after the intoxication has worn off.

People with alcohol dependence also develop alcohol withdrawal (a state of non-drinking) syndrome. The nervous system adapts to chronic ethanol exposure by increasing the activity of nerve cell mechanisms that counteract alcohol's depressant effects. Therefore, when drinking is abruptly reduced, the affected person develops disordered perceptions, **seizures**, tremor (often accompanied by irritability, nausea, and vomiting). Tremor of the hands called "morning shakes," usually occurs in the morning due to overnight abstinence. The most serious manifestation of alcohol withdrawal syndrome is delirium tremens, which occurs in approximately 5% of people dependent on alcohol. Delirium tremens consists of agitation, disorientation, **insomnia**, **hallucinations**, **delusions**, intense sweating, fever, and increased heart rate (tachycardia). This state is a medical emergency because it can be fatal, and affected persons must be immediately hospitalized and treated with medications that control vital physiological functions.

The APA publishes a manual for mental health professionals called the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM*. This manual lists criteria that each disorder must meet for **diagnosis**. The criteria are symptoms that must be present so that the diagnosis can be made. Alcohol dependence can be diagnosed if three or more of the following symptoms are present:

- tolerance
- withdrawal
- denial of problem
- preoccupation with seeking alcohol
- drinking is the focal point of person's life (using takes up most of the person's time)
- continued use despite problems

ALCOHOL ABUSE. In order for a person to be diagnosed with alcohol abuse, one of the following four criteria must be met. Because of drinking, a person repeatedly:

- fails to live up to his or her most important responsibilities
- physically endangers him- or herself, or others (for example, by drinking when driving)
- gets into trouble with the law
- experiences difficulties in relationships or jobs

Demographics

The lifetime prevalence in the general population for alcoholism is between 9.4% and 14.1%. The disorder occurs twice as often in males than in females. Alcoholism and alcohol abuse affect 20% or more of hospitalized and ambulatory patients (those receiving care on an outpatient basis). Alcoholism can develop in all people of all races and socioeconomic classes. Approximately two-thirds of Americans older than 14 years drink alcohol. People who drink excessive amounts of alcohol account for about half of the total alcohol consumed, and account for almost all the socioeconomic and medical complications of alcoholism at an annual cost of $100 billion. Alcoholism ranks third in the United States as a preventable disease and accounts for 5% of the total deaths in the U.S. amounting to about 100,000 people dying annually.

Diagnosis

The diagnosis of alcoholism can either be based on medical and/or psychological conditions. With a long-term history of abusive drinking, medical conditions can result, and these could lead the physician to suspect a patient's alcoholism. These medical conditions may include organ complications such as: cirrhosis (liver), hepatitis (liver), pancreatitis (pancreas), peripheral neuropathy (nervous system) or cardiomyopathy (heart). Additionally, recurrent trauma, resulting in bone fractures, **fatigue**, depression, sexual dysfunction, fluctuating blood pressure, and **sleep disorders** may prompt the clinician to further assess for alcoholism.

Psychological diagnosis can be accomplished through a clinical interview and history (biopsychosocial assessment), and from a choice of many standardized alcohol use tests. The biopsychosocial assessment is an extensive interview conducted by the clinician. During the interview, the clinician will ask the patient about many areas of life, including childhood, education, and medical history. One very simple tool for beginning the diagnosis of alcoholism is called the CAGE questionnaire. It consists of four questions, with the first letters of each key word spelling out the word CAGE:

- Have you ever tried to *Cut* down on your drinking?
- Have you ever been *Annoyed* by anyone's comments about your drinking?
- Have you ever felt *Guilty* about your drinking?
- Do you ever need an *Eye-opener* (a morning drink of alcohol) to start the day?

Other, longer lists of questions exist to help determine the severity and effects of a person's alcohol use. Given the recent research pointing to a genetic basis for alcoholism, the doctor will also attempt to ascertain whether anyone else in the person's family has ever suffered from alcoholism.

Diagnosis is sometimes facilitated when family members call the attention of a physician to a loved one's difficulties with alcohol.

Treatments

Comprehensive treatment for alcohol dependence has two components: **detoxification** and rehabilitation.

Detoxification

The goal of detoxification is to rid the patient's body of the toxic effects of alcohol. Because the person's body has become accustomed to alcohol, the person will need to be supported as he or she goes through withdrawal. Withdrawal will be different for different patients, depending on the severity of the alcoholism, as measured by the quantity of alcohol ingested daily and the length of time the patient has been dependent on alcohol. Withdrawal symptoms can range from mild to life-threatening. Mild withdrawal symptoms include nausea, achiness, diarrhea, difficulty sleeping, sweatiness, anxiety, and trembling. This phase is usually over in about three to five days. More severe effects of withdrawal can include hallucinations (in which a patient sees, hears, or feels something that is not actually real), seizures, a strong craving for alcohol, confusion, fever, fast heart rate, high blood pressure, and delirium (a fluctuating level of consciousness). Patients at highest risk for delirium tremens are those with other medical problems, including malnutrition, liver disease, or Wernicke's syndrome. Delirium tremens usually begins about three to five days after the patient's last drink, progressing from the more mild symptoms to the more severe, and may last a number of days.

Patients going through mild withdrawal are simply monitored carefully to make sure that more severe symptoms do not develop. No medications are necessary,

however. Treatment of a patient suffering the more severe effects of withdrawal may require the use of sedative medications to relieve the discomfort of withdrawal and to avoid the potentially life-threatening complications of high blood pressure, fast heart rate, and seizures. Benzodiazepines are medications that ease tension by slowing down the central nervous system and may be helpful in those patients suffering from hallucinations. Because of the patient's nausea, fluids may need to be given through a vein (intravenously), along with some necessary sugars and salts. It is crucial that thiamin be included in the fluids, because thiamin is usually quite low in patients with alcohol dependence, and deficiency of thiamin is responsible for **Wernicke-Korsakoff syndrome**.

Rehabilitation

After cessation of drinking has been accomplished, the next steps involve helping the patient stay healthy and avoid relapsing. (Relapse occurs when a patient returns to old behaviors that he or she was trying to change.) This phase of treatment is referred to as rehabilitation. The best programs incorporate the family into the therapy, because the family has undoubtedly been severely affected by the patient's drinking. Some therapists believe that family members, in an effort to deal with their loved one's drinking problem, sometimes develop patterns of behavior that accidentally support or "enable" the patient's drinking. This situation is referred to as "co-dependence," and must be addressed in order to treat a person's alcoholism successfully.

PSYCHOLOGICAL THERAPIES. **Psychotherapy** helps affected individuals to anticipate, understand, recognize, and prevent relapse. Behavioral therapy approaches typically include community-centered **support groups**, meetings such as Alcoholics Anonymous (AA), **cognitive-behavioral therapy** (CBT), and Motivated Enhancement Therapy (MET). CBT focuses on teaching alcoholics recognition and coping skills for craving states and high-risk situations that precipitate or trigger relapsing behaviors. MET can motivate patients to use their personal resources to initiate changes in behavior. Many people recovering from substance dependence find peer-led support groups helpful in helping them avoid relapse.

MEDICATIONS. Two medications called **naltrexone** (Revia) and acamprosate can help decrease craving states in alcoholics. In combination with psychotherapy, these medications can help reduce relapse. Another medication called **disulfiram** (Antabuse) affects the metabolism of alcohol and causes unpleasant effects in patients who consume alcohol while taking the medication. Antabuse should only be taken by people who are committed to recovery and understand that they are to avoid all contact with alcohol or alcohol-containing products. People who have alcohol dependence along with other disorders, such as depression, can work with their physician to determine if medication might be a feasible treatment option for them.

ADDITIONAL TREATMENTS. Alternative treatments can be a helpful adjunct for the alcoholic patient, once the medical danger of withdrawal has passed. Because many alcoholics have very stressful lives (whether because of or leading to the alcoholism is sometimes a matter of debate), many of the treatments for alcoholism involve managing and relieving **stress**. These include massage, **meditation**, and **hypnotherapy**. The malnutrition of long-term alcohol use is addressed by nutrition-oriented practitioners and dietitians with careful attention to a healthy diet and the use of nutritional supplements such as vitamins A, B complex, and C, as well as certain fatty acids, amino acids, zinc, magnesium, and selenium. **Acupuncture** is believed to decrease both withdrawal symptoms and to help improve a patient's chances for continued recovery from alcoholism.

Prognosis

Most people who use alcohol start to drink during adolescence or early adulthood. Approximately 50% of male drinkers have alcohol-related problems such as fighting, blackouts, or legal problems during their early drinking years, usually late teens or early twenties. People who cannot control their drinking behaviors will tend to accumulate drinking-related problems and become dependent on alcohol. Approximately 30% to 60% of alcoholics maintain about one year of sobriety with psychotherapeutic interventions alone. About 20% of alcoholics can achieve long-term abstinence without any type of active treatment.

Prevention

Good prevention includes education and a knowledge of family (genetic) propensity. If alcohol dependence is present in a close family member, then relatives should know and be discouraged to drink alcohol-containing beverages. Education of older children and young teenagers concerning the negative effects and consequences of drinking alcohol may help to decrease or recognize problems before start or worsen.

Alprazolam

Definition

Alprazolam is a tranquilizer. It belongs to a group of drugs called benzodiazepines. In the United States alprazolam is sold under brand name Xanax.

Purpose

The United States Food and Drug Administration has approved alprazolam to treat anxiety, **panic disorder**, and anxiety associated with depression. Occasionally alprazolam is used to treat alcohol withdrawal, but it is not FDA-approved for this use, and is not normally the first drug tried in treating alcohol withdrawal symptoms.

Description

Alprazolam is classified as a benzodiazepine. Benzodiazepines are sedative-hypnotic drugs that help to relieve nervousness, tension, and other anxiety symptoms by slowing the central nervous system. To do this, they block the effects of a specific chemical involved in the transmission of nerve impulses in the **brain**, decreasing the excitement level of the nerve cells.

KEY TERMS

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

All benzodiazepines cause sedation, including drowsiness and reduced mental alertness. However, one benefit of alprazolam is that it causes somewhat less drowsiness than many other benzodiazepine drugs.

Alprazolam comes in 0.25-mg, 0.5-mg, 1-mg and 2-mg tablets, and 1-mg/ml solution.

Recommended dosage

The recommended initial adult dose for anxiety is 0.25–0.5 milligrams (mg) taken three times daily. This dosage may be increased every three to four days to a maximum total of 4 mg daily. Dosage for alcohol withdrawal usually totals from 2–2.5 mg daily given in several small doses throughout the day.

The starting dose for treating panic disorder is 0.5 mg three times daily. This dosage may be increased every three to four days until the total daily dosage ranges from 2–10 mg. The total amount should be divided in at least three even daily doses. Average doses for anxiety associated with depression range from 2.5–3 mg daily divided into even doses.

Precautions

Alprazolam should not be used by patients who are pregnant, have narrow angle glaucoma, take ketoconazole or itraconazole, or those who are allergic to this or any other benzodiazepine drug. The dose of alprazolam must be carefully regulated and individualized in the elderly (over age 60), people with liver or kidney disease, and those taking other medications used to treat mental disorders.

Because alprazolam is a nervous system and respiratory depressant, it should not be taken with other similar depressants, such as alcohol, other sedatives, sleeping

pills, or tranquilizers. People taking this drug should not drive, operate dangerous machinery, or engage in hazardous activities that require mental alertness at least until they see how the drug affects them.

Alprazolam should be used under close physician supervision in patients with history of substance abuse. Like other benzodiazepines, alprazolam can be habit-forming. Risk and severity of dependence appears greater in patients taking doses larger than 4 mg daily. However, smaller doses may cause dependence if alprazolam is taken longer than 12 weeks.

Suddenly discontinuing alprazolam after several weeks may cause uncomfortable symptoms of withdrawal. Withdrawal symptoms in people who have taken alprazolam three months or longer may include **seizures**, anxiety, nervousness, and headache. Patients should discuss with their doctor how to gradually discontinue alprazolam use to avoid such symptoms.

Side effects

The most common side effects of alprazolam include sedation, dizziness, drowsiness, **insomnia**, and nervousness. The intensity of these side effects usually declines gradually and subsides in about eight weeks. A drop in blood pressure and an increase in heart rate may also occur in people who are taking alprazolam.

Decreased sex drive, menstrual disorders, and both weight gain and weight loss has been associated with alprazolam use. People who experience the side effects of stomach upset, nausea, vomiting, and dry mouth should eat frequent, small meals and/or chew sugarless gum. Alprazolam has been associated with both diarrhea and constipation, as well as tremor, muscle cramps, vision disturbances, and rash.

Interactions

Alprazolam interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. The most severe interactions occur with antifungal medications, such as ketoconazole, itraconazole, and fluconazole. These are associated with alprazolam toxicity (excessive sedation, **fatigue**, slurred speech, slowed reactions and other types of psychomotor impairment).

Estrogens (female hormones), erythromycin (an antibiotic), **fluoxetine** (Prozac, Sarafem), cimetidine (Tagamet), isoniazid, and **disulfiram** (Antabuse) can increase the effects of alprazolam. **Carbamazepine** can make alprazolam less effective. When alprazolam is combined with other sedative drugs (tranquilizers, sleeping pills) or alcohol, its depressants effects are more intense. These combinations should be avoided.

Alzheimer's disease

Definition

Alzheimer's disease, or AD, is a progressive, incurable disease of the **brain** caused by the degeneration and eventual death of neurons (nerve cells) in several areas of the brain.

Description

Patients with AD first lose such mental functions as short-term memory and the ability to learn new things. In the later stages of AD they gradually lose control over their sense of orientation, their emotions, and other aspects of behavior. End-stage AD is characterized by loss of control of body functions, an increased likelihood of **seizures**, loss of the ability to eat or swallow, and eventual death from infection or malnutrition. Alzheimer's disease is the most common cause of **dementia** (loss of cognitive abilities) in the elderly; it is thought to be responsible for 50%–70% of cases of dementia in the United States.

Alzheimer's disease was first identified in 1906 by a German **psychiatrist** and neuroanatomist named Alois Alzheimer. He was studying slides prepared from the brain of a fifty-one-year-old woman, known as Frau D., who had died after several years of dementia with symptoms that did not fit the definition of any brain disorder known at the time. Alzheimer was the first to describe the plaques and neurofibrillary tangles that are now used to identify AD at autopsy. Plaques are clumps or clusters of dead or dying nerve cells and other cellular debris found in the brains of patients with Alzheimer's disease. Neurofibrillary tangles are the accumulations of twisted protein fragments found inside the nerve cells in the brains of Alzheimer's patients. Because dementia had

been associated with elderly people and Frau D. had been middle-aged, AD was first known as presenile dementia and was thought to be a very rare disorder. It was not until the early 1950s that researchers at St. Elizabeth's Hospital in Washington, DC, came to recognize that AD is the single most common cause of dementia in adults.

Alzheimer's disease is now considered a very serious public health problem because of the growing numbers of people who are affected by it, the increasing length of their lives, and the direct and indirect costs of their care. It is estimated that four million people in the United States had AD as of 2000, with 360,000–400,000 new cases identified every year. One person in ten over the age of 65 has AD, and nearly 50% of those over 85 have the disease. Unless a cure or preventive treatment is discovered, 14 million Americans will have Alzheimer's by 2050. Very few people are wealthy enough to cover the cost of caring for an Alzheimer's patient in the seven–10 years that typically extend between the beginning of the person's dependency and death. The average lifetime cost of caring for one patient with AD is estimated at $174,000. The costs of laboratory tests, physicians' visits, medications, nursing services, home care, and adult day care come to $114.4 billion per year in the United States alone. This sum is greater than the combined annual budgets of six Federal departments (Commerce, Education, Justice, Labor, Energy, and Interior).

The problem is expected to be complicated in future years by the fact that the so-called "baby boomer" generation is better nourished and better educated than the generation now at risk for AD. When the baby boomers are old enough to be at risk for late-onset Alzheimer's, they are expected to live longer than the average Alzheimer's patient does in 2002. Public health researchers who are making future projections about the impact of AD in the mid-twenty-first century point out that a treatment that would delay the onset of the disease would reduce the overall prevalence of AD. One study estimates that a therapy that would delay the onset of Alzheimer's by only one year would save the United States $9 billion by 2007. The second approach, that of discovering a treatment for people who already have Alzheimer's, would alter the proportion of mild cases to those considered moderate or severe. The researchers conclude by stating: "None of our models predicts less than a threefold rise in the total number of persons with Alzheimer's disease between 2000 and 2050."

Types of Alzheimer's disease

As of 2002, some researchers think that Alzheimer's may be more accurately described as a group or family of diseases rather than a single disease. Moreover, more recent research is helping to differentiate Alzheimer's disease from other less common causes of dementia. In particular, some cases of dementia that were formerly thought to have been related to AD are now known to have been caused by Pick's disease or Lewy body dementia. Pick's disease is a rare type of dementia that affects certain areas of the brain and is characterized by a progressive loss of social skills, language, and memory. Lewy body dementia is a type of dementia in which the brain has characteristic Lewy bodies—areas of injury found on damaged nerve cells in certain parts of the brain.

Physicians now recognize three different forms of Alzheimer's disease.

EARLY-ONSET AD. Early-onset AD is a rare form of Alzheimer's found in fewer than 10% of AD patients. This group of patients, however, develops more of the brain abnormalities associated with AD than patients with the late-onset form. In addition, patients with early-onset Alzheimer's are more likely to develop myoclonus (a condition in which a muscle or group of muscles has sudden spasms or twitching).

LATE-ONSET AD. Late-onset AD is the most common form of the disease; its symptoms usually begin to appear after age 65. Late-onset Alzheimer's, which may or may not be affected by genetic variables, is also called sporadic Alzheimer's disease because it does not necessarily run in families.

FAMILIAL ALZHEIMER'S DISEASE (FAD). Familial Alzheimer's disease, or FAD, is a rare form that is entirely inherited. FAD accounts for fewer than 5% of all cases of AD. It has a very early onset, often in the patient's 40s, and there is a clear family history of the disease.

Stages

Health care professionals use the term "insidious" to describe Alzheimer's, which means that it is very gradual in onset. Many times people recognize the first symptoms of the disorder in a friend or family member only in hindsight. In addition, the present generation of people old enough to be at risk for Alzheimer's is the first generation in history to know what the **diagnosis** means; there are therefore very powerful emotional reasons for attributing the early signs of AD to normal aging, job **stress**, adjusting to retirement, and other less troubling factors. The insidious onset of Alzheimer's is a characteristic, however, that allows doctors to distinguish it from other causes of dementia, including **vascular dementia**.

EARLY-STAGE ALZHEIMER'S. Early-stage Alzheimer's may begin almost imperceptibly. The first symptoms usually include short-term memory loss, temporary

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Agitation—Excessive restlessness or emotional disturbance that is often associated with anxiety or psychosis. Agitation may be associated with middle-stage Alzheimer's disease.

Agnosia—Loss of the ability to recognize familiar people, places, and objects.

Amygdala—An almond-shaped brain structure in the limbic system that is activated in stressful situations to trigger the emotion of fear. It is thought that the emotional overreactions in Alzheimer's patients are related to the destruction of neurons in the amygdala.

Amyloid—A waxy translucent substance composed mostly of protein, that forms plaques (abnormal deposits) in the brain during the progression of Alzheimer's disease.

Aphasia—Loss of language abilities.

Apolipoprotein E—A protein that transports cholesterol through the body. One form of this protein, apoE4, is associated with a 60% risk of late-onset AD.

Apraxia—Inability to perform purposeful movements that is not caused by paralysis or loss of feeling.

Beta amyloid protein—A starchy substance that builds up in the brains of people with AD to form the plaques that are characteristic of the disease. Beta amyloid is formed when amyloid precursor protein, or APP, is not broken down properly by the body.

Bleomycin hydrolase—An enzyme involved in the body's processing of amyloid precursor protein. If the gene that governs production of BH mutates, the APP accumulates, producing the plaques in the brains of patients with AD.

Brain stem—The part of the brain that is continuous with the spinal cord and controls most basic life functions. It is the last part of the brain that is destroyed by Alzheimer's disease.

Cholinesterase inhibitors—A group of medications given to slow the progression of Alzheimer's disease.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from dementia by its relatively sudden onset and variation in the severity of the symptoms.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Down syndrome—A genetic disorder characterized by an extra chromosome 21 (trisomy 21), mental retardation, and susceptibility to early-onset Alzheimer's disease.

Gingko—A shade tree native to China with fan-shaped leaves and fleshy seeds with edible kernels. Gingko extract is being studied as a possible complementary or adjunctive treatment for Alzheimer's.

Hallucination—False sensory perceptions. A person experiencing a hallucination may "hear" sounds or "see" people or objects that are not real-

episodes of spatial disorientation, groping for words while one is speaking, minor problems with arithmetic, and small errors of judgment. For example, the person may light a stove burner under a saucepan before noticing that he has forgotten to put the food or water in the pan first, or he may have difficulty balancing a checkbook as quickly as he used to. At this stage in the disease, however, the patient can usually keep up with most activities of daily life. Although some persons at this point can still operate a motor vehicle safely, it is advisable to consult a physician about possible impairment behind the wheel. Many patients with early-stage AD voluntarily give up their driver's licenses for their own safety and that of other drivers on the roads.

MIDDLE-STAGE ALZHEIMER'S. In the middle stage, which typically begins two to three years after onset, the person begins to lose awareness of his or her cognitive deficits. Memory lapses are more frequent and the person begins to have more severe problems with language. Unlike early-stage AD, the problems caused by loss of cognitive functioning are impossible to ignore. The middle stage of AD is the point at which the behavioral and psychiatric symptoms that are so stressful to caregivers

KEY TERMS CONTINUED

ly present. Hallucinations can also affect the senses of smell, touch, and taste.

Hippocampus—A part of the brain that is involved in memory formation and learning. The hippocampus is shaped like a curved ridge and belongs to an organ system called the limbic system.

Insidious—Proceeding gradually and inconspicuously but with serious effect.

Lewy bodies—Areas of injury found on damaged nerve cells in certain parts of the brain associated with dementia. Lewy body dementia was first ecognized in the 1980s and is now distinguished from Alzheimer's disease.

Mild cognitive impairment (MCI)—A transitional phase of memory loss in older people that precedes dementia or Alzheimer's disease.

Multi-infarct dementia—Dementia caused by damage to brain tissue resulting from a series of blood clots or clogs in the blood vessels. It is also called vascular dementia.

Myoclonus—An abrupt spasm or twitching in a muscle or group of muscles. It is more common in early-onset AD than in late-onset Alzheimer's.

Neurofibrillary tangles—Accumulations of twisted protein fragments found inside the nerve cells in the brains of Alzheimer's patients.

Neurotransmitters—Chemicals that carry nerve impulses from one nerve cell to another. Alzheimer's disease causes a drop in the production of several important neurotransmitters.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness. It may be related in some way to Lewy body dementia.

Pick's disease—A rare type of primary dementia that affects the frontal lobes of the brain. It is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.

Plaques—Clumps or clusters of beta amyloid fragments, dead or dying nerve cells, and other cellular debris, found in the brains of patients with Alzheimer's disease.

Polygenic—A trait or disorder that is determined by a group of genes acting together. Most human characteristics, including height, weight, and general body build, are polygenic. Schizophrenia and late-onset Alzheimer's disease are considered polygenic disorders.

Post mortem—After death. The definitive diagnosis of Alzheimer's disease can be made only after the patient's death.

Presenile dementia—An older name for Alzheimer's disease.

Pseudodementia—A term for a depression with symptoms resembling those of dementia. The term "dementia of depression" is now preferred.

Systolic—Referring to the rhythmic contraction of the heart (systole), when the blood in the chambers of the heart is forced out. Systolic blood pressure is blood pressure measured during this phase.

Tau protein—A protein that is involved in maintaining the internal structure of nerve cells. The tau protein is damaged in Alzheimer's disease and ends up forming the neurofibrillary tangles.

often begin— the agitation, wandering, temper outbursts, depression, and disorientation. The patient is at high risk for falls and similar accidents. In addition, the patient becomes increasingly unable to understand simple instructions or to follow a conversation, and begins to lose his or her basic sense of personal identity.

END-STAGE ALZHEIMER'S. End-stage Alzheimer's is marked by the loss of the ability to walk and eventually even to sit up. Patients may be able to use a wheelchair for awhile but eventually become completely bedridden. They lose bladder and bowel control. When the disease begins to affect the patient's brain stem, the basic processes of digestion, respiration, and excretion shut down. Patients usually stop eating at this point and sleep most of the time. The hands and feet begin to feel cold, the breathing becomes shallow, and the patient is generally unresponsive to caregivers. Eventually the patient's breathing simply stops.

Causes and symptoms

Causes

Evidence has accumulated that Alzheimer's disease is multifactorial— that is, it is caused by a combination of several genetic and environmental factors.

GENETIC. Early-onset AD is caused by a defect in one of three genes known as APP, presenilin-1, and presenilin-2, found on human chromosomes 21, 14, and 1, respectively. Early-onset AD is also associated with Down syndrome, in that people with trisomy 21 (three forms of human chromosome 21 instead of a pair) often develop this form of Alzheimer's. The brains of people with Down syndrome age prematurely, so that those who develop early-onset AD are often only in their late 40s or early 50s when the symptoms of the disease first appear.

Genetic research indicates that late-onset Alzheimer's disease is a polygenic disorder; that is, its development is influenced by more than one gene. It has been known since 1993 that a specific form of a gene for apolipoprotein E (apoE4) on human chromosome 19 is a genetic risk factor for late-onset AD. People who have the apoE4 gene from one parent have a 50% chance of developing AD; a 90% chance if they inherited the gene from both parents. They are also likely to develop AD earlier in life. One of the remaining puzzles about this particular gene, however, is that it is not a consistent marker for AD. In other words, some people who have the apoE4 gene do not develop Alzheimer's, and some who do not have the gene do develop the disorder. In 1998 another gene on chromosome 12 that controls the production of bleomycin hydrolase (BH, an enzyme involved in the body's processing of amyloid precursor protein) was identified as a second genetic risk factor that acts independently of the APOE gene. In December 2000, three separate research studies reported that a gene on chromosome 10 that may affect the processing of a particular protein is also involved in the development of late-onset AD.

Familial Alzheimer's disease appears to be related to abnormal genes on human chromosomes 21 and 14.

NEUROBIOLOGICAL. Investigators since Alois Alzheimer's time have studied the abnormalities found at autopsy in the brains of patients with AD. One abnormality is plaques, or clumps, of a starchy protein called beta amyloid. Beta amyloid is formed when a substance called amyloid precursor protein, or APP, fails to be metabolized properly in the body. APP is a substance found in many parts of the body, but its precise function is not yet known. Following the formation of beta amyloid, pieces of it then stick to one another and gradually build up into plaques. The other abnormal finding is neurofibrillary tangles, which are twisted threads formed from parts of the dying nerve cell called the tau protein, which was discovered in 1986. If the tau protein is damaged by the addition of molecules of phosphorus, a process called hyperphosphorylation, it forms filaments that twist around each other to form the neurofibrillary tangles. As the plaques and tangles accumulate in the brain, they cause the nerve cells to wither and eventually die. As the nerve cells die, the affected parts of the brain start to shrink in size. It is not known as of 2002, however, whether the plaques and tangles are causes of AD or results of it. The relationship between the plaques and the tangles is another question that has not yet been answered. Although the plaques usually appear in brain tissue before the tangles, it is not clear that they cause the tangles. There are other brain disorders, such as Pick's disease, in which tangles appear in the brain cells without plaques.

Another nervous system abnormality in AD is the lowered level of **neurotransmitters** produced by the cells in the brain. Neurotransmitters are chemicals that carry nerve impulses across the small gaps (synapses) between nerve cells. The neurotransmitters whose production is affected by Alzheimer's include serotonin, norepinephrine, and acetylcholine. Many of the behavioral and psychiatric problems associated with AD are thought to result from the inadequate supply of these neurotransmitters.

ENVIRONMENTAL. Researchers have been studying the possibility that certain chemicals or other toxins in the environment may have a role in causing or triggering AD. The environmental factors that have been considered include aluminum, zinc, toxins in contaminated food, and viruses. Although there is little evidence as of 2002 that AD is caused by a virus or other infectious agent, the possibility cannot be completely excluded.

Other hypotheses about the causes of Alzheimer's include damage caused by oxidation, estrogen deficiency, and inflammation. All of these possibilities are presently under investigation.

RISK FACTORS. A number of factors have been identified that increase a person's risk of developing Alzheimer's:

- Age. The risk of developing AD rises after age 65, and rises sharply after age 75. While 1% of the population has AD at age 65, almost 50% of those over 85 have it.
- Sex. Women are more likely to develop AD than men. As of 2002, however, it is not known whether women are more susceptible to the disorder, or more likely to develop it because they live longer than men, on average.
- Family history of AD.
- Having Down syndrome.
- History of head injury.

- Substances in the environment. Higher-than-average amounts of aluminum have been found in the brains of patients with Alzheimer's. Some researchers in the late 1990s thought that exposure to aluminum might be a risk factor for the disorder. It now appears that the levels of aluminum in the brains of patients are a result rather than a cause of AD.
- Low occupational attainment and education level. Studies have found a clear correlation between employment in jobs that are not mentally challenging and an increased risk of AD. In addition, taking less rather than more challenging jobs as one grows older is associated with a higher risk of AD.
- High systolic blood pressure.
- High blood cholesterol levels. When both high systolic blood pressure and high cholesterol are present, the risk of developing AD increases by a factor of 3.5.
- Mild cognitive impairment (MCI). Mild cognitive impairment is a transitional decline in cognitive functioning that precedes the onset of AD. MCI is characterized primarily by memory loss while other cognitive functions remain intact. People with MCI are at higher risk for AD than people who do not develop the condition; 12% of people with mild cognitive impairment develop Alzheimer's disease each year, compared with 1–2% per year of people without MCI. After four years, 40% of people diagnosed with mild cognitive impairment have clear symptoms of Alzheimer's disease.

Symptoms

The symptoms of Alzheimer's can be grouped into three categories: cognitive deficits, or losses of brain function related to memory and learning; behavioral and psychiatric symptoms of dementia, or BPSD; and problems with activities of daily life, or ADLs.

COGNITIVE DEFICITS. There are four major symptoms of loss of cognitive capacities in Alzheimer's:

- **Amnesia**. Amnesia refers to memory impairment; however, loss of short-term memory also means that the patient loses his or her sense of time as well.
- Aphasia. Aphasia refers to loss of language function. The person may not remember the names of objects and may use words like "thing" or "it" instead; they may echo what other people say or repeat a word or phrase over and over. On occasion the person may lose the ability to speak except for curse words.
- Apraxia. Apraxia is the loss of the ability to perform voluntary movements in the absence of paralysis. A person with apraxia, for example, may have trouble putting on a hospital gown or brushing his or her teeth.

A brain segment affected by Alzheimer's disease on the right compared with a healthy brain segment (left). The brain affected by disease appears shrunken, and the fissures are noticeably larger. *(Simon Fraser/ MRC Unit, Newcastle General Hospital/ Science Photo Library. Photo Researchers, Inc. Reproduced by permission.)*

- Agnosia. Agnosia comes from a Latin word that means "to not know", and refers to inability to recognize familiar places and people. Patients with agnosia may even fail to recognize their own face in a mirror.

NEUROPSYCHIATRIC SYMPTOMS. Symptoms associated with BPSD include:

- Depression. Depression associated with AD is thought to result from the lowered production of the neurotransmitter serotonin. Depression in AD can be treated with medication, usually with one of the selective serotonin reuptake inhibitors, or SSRIs.
- **Delusions**. A delusion is a false belief that a person maintains even when presented with contrary evidence. For example, patients with AD may say that a person is stealing their things when they cannot remember where they have put them. Suspicions of other people caused by delusions can sometimes be treated with medication.
- Wandering. This behavior may result from becoming disoriented and getting lost, but sometimes people with AD wander for no apparent reason. The Alzheimer's Association in Chicago has a Safe Return Hotline (list-

ed under "Resources," below) that can be contacted for information about registering a patient with AD. If the registered patient should wander from home, the Safe Return Hotline can help identify him or her and return them to their family or nursing home.

- **Hallucinations**. Like delusions, hallucinations in AD patients are thought to be related to the deterioration of the patient's brain tissue. In a hallucination, the patient has a sensory experience that is real to him or her but not to other people. Hallucinations can affect any of the senses, but most are either visual or auditory. For example, a patient with AD may say that he or she sees little Martians in the corner of the room, or that he or she hears the voice of a long-dead parent calling to them. Hallucinations are sometimes caused by medications that the patient may be taking.
- Aggression. Aggression refers to hitting, shoving, pushing, or threatening behavior.
- Agitation. Agitation refers to emotionally excited behavior (screaming, shouting, cursing, pacing, fidgeting, etc.) that is disruptive or unsafe. Agitation may result from the changes in the patient's brain tissue, or it may be a symptom of depression associated with Alzheimer's disease.

For most of the twentieth century, studies of Alzheimer's patients focused on the cognitive symptoms of the disorder. It was not until the 1980s and 1990s that researchers began to look more closely at the behavioral and psychiatric symptoms of AD. Such methods of standardized assessment of these symptoms as the neuropsychiatric inventory are very recent developments.

PROBLEMS WITH ACTIVITIES OF DAILY LIVING (ADLS). Needing help with ADLs, or personal care activities that are part of everyday living, is among the earliest symptoms of Alzheimer's. The functions that are often affected include:

- eating, including simple cooking and washing dishes
- bathing, showering, or shaving
- grooming and dressing in clothing appropriate to the weather and activity
- toileting
- other aspects of personal hygiene (brushing teeth or cleaning dentures, washing hair, etc.)
- shopping for groceries and other necessary items

Health care professionals usually assess the ADLs of a patient diagnosed with Alzheimer's in order to determine what type of care is needed.

Demographics

Some demographic statistics in the developed countries have already been cited in the context of risk factors for AD and public health concerns related to the disorder.

Relatively little is known about the demographics of AD and other forms of dementia in the developing countries. Alzheimer's Disease International, which is based in London, supports a group of researchers called the 10/66 Dementia Research Group. The 10/66 group is trying to correct the global imbalance of AD research; as of 2001, fewer than 10% of all population-based research studies of AD and related forms of dementia has been directed toward the 66% of people with these disorders who live outside the developed countries. Of the estimated 18 million people in the world with dementia, 12 million live in China, India, Latin America, and other developing nations.

Diagnosis

As of 2002, the diagnosis of AD is essentially a process of exclusion. The only definitive diagnosis of Alzheimer's is made post mortem (after death), by performing an autopsy and examining the patient's brain tissue. There are no present tests that can be done on a living person to make the diagnosis of AD more than probable.

Diagnostic evaluation of AD

At present, the diagnostic process includes the following components:

- Clinical interview. In the absence of laboratory tests or **imaging studies** that can provide definite diagnoses, the physician must rely on his or her clinical judgment. In evaluating the patient, the doctor will assess signs of cognitive impairment other than short-term memory loss. In most cases, the doctor will ask a family member or close friend of the patient about the suddenness of symptom onset and the length of time that the patient seems to have been impaired.
- Physical examination. The patient will be given a complete physical and have blood and urine samples taken to rule out vitamin deficiencies, head trauma, tertiary syphilis, thyroid disorders, and other possible causes of dementia. The doctor will also review all the medications that the patient is taking (including alternative remedies) in order to exclude reversible dementia caused by drug interactions.
- Neurological examination. In early AD, the neurological findings are usually normal. If the patient appears to have had a **stroke**, he or she will be referred for a more thorough assessment by a neurologist.

- Tests of cognitive function. The patient will be given the mini-mental status examination (MMSE) and such other tests of cognitive function as the clock test or verbal fluency tests. The MMSE is a screening test and should not be used by itself to make the diagnosis of AD. In addition, the MMSE is not very sensitive in detecting cognitive impairment in people who previously functioned at a high level and were well educated. It is possible for a well-educated person to score a perfect 30 on the MMSE and still suffer cognitive impairment. The clock test is a test in which patients are asked to draw a clock face. Sometimes, patients will also be asked to include a specific time on the clock, such as 3:20. Patients with Alzheimer's often draw the face of the clock with numbers out of order, or all of the hour markers in a portion of the clock face instead of evenly spaced around the face, and often have difficulty adding the clock hands.
- Neuropsychiatric evaluation. A neuropsychiatric examination may be given to determine the pattern of the patient's cognitive impairment and probe his or her level of functioning more deeply. The patient may be asked to write a sample check, to describe how they answer the phone, to interpret sample traffic signs, and to look at a shopping list and pick out the items on the list from a display.
- Diagnostic imaging. Imaging studies are useful in detecting such causes of dementia as a previously undiagnosed brain tumor or abnormal brain structure. Scans can show doctors that certain areas of the brain have lost tissue (as happens in AD), and can strengthen a physician's suspicion of a patient's AD diagnosis, but scans cannot diagnose AD on their own. Scans are used more to rule out other possible diagnoses and to confirm a suspected diagnosis. CT (**computed tomography**) scans are commonly performed, as well as MRI (**magnetic resonance imaging**) scans in patients who are having problems with gait or balance. PET (**positron emission tomography**) and SPECT (**single photon emission computed tomography**) scans can be used to evaluate patterns of glucose (sugar) metabolism in the brain and to differentiate the patterns that are characteristic of Alzheimer's from those associated with vascular dementia and Pick's disease. PET scans are more precise than SPECT scans, but their cost is prohibitive.

Ethical considerations

With regard to genetic factors, tests are now available for the apoE4 gene implicated in late-onset Alzheimer's, but the American College of Medical Genetics and the American Neurological Association do not recommend these tests as of 2002. One reason is that the test results are not conclusive— about 20% of people who eventually develop AD do not carry this gene. Another important reason is the ethical implications of testing for a disease that presently has no cure, in terms of the psychological consequences for patients and their families, and the possible loss of health insurance for people found to be carrying the gene. These considerations may change, however, if researchers discover better treatments for primary dementia, more effective preventive methods, or more reliable genetic markers for AD.

Treatments

At present the mainstay of Alzheimer's treatment is medication, both to slow symptom progression and to manage the behavioral and psychiatric symptoms of AD.

Medications to slow symptom progression

The medications most commonly given to delay the progression of symptoms in Alzheimer's are a group of drugs called cholinesterase inhibitors. These drugs were approved by the FDA over a decade ago. They work by slowing down the body's destruction of the neurotransmitter acetylcholine.

The cholinesterase inhibitors include:

- **Tacrine** (Cognex). This drug is the oldest cholinesterase inhibitor in use. It is used less often than newer agents because it must be taken four times a day and may cause liver damage.
- **Donepezil** (Aricept). This drug is the one used most commonly as of 2002 to treat AD. It has fewer side effects than tacrine and can be given in one daily dose.

- **Rivastigmine** (Exelon). This drug is taken twice daily.
- **Galantamine** (Reminyl). This is the newest cholinesterase inhibitor, approved in late 2001. It acts on an additional acetylcholine receptor.

None of these medications provide more than modest benefits to patients with AD: they slow the progression of symptoms for about six months to a year in one-third to one-half of patients with AD. In addition, the cholinesterase inhibitors have side effects, most commonly nausea, vomiting, diarrhea, muscle cramps, and sleep disturbances.

Medications for BPSD

Medications are also prescribed to manage the behavioral and psychiatric symptoms of AD, which are often quite stressful for caregivers if the patient is being cared for at home. These medications are usually prescribed for specific symptoms:

- Delusions: Antipsychotic drugs, usually **haloperidol** (Haldol) or **risperidone** (Risperdal).
- Agitation: Short-term anti-anxiety drugs, usually **lorazepam** (Ativan) or **buspirone** (BuSpar).
- Depression: One of the selective serotonin reuptake inhibitors (SSRIs), at half the dosage for a young adult.
- Pain: Acetaminophen or a very low dose of codeine.

In general, older patients require lower dosages than those given to younger adults. Patients with AD are also more susceptible to the side effects of medications. For these reasons, physicians often recommend making changes in the patient's environment to reduce the behavioral symptoms before trying medications.

Alternative and complementary treatments

Some complementary therapies have been shown to benefit patients with Alzheimer's.

NATUROPATHY. A naturopathic approach to Alzheimer's includes supplementing antioxidant vitamins (vitamins A, E, and C) in the patient's diet, along with adding carotenoids, small amounts of selenium and zinc, and thiamin. Botanical supplements that have been said to improve cognitive function include Huperzine A, a Chinese tea, and an extract made from *Gingko biloba*, a tree that is native to China and is said to be the world's oldest living deciduous tree. GBE, or gingko biloba extract, is the most frequently used herbal medicine in Europe. It is available in Germany by prescription and in an over-the-counter form; and has been approved by the German Commission E for dementia-related memory loss. Gingko extract is thought to work in a manner similar to the cholinesterase inhibitors. At present the National Center for Complementary and Alternative Medicine (NCCAM) is conducting studies of gingko extract as a treatment for Alzheimer's.

MUSIC THERAPY. Music therapy has been found to calm agitated patients with Alzheimer's, to improve mood, and to enhance their long-term memory. Old familiar songs are particularly effective in improving recall. In other studies, music therapy has been shown to reduce sensations of chronic pain in patients with AD.

Prognosis

There is no cure for Alzheimer's disease as of 2002. The prognosis is progressive loss of mental and bodily functions leading to death within seven to ten years. Some patients, however, die within three years of diagnosis and others may survive for as long as fifteen.

Prevention

Researchers are considering several different strategies to prevent Alzheimer's, ranging from development of a vaccine to prevent the formation of beta amyloid plaques to finding a drug that would stop the conversion of APP to beta amyloid. As of 2002, the vaccine, which was originally developed and tested on mice, does not appear to have any serious side effects in humans. It is presently being tested in Phase II trials on human subjects.

Amantadine

Definition

Amantadine is a synthetic antiviral agent that also has strong antiparkinsonian properties. It is sold in the United States under the brand name Symmetrel, and is also available under its generic name.

Purpose

Amantadine is used to treat a group of side effects (called parkinsonian side effects) that include tremors, difficulty walking, and slack muscle tone. These side effects may occur in patients who are taking antipsychotic medications used to treat mental disorders such as **schizophrenia**. An unrelated use of amantadine is in the treatment of viral infections of some strains of influenza A.

Description

Some medicines, called antipsychotic drugs, that are used to treat schizophrenia and other mental disorders can cause side effects similar to the symptoms of Parkinson's disease. The patient does not have Parkinson's disease, but he or she may experience shaking in muscles while at rest, difficulty with voluntary movements, and poor muscle tone. These symptoms are similar to the symptoms of Parkinson's disease.

One way to eliminate these undesirable side effects is to stop taking the antipsychotic medicine. Unfortunately, the symptoms of the original mental disorder usually come back, so in most cases simply stopping the antipsychotic medication is not a reasonable option. Some drugs such as amantadine that control the symptoms of Parkinson's disease also control the parkinsonian side effects of antipsychotic medicines.

Amantadine works by restoring the chemical balance between dopamine and acetylcholine, two neurotransmitter chemicals in the **brain**. Taking amantadine along with the antipsychotic medicine helps to control symptoms of the mental disorder, while reducing parkinsonian side effects. Amantadine is in the same family of drugs (commonly known as anticholinergic drugs) as **biperiden** and **trihexyphenidyl**.

Recommended dosage

Amantadine is available in 100-mg tablets and capsules, as well as a syrup containing 50 mg of amantadine in each teaspoonful. For the treatment of drug-induced parkinsonian side effects, amantadine is usually given in a dose of 100 mg orally twice a day. Some patients may need a total daily dose as high as 300 mg. Patients who are taking other antiparkinsonian drugs at the same time may require lower daily doses of amantadine (100 mg daily, for example).

People with kidney disease or who are on hemodialysis must have their doses lowered. In these patients, doses may range from 100 mg daily to as little as 200 mg every seven days.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinsonian—Related to symptoms associated with Parkinson's disease, a nervous system disorder characterized by abnormal muscle movement of the tongue, face, and neck, inability to walk or move quickly, walking in a shuffling manner, restlessness, and/or tremors.

Precautions

Amantadine increases the amount of the neurotransmitter dopamine (a central nervous system stimulant) in the brain. Because of this, patients with a history of epilepsy or other seizure disorders should be carefully monitored while taking this drug. This is especially true in the elderly and in patients with kidney disease. Amantadine may cause visual disturbances and affect mental alertness and coordination. People should not

operate dangerous machinery or motor vehicles while taking this drug.

Side effects

Five to ten percent of patients taking amantadine may experience the following nervous system side effects:

- dizziness or lightheadedness
- insomnia
- nervousness or anxiety
- impaired concentration

One to five percent of patients taking amantadine may experience the following nervous system side effects:

- irritability or agitation
- depression
- confusion
- lack of coordination
- sleepiness or nightmares
- fatigue
- headache

In addition, up to 1% of patients may experience **hallucinations**, euphoria (excitement), extreme forgetfulness, aggressive behavior, personality changes, or **seizures**. Seizures are the most serious of all the side effects associated with amantadine.

Gastrointestinal side effects may also occur in patients taking amantadine. Five to ten percent of people taking this drug experience nausea and up to 5% have dry mouth, loss of appetite, constipation, and vomiting. In most situations, amantadine may be continued and these side effects treated symptomatically.

One to five percent of patients taking amantadine have also reported a bluish coloring of their skin (usually on the legs) that is associated with enlargement of the blood vessels (called livedo reticularis). This side effect usually appears within one month to one year of starting the drug and subsides within weeks to months after the drug is discontinued. People who think they may be experiencing this or other side effects from any medication should tell their physician.

Interactions

Taking amantadine along with other drugs used to treat parkinsonian side effects may cause increased confusion or even hallucinations. The combination of amantadine and central nervous system stimulants (such as **amphetamines** or decongestants) may cause increased central nervous stimulation or increase the likelihood of seizures.

Amitriptyline

Definition

Amitriptyline is a medication used to treat various forms of depression, pain associated with the nerves (neuropathic pain), and to prevent migraine headaches. It is sold in the United States under the brand names Elavil and Endep.

Purpose

Amitriptyline helps relieve depression and pain. This medication, usually given at bedtime, also helps patients sleep better.

Description

This medication is one of several tricyclic antidepressants, so-called because of the three-ring chemical structure common to these drugs. Amitriptyline acts to block reabsorption of **neurotransmitters** (chemicals that transmit nerve messages in the **brain**). Amitriptyline and the other tricyclic antidepressants are primarily used to treat mental depression but are increasingly being replaced by a newer and more effective group of antidepressant drugs called selective serotonin reuptake inhibitors (SSRIs). Amitriptyline is sometimes prescribed to help treat pain associated with cancer. In addition, it is sometimes prescribed for various types of chronic pain. Tablets are available in 10, 25, 50, 70, and 150 mg.

KEY TERMS

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Methylphenidate—A mild central nervous system stimulant that is used to treat hyperactivity.

Monoamine oxidase inhibitors (MAOIs)—A group of antidepressant drugs that decreases the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Urinary retention—Excessive storage of urine in the body.

Recommended dosage

The usual adult dose for pain management ranges from 10 mg to 150 mg at bedtime. Patients are generally started on a low dose and the amount may be increased as needed. Side effects, such as a dry mouth and drowsiness, may make it difficult to increase the dose in older adults. Bedtime dosing helps the patient sleep. Doctors generally prescribe 75–150 mg for depression. It is given at bedtime or in divided doses during the day. It may take 30 days for the patient to feel less depressed. Pain relief is usually noticed sooner than the mood change. Teens and older adults usually receive a lower dose. If the nightly dose is missed, it should not be taken the next morning. Taking amitriptyline during waking hours could result in noticeable side effects. Patients should check with their doctor if the daily dose is missed. Those on more than one dose per day should take a missed dose as soon as it is remembered but should not take two doses at the same time. While amitriptyline is usually administered orally, injectable amitriptyline is available. It should not be used in this form long-term; patients should switch to tablets as soon as possible.

Precautions

Patients should not stop taking this medication suddenly. The dose should gradually be decreased, then discontinued. If the drug is stopped abruptly, the patient may experience headache, nausea, or discomfort throughout the body, and a worsening of original symptoms. The effects of the medication last for three to seven days after it has been stopped, and older patients usually are more prone to some side effects such as drowsiness, dizziness, mental confusion, blurry vision, dry mouth, difficulty urinating, and constipation. Taking a lower dose may help resolve these problems. Patients may need to stop this medication before surgery.

Amitriptyline should not be given to anyone with allergies to the drug or to patients recovering from a heart attack. Patients taking the monoamine oxidase inhibitors (MAOIs) Parnate (**tranylcypromine**) and Nardil (**phenelzine**) —different types of antidepressants—should not use amitriptyline in combination. It should be administered with caution to patients with glaucoma, **seizures**, urinary retention, overactive thyroid, poor liver or kidney function, alcoholism, asthma, digestive disorders, enlarged prostate, seizures, or heart disease. This medication should not be given to children under 12 years of age. Pregnant women should discuss the risks and benefits of this medication with their doctor as fetal deformities have been associated with taking this drug during pregnancy. Women should not breast feed while using amitriptyline.

Side effects

Common side effects include dry mouth, drowsiness, constipation, and dizziness or lightheadedness when standing. Patients can suck on ice cubes or sugarless hard candy to combat the dry mouth. Increased fiber in the diet and additional fluids may help relieve constipation. Dizziness is usually caused by a drop in blood pressure when suddenly changing position. Patients should slowly rise from a sitting or lying position if dizziness is noticed. Amitriptyline may increase the risk of falls in older adults. Patients should not drive or operate machinery or appliances while under the influence of this drug. Alcohol and other central nervous system depressants can increase drowsiness. Amitriptyline may also produce blurry vision, irregular or fast heartbeat, high or low blood pressure, palpitations, and an increase or decrease in a diabetic patient's blood sugar levels. Patients' skin may become more sensitive to the sun and thus direct sunlight should be avoided by wearing protective clothing and the application of sunscreen with a protective factor of 15 or higher.

Amitriptyline may increase appetite, cause weight gain, or produce an unpleasant taste in the mouth. It may also cause diarrhea, vomiting, or heartburn. Taking this medication with food may decrease digestive side effects. Other less likely side effects include muscle tremors, nervousness, impaired sexual function, sweating, rash, itching, hair loss, ringing in the ears, or changes in the makeup of the patient's blood. Patients with **schizophrenia** may develop an increase in psychiatric symptoms.

Interactions

Patients should always tell all doctors and dentists that they are taking this medication. It may decrease the

effectiveness of some drugs used to treat high blood pressure and should not be taken with other antidepressants, epinephrine and other adrenaline-type drugs, or **methylphenidate**. Patients should not take over-the-counter medications without checking with their doctor. For instance, amitriptyline should not be taken with Tagamet (cimetidine) or Neosynephrine. Patients taking this drug should avoid the dietary supplements **St. John's wort**, belladonna, henbane, and scopolia. Black tea may decrease the absorption of this drug. Patients should ingest the drug and tea at least two hours apart.

Amnesia

Definition

Amnesia is a partial or total loss of memory.

Description

There are numerous causes of amnesia, including **stroke**, injury to the **brain**, surgery, alcoholism, encephalitis (inflammation of the brain), and **electroconvulsive therapy** (ECT, a treatment for various mental disorders in which electricity is sent to the brain through electrodes).

Contrary to the popular notion of amnesia—in which a person suffers a severe blow to the head, for example, and cannot recall his or her past life and experiences—the principal symptom of amnesia is the inability to retain new information, beginning at the point at which the amnesia began. The capacity to recall past experiences may vary, depending on the severity of the amnesia.

There are two types of amnesia: retrograde and anterograde. Retrograde amnesia refers to the loss of memory of one's past, and can vary from person to person. Some retain virtually full recall of things that happened prior to the onset of amnesia; others forget only their recent past, and still others lose all memory of their past lives. Anterograde amnesia refers to the inability to recall events or facts introduced since the amnesia began.

Amnesia is not always obvious to the casual observer—motor skills such as tying shoelaces and bike riding are retained, as is the ability to read and comprehend the meaning of words. Because of this phenomenon, researchers have suggested that there is more than one area of the brain used to store memory. General knowledge and perceptual skills may be stored in a memory separate from the one used to store personal facts.

Childhood amnesia, a term coined by Anna Freud in the late 1940s, refers to the fact that most people cannot recall childhood experiences during the first three to five years of life. It has been suggested that this type of amnesia occurs because children and adults organize memories in different ways based on their brain's physical development. Others believe children begin remembering facts and events once they have accumulated enough experience to be able to relate experiences to each other.

Amnestic disorders

Definition

The amnestic disorders are a group of disorders that involve loss of memories previously established, loss of the ability to create new memories, or loss of the ability to learn new information. As defined by the mental health professional's handbook, the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revision (2000), also known as *DSM-IV-TR*, the amnestic disorders result from two basic causes: general medical conditions that produce memory disturbances; and exposure to a chemical (drug of abuse, medication, or environmental toxin). An amnestic disorder whose cause cannot be definitely established may be given the **diagnosis** of amnestic disorder not otherwise specified.

KEY TERMS

Anterograde amnesia—Amnesia for events that occurred after a physical injury or emotional trauma but before the present moment.

Confabulation—In psychiatry, the filling-in of gaps in memory with false information that the patient believes to be true. It is not deliberate telling of lies.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Factitious disorder—A type of mental disturbance in which patients intentionally act physically or mentally ill without obvious benefits. It is distinguished from malingering by the absence of an obvious motive, and from conversion disorder by intentional production of symptoms.

Hypnotic—A type of medication that induces sleep.

Korsakoff's syndrome—A disorder of the central nervous system resulting from long-term thiamin deficiency. It is characterized by amnesia, confusion, confabulation, and unsteady gait; and is most commonly seen in alcoholics.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Orientation—In psychiatry, the ability to locate oneself in one's environment with respect to time, place and people.

Retrograde amnesia—Amnesia for events that occurred before a traumatic injury.

Thiamin—A B-vitamin that is essential to normal metabolism and nerve function, and whose absorption is affected by alcoholism.

Description

The amnestic disorders are characterized by problems with memory function. There is a range of symptoms associated with the amnestic disorders, as well as differences in the severity of symptoms. Some people experience difficulty recalling events that happened or facts that they learned before the onset of the amnestic disorder. This type of **amnesia** is called retrograde amnesia. Other people experience the inability to learn new facts or retain new memories, which is called anterograde amnesia. People with amnestic disorders do not usually forget all of their personal history and their identity, although memory loss of this degree of severity occurs in rare instances in patients with dissociative disorders.

Causes and symptoms

Causes

In general, amnestic disorders are caused by structural or chemical damage to parts of the **brain**. Problems remembering previously learned information vary widely according to the location and the severity of brain damage. The ability to learn and remember new information, however, is always affected in an amnestic disorder.

Amnestic disorder due to a general medical condition can be caused by head trauma, tumors, **stroke**, or cerebrovascular disease (disease affecting the blood vessels in the brain). Substance-induced amnestic disorder can be caused by alcoholism, long-term heavy drug use, or exposure to such toxins as lead, mercury, carbon monoxide, and certain insecticides. In cases of amnestic disorder caused by alcoholism, it is thought that the root of the disorder is a vitamin deficiency that is commonly associated with alcoholism, known as Korsakoff's syndrome. The causes of transient global amnesia, or TGA, are unclear.

Symptoms

In addition to problems with information recall and the formation of new memories, people with amnestic disorders are often disoriented with respect to time and space, which means that they are unable to tell an examiner where they are or what day of the week it is. Most patients with amnestic disorders lack insight into their loss of memory, which means that they will deny that

there is anything wrong with their memory in spite of evidence to the contrary. Others will admit that they have a memory problem but have no apparent emotional reaction to their condition. Some persons with amnestic disorders undergo a personality change; they may appear apathetic or bland, as if the distinctive features of their personality have been washed out of them.

Some people experiencing amnestic disorders confabulate, which means that they fill in memory gaps with false information that they believe to be true. Confabulation should not be confused with intentional lying. It is much more common in patients with temporary amnestic disorders than it is in people with long-term amnestic disorders.

Transient global amnesia (TGA) is characterized by episodes during which the patient is unable to create new memories or learn new information, and sometimes is unable to recall past memories. The episodes occur suddenly and are generally short. Patients with TGA often appear confused or bewildered.

Demographics

The overall incidence of the amnestic disorders is difficult to estimate. Amnestic disorders related to head injuries may affect people in any age group. Alcohol-induced amnestic disorder is most common in people over the age of 40 with histories of prolonged heavy alcohol use. Amnestic disorders resulting from the abuse of drugs other than alcohol are most common in people between the ages of 20 and 40. Transient global amnesia usually appears in people over 50. Only 3% of people who experience transient global amnesia have symptoms that recur within a year.

Diagnosis

Amnestic disorders may be self-reported, if the patient has retained insight into his or her memory problems. More often, however, the disorder is diagnosed because a friend, relative, employer, or acquaintance of the patient has become concerned about the memory loss or recognizes that the patient is confabulating, and takes the patient to a doctor for evaluation. Patients who are disoriented, or whose amnesia is associated with head trauma or substance abuse, may be taken to a hospital emergency room.

The doctor will first examine the patient for signs or symptoms of traumatic injury, substance abuse, or a general medical condition. He or she may order **imaging studies** to identify specific areas of brain injury, or laboratory tests of blood and urine samples to determine exposure to environmental toxins or recent consumption of alcohol or drugs of abuse. If general medical conditions and substance abuse are ruled out, the doctor may administer a brief test of the patient's cognitive status, such as the **mini-mental state examination** or MMSE. The MMSE is often used to evaluate a patient for **dementia**, which is characterized by several disturbances in cognitive functioning (speech problems, problems in recognizing a person's face, etc.) that are not present in amnestic disorders. The doctor may also test the patient's ability to repeat a string of numbers (the so-called digit span test) in order to rule out **delirium**. Patients with an amnestic disorder can usually pay attention well enough to repeat a sequence of numbers whereas patients with delirium have difficulty focusing or shifting their attention. In some cases the patient may also be examined by a neurologist (a doctor who specializes in disorders of the central nervous system)

If there is no evidence of a medical condition or substance use that would explain the patient's memory problems, the doctor may test the patient's memory several times in order to rule out **malingering** or a **factitious disorder**. Patients who are faking the symptoms of an amnestic disorder will usually give inconsistent answers to memory tests if they are tested more than once.

DSM-IV-TR specifies three general categories of amnestic disorders. These are: amnestic disorder due to a general medical condition, substance-induced persisting amnestic disorder, and amnestic disorder not otherwise specified. The basic criterion for diagnosing an amnestic disorder is the development of problems remembering information or events that the patient previously knew, or inability to learn new information or remember new events. In addition, the memory disturbance must be sufficiently severe to affect the patient's social and occupational functioning, and to represent a noticeable decline from the patient's previous level of functioning. *DSM-IV-TR* also specifies that the memory problems cannot occur only during delirium, dementia, substance use or withdrawal.

Treatments

There are no treatments that have been proved effective in most cases of amnestic disorder, as of 2002. Many patients recover slowly over time, and sometimes recover memories that were formed before the onset of the amnestic disorder. Patients generally recover from transient global amnesia without treatment. In people judged to have the signs that often lead to alcohol-induced persisting amnestic disorder, treatment with thiamin may stop the disorder from developing.

Prognosis

Amnestic disorders caused by alcoholism do not generally improve significantly over time, although in a small number of cases the patient's condition improves completely. In many cases the symptoms are severe, and in some cases warrant long-term care for the patient to make sure his or her daily needs are met. Other substance-induced amnestic disorders have a variable rate of recovery, although in many cases full recovery does eventually occur. Transient global amnesia usually resolves fully.

Prevention

Amnestic disorders resulting from trauma are not generally considered preventable. Avoiding exposure to environmental toxins, refraining from abuse of alcohol or other substances, and maintaining a balanced diet may help to prevent some forms of amnestic disorders.

Amobarbitol *see* **Barbiturates**

Amoxapine

Definition

Amoxapine is an oral tricyclic antidepressant. Formerly sold in the United States under the brand name Asendin, it is now manufactured and sold only under its generic name.

Purpose

Amoxapine is used primarily to treat depression and to treat the combination of symptoms of anxiety and depression. Like most antidepressants of this chemical and pharmacological class, amoxapine has also been used in limited numbers of patients to treat **panic disorder**, **obsessive-compulsive disorder**, **attention-deficit/hyperactivity disorder**, **enuresis** (bed-wetting), eating disorders such as **bulimia nervosa**, cocaine dependency, and the depressive phase of bipolar (manic-depressive) disorder. It has also been used to support smoking cessation programs.

Description

Tricyclic antidepressants act to change the balance of naturally occurring chemicals in the **brain** that regulate the transmission of nerve impulses between cells. Amoxapine acts primarily by increasing the concentration of norepinephrine and serotonin (both chemicals that stimulate nerve cells) and, to a lesser extent, by blocking the action of another brain chemical, acetylcholine. Amoxapine shares most of the properties of other tricyclic antidepressants, such as **amitriptyline**, **clomipramine**, **desipramine**, **imipramine**, **nortriptyline**, **protriptyline**, and **trimipramine**. Studies comparing amoxapine with these other drugs have shown that amoxapine is no more or less effective than other antidepressants of its type. Its choice for treatment is as much a function of physician preference as any other factor.

The therapeutic effects of amoxapine, like other antidepressants, appear slowly. Maximum benefit is often not evident for at least two weeks after starting the drug. People taking amoxapine should be aware of this and continue taking the drug as directed even if they do not see immediate improvement.

Recommended dosage

As with any antidepressant, amoxapine must be adjusted by the physician to produce the desired therapeutic effect. Amoxapine is available as 25-mg, 50-mg, 100-mg, and 150-mg oral tablets. Therapy is usually started at 100 to 150 mg per day and increased to 200 to 300 mg daily

by the end of the first week. If no improvement is seen at this dose after two weeks, the physician may increase the dose up to 400 mg per day in outpatients and up to 600 mg per day in hospitalized patients. Doses up to 300 mg may be given in single or divided doses. Doses of more than 300 mg per day should be divided in two or three doses daily.

Because of changes in drug metabolism of older patients, starting at about age 60, the initial dose of amoxapine should be adjusted downward to 50 to 75 mg per day and increased to 100 to 150 mg daily by the end of the first week. Some older patients may require up to 300 mg daily, but doses should never be increased beyond that.

Precautions

Like all tricyclic antidepressants, amoxapine should be used cautiously and with close physician supervision in people, especially the elderly, who have benign prostatic hypertrophy, urinary retention, and glaucoma, especially angle-closure glaucoma (the most severe form). Before starting treatment, people with these conditions should discuss the relative risks and benefits of treatment with their doctors to help determine if amoxapine is the right antidepressant for them.

A common problem with tricyclic antidepressants is sedation (drowsiness, lack of physical and mental alertness). This side effect is especially noticeable early in therapy. In most patients, sedation decreases or disappears entirely with time, but until then patients taking amoxapine should not perform hazardous activities requiring mental alertness or coordination. The sedative effect is increased when amoxapine is taken with other central nervous system depressants, such as alcoholic beverages, sleeping medications, other sedatives, or antihistamines. It may be dangerous to take amoxapine in combination with these substances. Amoxapine may increase the possibility of having **seizures**. Patients should tell their physician if they have a history of seizures, including seizures brought on by the abuse of drugs or alcohol. These people should use amoxapine only with caution and be closely monitored by their physician.

Amoxapine may increase heart rate and stress on the heart. It may be dangerous for people with cardiovascular disease, especially those who have recently had a heart attack, to take this drug or other antidepressants in the same pharmacological class. In rare cases in which patients with cardiovascular disease must receive amoxapine, they should be monitored closely for cardiac rhythm disturbances and signs of cardiac stress or damage.

Side effects

Amoxapine shares side effects common to all tricyclic antidepressants. The most frequent of these are dry mouth, constipation, urinary retention, increased heart rate, sedation, irritability, dizziness, and decreased coordination. As with most side effects associated with tricyclic antidepressants, the intensity is highest at the beginning of therapy and tends to decrease with continued use.

Dry mouth, if severe to the point of causing difficulty speaking or swallowing, may be managed by dosage reduction or temporary discontinuation of the drug. Patients may also chew sugarless gum or suck on sugarless candy in order to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement who take amoxapine may be especially likely to have problems with urinary retention. Symptoms include having difficulty starting a urine flow and more difficulty than usual passing urine. In most cases, urinary retention is managed with dose reduction or by switching to another type of antidepressant. In extreme cases, patients may require treatment with bethane-

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Benign prostate hypertrophy—Enlargement of the prostate gland.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

chol, a drug that reverses this particular side effect. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Interactions

Dangerously high blood pressure has resulted from the combination of tricyclic antidepressants, such as amoxapine, and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Because of this, amoxapine should never be taken in combination with MAO inhibitors. Patient taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor then wait at least 14 days before starting amoxapine or any other tricyclic antidepressant. The same holds true when discontinuing amoxapine and starting an MAO inhibitor.

Amoxapine may decrease the blood pressure–lowering effects of **clonidine**. Patients who take both drugs should be monitored for loss of blood-pressure control and the dose of clonidine may be increased as needed.

The sedative effects of amoxapine are increased by other central nervous system depressants such as alcohol, sedatives, sleeping medications, or medications used for other mental disorders such as **schizophrenia**. The anticholinergic effects of amoxapine are additive with other anticholinergic drugs such as **benztropine**, **biperiden**, **trihexyphenidyl**, and antihistamines.

Amphetamines

Definition

Amphetamines are a group of drugs that stimulate the central nervous system. Some of the brand names of amphetamines sold in the United States are Dexedrine, Biphetamine, Das, Dexampex, Ferndex, Oxydess II, Spancap No 1, Desoxyn, and Methampex. Some generic names of amphetamines include amphetamine, dextroamphetamine, and methamphetamine.

Purpose

Amphetamines stimulate the nervous system and are used in the treatment of depression, attention-deficit disorder, **obesity**, and **narcolepsy**, a disorder that causes individuals to fall asleep at inappropriate times during the day. Amphetamines produce considerable side effects and are especially toxic in large quantities. Amphetamines are commonly abused recreational drugs and are highly addictive.

Description

Amphetamines are usually given orally and their effects can last for hours. Amphetamines produce their effects by altering chemicals that transmit nerve messages in the body.

Recommended dosage

The typical dose for amphetamines in the treatment of narcolepsy in adults ranges from 5 mg to 60 mg per day. These daily doses are usually divided into at least two small doses taken during the day. Doses usually start on the low end of the range and are increased until the desired effects occur. Children over the age of 12 years with narcolepsy receive 10 mg per day initially. Children between the ages of six and 12 years start with 5 mg per day. The typical dose for adults with obesity ranges from 5 mg to 30 mg per day given in divided doses. The medication is usually given about one-half hour to one hour before meals.

The typical starting dose of amphetamines given to children with attention-deficit disorder over the age of six years is 5 mg per day. This is increased by 5 mg per day over a period of time until the desired effect is achieved. Children under the age of six years with this condition are usually started at 2.5 mg per day.

Precautions

People who are taking amphetamines should not stop taking these drugs suddenly. The dose should be lowered gradually and then discontinued. Amphetamines should only be used while under the supervision of a physician. People should generally take the drug early in the day so that it does not interfere with sleep at night. Hazardous activities should be avoided until the person's condition has been stabilized with medication. The effects of amphetamine can last up to 20 hours after the medication has last been taken. Amphetamine therapy given to women for medical reasons does not present a

significant risk to the developing fetus for congenital disorders. In such cases, there may be mild withdrawal in the newborn. However, illicit use of amphetamines for non-medical reasons presents a significant risk to the fetus and the newborn because of uncontrolled doses.

Amphetamines are highly addictive and should be used only if alternative approaches have failed. They should be used with great caution in children under three years of age, anyone with a history of slightly elevated blood pressure, people with neurological tics, and in individuals with Tourette's syndrome. Amphetamines should not be taken by individuals with a history of an overactive thyroid, those with moderate-to-severe high blood pressure, those with the eye disease called glaucoma, those who have severe arteriosclerosis (hardening of the arteries), or anyone with psychotic symptoms (**hallucinations** and **delusions**). Individuals with a history of drug abuse, psychological agitation, or cardiovascular system disease should also not receive amphetamine therapy. In addition, patients who have taken MAO inhibitors, a type of antidepressant, within the last 14 days should not receive amphetamines. MAO inhibitors include **phenelzine** (Nardil), and **tranylcypromine** (Parnate).

Side effects

The most common side effects that are associated with amphetamines include the development of an irregular heartbeat, increased heart rate, increased blood pressure, dizziness, **insomnia**, restlessness, headache, shakiness, dry mouth, metallic taste, diarrhea, constipation, and weight loss. Other side effects can include changes in sexual drive, nausea, vomiting, allergic reactions, chills, depression, irritability, and other problems involving the digestive system. High doses, whether for medical purposes or illicit ones, can cause **addiction**, dependence, increased aggression, and, in some cases, psychotic episodes.

Interactions

Patients taking amphetamines should always tell their physicians and dentists that they are using this medication. Patients should consult their physician before taking any over-the-counter medication while taking amphetamines. The interaction between over-the-counter cold medications with amphetamine, for instance, is particularly dangerous because this combination can significantly increase blood pressure. Such cold medications should be avoided when using amphetamine unless a physician has carefully analyzed the combination.

KEY TERMS

Anticonvulsant drugs—Medications that relieve or prevent seizures.

Arteriosclerosis—A thickening, hardening, and loss of elasticity of the walls of the arteries.

Attention-deficit disorder—A condition that mostly affects children and involves the inability to concentrate on various tasks.

Congenital—Present at birth.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

MAO inhibitors—A group of antidepressant drugs that decreases the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Tic—A sudden involuntary behavior that is difficult or impossible for the person to suppress. Tics may be either motor (related to movement) or vocal, and may become more pronounced under stress.

Tourette's syndrome—Neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics that come and go over years, usually beginning in childhood and becoming chronic. Sometimes the tics include inappropriate language.

Tricyclic antidepressants—Antidepressant medications that have the common characteristic of a three-ring nucleus in their chemical structure. Imipramine and amitriptyline are examples of tricyclic antidepressants.

The combination of amphetamines and antacids slows down the ability of the body to eliminate the amphetamine. Furazolidone (Furoxone) combined with amphetamine can significantly increase blood pressure. Sodium bicarbonate can reduce the amount of amphetamine eliminated from the body and dangerously increase amphetamine levels in the body. Certain medications taken to control high blood pressure, including guanadrel (Hylorel) and guanethidine (Ismelin), MAO inhibitors, and selegiline (Eldepryl) should not be used in conjunction with amphetamines. In addition, tricyclic antidepressants [including **desipramine** (Norpramin) and **imipramine** (Tofranil)],

antihistamines, and anticonvulsant drugs should not be combined with amphetamines.

Amphetamines and related disorders

Definition

Amphetamines are a group of powerful and highly addictive substances that dramatically affect the central nervous system. They induce a feeling of well-being and improve alertness, attention, and performance on various cognitive and motor tasks. Closely related are the so-called "designer amphetamines," the most well known of which is the "club drug" MDMA, best known as "ecstasy." Finally, some over-the-counter drugs used as **appetite suppressants** also have amphetamine-like action. Amphetamine-related disorders refer to the effects of abuse, dependence, and acute intoxication stemming from inappropriate amphetamine and amphetamine-related drug usage.

Description

Several amphetamines are currently available in the United States. These include dextroamphetamine (Dexedrine), methamphetamine (Desoxyn), and **methylphenidate** (Ritalin). These Schedule II stimulants, known to be highly addictive, require a triplicate prescription that cannot be refilled. Amphetamines are also known as sympathomimetics, stimulants, and psychostimulants. Methamphetamine, the most common illegally produced amphetamine, goes by the street name of "speed," "meth," and "chalk." When it is smoked, it is called "ice," "crystal," "crank," and "glass." Methamphetamine is a white, odorless, bitter-tasting crystalline powder that dissolves in water or alcohol.

The leaves of the East African bush *Catha edulis* can be chewed for their stimulant effects. This drug, cathinone or Khat, has an effect on most of the central nervous system, in addition providing the other properties of amphetamines. Illegal laboratories have begun making methcathinone, which has effects similar to cathinone. Methcathinone, also known as "crank," is easily synthesized from ephedrine or pseudoephedrine.

Amphetamines were initially produced for medical use, and were first used in nasal decongestants and bronchial inhalers. Early in the 1900s, they were also used to treat several medical and psychiatric conditions, including **narcolepsy** (a rare condition in which an individuals falls asleep at dangerous and inappropriate moments and cannot maintain normal alertness), attention-deficit disorders, **obesity**, and depression. They are still used to treat these disorders today.

Amphetamine-like substances called ephedrine and propranolamine are available over the counter in the United States and are used as nasal decongestants. Phenylpropanolamine is also used as an appetite suppressant, and is available over the counter as well. These are less potent than the classic amphetamines, but are still subject to abuse, partly because of their ready availability and low price.

In the 1970s, governmental agencies initiated restrictions increasing the difficulty of obtaining amphetamines legally through prescription. During this same time period, a drug chemically related to the amphetamines began to be produced. This so-called designer drug, best known as "ecstasy," but also as MDMA, XTC, and Adam, has behavioral effects that combine amphetamine-like and hallucinogen-like properties.

The structure of amphetamines differs significantly from that of cocaine, even though both are stimulants with similar behavioral and physiological effects. Like cocaine, amphetamine results in an accumulation of the neurotransmitter dopamine. It is this excessive dopamine concentration that appears to produce the stimulation and feelings of euphoria experienced by the user. Cocaine is much more quickly metabolized and removed from the body, whereas amphetamines have a much longer duration of action. A large percentage of the drug remains unchanged in the body, leading to prolonged stimulant effects.

The handbook that mental health professionals use to diagnose mental disorders is the ***Diagnostic and***

KEY TERMS

Amphetamine abuse—An amphetamine problem in which the user experiences negative consequences from the use, but has not reached the point of dependence.

Amphetamine dependence—The most serious type of amphetamine problem.

Amphetamine intoxication—The effects on the body that develop during or shortly after amphetamine use.

Amphetamine withdrawal—Symptoms that develop shortly after reducing or stopping heavy amphetamine use.

Amphetamines—A group of powerful and highly addictive substances that stimulate the central nervous system. May be prescribed for various medical conditions, but are often purchased illicitly and abused.

Catecholamine—A group of neurotransmitters synthesized from the amino acid tyrosine and released by the hypothalamic-pituitary-adrenal system in the brain in response to acute stress. The catecholamines include dopamine, serotomin, norepinephrine, and epinephrine.

Catha edulis—Leaves of an East African bush that can be chewed for their stimulant effect.

Designer amphetamines—Substances close in chemical structure to classic amphetamines that provide both stimulant and hallucinogenic effects.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions. Large amounts of dopamine are released following ingestion of amphetamines.

Ecstasy—Best known of the so-called designer amphetamines, also known as MDMA. It produces both stimulant and hallucinogenic effects.

Ephedrine—An amphetamine-like substance used as a nasal decongestant.

Formication—The sensation of bugs creeping on the skin.

Hyperthermia—Elevated body temperature resulting from ingestion of amphetamines.

Methamphetamine—The most common illegally produced amphetamine.

Propranolamine—An amphetamine-like substance used as a nasal decongestant and diet aid.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression. Large amounts of serotonin are released after ingestion of MDMA.

"Speed run"—The episodic bingeing on amphetamines.

Statistical Manual of Mental Disorders, also known as the *DSM*. The 2000 edition of this manual (the Fourth Edition Text Revision, also known as *DSM-IV-TR*) describes four separate amphetamine-related disorders. These are:

- Amphetamine dependence, which refers to chronic or episodic binges (known as "speed runs"), with brief drug-free periods of time in between use.
- Amphetamine abuse, which is less severe than dependence. Individuals diagnosed with amphetamine abuse have milder but nevertheless still substantial problems due to their drug usage.
- Amphetamine intoxication, which refers to serious maladaptive behavioral or psychological changes that develop during, or shortly after, use of an amphetamine or related substance.
- Amphetamine withdrawal, which refers to symptoms that develop within a few hours to several days after reducing or stopping heavy and prolonged amphetamine use. Withdrawal symptoms are, in general, opposite to those seen during intoxication and include **fatigue**, vivid and unpleasant dreams, **insomnia** or **hypersomnia** (too much sleep), increased appetite and agitation or slowing down.

Causes and symptoms

Causes

All amphetamines are rapidly absorbed when taken orally, and even more rapidly absorbed when smoked, snorted, or injected. Tolerance develops with both standard and designer amphetamines, leading to the need for increasing doses by the user.

The classic amphetamines, dextroamphetamine, methamphetamine, and methylphenidate, produce their primary effects by causing the release of catecholamines, especially dopamine, in the **brain**. These effects are particularly strong in areas of the brain associated with pleasure, specifically, the cerebral cortex and the limbic system, known as the "reward pathway." The effect on this pathway is probably responsible for the addicting quality of the amphetamines. Catecholamines are any of several compounds found naturally in the body and act as hormones or **neurotransmitters** in the sympathetic nervous system. Dopamine, an intermediate substance that emerges from the biosynthesis of ephinephrine and norepinephrine, is one of those compounds.

Designer amphetamines, most notably MDMA, causes the release of catecholamines, dopamine and norepinephrine; and in addition, releases serotonin. Serotonin, also a neurotransmitter, produces hallucinogenic effects. The clinical effects of designer amphetamines blend the effects of classic amphetamines with those of hallucinogenic drugs, such as LSD.

Symptoms

CLASSIC AMPHETAMINES. According to the *DSM-IV-TR*, symptoms of heavy, chronic, or episodic use of amphetamine, known as amphetamine dependence, can be very serious. Amphetamine dependence is characterized by compulsive drug-seeking and drug use leading to functional and molecular changes in the brain. Aggressive or violent behavior may occur, especially when high doses are ingested. The individual may develop anxiety or paranoid ideas, also with the possibility of experiencing terrifying psychotic episodes that resemble **schizophrenia**, with visual or auditory **hallucinations**, **delusions** such as the sensation of insects creeping on the skin, known as "formication." hyperactivity, hypersexuality, confusion, and incoherence. Amphetamine-induced **psychosis** differs from true psychosis in that despite other symptoms, the disorganized thinking that is a hallmark of schizophrenia tends to be absent. Amphetamine dependence consistently affects relationships at home, school and/or work.

Amphetamine abuse is less serious than dependence, but can cause milder versions of the symptoms described above, as well as problems with family, school, and work. Legal problems may stem from aggressive behavior while using, or from obtaining drugs illegally. Individuals may continue to use despite the awareness that usage negatively impacts all areas of their lives.

Acute amphetamine intoxication begins with a "high" feeling which may be followed by feelings of euphoria. The user experiences enhanced energy, becoming more outgoing and talkative, and more alert. Other symptoms include anxiety, tension, grandiosity, repetitive behavior, anger, fighting, and impaired judgment.

In both acute and chronic intoxication, the individual may experience dulled feelings, along with fatigue or sadness, and social withdrawal. These behavioral and psychological changes are accompanied by other signs and symptoms including increased or irregular heartbeat, dilation of the pupils, elevated or lowered blood pressure, heavy perspiring or chills, nausea and/or vomiting, motor agitation or retardation, muscle weakness, respiratory depression, chest pain, and eventually confusion, **seizures**, coma, or a variety of cardiovascular problems, including **stroke**. With amphetamine overdoses, death can result if treatment is not received immediately. Long-term abuse can lead to memory loss as well, and contributes to increased transmission of hepatitis and HIV/AIDs. Impaired social and work functioning is another hallmark of both acute and chronic intoxication.

Following amphetamine intoxication, a "crash" occurs with symptoms of anxiety, shakiness, depressed mood, lethargy, fatigue, nightmares, headache, perspiring, muscle cramps, stomach cramps, and increased appetite. Withdrawal symptoms usually peak in two to four days and are gone within one week. The most serious withdrawal symptom is depression, possibly very severe and leading to suicidal thoughts.

DESIGNER AMPHETAMINES. Use of so-called designer amphetamines, the best-known of which is MDMA, leads to symptoms of classic amphetamine use. Users report a sense of feeling unusual closeness with other people and enhanced personal comfort. They describe seeing an increased luminescence of objects in the environment, although these hallucinogenic effects are less than those caused by other hallucinogens, such as LSD. Some psychotherapists have suggested further research into the possible use of designer amphetamines in conjunction with **psychotherapy**. This idea is highly controversial, however.

Like classic amphetamines, use of MDMA produces cardiovascular effects of increased blood pressure, heart rate, and heart oxygen consumption. People with pre-existing heart disease are at increased risk of cardiovascular catastrophe resulting from MDMA use. MDMA is not processed and removed from the body quickly, and remains active for a long period of time. As a result, toxicity may rise dramatically when users take multiple doses over brief time periods, leading to harmful reactions such as dehydration, hyperthermia, and seizures.

MDMA tablets often contain other drugs, such as ephedrine, a stimulant, and dextromethorphan, a cough suppressant with PCP-like effects at high doses. These

additives increase the harmful effects of MDMA. It appears also to have toxic effects on the brain's serotonin system. In tests of learning and memory, MDMA users perform more poorly than nonusers. Research with primates show that MDMA can cause long-lasting brain damage. Exposure to MDMA during the period of pregnancy in which the fetal brain is developing is associated with learning deficits that last into adulthood.

Demographics

Classic amphetamines

Amphetamine dependence and abuse occur at all levels of society, most commonly among 18- to 30-year-olds. Intravenous use is more common among individuals from lower socioeconomic groups, and has a male-to-female ratio of three or four to one. Among non-intravenous users, males and females are relatively equally divided.

An annual study known as the *Monitoring the Future Study*, or *MTF*, examines drug use and attitudes related to drugs held by American teenagers. It focuses primarily on teens in the eighth, 10th, and 12th grades, but also on young adults across the country. Recent data on methamphetamine use showed that in 1997, 4.4% of 12th graders had tried crystal methamphetamine at least once in their lifetime. This represented an increase from 2.7% in 1990. Also in 1997, 2.3% of seniors reported having used crystal methamphetamine at least once during the past year. This represented an increase from 1.3% in 1990.

According to the 2000 *National Household Survey on Drug Abuse*, approximately 8.8 million Americans have tried methamphetamine at some time during their lives. Data from the 2000 *Drug Abuse Warning Network (DAWN)*, which collects information on drug usage problems from emergency room departments in 21 metropolitan areas found that methamphetamine-related problems increased from 10,400 in 1999 to 13,500 in 2000, an increase of 30%.

Treatment admissions reports by the National Institute of Drug Abuse (NIDA) *Community Epidemiology Work Group*, or *CEWG*, showed that as of June 2001, methamphetamine usage continued to be the leading drug of abuse among clients in treatment in the San Diego area and Hawaii. Methamphetamine is the most prevalent illegal drug in San Diego. Both San Francisco and Honolulu also reported substantial methamphetamine use problems during the late 1990s. Increased use was also reported in Denver, Los Angeles, Minneapolis/St.Paul, Phoenix, Seattle, and Tucson.

Amphetamines are a group of powerful and highly addictive substances that dramatically affect the central nervous system. Closely related are the so-called "designer amphetamines," the most well-known of which is the "club drug" MDMA, or "ecstasy" (pictured above). Use of MDMA produces increased blood pressure, heart rate, and heart oxygen consumption. MDMA is not processed and removed from the body quickly, and remains active for a long period of time. As a result, toxicity may rise dramatically when users take multiple doses over brief time periods, leading to harmful reactions such as dehydration, hyperthermia, and seizures. *(Andrew Brookes/ CORBIS. Photo reproduced by permission.)*

Designer amphetamines

According to the NIDA, at a time when abuse of most illicit drugs has leveled off or declined slightly among youth in the United States, one drug has greatly increased in popularity: MDMA. It is the only drug for which an increase in use was shown among American 10th and 12th graders between 1999-2000. That year, even younger adolescents at the eighth-grade level showed an increase in use. Other evidence from NIDA shows that MDMA use is also increasing among older Americans who attend dance clubs, or all-night parties called "raves." Increasingly, Americans of diverse ages, social classes, and sexual orientations are using this drug in diverse social settings around the country.

Evidence indicates that in 2001, the rate of increase in teen use of MDMA slowed down. At the time the 2001 survey was conducted, of teens in grade eight, 1.8% reported using MDMA in the last month. Teens in grade 10 reported a 2.6% use, and in grade 12, 2.8% use in the last month. Survey data from 2001 show that an increas-

ing number of high school seniors—nearly half— say they believe that MDMA poses a great health risk.

Diagnosis

Classic amphetamines

Four classic ampetamine-related diagnostic categories are listed in the *DSM-IV-TR*. These are:

- amphetamine dependence
- amphetamine abuse
- amphetamine intoxication
- amphetamine withdrawal

Amphetamine dependence refers to chronic or episodic use of amphetamine involving drug binges known as "speed runs." These episodes are punctuated by brief, drug-free periods. Aggressive or violent behavior is associated with amphetamine dependence, particularly when high doses are ingested. Intense but temporary anxiety may occur, as well as paranoid ideas and psychotic behavior resembling schizophrenia. Increased tolerance and withdrawal symptoms are part of the diagnostic picture. Conversely, some individuals with amphetamine dependence become sensitized to the drug, experiencing increasingly greater stimulant, and other negative mental or neurological effects, even from small doses.

Amphetamine abuse, while not as serious as amphetamine dependence, can also cause multiple problems. Legal difficulties are common, in addition to increased arguments with family and friends. If tolerance or withdrawal occur, amphetamine dependence is diagnosed.

Amphetamine intoxication refers to serious behavioral or psychological changes that develop during, or shortly after, use of amphetamine. Intoxication begins with a "high" feeling, followed by euphoria, enhanced energy, talkativeness, hyperactivity, restlessness, hypervigilance indicated by an individual's extreme sensitivity, and closely observant of everything in the environment). Other symptoms are anxiety, tension, repetitive behavior, anger, fighting, and impaired judgment. With chronic intoxication, there may be fatigue or sadness and withdrawal from others. Other signs and symptoms of intoxication are increased heartrate, dilation of the pupils, elevated or lowered blood pressure, perspiration or chills, nausea or vomiting, weight loss, cardiac irregularities and, eventually, confusion, seizures, coma, or death.

During amphetamine withdrawal, intense symptoms of depression are typical. Additional diagnostic symptoms are fatigue, vivid and unpleasant dreams, insomnia or sleeping too much, increased appetite, and agitation.

Treatments

According to the NIDA, the most effective treatments for amphetamine **addiction** are cognitive-behavioral interventions. These are psychotherapeutic approaches that help the individual learn to identify their problematic patterns of thoughts and beliefs, and to change them. As a result of changed thoughts and beliefs, feelings become more manageable and less painful. They also help individuals increase their skills for coping with life's stressors. Amphetamine recovery groups, and Narcotics Anonymous also appear to help, along with cognitive-behavioral interventions.

No specific medications are known to exist that are helpful for treating amphetamine dependence. On occasion, antidepressant medications can help combat the depressive symptoms frequently experienced by newly abstinent amphetamine users.

Overdoses of amphetamines are treated in established ways in emergency rooms. Because hyperthermia (elevated body temperature), and convulsions are common, emergency room treatment focuses on reducing body temperature and administering anticonvulsant medications.

Acute methamphetamine intoxication is often handled by observation in a safe, quiet environment. When extreme anxiety or panic is part of the reaction, treatment with anti-anxiety medications may be helpful. In cases of methamphetamine-induced psychoses, short-term use of antipsychotic medications is usually successful.

Prognosis

Classic amphetamines

According to the *DSM-IV-TR*, some individuals who develop abuse or dependence on amphetamines initiate use in an attempt to control their weight. Others become introduced through the illegal market. Dependence can occur very quickly when the substance is used intravenously, or is smoked. The few long-term data available show a tendency for people who have been dependent on amphetamines to decrease or stop using them after eight to 10 years. This may result from the development of adverse mental and physical effects that emerge with long-term dependence. Few data are available on the long-term course of abuse.

Designer amphetamines

The NIDA reports that studies provide direct evidence that chronic use of MDMA causes brain damage in humans. Using advanced brain imaging techniques, one study found that MDMA harms neurons that release serotonin. Serotonin plays an important role in regulating memory and other mental functions.

In a related study, researchers found that heavy MDMA users have memory problems that persist for at least two weeks after stopping use of the drug. Both studies strongly suggest that the extent of damage is directly related to the amount of MDMA used.

Prevention

In 1999, NIDA began a program known as the "Club Drug Initiative" in response to recent increases in abuse of MDMA and related drugs. This ongoing program seeks to increase awareness of the dangers of these drugs among teens, young adults, parents, and communities.

Research indicates a pervasive perception among users that MDMA is a "fun" drug with minimal risks. This myth might point to the main reason for the widespread increase in the drug's abuse. The Club Drug Initiative seeks to make the dangers of MDMA use far better known. Evidence of the program's initial success of this initiative might be seen in what is considered a growing perception by high school seniors that MDMA is a dangerous drug.

Anorexia nervosa

Definition

Anorexia nervosa (AN) is an eating disorder characterized by an intense fear of gaining weight and becoming fat. Because of this fear, the affected individual starves herself or himself, and the person's weight falls to about 85% (or less) of the normal weight for age and height.

Description

AN affects females more commonly than males—90% of those affected are female. Typically, the disorder begins when an adolescent or young woman of normal or slightly overweight stature decides to diet. As weight falls, the intensity and **obsession** with dieting increases. Affected individuals may also increase physical exertion or exercise as weight decreases to lose more pounds. An affected person develops peculiar rules concerning exercise and eating. Weight loss and avoidance of food is equated in these patients with a sense of accomplishment and success. Weight gain is viewed as a sign of weakness (succumbing to eat food) and as failure. Eventually, the affected person becomes increasingly focused on losing weight and devotes most efforts to dieting and exercise.

Anorexia nervosa is a complex eating disorder that has biological, psychological, and social consequences for those who suffer from it. When diagnosed early, the prognosis for AN is good.

Causes and symptoms

Causes

The exact causes of AN are not currently known, but the current thinking about AN is that it is caused by multiple factors. There are several models that can identify risk factors and psychological conditions that predispose people to develop AN. The predisposing risk factors include:

- female gender
- perfectionism
- personality factors, including being eager to please other people and high expectations for oneself
- family history of eating disorders
- living in an industrialized society
- difficulty communicating negative emotions such as anger or fear
- difficulty resolving problems or conflict
- low self-esteem

KEY TERMS

Amenorrhea—Absence of menstrual periods.

Anemia—Condition that results when there is a deficiency of oxygen in the blood. Can cause fatigue and impair mental functions.

False-positive—A test result that is positive for a specific condition or disorder, but this result is inaccurate.

Lanugo—Downy hair, usually associated with infants, that sometimes develops on the face and back of people affected by anorexia nervosa.

Specialists in **family therapy** have demonstrated that dysfunctional family relationships and impaired family interaction can contribute to the development of AN. Mothers of persons with AN tend to be intrusive, perfectionistic, overprotective, and have a fear of separation. Fathers of AN-affected individuals are often described as passive, withdrawn, moody, emotionally constricted, obsessional, and ineffective. Sociocultural factors include the messages given by society and the culture about women's roles and the thinness ideal for women's bodies. Developmental causes can include adolescent "acting out" or fear of adulthood transition. In addition, there appears to be a genetic correlation since AN occurs more commonly in biological relatives of persons who have this disorder.

Precipitating factors are often related to the developmental transitions common in adolescence. The onset of menarche (first menstrual cycle) may be threatening in that it represents maturation or growing up. During this time in development, females gain weight as part of the developmental process, and this gain may cause a decrease in self-esteem. Development of AN could be a way that the adolescent retreats back to childhood so as not to be burdened by maturity and physical concerns. Autonomy and independence struggles during adolescence may be acted out by developing AN. Some adolescents may develop AN because of their ambivalence about adulthood or because of loneliness, isolation, and abandonment they feel.

Symptoms

Most of the physical symptoms associated with AN are secondary to starvation. The **brain** is affected— there is evidence to suggest alterations in brain size, neurotransmitter balance, and hormonal secretion signals originating from the brain. **Neurotransmitters** are the chemicals in the brain that transmit messages from nerve cell to nerve cell. Hormonal secretion signals modulate sex organ activity. Thus, when these signals are not functioning properly, the sex organs are affected. Significant weight loss (and loss in body fat, in particular) inhibits the production of estrogen, which is necessary for menstruation. AN patients experience a loss of menstrual periods, known as amenorrhea. Additionally, other physiologic systems are affected by the starvation. AN patients often suffer from electrolyte (sodium and potassium ion) imbalance and blood cell abnormalities affecting both white and red blood cells. Heart function is also compromised and a person affected with AN may develop congestive heart failure (a chronic weakening of the heart due to work overload), slow heart rate (bradycardia), and abnormal rates and rhythms (arrhythmias). The gastrointestinal tract is also affected, and a person with AN usually exhibits diminished gastric motility (movement) and delayed gastric emptying. These abnormalities may cause symptoms of bloating and constipation. In addition, bone growth is affected by starvation, and over the long term, AN patients can develop osteoporosis, a bone loss disease.

Physically, people with AN can exhibit cold hands and feet, dry skin, hair loss, headaches, fainting, dizziness, and lethargy (loss of energy). Individuals with AN may also develop lanugo (a fine downy hair normally seen in infants) on the face or back. Psychologically, these people may have an inability to concentrate, due to the problems with cognitive functioning caused by starvation. Additionally, they may be irritable, depressed, and socially withdrawn, and they obsessively avoid food. People affected with AN may also suffer from lowered body temperature (hypothermia), and lowered blood pressure, heart rate, glucose and white blood cells (cells that help fight against infection). They may also have a loss of muscle mass.

In order to diagnose AN, a patient's symptoms must meet the symptom criteria established in the professional's handbook, the ***Diagnostic and Statistical Manual of Mental Disorders***, also called the *DSM*. These symptoms include:

- Refusal to maintain normal body weight, resulting in a weight that is less than 85% of the expected weight.
- Even though the affected person is underweight, he or she has an intense fear of gaining weight.
- Distorted body image, obsession with body weight as key factor in self-evaluation, or **denial** of the seriousness of the low body weight.
- Amenorrhea.

Demographics

AN is considered to be a rare illness. The prevalence even in high-risk groups and high-risk situations is approximately 0.5%–1%. Partial disorders (diagnosed when symptoms are present, but do not meet the full criteria as established in the *DSM*) are more commonly seen in psychological practice. The incidence (number of new cases) of AN has increased during the last 50 years due to increased societal concerns regarding body shape, weight, and appearance. Some occupations such as ballet dancing and fashion modeling may predispose persons to develop AN, due to preoccupation with physical appearance. This disorder usually affects women more than men in a ratio of between one to 20 and one to 10.

Diagnosis

Initial assessment usually includes a careful interview and history (clinical evaluation). A weight history, menstrual history, and description of daily food intake are important during initial evaluation. Risk factors and family history are also vital in suspected cases. Laboratory results can reveal anemia (low red blood cell count in the blood), lowered white blood cells, pulse, blood pressure, and body temperature. The decreased temperature in extremities may cause a slight red-purple discoloration in limbs (acrocynanosis). There are two psychological questionnaires that can be administered to aid in **diagnosis**, called the Eating Attitudes Test (EAT) and Eating Disorders Inventory (EDI). The disadvantage of these tests is that they may produce false-positive results, which means that a test result may indicate that the test taker has anorexia, when, actually, s/he does not.

During adolescence, females gain weight as part of the normal developmental process. Typically, anorexia nervosa begins when an adolescent or young woman decides to diet. As weight falls, the intensity and obsession with dieting increases. The incidence of this disorder has increased during the last 50 years due to increased societal concerns regarding body shape, weight, and appearance. *(Richard Hutchings. Photo Researchers, Inc. Reproduced by permission.)*

Treatments

People affected with AN are often in denial, in that they don't see themselves as thin or in need of professional help. Education is important, as is engagement on the part of the patient—a connection from the patient to her treatment, so that she agrees to be actively involved. Engagement is a necessary but difficult task in the treatment of AN. If the affected person's medical condition has deteriorated, **hospitalization** may be required. Initially, treatment objectives are focused on reversing behavioral abnormalities and nutritional deficiencies. Emotional support and reassurance that eating and caloric restoration will not make the person overweight, are essential components during initial treatment sessions. Psychosocial (both psychological and social) issues and family dysfunction are also addressed, which may reduce the risk of relapsing behaviors. (Relapsing behaviors occur when an individual goes back to the old patterns that he or she is trying to eliminate.) At present, there is no standardized psychotherapeutic treatment model to address the multifactorial problems associated with AN. **Cognitive-behavioral therapy** (CBT) may help to improve and modify irrational perceptions and overemphasis of weight gain. Current treatment usually begins with behavioral interventions and should include family therapy (if age appropriate). **Psychodynamic psychotherapy** (also called exploratory **psychotherapy**) is often helpful in the treatment of AN. There are no medications to treat AN. Treatment for this disorder is often long term.

Prognosis

If this disorder is not successfully diagnosed or treated, the affected person may die of malnutrition and multi-organ complications. However, early diagnosis and

appropriate treatment interventions are correlated with a favorable outcome.

Research results concerning outcome of specific AN treatments are inconsistent. Some results, however, have been validated. The prognosis appears to be more positive for persons who are young at onset of the disorder, and/or who have experienced a low number of disorder-related hospitalizations. The prognosis is not as positive for people with long duration illness, very low body weight, and persistent family dysfunction. Additionally, the clinical outcome can be complicated by comorbid, or co-occurring or concurrent, disorders (without any causal relationship to AN) such as depression, anxiety, and substance abuse.

Prevention

A nurturing and healthy family environment during developing years is particularly important. Recognition of the clinical signs with immediate treatment can possibly prevent disorder progression, and, as stated, early diagnosis and treatment are correlated with a favorable outcome.

Antabuse *see* **Disulfiram**

Anti-anxiety drugs and abuse

Definition

Anti-anxiety drugs, or "anxiolytics," are powerful central nervous system (CNS) depressants that can slow normal **brain** function. They are often prescribed to reduce feelings of tension and anxiety, and/or to bring about sleep. Anti-anxiety medications are among the most abused drugs in the United States, obtained both legally, via prescription, and illegally, through the black market. These drugs are also known as sedatives.

Description

The drugs associated with this class of substance-related disorders are the benzodiazepines [such as **diazepam** (Valium), **chlordiazepoxide** (Librium), **alprazolam** (Xanax), **triazolam** (Halcion), and **estazolam** (ProSom)], the **barbiturates** [such as Seconal and pentobarbital (Nembutal)], and barbiturate-like substances including Quaalude, Equanil, and Doriden. Any of these drugs is capable of producing wakeful relief from tension, or sleep, depending upon dosage. Some non-psychiatric uses of anti-anxiety medications include treatment and prevention of **seizures**, muscle relaxants, anesthetics, and drugs to make other anesthetics work more effectively (known as "adjuvants").

Although the types of central nervous system depressants work differently, they all produce a pleasant drowsy or calming effect. If used over a long period of time, tolerance develops, and larger doses are needed to achieve the initial effects. Continued use can lead both to physical dependence when use is reduced or stopped, and to withdrawal symptoms. When combined with each other or other CNS depressants, such as alcohol, the effects are additive.

In addition to the drugs available in the United States by prescription, there are three other drugs that are predominantly central nervous system depressants with significant potential for abuse. These are:

- gamma hydroxybutyrate (GHB)
- flunitrazepam (Rohypnol)
- Ketamine

GHB has been abused in the United States since about 1990, for its euphoric, sedative, and anabolic (bodybuilding) effects. It was widely available over the counter in health food stores until 1992. Bodybuilders used it to aid in reducing percentage of body fat, and to build muscle. Street names for GHB include "Liquid ecstasy," "soap," "Easy lay," and "Georgia home boy."

Rohypnol has been of particular concern during the last few years because of its abuse in date rape. When mixed with alcohol, Rohypnol can incapacitate its victims and prevent them from resisting sexual assault. It can also lead to anterograde **amnesia**, in which individuals cannot remember what they experienced while under the influence. Rohypnol can be lethal when mixed with alcohol and/or other depressants. Rohypnol is not available by prescription in the United States, and it is illegal to import it. Even so, illegal use of Rohypnol started appearing in the United States in the early 1990s, where it became known as "rophies," "roofies," "roach," and "rope."

Ketamine is an anesthetic used predominately by veterinarians to treat animals. It can be injected or snorted. Ketamine goes by the street names of "Special K," or "Vitamin K." At certain doses, ketamine can cause dream-like states and **hallucinations**. It has become particularly common in club and rave (large, all-night dance marathon) settings, and has been used as a date rape drug. At high doses, it can cause **delirium**, amnesia, impaired motor functioning, high blood pressure, and depression. It can also cause potentially fatal respiratory problems.

Causes and symptoms

Causes

Anti-anxiety drugs can be taken orally to bring about a general calming or drowsy effect, usually experienced as pleasant. Abuse of anti-anxiety medication can develop with prolonged use, as tolerance grows relatively quickly. Increasing amounts of the drug are then needed to produce the initial effect. It is possible to become addicted to anti-anxiety drugs even when they are medically prescribed.

A second cause of anti-anxiety drug abuse is the use of these drugs, especially when combined with other drugs, such as cocaine. It is not uncommon for an addict to pair the use of a stimulant, such as cocaine or methamphetamine, with a CNS depressant. This allows the user to feel alert for an extended period of time, and then be able to "come down" from the high, and even fall asleep.

Symptoms

Even when prescribed for medical reasons, an individual taking central nervous system depressants usually feels sleepy and uncoordinated during the first few days of treatment. As the body adjusts to the effects of the drug, these feelings begin to disappear. If the drug is used long term, the body develops tolerance, and increasing doses are needed to obtain the desired effect of general calming or drowsiness.

KEY TERMS

Abuse—Substance abuse is a milder form of addiction than substance dependence. Generally, people who have been diagnosed with substance abuse don't experience the tolerance or withdrawal symptoms— the signs of physiological dependence— that people dependent on a substance experience.

Anxiolytic—A preparation or substance given to relieve anxiety; a tranquilizer.

Barbiturates—A class of medications (including Seconal and Nembutal) that causes sedation and drowsiness. They may be prescribed legally, but may also be used as drugs of abuse.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Dependence—The adaptation of neurons and other physical processes to the use of a drug, followed by withdrawal symptoms when the drug is removed; physiological and/ or psychological addiction.

GHB—GHB, or gamma hydroxybutyrate, is a central nervous system depressant that has been abused in the United States for euphoric, sedative, bodybuilding, and date-rape purposes.

Intoxication—the presence of significant problem behaviors or psychological changes following ingestion of a substance.

Ketamine—An anesthetic used predominately by veterinarians to treat animals that can be used as a date-rape drug.

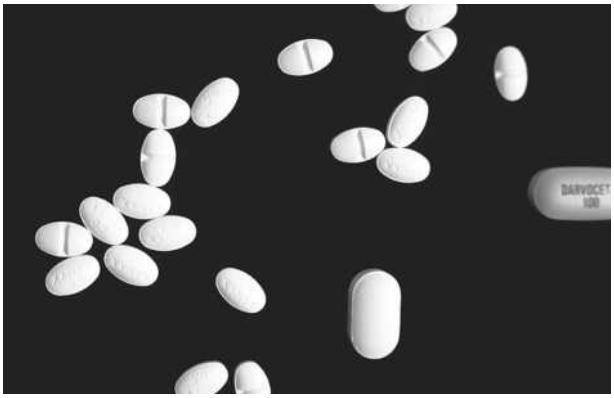
Rohypnol—Rohypnol, or flunitrazepam, is a central nervous system depressant that is not legal in the United States, but is used as a date-rape drug.

Sedative—A medication that induces relaxation and sleep.

Tranquilizer—A medication that induces a feeling of calm and relaxation.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

The use of anti-anxiety drugs can pose extreme danger when taken along with other medications that cause CNS depression, such as prescription pain medicines, some over-the-counter cold and allergy medications, or



Anti-anxiety drugs are powerful central nervous system depressants. They are often prescribed to reduce feelings of tension and anxiety, and/or to induce sleep. Anti-anxiety medications are among the most abused drugs in the United States. *(Thomas Craig/FPG International Corp. Reproduced by permission.)*

alcohol. Use of additional depressants can slow breathing and respiration, and can even lead to death.

Withdrawal from anti-anxiety medications can be dangerous if not done under medical supervision. The safest method of withdrawal involves a gradual reduction of dosage. Abrupt withdrawal from these medications can lead to seizures due to sudden increase in brain activity.

Demographics

Several studies conducted by the National Institute of Drug Abuse, or NIDA, suggest that prescription drug abuse is on the rise in the United States. According to the 1999 *National Household Survey on Drug Abuse*, an estimated 1.6 million Americans first tried prescription pain relievers for non-medical purposes in 1998. Between 1990 and 1998, the number of people who used tranquilizers increased by 132%, and the number of new sedative users increased by 90%. In 1999, an estimated four million people —almost 2% of the population aged 12 and older— by 2001 were using prescription drugs for non-medical purposes. Sedatives and tranquilizers were used by 1.3 million of these people.

In 1999, an estimated four million Americans, about 2% of the population age 12 and older, had used prescription drugs non-medically within the past month. Of these, 1.3 million misused sedatives and tranquilizers. Of particular concern is the growing abuse among older adults, adolescents, and women.

Misuse of prescribed medications may be the most common form of drug abuse among the elderly, according to the NIDA. Older people are given prescriptions approximately three times more often than the general population, and have poorer **compliance** with directions for use.

The *National Household Survey on Drug Abuse* indicates the steepest increase in new users of prescription drugs for non-medical purposes occur in 12- to 17- and 18- to 25-year-olds. Among 12- to 14-year-olds, psychoactive medications, including anti-anxiety drugs, were reportedly among the primary drugs used.

The 1999 *Monitoring the Future Survey*, a yearly survey of drug use and related attitudes conducted among eighth, 10th and 12th graders nationwide, found that for barbiturates, tranquilizers, and narcotics other than heroin, long-term declines in use during the 1980s leveled off in the early 1990s, with modest increases in use starting again in the mid-1990s.

Overall, men and women have approximately equal rates of non-medical use of prescription drugs, with the exception of 12- to 17-year-olds. In this age category, young women are more likely to use psychoactive drugs non-medically. Also, among women and men who use anti-anxiety drugs non-medically, women are almost twice as likely to become addicted.

GHB-related emergency room visits increased from 55 in 1994 to 2,973 in 1999, according to the NIDA. There were 13 reported Rohypnol-related emergency room visits in 1994, versus 634 in 1998. The number decreased to 540 in 1999. Ketamine-related emergency room visits rose from a reported 19 in 1994 to 396 in 1999. Recent use have been reported more frequently among white youth in many major metropolitan areas.

Diagnosis

The manual used by mental health professionals to diagnose mental illnesses, the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR*, includes specific diagnostic criteria for four types of anti-anxiety medication abuse. These are:

- dependence
- abuse
- intoxication
- withdrawal

Dependence, the more severe form of **addiction**, refers to very significant levels of physiological dependence, with both tolerance and withdrawal symptoms. Abuse, the less severe form of addiction, may still result in risky behavior, such as driving while under the influence. An individual with an abuse disorder may miss work or school, or get into arguments with parents or spouse about substance use. The problem can easily escalate into full-blown dependence.

Intoxication refers to the presence of clinically significant problem behaviors or psychological changes, such as inappropriate sexual or aggressive behavior, mood swings, impaired judgment, or impaired social or work functioning that develop during or shortly after use of an anti-anxiety medication. As with other CNS depressants such as alcohol, these behaviors may be accompanied by slurred speech, unsteady gait, memory or attention problems, poor coordination, and eventually, stupor or coma. Memory impairment is relatively common, especially a kind known as anterograde amnesia that resembles alcoholic blackouts.

Withdrawal is a characteristic syndrome that develops when use of anti-anxiety medication is severely reduced or stopped abruptly. It is similar to abrupt cessation of heavy alcohol use. Symptoms may include increases in heart rate, respiratory rate, blood pressure or body temperature, sweating, hand tremor, **insomnia**, anxiety, nausea, and restlessness. Seizures may occur in perhaps as many as 20-30% of individuals undergoing untreated withdrawal. In the more severe forms of withdrawal, hallucinations and delirium can occur. Withdrawal symptoms are generally the opposite of the acute effects experience by first-time users of the drugs. Length of withdrawal varies depending upon the drug, and may last as few as 10 hours, or as long as three to four weeks. The longer the substance has been taken, and the higher the dosages used, the more likely that withdrawal will be severe.

Treatments

According to the NIDA, successful treatment for anti-anxiety medication addiction needs to incorporate several components. Counseling, particularly cognitive-behavior counseling, focuses on helping addicted individuals identify and change behaviors, attitudes, and beliefs that contributed to their drug usage. Combined with prescribed medications to make withdrawal safer and easier, counseling can help the addicted individual eventually make a full recovery. Often, it takes multiple courses of treatment before full recovery can be achieved. Various levels of care, from outpatient to residential care for up to 18 months, are available, depending upon need. Narcotics Anonymous also offers ongoing recovery support.

Prognosis

The most typical course, according to the *DSM-IV-TR* involves teens or young people in their early 20s who may escalate occasional use of anti-anxiety medications to the point at which they develop problems such as abuse or dependence. This is particularly likely for individuals who also abuse other substances. An initial pattern of use at parties can eventually lead to daily use and high degrees of tolerance.

A second course, observed somewhat less frequently, involves individuals who initially obtain medications by prescription, usually for treatment of anxiety or insomnia. Though the vast majority of people who use medications as prescribed do not go on to develop substance abuse problems, a small minority do. Again, tolerance develops and the need for higher dosages to reach the initial effects occurs. Individuals may justify their continued use on the basis of the original symptoms, but active substance-seeking becomes increasingly part of the picture. Others at higher risk are those with alcohol dependence who might be given prescription anti-anxiety medications to reduce their anxiety or insomnia.

Prevention

Health care professionals play a very important role in preventing and detecting abuse of prescription drugs. Primary care physicians, nurse practitioners and pharmacists can all play a role.

It is estimated by the NIDA that approximately 70% of all Americans visit a health care provider, at least once every two years. Thus, health care providers are in a unique position not only to prescribe medications as appropriate, but also to identify prescription drug abuse when it exists and recommend appropriate treatment for recovery. Screening for substance abuse should be incorporated into routine history taking, or if a patient presents with symptoms associated with problem drug use.

Over time, providers should be alert to any increases in the amount of medication being used, which may be a sign of tolerance. They should also be aware that individuals addicted to prescription medications may engage in "doctor shopping," that is, going from provider to provider in an effort to obtain multiple prescriptions of their abused drug.

Pharmacists can play a role in preventing prescription drug abuse as well. They should provide information and advice about the correct way to take prescribed medications, and be alert to drug interactions. They can also play a role in detecting prescription fraud by noticing suspicious-looking prescription forms.

Antisocial personality disorder

Definition

Also known as psychopathy, sociopathy or dyssocial personality disorder, antisocial personality disorder (APD) is a **diagnosis** applied to persons who routinely behave with little or no regard for the rights, safety or feelings of others. This pattern of behavior is seen in children or young adolescents and persists into adulthood.

The most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders,* (the fourth edition, text revision or *DSM-IV-TR*) classifies APD as one of four "Cluster B Personality Disorders" along with borderline, histrionic, and narcissistic **personality disorders**.

Description

People diagnosed with APD in prison populations act as if they have no conscience. They move through society as predators, paying little attention to the consequences of their actions. They cannot understand feelings of guilt or remorse. Deceit and manipulation characterize their interpersonal relationships.

Men or women diagnosed with this personality disorder demonstrate few emotions beyond contempt for others. Their lack of empathy is often combined with an inflated sense of self-worth and a superficial charm that tends to mask an inner indifference to the needs or feelings of others. Some studies indicate people with APD can only mimic the emotions associated with committed love relationships and friendships that most people feel naturally.

People reared by parents with antisocial personality disorder or substance abuse disorders are more likely to develop APD than members of the general population. People with the disorder may be homeless, living in poverty, suffering from a concurrent substance abuse disorder, or piling up extensive criminal records, as antisocial personality disorder is associated with low socioeconomic status and urban backgrounds. Highly intelligent individuals with APD, however, may not come to the attention of the criminal justice or mental health care systems and may be underrepresented in diagnostic statistics.

Some legal experts and mental health professionals do not think that APD should be classified as a mental disorder, on the grounds that the classification appears to excuse unethical, illegal, or immoral behavior. Despite these concerns, juries in the United States have consistently demonstrated that they do not regard a diagnosis of APD as exempting a person from prosecution or punishment for crimes committed.

Furthermore, some experts disagree with the American Psychiatric Association's (APA's) categorization of antisocial personality disorder. The APA considers the term *psychopathy* as another, synonymous name for APD. However, some experts make a distinction between psychopathy and APD. Dr. Robert Hare, an authority on psychopathy and the originator of the **Hare Psychopathy Checklist**, claims that all psychopaths have APD but not all individuals diagnosed with APD are psychopaths.

Causes and symptoms

Causes

Studies of adopted children indicate that both genetic and environmental factors influence the development

of APD. Both biological and adopted children of people diagnosed with the disorder have an increased risk of developing it. Children born to parents diagnosed with APD but adopted into other families resemble their biological more than their adoptive parents. The environment of the adoptive home, however, may lower the child's risk of developing APD.

Researchers have linked antisocial personality disorder to childhood physical or sexual abuse; neurological disorders (which are often undiagnosed); and low IQ. But, as with other personality disorders, no one has identified any specific cause or causes of antisocial personality disorder. Persons diagnosed with APD also have an increased incidence of somatization and substance-related disorders.

DSM-IV-TR adds that persons who show signs of **conduct disorder** with accompanying **attention-deficit/hyperactivity disorder** before the age of ten have a greater chance of being diagnosed with APD as adults than do other children. The manual notes that abuse or **neglect** combined with erratic parenting or inconsistent discipline appears to increase the risk that a child diagnosed with conduct disorder will develop APD as an adult.

Symptoms

The central characteristic of antisocial personality disorder is an extreme disregard for the rights of other people. Individuals with APD lie and cheat to gain money or power. Their disregard for authority often leads to arrest and imprisonment. Because they have little regard for others and may act impulsively, they are frequently involved in fights. They show loyalty to few if any other people and are likely to seek power over others in order to satisfy sexual desires or economic needs.

People with APD often become effective "con artists." Those with well-developed verbal abilities can often charm and fool their victims, including unsuspecting or inexperienced therapists. People with APD have no respect for what others regard as societal norms or legal constraints. They may quit jobs on short notice, move to another city, or end relationships without warning and without what others would consider good reason. Criminal activities typically include theft, selling illegal drugs and check fraud. Because persons with antisocial personality disorder make "looking out for number one" their highest priority, they are quick to exploit others. They commonly rationalize these actions by dismissing their victims as weak, stupid or unwary.

KEY TERMS

Attention-deficit/hyperactivity disorder—A learning and behavioral disorder characterized by difficulty in sustaining attention, impulsive behavior, and excessive activity.

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence in which children display physical aggression and infringe on or violate the rights of others. Youths diagnosed with conduct disorder may set fires, exhibit cruelty toward animals or other children, sexually assault others, or lie and steal for personal gain.

Psychopathy—A psychological syndrome that includes lack of a conscience or sense of guilt, lack of empathy, egocentricity, pathological lying, repeated violations of social norms, disregard of the law, shallow emotions and a history of victimizing others.

Somatization disorder—A type of mental disorder in which the patient suffers from physical complaints that serve as coping strategies for emotional distress.

Substance abuse disorder—Disorder that is characterized by: an individual's need for more of a drug or alcohol than intended, an inability to stop using by choice, and an ongoing difficulty in recovering from the effects of the substance.

Demographics

APD is estimated to affect 3% of males and 1% of females in the general United States population. Mental health professionals may diagnose 3%–30% of the population in clinical settings as having the disorder. The percentages may be even higher among prison inmates or persons in treatment for substance abuse. By some estimates, three-quarters of the prison population may meet the diagnostic criteria for APD.

Diagnosis

The diagnosis of antisocial personality disorder is usually based on a combination of a careful medical as well as psychiatric history and an interview with the patient. The doctor will look for recurrent or repetitive patterns of antisocial behavior. He or she may use a diagnostic questionnaire for APD, such as the Hare Psychopathy Checklist, if the patient's history suggests the diagnosis. A person aged 18 years or older with a

childhood history of disregard for the rights of others can be diagnosed as having APD if he or she gives evidence of three of the following seven behaviors associated with disregard for others:

- Fails to conform to social norms, as indicated by frequently performing illegal acts or pursuing illegal occupations.
- Deceives and manipulates others for selfish reasons, often in order to obtain money, sex, drugs or power. This behavior may involve repeated lying, conning or the use of false names.
- Fails to plan ahead or displays impulsive behavior, as indicated by a long succession of short-term jobs or frequent changes of address.
- Engages in repeated fights or assaults as a consequence of irritability and aggressiveness.
- Exhibits reckless disregard for safety of self or others.
- Shows a consistent pattern of irresponsible behavior, including failure to find and keep a job for a sustained length of time and refusal to pay bills or honor debts.
- Shows no evidence of sadness, regret or remorse for actions that have hurt others.

In order to meet *DSM-IV-TR* criteria for APD, a person must also have had some symptoms of conduct disorder before age 15. An adult 18 years or older who does not meet all the criteria for APD may be given a diagnosis of conduct disorder.

Antisocial behavior may appear in other mental disorders as well as in APD. These conditions must be distinguished from true APD. For instance, it is not uncommon for a person with a substance abuse disorder to lie to others in order to obtain money for drugs or alcohol. But unless indications of antisocial behavior were present during the person's childhood, he or she would not be diagnosed with antisocial personality disorder. People who meet the criteria for a substance abuse disorder as well as APD would be given a **dual diagnosis**.

Treatments

Antisocial personality disorder is highly unresponsive to any form of treatment, in part because persons with APD rarely seek treatment voluntarily. If they do seek help, it is usually in an attempt to find relief from depression or other forms of emotional distress. Although there are medications that are effective in treating some of the symptoms of the disorder, noncompliance with medication regimens or abuse of the drugs prevents the widespread use of these medications. The most successful treatment programs for APD are long-term structured residential settings in which the patient systematically earns privileges as he or she modifies behavior. In other words, if a person diagnosed with APD is placed in an environment in which they cannot victimize others, their behavior may improve. It is unlikely, however, that they would maintain good behavior if they left the disciplined environment.

If some form of individual **psychotherapy** is provided along with **behavior modification** techniques, the therapist's primary task is to establish a relationship with the patient, who has usually had very few healthy relationships in his or her life and is unable to trust others. The patient should be given the opportunity to establish positive relationships with as many people as possible and be encouraged to join **self-help groups** or prosocial reform organizations.

Unfortunately, these approaches are rarely if ever effective. Many persons with APD use therapy sessions to learn how to turn "the system" to their advantage. Their pervasive pattern of manipulation and deceit extends to all aspects of their life, including therapy. Generally, their behavior must be controlled in a setting where they know they have no chance of getting around the rules.

Prognosis

APD usually follows a chronic and unremitting course from childhood or early adolescence into adult life. The impulsiveness that characterizes the disorder often leads to a jail sentence or an early death through accident, homicide or **suicide**. There is some evidence that the worst behaviors that define APD diminish by midlife; the more overtly aggressive symptoms of the disorder occur less frequently in older patients. This improvement is especially true of criminal behavior but may apply to other antisocial acts as well.

Prevention

Measures intended to prevent antisocial personality disorder must begin with interventions in early childhood, before youths are at risk for developing conduct disorder. Preventive strategies include education for parenthood and other programs intended to lower the incidence of child abuse; Big Brother/Big Sister and similar mentoring programs to provide children at risk with adult role models of responsible and prosocial behavior; and further research into the genetic factors involved in APD.

Anxiety and anxiety disorders

Definition

Anxiety is an unpleasant emotion triggered by anticipation of future events, memories of past events, or ruminations about the self.

Description

Stimulated by real or imagined dangers, anxiety afflicts people of all ages and social backgrounds. When the anxiety results from irrational fears, it can disrupt or disable normal life. Some researchers believe anxiety is synonymous with fear, occurring in varying degrees and in situations in which people feel threatened by some danger. Others describe anxiety as an unpleasant emotion caused by unidentifiable dangers or dangers that, in reality, pose no threat. Unlike fear, which is caused by realistic, known dangers, anxiety can be more difficult to identify and to alleviate.

Rather than attempting to formulate a strict definition of anxiety, most psychologists simply make the distinction between normal anxiety and neurotic anxiety, or anxiety disorders. Normal (sometimes called objective) anxiety occurs when people react appropriately to the situation causing the anxiety. For example, most people feel anxious on the first day at a new job for any number of reasons. They are uncertain how they will be received by coworkers, they may be unfamiliar with their duties, or they may be unsure they made the correct decision in taking the job. Despite these feelings and any accompanying physiological responses, they carry on and eventually adapt. In contrast, anxiety that is characteristic of anxiety disorders is disproportionately intense. Anxious feelings interfere with a person's ability to carry out normal or desired activities. Many people experience stage fright—the fear of speaking in public in front of large groups of people. There is little, if any, real danger posed by either situation, yet each can stimulate intense feelings of anxiety that can affect or derail a person's desires or obligations. Sigmund Freud described neurotic anxiety as a danger signal. In his id-ego-superego scheme of human behavior, anxiety occurs when unconscious sexual or aggressive tendencies conflict with physical or moral limitations.

According to a standard manual for mental health clinicians, the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revised (also known as the *DSM-IV-TR*), the following disorders are considered anxiety disorders:

- **Panic disorder** without agoraphobia—A person with this disorder suffers from recurrent panic attacks and worries about experiencing more attacks, but **agoraphobia** is not present. Panic attacks are sudden attacks of intense fear or apprehension during which the sufferer may experience shortness of breath, increased heart rate, choking, and/or a fear of losing control. Agoraphobia is anxiety about places or situations from which escape might be difficult, or in which help might not be available.
- Panic disorder with agoraphobia—A person with this disorder also experiences recurrent panic attacks but also has agoraphobia. The anxiety about certain places or situations may lead to avoidance of those places or situations.
- Agoraphobia without history of panic disorder—The person with this disorder suffers from agoraphobia and experiences panic-like symptoms but does not experience recurring panic attacks.
- **Specific phobias**—A person diagnosed with a specific phobia suffers from extreme anxiety when he or she is exposed to a particular object or situation. The feared stimuli may include: particular animals (dogs, spiders, snakes, etc.), situations (crossing bridges, driving through tunnels), storms, heights, and many others.
- Social phobia—A person with **social phobia** fears social situations or situations in which the individual is expected to perform. These situations may include eating in public or speaking in public, for example.

- **Obsessive-compulsive disorder**—A person with this disorder feels anxiety in the presence of a certain stimulus or situation, and feels compelled to perform an act (a **compulsion**) to neutralize the anxiety. For example, upon touching a doorknob, a person may feel compelled to wash his or her hands four times, or more.
- **Post-traumatic stress disorder**—This disorder may be diagnosed after a person has experienced a traumatic event, and long after the event, the person still mentally re-experiences the event along with the same feelings of anxiety that the original event produced.
- **Acute stress disorder**— Disorder with similar symptoms to post-traumatic stress disorder, but is experienced immediately after the traumatic event. If this disorder persists longer than one month, the **diagnosis** may be changed to post-traumatic stress disorder.
- **Generalized anxiety disorder**—A person who has experienced six months or more of persistent and excessive worry and anxiety may receive this diagnosis.
- Anxiety due to a general medical condition—Anxiety that the clinician deems is caused by a medical condition.
- Substance-induced anxiety disorder—Symptoms of anxiety that are caused by a drug, a medication, or a toxin.
- Anxiety disorder not otherwise specified—This diagnosis may be given when a patient's symptoms do not meet the exact criteria for each of the above disorders as specified by *DSM-IV-TR*.

Anxiety reduction techniques

Definition

Anxiety reduction techniques are skills that are taught by a therapist to help an individual overcome anxiety, **stress**, and tension. Anxiety can be experienced in a variety of ways including tension, worry, and nervousness, and can occur in thoughts or experienced as bodily senations. The techniques to reduce anxiety can include relaxation, visualization and imagery, diaphragmatic breathing, stress inoculation, and **meditation**.

Relaxation or progressive relaxation

This anxiety reduction technique is based on the premise that anxiety and stress are associated with muscle tension. When one achieves deep muscle relaxation, muscle tension is reduced, and this relaxed state is incompatible with anxiety.

Visualization and imagery

This anxiety reduction technique aids the person in making a mental image of what he or she wants to accomplish. For example, a person might wish to release worries or concerns, or create a relaxing image to escape momentarily from a stressful event.

Diaphragmatic breathing

This technique involves teaching a person to breathe sufficient amounts of air to help the person's blood be purified properly and filled with oxygen. In this technique, the individual breathes deeply from the diaphragm, which is located low in the chest, near the abdomen.

Stress inoculation

Self-talk, or the things that people tell themselves about stressful situations, can be habitual. For example, a person may take an ordinary event and automatically magnify its importance. Stress inoculation training is a type of therapy that trains clients to cope with anxiety and stressful situations by learning more functional patterns of self-talk.

Meditation

In this anxiety reduction technique, a person is trained to focus his or her attention on one thing at a time.

Purpose

The goal of learning and implementing anxiety reduction techniques is to help reduce the intensity of anxiety that a person feels. These techniques are also helpful in teaching people how to relax and manage stress. Many of the techniques are used in combination with each other. For example, a person may be taught diaphragmatic breathing while also engaging in relax-

ation techniques, a visualization and imagery exercise, and/or meditation.

Relaxation or progressive relaxation

Relaxation has been used to help women during childbirth and people with chronic pain. Relaxation has also been used to treat muscle tension, muscle spasms, neck and back pain, and to decrease perspiration and respiratory rates. Furthermore, relaxation can help with **fatigue**, depression, **insomnia**, irritable bowel syndrome, high blood pressure, mild phobias, and **stuttering**.

Visualization and imagery

Visualization and imagery techniques have been helpful in treating general or specific anxiety, headaches, muscle tension and spasms, reducing or eliminating pain, and in the recovery from illnesses and injuries. Visualization and imagery techniques have also been used by athletes to help them achieve peak performance.

Diaphragmatic breathing

Diaphragmatic breathing has been found to help people reduce anxiety, depression, irritability, muscle tension, circulation, and fatigue.

Stress inoculation

Stress inoculation has been helpful in reducing interpersonal and general anxiety. For example, these techniques may be used when a person has an upcoming job interview, speech, or test. Stress inoculation has also been used to treat phobias, fear of heights, and chronic anger problems.

Meditation

Meditation has been used to treat and prevent high blood pressure, heart disease, strokes, migraine headaches, immunization diseases, obsessive thinking, attention problems, anxiety, depression, and anger difficulties.

Description

These various techniques are often practiced and demonstrated in therapy sessions with a trained professional. In addition, the person learning the techniques would need to continue to practice them on a regular basis, outside of the therapy sessions.

Relaxation or progressive relaxation

In progressive relaxation, a person is instructed to tighten and then relax various muscles. A person either lies down or sits in a chair with his or her head supported. Each muscle group (such as face muscles, arm muscles, leg muscles, etc.) is tensed for five to seven seconds and then relaxed for 20 to 30 seconds. This helps the person recognize the feeling of tense and relaxed muscles. This entire procedure is repeated one to five times, and usually starts with the face muscles and moves downward to the foot muscles. When relaxation is used with chronic pain and childbirth, the techniques focus the person's attention on breathing and relaxing muscles as a distraction from the pain. For mastery, relaxation techniques are typically practiced every day for one to two weeks. A person may engage in these techniques anywhere from 15 minutes to an hour per session. Sometimes, a person will record and replay instructions on tightening and relaxing various muscle groups until the person becomes familiar with the muscle groups and establishes a routine in which he or she is comfortable.

Visualization and imagery

The basic premise behind visualization and imagery is that one's thoughts become reality. For example, if one thinks anxious thoughts, then he or she will become tense. The principles behind visualization and imagery maintain that a person can use his or her imagination to be persuaded to feel a certain way or do anything that is physically possible to do. There are three basic types of visualization: programmed, receptive, and guided visualization.

In programmed visualization, the person creates a vivid image including sight, taste, sound, and smell. The person then imagines a goal he or she wants to attain or some type of healing that is desired. In the visualization, the goal is achieved, or the healing occurs.

An idea underlying both receptive visualization and guided visualization is that the person is seeking an answer to a life question or resolution to an issue, and the answer or resolution is within the person, but is buried or inaccessible to him or her because of fear, doubt, or anxiety. These techniques are similar to dream interpretation and free association techniques used in **psychoanalysis** or psychodynamic therapy. For example, an individual wonders whether he should remain in his current position. A proponent of these techniques would maintain that "deep down," below the level of conscious thought or subconsciously, the man knows what he really wants to do, but he is not allowing himself to listen to his desires or to act—he is blocking the message his subconsciousness is sending him. The goal of these techniques is to enable the person to relax and focus enough to receive that message, so that the person can do what needs to be done. In receptive visualization, the person creates a peaceful scene in his or her mind. For example, the person might imagine being on a beach. After the

image is formed, the person asks a question and waits for the answer. To continue the example above, the man imagines a beach, and he asks himself the question, "Should I leave my job?" He continues to relax and remain in the scene, and he may "hear" an answer blowing in the breeze or "see" a boat sailing away, which may be symbolic of his wish to leave his job.

In guided visualization, the person creates a very vivid image, as in programmed visualization, but omits some important elements. The person then waits for the subconscious to supply the missing pieces. For example, a computer programmer may wonder if she should stay in her present job or return to school for an advanced degree. In engaging in guided visualization, she may visualize her cubicle at work, the pictures on her desk, the feel of her desk chair, the sounds of people outside her cubicle typing and talking, but she will omit an element from the scene. In this case, she may omit her computer. She will then wait to see what her subconscious uses to replace her computer. This woman may find in her visualization that her computer has been replaced by books, which may represent her desire to return to school.

Visualization and imagery exercises work best when a person is relaxed. Visualization and imagery exercises are typically practiced two to three times a day for 10 to 20 minutes at a time. How quickly a person will see results can vary. Many times people report immediate symptom relief. However, the goals a person sets for him or herself, the power of a person's imagination, and the willingness to practice can all influence how rapidly benefits can be obtained. Some people find it helpful to tape record and replay detailed descriptions of what they want to visualize or imagine.

Diaphragmatic breathing

Diaphragmatic breathing can typically be learned in minutes; however, the benefits may not be recognized until after several months of persistent practice. When breathing from the diaphragm, clients are often told to lie down on a rug or blanket, with their legs slightly apart, arms to the sides, not touching the body, and eyes closed. Attention is brought to the client's breathing by placing one hand on the chest and the other hand on the abdomen area. The client is then instructed to breathe through the nose and exhale out the mouth. Each time the client breathes in, he or she should try to breathe deeper. This should be practiced for a minimum of five minutes once or twice a day. Over a few weeks of practice, the time period engaged in diaphragmatic breathing should be increased to 20 minutes and the activity can be performed while lying down, sitting, or standing.

Stress inoculation

As people go about their daily lives, they often have thoughts in which they are talking to themselves. Stress inoculation involves this self-talk in helping clients decrease their anxiety and stress. Stress inoculation therapy works on the basis of turning the client's own thought patterns into a "vaccine" against stress-induced anxiety. The first step is to develop a list of stressful situations and arrange them from least to most stressful. Once anxiety-producing situations are identified, the client is taught to curb the anxiety-provoking thoughts and replace them with more positive coping thoughts. Once these new thoughts are learned, they can be tried out in real situations. The time it takes to replace old habitual thoughts with new thoughts can vary depending on the amount of practice and commitment to make this change.

Meditation

There are various forms of meditation. Depending on the type used, the person focuses his or her attention in slightly different ways. For example, Zen meditation focuses on breathing, whereas in transcendental meditation, the person makes a sound or says a mantra selected to keep all other images and problems from intruding on his or her thoughts. With practice, a person can reach a meditative state and obtain its benefits within a few minutes.

Aftercare

After a person has learned and practiced anxiety reduction techniques, he or she may need additional instruction from a trained professional. Having a trained professional review these techniques with a person can help reinforce what the person has already learned and been practicing. Furthermore, the person may identify aspects of the techniques that he or she is doing incorrectly, areas that need more attention or focus, and alternative methods of engaging in the techniques.

Risks

There are minimal risks associated with these techniques, but some physical problems have occurred. For example, precautions should be taken when doing progressive relaxation and tensing the neck and back. Excessive tightening can create muscle or spinal damage. Additionally, tightening various muscle groups, such as the toes or feet, could result in muscle cramps. If physical problems occur, such as difficulty taking deep breaths, unusual muscle pain, or an increased level of anxiety, then the individual should seek assistance from a physician.

Normal results

In general, after engaging in these anxiety reduction techniques, many people report an increased sense of well-being and relaxation. People have a greater sense of control, and confidence in their coping abilities. This results in a decreased need to fear or avoid stressful situations.

Relaxation or progressive relaxation

Progressive relaxation can be useful in reducing muscle tension. Engaging in relaxation may help to improve a person's energy level, depression, and anxiety, as well as a person's ability to retrieve information from memory.

Visualization and imagery

By engaging in the positive thinking often associated with visualization and imagery, a person can create a clearer image of what he or she wants to accomplish. By repeating the image again and again, the person comes to expect what he or she wants will occur. As a result, the person will often begin to act in a way more consistent with accomplishing the goal.

Diaphragmatic breathing

Sufficient amounts of air reach the lungs, which purifies and oxygenates the blood. Waste products in the blood are removed, and organs and tissues become nourished.

Stress inoculation

A person will have more realistic views of stressful and anxiety-producing situations in his or her life. The person will be able to relax away tension by effectively thinking useful coping thoughts rather than negative interpretations of situations.

Meditation

As people learn to meditate, they often discover that they have some control over the thoughts that come to their minds, as opposed to feeling as though thoughts "pop" into their heads. Many people begin to recognize dysfunctional patterns of thought and perceptions that have influenced their lives. Additionally, many people report a greater ability to manage their emotions and gain a greater sense of stability. When a person meditates, he or she often suppresses the activity of the sympathetic nervous system, the part of the nervous system that activates the body for emergencies and activities. Meditation also lowers a person's metabolism, heart, and breathing rates. Additionally, meditation decreases the chemical in the body often associated with stress.

Abnormal results

Once a person begins to implement these anxiety reduction techniques effectively, he or she may discover old or hidden psychological pain. The person may feel angry, frightened, or depressed, and it may be beneficial for him or her to talk to a friend, mental health professional, or meditation teacher.

Some individuals have difficulty with various aspects of the different techniques. For example, people may feel restless when first learning how to meditate, or they may feel as though a thousand thoughts are running through their minds. However, with practice and assistance from a trained professional, these difficulties will subside. People who feel frustrated or discouraged may simply need to find ways to make the practice of these techniques more comfortable. As is the case with many other skills, effectively reducing anxiety with these techniques requires patience and practice. If an individual does not consistently practice these techniques, the benefits will probably not be obtained.

Apathy

Definition

Apathy can be defined as an absence or suppression of emotion, feeling, concern or passion. Further, apathy is an indifference to things generally found to be exciting or moving.

Description

A strong connection exists between apathy and mental disorders. Apathy is one of the hallmark symptoms of **schizophrenia**. Many people with schizophrenia express little interest in the events surrounding them. Apathy can also occur in **depression and depressive disorders**. For example, people who are depressed and have **major depressive disorder** or **dysthymic disorder** often feel numb to events occurring around them, and do not derive pleasure from experiences that they once found enjoyable.

The World Health Organization (WHO) defines health as an optimal state of being that maximizes one's potential for physical, mental, emotional and spiritual growth. It does not confine health to physical parameters or measures. Passion, interest and action are needed for optimal mental and emotional health. Persons who are apathetic would seem to fall short of the WHO definition of health.

All people may experience periods of apathy. Disappointment and dejection are elements of life, and apathy is a normal way for humans to cope with such stresses— to be able to "shrug off" disappointments enables people to move forward and try other activities and achieve new goals. When the stresses pass, the apparent apathy also disappears. A period of apathy can also be viewed as a normal and transient phase through which many adolescents pass.

It is important to note, however, that long-term apathy and detachment are not normal.

Treatment

Transient apathy can be overcome. Friends and professionals may be able to assist individuals to develop an interest in their surroundings. Attitude is important. Persons who desire to overcome apathy have much higher odds of succeeding than do persons lacking a positive attitude.

Other than support, no specific treatment is needed for apathy associated with adolescence, unless other, more troubling disorders are also present.

The treatment of more persistent apathy (in a depressive disorder, for example), or the apathy that is characteristic of schizophrenia, may respond to treatment for the primary disorder.

DEPRESSION. For depressive disorders, a number of antidepressants may be effective, including tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs) and selective serotonin reuptake inhibitors (SSRIs). The tricyclic antidepressants include **amitriptyline** (Elavil), **imipramine** (Tofranil), and **nortriptyline** (Aventyl, Pamelor). MAOIs include **tranylcypromine** (Parnate) and **phenelzine** (Nardil). The most commonly prescribed SSRIs are **fluoxetine** (Prozac), **sertraline** (Zoloft), **paroxetine** (Paxil), **fluvoxamine** (Luvox), and **citalopram** (Celexa).

SCHIZOPHRENIA. For schizophrenia, the primary goal is to treat the more prominent symptoms (**positive symptoms**) of the disorder, such as the thought disorder and **hallucinations** that patients experience. Atypical antipsychotics are newer medications introduced in the 1990s that have been found to be effective for the treatment of schizophrenia. These medications include **clozapine** (Clozaril), **risperidone** (Risperdal), **quetiapine** (Seroquel), **ziprasidone** (Geodon), and **olanzapine** (Zyprexa). These newer drugs are more effective in treating the **negative symptoms** of schizophrenia (such as apathy) and have fewer side effects than the older antipsychotics. Most atypical antipsychotics, however, do have weight gain as a side effect; and patients taking clozapine must have their blood monitored periodically for signs of agranulocytosis, or a drop in the number of white blood cells.

KEY TERMS

Appetite suppressants—Medications that assist in weight loss by reducing appetite or increasing the sensation of fullness

Dexfenfluramine (Redux)—A prescription appetite suppressant for weight loss that was withdrawn from the market due to unacceptable health risks.

Diethylpropion (Tenuate, Tenuate dospan)—A prescription appetite suppressant currently on the market for weight loss.

"Fen/phen"—The commonly used name for a combination of fenfluramine and phentermine that is no longer available due to the withdrawal of fenfluramine from the market.

Fenfluramine (Pondimin)—A prescription appetite suppressant for weight loss that was withdrawn from the market due to unacceptable health risks.

Insulin resistance—The body's inability to utilize blood sugar, at times leading to diabetes

Mazindol (Sanorex, Mazanor)—A prescription medication for weight loss currently on the market.

Orlistat (Xenical)—A prescription medication for weight loss currently on the market.

Phendimetrazine (Bontril, Plegine, Prelu-2, X-Trozine)—A prescription appetite suppressant for weight loss currently on the market.

Phentermine (Adipex-P, Fastin, Ionamin, Obytrim)—A prescription appetite suppressant currently on the market for weight loss.

Primary pulmonary hypertension (PPH)—A rare but potentially fatal disorder that affects the blood vessels in the lungs

Triglycerides—Fats in the blood

Appetite suppressants

Definition

Appetite-suppressant medications are drugs that promote weight loss by decreasing appetite or increasing the sensation of fullness.

Description

Obesity is a disease that affects millions of American adults, adolescents, and children, posing serious health risks. Medical professionals generally consider obesity to be a chronic illness requiring life-long treatment and management. It is often grouped with other chronic conditions, such as high blood pressure and diabetes, as a condition that can be controlled but not cured. One is considered obese if 20% over ideal body weight, according to standard height-weight charts, or if one's Body Mass Index, or BMI, (a ratio of height to weight, indicaating the amount of fat tissue in the body) exceeds 30%.

The most important strategies for managing obesity are not medications but rather, a healthy diet coupled with moderate exercise. As in other chronic conditions, the use of prescription medications may assist in managing the condition for some individuals but it is never the sole treatment for obesity, nor is it ever considered a cure.

The class of medications used most often for weight loss are commonly referred to as "appetite suppressants."

These medications promote weight loss by helping to diminish appetite, and/or by increasing the subjective feeling of fullness. They work by increasing serotonin or catecholamines, two **neurotransmitters** (chemicals) in the **brain** that affect both mood and appetite.

Several prescription medications are currently approved for treatment of obesity. In general, the effects of these medications are modest, leading to an average initial weight loss of between 5 and 22 pounds; though studies show that weight returns after cessation of the drugs. There is considerable individual difference in response to these medications; some people experience greater weight loss than others. The goal of prescribing weight loss medication is to help the medically at-risk obese patient "jump-start" their weight loss effort and lose 10% or more of their starting body weight. When this can be accomplished, it usually leads to a reduction in risk for obesity-related illnesses, such as high blood pressure, heart disease and diabetes. Weight loss tends to be greatest during the first few weeks or months of treatment, leveling off after about six months. Research suggests that if a patient does not lose at least four pounds during the first four weeks on a particular medication, that medication is unlikely to be effective over the long run. Few studies have addressed safety or effectiveness of medications taken for more than a few months at a time. Little data exists on the long-term effectiveness of the drugs.

All but two of the prescription appetite suppressants in the United States have been approved by the U.S. Food and Drug Administration (FDA), for short-term use only. Short-term use generally means a few weeks or months at the longest. One appetite suppressant medication was approved for longer-term use within the past decade, but that drug, dexfenfluramine (Redux) was withdrawn from the market because of unacceptable risks associated with its use.

Another medication was approved within the past few years for longer-term use, up to a year and possibly longer, in significantly obese patients. This drug, an appetite suppressant, is called sibutramine (Meridia). Individuals with a history of heart disease, irregular heartbeat, high blood pressure, or history of **stroke** should not take sibutramine. All patients taking this medication should have their blood pressure monitored regularly.

A relatively new drug, orlistat (Xenical), was approved in 1999 by the FDA for at least a year or longer, as well. Orlistat is not an appetite suppressant, but rather, a member of a new class of anti-obesity drugs known as "lipase inhibitors." These medications work by preventing enzymes in the gastrointestinal tract from breaking down dietary fats into smaller molecules that can be absorbed by the body. The result is that fat absorbed from food is decreased by about 30%. This effectively reduces the calories absorbed by the body by 30%, aiding in weight loss.

While the FDA regulates how a medication can be advertised or promoted by the manufacturer, these regulations do not constrain physicians from prescribing them as they believe appropriate. This practice of prescribing medications for conditions other than those for which they were approved, or at different dosages, or for different lengths of time, is known as "off-label" use. Many of the prescription medications available for weight management are used in an "off-label" manner.

Most of the side effects of prescription medications for weight loss are mild; but some very serious complications have been reported in recent years. They were so serious that two medications were voluntarily removed from the market by the manufacturers in 1997.These two medications, fenfluramine (Pondimin), and dexfenfluramine (Redux), were shown to be associated with a rare but very serious and potentially fatal disorder known as primary pulmonary hypertension (PPH), a disease of the lungs. Forty-five percent of patients with PPH die within four years of **diagnosis**.

Medications for weight loss

Prescription medications

Prescription medications currently prescribed for weight loss include:

- Generic name: Diethylpropion (Trade names: Tenuate, Tenuate dospan)
- Generic name: Mazindole (Trade name: Sanorex)
- Generic name: Orlistat (Trade name: Xenical)
- Generic name: Phendimetrazine (Trade names: Bontril, Plegine, Prelu-2, X-Troxine)
- Generic name: Phentermine (Trade name: Adipex-P, Fastin, Ionamin, Oby-trim)
- Generic name: Sibutramine (Trade name: Meridia)

Some antidepressant medications have been studied for use as possible appetite depressants, because they frequently depress appetite in the early weeks and months of use. Research indicates, however, that while individuals may lose weight initially during antidepressant treatment, a tendency to lose only modest amounts of weight arises after six months. Furthermore, most patients who lose weight early in antidepressant medication treatment tend to regain the weight while still using the medication.

Amphetamines and similar medications were frequently prescribed in the United States, during the 1960s

and 70s, as appetite suppressants. However, because of their addictive potential, they are not prescribed today for weight control, except by a remainder of "diet doctors" who defy political correctness and continue to distribute them.

SINGLE DRUG TREATMENT. The medications listed above are currently used to treat obesity. In general, these medications are modestly effective, especially when used in conjunction with a healthy diet and moderate exercise. Average weight losses between five and 22 pounds can be expected beyond those seen with non-drug obesity treatments, when only a low-calorie diet and exercise regimen are followed. There is considerable individual variation in response to weight-loss medications; some people experience more weight loss than others.

COMBINED DRUG TREATMENT. Combined drug treatment using fenfluramine and phentermine ("fen/phen") is no longer available due to the withdrawal of fenfluramine from the market. There is little information about the safety or effectiveness of other prescription drug combinations for weight loss. Until further research is conducted on safety or effectiveness, using combinations of medications for weight loss is not advised unless a patient is participating in a research study.

POTENTIAL BENEFITS OF APPETITE SUPPRESSANT TREATMENT. Short-term use of appetite suppressant medications has been shown to modestly reduce health risks for obese individuals. Studies have found that these medications can lower blood pressure, blood cholesterol, blood fats (triglycerides), and decrease insulin resistance (the body's ability to utilize blood sugar). Long-term studies need to be conducted to determine if weight loss assisted by appetite suppressant medications can improve health long-term.

POTENTIAL RISKS OF APPETITE SUPPRESSANT TREATMENT. All prescription medications used to treat obesity, with the exception of orlistat, are controlled substances. This means that doctors need to follow rigid guidelines when prescribing them. Although abuse and dependence are uncommon with non-amphetamine appetite suppressant medications, doctors need to exercise caution when prescribing them, especially for patients with a history of alcohol or drug abuse.

DEVELOPMENT OF TOLERANCE. Studies of appetite suppressant medications indicate that an individual's weight tends to level off after four to six months of treatment. While some patients and doctors may be concerned that this indicates growing tolerance to the medications, the leveling off may indicate that the medication has reached its limit of effectiveness. Current research is not clear regarding whether weight gained with continued medication is due to drug tolerance, or to reduced effectiveness of the medication over time.

Dexfenfluramine (Redux) was withdrawn from the market. The medication was shown to be associated with a rare but very serious and potentially fatal disorder known as primary pulmonary hypertension (PPH), a disease of the lungs. *(Miller/Custom Medical Stock Photo. Reproduced by permission.)*

SIDE EFFECTS. Because obesity is a condition affecting millions of Americans, many of whom are basically healthy, the side effects of using powerful medications such as appetite suppressants are of great concern. Most side effects of these medications are mild and diminish as treatment continues. Rarely, serious and even fatal outcomes have been reported. The FDA-approved appetite suppressant medications that affect serotonin (fenfluramine and dexfenfluramine) have been withdrawn from the market. Medications that affect catecholamine levels (such as phentermine, dietylpropion, and mazindol) may cause symptoms of sleeplessness, nervousness, and euphoria.

Primary pulmonary hypertension (PPH) is a rare but potentially fatal disease that affects the blood vessels in the lungs and causes death within four years in 45% of its victims. Patients who use the appetite suppressant medications that are prescribed for a use of three months are at increased risk of developing this condition if used longer. Estimates are that between 1 in 22,000 and 1 in 44,000 individuals will develop the disorder each year. While the risk of developing PPH is very small, doctors and patients should be aware of this potentially deadly complication when they consider the risks and benefits of using appetite suppressant medications for long-term treatment of obesity. Patients taking appetite suppressants should contact their doctors if they experience shortness of breath, chest pain, faintness, or swelling in the lower legs and ankles. The vast majority of cases of PPH related to appetite suppressant use have occurred in patients taking fenfluarmine or dexfenfluramine, either alone or in combination with each other or other drugs, such as phentermine. There have been only a few cases of PPH reported among patients taking phentermine alone, although the

possibility that phentermine alone may be associated with PPH cannot be ruled out at this time.

Animal research has suggested that appetite suppressant medications affecting the neurotransmitter serotonin, such as fenfluramine and dexfenfluramine, can damage the central nervous system. These findings have not been reported in humans. Some patients have reported depression or memory loss when using appetite suppressant medications alone or in combination, but it is not known if these problems are actually caused by the medications or by other factors.

Over-the-counter appetite suppressants

In addition to the numerous prescription medications for weight loss, a few over-the-counter agents are marketed for weight loss. The most common, phenylpropanalomine, is an appetite suppressant that is distantly related to the amphetamines. Like the amphetamines, this drug has the side effect of increased blood pressure and heart rate, and thus should not be used by anyone with hypertension or heart disease. Other over-the-counter medications contain fiber or bulking agents, and presumably work by increasing the sensation of fullness. Some preparations contain the anesthetic benzocaine. This agent numbs the mouth and may make eating less appealing temporarily. No evidence exists that any of these medications is effective in producing significant weight loss.

Aromatherapy

Definition

Aromatherapy is a holistic treatment based on the external use of essential aromatic plant oils to maintain and promote physical, physiological, and spiritual well-being. The essential oils may be used in massage, added to a warm bath, used to moisten a compress that is applied to the affected part of the body, added to a vaporizer for inhalation, or diffused throughout a room.

The term aromatherapy (*aromatherapie* in the original French) was coined in 1928 by a French chemist, René Maurice Gattefossé, to describe the therapeutic use of aromatic substances (essential oils) in wound healing. Gattefossé discovered the healing properties of essential plant oils accidentally; after burning his hand in a laboratory accident, he found that **lavender** oil healed his burns in a very short time. He then experimented with plant oils in treating soldiers wounded in World War I, and found that there were several essential oils that speeded physical healing. As the practice of aromatherapy expanded, it came to incorporate a holistic emphasis on healing or invigorating all levels of a person's being. In the United States and Great Britain, the contemporary practice of aromatherapy is often associated with naturopathy and Western herbal medicine. In Great Britain, aromatherapy is one of the most frequently used forms of alternative medicine; in the United States, many hospital-affiliated centers for the study of complementary and alternative medicine (CAM) offer aromatherapy as well as other alternative approaches. Aromatherapy has also been added to holistic nursing board examinations in the United States within the last few years.

Purpose

One of the basic concepts of mind/body medicine is that a positive frame of mind helps to keep people in good health. Aromatherapists maintain that essential oils derived from plants help people to slow down, relax from **stress**, and enjoy the sensory experiences of massage, warm water, and pleasant smells. Aromatherapy is thought to improve a person's mental outlook and sense of well-being by affecting the limbic system via the olfactory nerve, or the sense of smell. The limbic system is the area of the **brain** that regulates emotions. Relaxing and pleasant smells stimulate emotional responses of pleasure and relaxation. From a holistic perspective, aromatherapy is a form of preventive health care. Most aromatherapists believe that aromatherapy should not be used as a substitute for mainstream medical or psychiatric care, but as an adjunct to it.

Aromatherapy is considered to be a useful complementary treatment for the relief of depression, anxiety, **insomnia**, **panic disorder**, stress-related physical disorders, menstrual cramps, and some gastrointestinal complaints. For example, peppermint oil calms gastrointestinal spasms when ingested, or taken by mouth. A recent Scottish study found that aromatherapy has a measurably calming effect on the symptoms of **dementia** in elderly people.

Aromatherapy can be used by itself, or combined with Swedish massage, shiatsu, acupressure, reflexology, or **light therapy** to reinforce the positive results of these treatments.

Although there are professional aromatherapists as well as practitioners of holistic medicine who offer aromatherapy among their other services, people can also use aromatherapy at home as part of self-care. There are many guides to the various techniques of aromatherapy and the proper use of essential plant oils available in inexpensive paperback editions.

Precautions

People who are interested in using essential oils at home should be careful to purchase them from reliable sources. The U. S. Food and Drug Administration (FDA) does not regulate the manufacture of essential plant oils. Consequently, instances of consumer fraud have been reported. In the case of essential oils, the most common form of fraud is substitution of synthetic compounds for natural essential oils, which are expensive to produce.

Another precaution is to avoid applying essential oils directly to the skin as a form of perfume. Some essential oils such as oil of orange or oil of peppermint are irritating to the skin if applied full-strength. When essential oils are used in massage, they are always diluted in a carrier oil.

A final precaution is to avoid taking essential oils internally without a consultation with a physician or naturopathist. Possible exceptions may be peppermint oil and aloe vera.

KEY TERMS

Carrier—A vegetable oil such as safflower, olive, grapeseed, or wheatgerm oil used to dilute essential oils for massage.

Enfleurage—A technique for extracting essential oils from flower petals by placing them on a layer of purified fat.

Essential oil—The product of special ducts or cells in the tissues of aromatic plants (or the sap of certain trees) that gives the plant its characteristic aroma and therapeutic properties. Essential oils are sometimes called volatile oils because they evaporate readily at room temperature.

Limbic system—A group of structures in the brain that includes the amygdala, hippocampus, olfactory bulbs, and hypothalamus. The limbic system is associated with homeostasis and the regulation and arousal of emotions.

Maceration—A technique for extracting essential oils from plant leaves and stems by crushing the plant parts and soaking them in warm vegetable oil.

Olfactory nerve—The cranial nerve that regulates the sense of smell.

Description

Essential plant oils are prepared for use in aromatherapy in several different ways. Most are prepared by steam distillation, a process in which the flowers, leaves, or other plant parts are heated by steam from boiling water. The vapors that result then pass through a condenser that separates the scented water from the essential oil, which is siphoned off into a separate container. Other methods of extracting essential oils include expression, or squeezing, which is limited to citrus oils; *enfleurage*, in which flower petals are placed on a bed of purified fat that soaks up the essential oils; and maceration, in which the plant parts are crushed and covered with warm vegetable oil that absorbs the essential oils.

There are several different techniques for the use of essential oils in aromatherapy:

- Massage: This is the technique that most people associate with aromatherapy. For use in massage, essential oils are mixed with a vegetable carrier oil, usually wheatgerm, avocado, olive, safflower, grapeseed, or soya bean oil. A ratio that is commonly recommended is 2.5–5% essential oil to 95–97.5% carrier oil.
- Full-body baths: In this technique, the essential oil is added to a tubful of warm (but not hot) water as the water is running. The dosage of essential oil is usually 5–10 drops per bath.
- Hand or foot baths: These are often recommended to treat arthritis or skin disorders of the hands or feet as well as sore muscles. The hands or feet are soaked for 10–15 minutes in a basin of warm water to which 5–7 drops of essential oil have been added.
- Inhalations: This technique is used to treat sinus problems or such nasal allergies as hay fever. Two cups of water are brought to a boil and then allowed to cool for five to ten minutes. Two to five drops of essential oil are added to the steaming water, and the person leans over the container and inhales the fragrant vapors for five to ten minutes.
- Diffusion: This technique requires the use of a special nebulizer to disperse microscopic droplets of essential oil into the air, or a clay diffuser that allows the oil to evaporate into the air when it is warmed by a small votive candle or electric bulb. Diffusion is recommended for treating emotional upsets.
- Compresses: These are made by soaking four or five layers of cotton cloth in a solution of warm water and essential oil, wringing out the cloth so that it is moist but not dripping, and applying it to the affected part of the body. The compress is then covered with a layer of plastic wrap, followed by a pre-warmed towel, and kept in place for one or two hours. Aromatherapy compresses are used to treat wounds, sprains, bruises, sore muscles, menstrual cramps, and respiratory congestion.
- Aromatic salves: Salves are made by melting together 1 1/4 cup of vegetable oil and 1 oz of beeswax in a double boiler over medium heat, and adding the desired combination of essential oils.
- Internal use: Some essential oils such as oil of peppermint and cinnamon can be used to make teas or mouthwashes, or mixed with a glass of honey and water. The dose depends on the oil, but a physician, naturopathist, or other practitioner should be consulted.

Preparation

Aromatherapists recommend the use of fresh oils and oil mixtures in the techniques described above. Both essential oils and vegetable carrier oils deteriorate over time and should not be kept longer than one or two months; thus, it is best to mix only small quantities of massage oils or salves at any one time.

No special preparation for an aromatherapy treatment is required on the patient's part.

Aftercare

Aromatherapy does not require any particular form of aftercare, although many patients like to rest quietly for a few minutes after a bath or massage with essential oils.

Risks

There are no risks involved in external aromatherapy when essential oils are diluted as recommended. Not all essential oils, however, should be taken internally. Benzoin and other essential oils derived from tree resins should not be used internally.

A few cases have been reported of dissociative episodes triggered by fragrances associated with traumatic experiences. Patients in treatment for **post-traumatic stress disorder** (PTSD) or any of the dissociative disorders should consult their therapist before they use aromatherapy.

Normal results

Normal results from aromatherapy include a sense of relaxation, relief from tension, and improved well-being.

Abnormal results

Abnormal results include skin irritations or other allergic reactions to essential oils, and the development of traumatic memories associated with specific smells.

Asperger's disorder

KEY TERMS

Autistic psychopathy—Hans Asperger's original name for the condition now known as Asperger's disorder. It is still used occasionally as a synonym for the disorder.

DSM—Abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders,* a handbook for mental health professionals that includes lists of symptoms that indicate specific diagnoses. The text is periodically revised, and the latest version was published in 2000 and is called *DSM-IV-TR*, for Fourth Edition, Text Revised.

Gillberg's criteria—A six-item checklist for AS developed by Christopher Gillberg, a Swedish researcher. It is widely used in Europe as a diagnostic tool.

High-functioning autism (HFA)—A subcategory of autistic disorder consisting of children diagnosed with IQs of 70 or higher. Children with AS are often misdiagnosed as having HFA.

Nonverbal learning disability (NLD)—A learning disability syndrome identified in 1989 that may overlap with some of the symptoms of AS.

Pervasive developmental disorders (PDDs)—A category of childhood disorders that includes Asperger's syndrome and Rett's disorder. The PDDs are sometimes referred to collectively as autistic spectrum disorders.

Semantic-pragmatic disorder—A term that refers to the difficulty that children with AS and some forms of autism have with pragmatic language skills. Pragmatic language skills include knowing the proper tone of voice for a given context, using humor appropriately, making eye contact with a conversation partner, maintaining the appropriate volume of one's voice, etc.

Definition

Asperger's disorder, which is also called Asperger's syndrome (AS) or autistic psychopathy, belongs to a group of childhood disorders known as **pervasive developmental disorders** (PDDs) or autistic spectrum disorders. The essential features of Asperger's disorder are severe social interaction impairment and restricted, repetitive patterns of behavior and activities. It is similar to **autism**, but children with Asperger's do not have the same difficulties in acquiring language that children with autism have.

In the mental health professional's diagnostic handbook, the ***Diagnostic and Statistical Manual of Mental Disorders*** fourth edition text revised, or *DSM-IV-TR*, Asperger's disorder is classified as a developmental disorder of childhood.

Description

AS was first described by Hans Asperger, an Austrian **psychiatrist**, in 1944. Asperger's work was unavailable in English before the mid-1970s; as a result, AS was often unrecognized in English-speaking countries until the late 1980s. Before *DSM-IV* (published in 1994) there was no officially agreed-upon definition of AS. In the words of ICD-10, the European equivalent of the *DSM-IV,* Asperger's is "a disorder of uncertain nosological validity." (Nosological refers to the classification

of diseases.) There are three major reasons for this lack of clarity: differences between the diagnostic criteria used in Europe and those used in the United States; the fact that some of the diagnostic criteria depend on the observer's interpretation rather than objective measurements; and the fact that the clinical picture of Asperger's changes as the child grows older.

Asperger's disorder is one of the milder pervasive developmental disorders. Children with AS learn to talk at the usual age and often have above-average verbal skills. They have normal or above-normal intelligence and the ability to feed or dress themselves and take care of their other daily needs. The distinguishing features of AS are problems with social interaction, particularly reciprocating and empathizing with the feelings of others; difficulties with nonverbal communication (such as facial expressions); peculiar speech habits that include repeated words or phrases and a flat, emotionless vocal tone; an apparent lack of "common sense" a fascination with obscure or limited subjects (for example, the parts of a clock or small machine, railroad schedules, astronomical data, etc.) often to the exclusion of other interests; clumsy and awkward physical movements; and odd or eccentric behaviors (hand wringing or finger flapping; swaying or other repetitious whole-body movements; watching spinning objects for long periods of time).

Causes and symptoms

Causes

There is some indication that AS runs in families, particularly in families with histories of depression and **bipolar disorder**. Asperger noted that his initial group of patients had fathers with AS symptoms. Knowledge of the genetic profile of the disorder, however, is quite limited as of 2002.

In addition, about 50% of AS patients have a history of oxygen deprivation during the birth process, which has led to the hypothesis that the disorder is caused by damage to **brain** tissue before or during childbirth. Another cause that has been suggested is an organic defect in the functioning of the brain.

As of 2002, there is no known connection between Asperger's disorder and childhood trauma, **abuse** or **neglect**.

Symptoms

In young children, the symptoms of AS typically include problems picking up social cues and understanding the basics of interacting with other children. The child may want friendships but find him- or herself unable to make friends.

Most children with Asperger's are diagnosed during the elementary school years because the symptoms of the disorder become more apparent at this point. They include:

- Poor pragmatic language skills. This phrase means that the child does not use the right tone or volume of voice for a specific context, and does not understand that using humorous or slang expressions also depends on social context.
- Problems with hand-eye coordination and other visual skills.
- Problems making eye contact with others.
- Learning difficulties, which may range from mild to severe.
- Tendency to become absorbed in a particular topic and not know when others are bored with conversation about it. At this stage in their education, children with AS are likely to be labeled as "nerds."
- Repetitive behaviors. These include such behaviors as counting a group of coins or marbles over and over; reciting the same song or poem several times; buttoning and unbuttoning a jacket repeatedly; etc.

Adolescence is one of the most painful periods of life for young people with Asperger's, because social interactions are more complex in this age group and require more subtle social skills. Some boys with AS become frustrated trying to relate to their peers and may become aggressive. Both boys and girls with the disorder are often quite naive for their age and easily manipulated by "street-wise" classmates. They are also more vulnerable than most youngsters to peer pressure.

Little research has been done regarding adults with AS. Some have serious difficulties with social and occupational functioning, but others are able to finish their schooling, join the workforce, and marry and have families.

Demographics

Although the incidence of AS has been variously estimated between 0.024% and 0.36% of the general population in North America and northern Europe, further research is required to determine its true rate of occurrence—especially because the diagnostic criteria have been defined so recently. In addition, no research regarding the incidence of AS has been done on the populations of developing countries, and nothing is known about the incidence of the disorder in different racial or ethnic groups.

With regard to gender differences, AS appears to be much more common in boys. Dr. Asperger's first patients were all boys, but girls have been diagnosed with AS

since the 1980s. One Swedish study found the male/female ratio to be 4:1; however, the World Health Organization's ICD-10 classification gives the male to female ratio as 8 to 1.

Diagnosis

As of early 2002, there are no blood tests or brain scans that can be used to diagnose AS. Until *DSM-IV* (1994), there was no "official" list of symptoms for the disorder, which made its **diagnosis** both difficult and inexact. Although most children with AS are diagnosed between five and nine years of age, many are not diagnosed until adulthood. Misdiagnoses are common; AS has been confused with such other neurological disorders as Tourette's syndrome, or with attention-deficit disorder (ADD), **oppositional defiant disorder** (ODD), or **obsessive-compulsive disorder** (OCD). Some researchers think that AS may overlap with some types of learning disability, such as the nonverbal learning disability (NLD) syndrome identified in 1989.

The inclusion of AS as a separate diagnostic category in *DSM-IV* was justified on the basis of a large international field trial of over a thousand children and adolescents. Nevertheless, the diagnosis of AS is also complicated by confusion with such other diagnostic categories as "high-functioning (IQ higher than 70) autism" or HFA, and "schizoid personality disorder of childhood." Unlike **schizoid personality disorder** of childhood, AS is not an unchanging set of personality traits—AS has a developmental dimension. AS is distinguished from HFA by the following characteristics:

- Later onset of symptoms (usually around three years of age).
- Early development of grammatical speech; the AS child's verbal IQ (scores on verbal sections of standardized **intelligence tests**) is usually higher than performance IQ (how well the child performs in school). The reverse is usually true for autistic children.
- Less severe deficiencies in social and communication skills.
- Presence of intense interest in one or two topics.
- Physical clumsiness and lack of coordination.
- Family is more likely to have a history of the disorder.
- Lower frequency of neurological disorders.
- More positive outcome in later life.

DSM-IV-TR criteria for Asperger's disorder

The *DSM-IV-TR* specifies the following diagnostic criteria for AS:

- The child's social interactions are impaired in at least two of the following ways: markedly limited use of nonverbal communication (facial expressions, for example); lack of age-appropriate peer relationships; failure to share enjoyment, interests, or accomplishment with others; lack of reciprocity (turn-taking) in social interactions.
- The child's behavior, interests, and activities are characterized by repetitive or rigid patterns, such as an abnormal preoccupation with one or two topics, or with parts of objects; repetitive physical movements; or rigid insistence on certain routines and rituals.
- The patient's social, occupational, or educational functioning is significantly impaired.
- The child has normal age-appropriate language skills.
- The child has normal age-appropriate cognitive skills, self-help abilities, and curiosity about the environment.
- The child does not meet criteria for another specific PDD or schizophrenia.

To establish the diagnosis, the child psychiatrist or **psychologist** would observe the child, and would interview parents, possibly teachers, and the affected child (depending on the child's age), and would gather a comprehensive medical and social history.

Other diagnostic scales and checklists

Other instruments that have been used to identify children with AS include Gillberg's criteria, a six-item list compiled by a Swedish researcher that specifies problems in social interaction, a preoccupying narrow interest, forcing routines and interests on the self or others, speech and language problems, nonverbal communication problems, and physical clumsiness; and the Australian Scale for Asperger's Syndrome, a detailed multi-item questionnaire developed in 1996.

Brain imaging findings

As of 2002, only a few structural abnormalities of the brain have been linked to AS. Findings include abnormally large folds in the brain tissue in the left frontal region, abnormally small folds in the operculum (a lid-like structure composed of portions of three adjoining brain lobes), and damage to the left temporal lobe (a part of the brain containing a sensory area associated with hearing). The first single photon emission tomography (SPECT) study of an AS patient found a lower-than-normal supply of blood to the left parietal area of the brain, an area associated with bodily sensations. Brain **imaging studies** on a larger sample of AS patients is the next stage of research.

Yoga instructor and three teenagers in an integrated movement therapy session. The teens have various pervasive developmental disorders, including Asperger's disorder and autism. These therapy sessions combine social interaction and movement, both of which are beneficial for adolescents with autistic disorders. *(AP Photo/Cheryl Hatch. Photo reproduced by permission.)*

Treatments

As of 2002, there is no cure for AS and no prescribed treatment regimen for all AS patients. Specific treatments are based on the individual's symptom pattern.

Medications

Many children with AS do not require any medication. For those who do, the drugs that are recommended most often include psychostimulants (**methylphenidate**, **pemoline**), **clonidine**, or one of the tricyclic antidepressants (TCAs) for hyperactivity or inattention; **beta blockers**, neuroleptics (antipsychotic medications), or lithium (**lithium carbonate**) for anger or aggression; selective serotonin reuptake inhibitors (SSRIs) or TCAs for rituals (repetitive behaviors) and preoccupations; and SSRIs or TCAs for anxiety symptoms. One alternative herbal remedy that has been tried with AS patients is **St. John's wort**.

Psychotherapy

AS patients often benefit from individual **psychotherapy**, particularly during adolescence, in order to cope with depression and other painful feelings related to their social difficulties. Many children with AS are also helped by **group therapy**, which brings them together with others facing the same challenges. There are therapy groups for parents as well.

Therapists who are experienced in treating children with Asperger's disorder have found that the child should be allowed to proceed slowly in forming an emotional bond with the therapist. Too much emotional intensity at the beginning may be more than the child can handle. Behavioral approaches seem to work best with these children. **Play therapy** can be helpful in teaching the child to recognize social cues as well as lowering the level of emotional tension.

Adults with AS are most likely to benefit from individual therapy using a cognitive-behavioral approach, although many also attend group therapy. Some adults have been helped by working with speech therapists on their pragmatic language skills. A relatively new approach called behavioral coaching has been used to help adults with Asperger's learn to organize and set priorities for their daily activities.

Educational considerations

Most AS patients have normal or above-normal intelligence, and are able to complete their education up through the graduate or professional school level. Many are unusually skilled in music or good in subjects requiring rote memorization. On the other hand, the verbal skills of children with AS frequently cause difficulties with teachers, who may not understand why these "bright" children have social and communication problems. Some AS children are dyslexic; others have difficulty with writing or mathematics. In some cases, AS children have been mistakenly put in special programs either for children with much lower levels of functioning, or for children with conduct disorders. AS children do best in structured learning situations in which they learn problem-solving and social skills as well as academic subjects. They frequently need protection from the teasing and bullying of other children, and often become hypersensitive to criticism by their teenage years. One approach that has been found helpful at the high-school level is to pair the adolescent with AS with a slightly older teenager who can serve as a mentor. The mentor can "clue in" the younger adolescent about the slang, dress code, cliques, and other "facts of life" at the local high school.

Employment

Adults with AS are productively employed in a wide variety of fields, including the learned professions. They do best, however, in jobs with regular routines or occupations that allow them to work in isolation. In large companies, employers or supervisors and workplace colleagues may need some information about AS in order to understand the new employee's "eccentricities."

Prognosis

AS is a lifelong but stable condition. The prognosis for children with AS is generally good as far as intellectual development is concerned, although few school districts as of 2002 are equipped to meet the special social needs of this group of children. Adults with AS appear to be at greater risk of depression than the general population. In addition, some researchers believe that people with AS have an increased risk of a psychotic episode (a period of time during which the affected person loses touch with reality) in adolescence or adult life.

Prevention

Effective prevention of Asperger's disorder awaits further genetic mapping together with ongoing research in the structures and functioning of the brain. The only practical preventive strategy as of 2002 is better protection of the fetus against oxygen deprivation during childbirth.

Assertiveness training

Definition

Assertiveness training is a form of behavior therapy designed to help people stand up for themselves—to empower themselves, in more contemporary terms. Assertiveness is a response that seeks to maintain an appropriate balance between passivity and aggression. Assertive responses promote fairness and equality in human interactions, based on a positive sense of respect for self and others.

Assertiveness training has a decades-long history in mental health and personal growth groups, going back to the women's movement of the 1970s. The approach was introduced to encourage women to stand up for themselves appropriately in their interactions with others, particularly as they moved into graduate education and the workplace in greater numbers. The original association of assertiveness training with the women's movement in the United States grew out of the discovery of many women in the movement that they were hampered by their inability to be assertive. Today, assertiveness training is used as part of communication training in settings as diverse as schools, corporate boardrooms, and psychiatric hospitals, for programs as varied as substance abuse treatment, **social skills training**, vocational programs, and responding to harassment.

Purpose

The purpose of assertiveness training is to teach persons appropriate strategies for identifying and acting on their desires, needs, and opinions while remaining respectful of others. This form of training is tailored to the needs of specific participants and the situations they find particularly challenging. Assertiveness training is a broad approach that can be applied to many different personal, academic, health care, and work situations.

Learning to communicate in a clear and honest fashion usually improves relationships within one's life. Women in particular have often been taught to hide their real feelings and preferences, and to try to get their way by manipulation or other indirect means. Specific areas of **intervention** and change in assertiveness training include conflict resolution, realistic goal-setting, and **stress** management. In addition to emotional and psychological benefits, taking a more active approach to self-determination has been shown to have positive outcomes in many personal choices related to health, including being assertive in risky sexual situations; abstaining from using drugs or alcohol; and assuming responsibility for self-care if one has a chronic illness like diabetes or cancer.

Precautions

There are a few precautions with assertiveness training. One potential caution would be to remain within assertive responses, rather than become aggressive in standing up for oneself. Some participants in assertiveness training programs who are just learning the techniques of appropriate assertiveness may "overdo" their new behaviors and come across as aggressive rather than assertive. Such overcompensation would most likely disappear with continued practice of the techniques.

One additional precaution about assertiveness training is that it should not be regarded as the equivalent of martial arts training or similar physical self-defense techniques. It is important to distinguish between contexts or situations in which verbal assertiveness is appropriate and useful, and those in which it is irrelevant. In some situations, a person's decision to leave the situation or seek help because they sense danger is preferable to an encounter with a criminal.

Description

Assertiveness training is often included within other programs, but "stand-alone" programs in self-assertion are often given in women's centers or college counseling centers. Corporate programs for new personnel sometimes offer assertiveness training as part of communication or teamwork groups, or as part of a program on sexual harassment.

Assertiveness training typically begins with an information-gathering exercise in which participants are asked to think about and list the areas in their life in which they have difficulty asserting themselves. Very often they will notice specific situations or patterns of behavior that they want to focus on during the course. The next stage in assertive training is usually role-plays designed to help participants practice clearer and more direct forms of communicating with others. The role-plays allow for practice and repetition of the new techniques, helping each person learn assertive responses by acting on them. Feedback is provided to improve the response, and the role-play is repeated. Eventually, each person is asked to practice assertive techniques in everyday life, outside the training setting. Role-plays usually incorporate specific problems for individual participants, such as difficulty speaking up to an overbearing boss; setting limits to intrusive friends; or stating a clear preference about dinner to one's spouse. Role-plays often include examples of aggressive and passive responses, in

addition to the assertive responses, to help participants distinguish between these extremes as they learn a new set of behaviors.

Assertiveness training promotes the use of "I" statements as a way to help individuals express their feelings and reactions to others. A commonly used model of an "I" statement is "when you _____, I feel _____", to help the participant describe what they see the other person as doing, and how they feel about that action. "I" statements are often contrasted with "you" statements, which are usually not received well by others. For example, "When you are two hours late getting home from work, I feel both anxious and angry," is a less accusing communication than "You are a selfish and inconsiderate jerk for not telling me you would be two hours late." Prompts are often used to help participants learn new communication styles. This approach helps participants learn new ways of expressing themselves as well as how it feels to be assertive.

Learning specific techniques and perspectives, such as self-observation skills, awareness of personal preferences and assuming personal responsibility are important components of the assertiveness training process. Role-play and practice help with self-observation, while making lists can be a helpful technique for exploring personal preferences for those who may not have a good sense of their own needs and desires. Participants may be asked to list anything from their ten favorite movies or pieces of music to their favorite foods, places they would like to visit, subjects that interest them, and so on.

Preparation

Preparation for assertiveness training varies from person to person. For some participants, no preparation is needed before practicing the techniques; for others, however, individual counseling or therapy may help prepare the individual for assertiveness training. For participants who may be more shy and feel uncomfortable saying "no" or speaking up for themselves, a brief course of individual therapy will help to prepare them psychologically and emotionally to use assertive techniques.

Aftercare

Aftercare can involve ongoing supportive therapy, again based on the individual's level of comfort in using the assertive techniques. For those who are comfortable using the techniques on their own, a supportive social network or occasional participation in a support group will be enough to help maintain the new behavioral patterns. The ultimate goal is for each participant to self-monitor effectively his or her use of assertive techniques on an ongoing basis.

KEY TERMS

Assertive—Confidently self-assured; able to express oneself constructively and directly.

Overcompensation—An attempt to overcome or correct a behavior by going too far in the opposite direction.

Role-playing—A technique used in assertiveness training and other forms of therapy in which participants act out roles relevant to real-life situations in order to change their attitudes and behaviors.

Risks

There are minimal risks associated with assertiveness training. Personal relationships may be affected if those around the participant have difficulty accepting the changes in their friend or family member. This risk, however, is no greater than that associated with any other life change.

Another potential risk is that of overcompensating in the early stages of training by being too aggressive. With appropriate feedback, participants can usually learn to modify and improve their responses.

People who are very shy or self-conscious, or who were harshly treated as children, may also experience anxiety during the training as they work toward speaking up and otherwise changing their behaviors. The anxiety may be uncomfortable, but should decrease as the person becomes more comfortable with the techniques and receives encouragement from others in the program.

Normal results

An enhanced sense of well-being and more positive self-esteem are typical results from assertiveness training. Many participants report that they feel better about themselves and more capable of handling the stresses of daily life. In addition, people who have participated in assertiveness training have a better sense of boundaries, and are able to set appropriate and healthy limits with others. Being able to set appropriate limits (such as saying "no") helps people to avoid feeling victimized by others.

A healthy sense of self-determination and respect for others is the ultimate outcome of assertiveness training. Such a balance helps each person work better with others, and make appropriate decisions for themselves.

Abnormal results

Unusual results may include becoming too aggressive in setting boundaries, as if the individual is overcompensating. With appropriate training, role-play, and feedback, this response can be re-learned. Alternatively, for very shy individuals, a heightened sense of anxiety may be experienced when using the techniques initially. The nervousness or anxiety is usually due to the individual's concern about others' reactions to their assertive responses. Over time, the anxiety will usually decrease.

Assessment and diagnosis

Definition

The psychological assessment is a structured interview that gathers information from and/or tests a person to evaluate a mental health complaint.

Purpose

The psychological assessment (also called the biopsychosocial or psychiatric assessment) gathers information to diagnose any mental disorder that the person may have; it is the first step in treating a diagnosed disorder. The process typically starts with a chief complaint or presenting problem—this is usually what prompts the person to seek help. A complete psychological assessment should include:

- biopsychosocial history
- neurological assessment
- psychological testing (if applicable)
- physical examination (if required by a **psychiatrist**)
- **brain** imaging (if necessary)

Once complete, the assessment will help establish either a tentative or definitive **diagnosis**. With this information, the clinician can inform the patient of the results, and treatment can begin.

Precautions

Accurate information gathering and objective notes are essential for psychological assessment. However, these can be difficult to obtain if the person is not willing to disclose all necessary information, either out of embarrassment or through **denial** that symptoms of a mental problem even exist.

Description

The psychological assessment, an extremely effective and accepted diagnostic tool, is a structured interview that has several parts:

- identifying information
- chief complaint (presenting problem)
- history of present illness
- past medical and psychological history
- personal history
- family history
- substance abuse history
- mental status examination (MSE)

Before beginning, the clinician should introduce himself or herself and attempt to make the person comfortable in a professional setting. A common fluency in language or competent translator is essential for information gathering and questioning.

Identifying information

These are general and emotionally neutral questions that usually include name, age, occupation, and marital status.

Chief complaint (presenting problem)

This consists of questions such as "Why are you seeking psychological help today?" that reveal past mental disorders and/or the symptoms that made the person seek **psychotherapy**. The patient's responses can also help the clinician ask pertinent questions during other parts of the interview, and can help clarify the presence of symptoms.

History of present illness

The patient describes the onset of signs and symptoms that comprise the current mental problem.

Past medical and psychological history

Because medical problems—including thyroid disease, Parkinson's disease, head trauma, and brain infections—can cause psychological symptoms, a thorough medical history must be taken. The interviewer also asks about previous psychological/psychiatric treatment, including **hospitalization**, outpatient or substance abuse treatment, and medication prescribed for mental disorders. The treatment's duration, effectiveness, and outcome is also noted.

Personal history

This portion of the assessment provides information on the patient's entire life, beginning with prenatal development, including maternal abortions, nutrition, and drug use during pregnancy; birth trauma; and birth order. The patient's life is then discussed in distinct phases:

EARLY CHILDHOOD (INFANCY–THREE YEARS). Questions include information about temperament, walking, talking, toilet training, nutrition and feeding, family relationships, behavioral problems, hospitalization, and separation from early childhood caregivers.

MIDDLE CHILDHOOD (THREE–11 YEARS). Pertinent information will be gathered concerning learning, relationship with peers and family, behavioral problems, and general personality development.

ADOLESCENCE (12–18 YEARS). Information typically includes school history, behavioral problems, and sexual development.

ADULTHOOD. This section details the patient's education, sexual history, relationships and/or marriages, peer relationships, occupation, and current circumstances.

Family history

Family history is crucially important since many mental disorders can be inherited genetically. Additionally, family interactions may affect the patient's symptoms and disorder.

KEY TERMS

Affect—The expression of emotion displayed to others through facial expressions, hand gestures, tone of voice, etc. Types of affect include: flat (inanimate, no expression), blunted (minimally responsive), inappropriate (incongruous expressions of emotion relative to the content of a conversation), and labile (sudden and abrupt changes in type and intensity of emotion).

Assessment—In the context of psychological assessment (a structured interview), assessment is information-gathering to diagnose a mental disorder.

Biopsychosocial history—A history of significant past and current experiences that influence client behaviors, including medical, educational, employment, and interpersonal experiences. Alcohol or drug use and involvement with the legal system are also assessed in a biopsychosocial history.

Delusion—A false belief that is resistant to reason or contrary to actual fact. A patient may be convinced, for example, that someone is trying to poison him or her, or that he or she has a fatal illness despite evidence to the contrary.

Dependence—The adaptation of neurons and other physical processes to the use of a drug, followed by withdrawal symptoms when the drug is removed; physiological and/ or psychological addiction.

Hallucinations—False sensory perceptions. A person experiencing a hallucination may "hear" sounds or "see" people or objects that are not really present. Hallucinations can also affect the senses of smell, touch, and taste.

Phobia—Irrational fear of places, things, or situations that lead to avoidance.

Psychotropic drug—Medication that has an effect on the mind, brain, behavior, perceptions, or emotions. Psychotropic medications are used to treat mental illnesses because they affect a patient's moods and perceptions.

Tolerance—Progressive decrease in the effectiveness of a drug with long-term use.

The psychological assessment (also called the biopsychosocial or psychiatric assessment) gathers information to diagnose any mental disorder that the person may have. A complete psychological assessment should include: complete and extensive medical and psychological history, neurological assessment, and may also include further tests and imaging studies. Once complete, the assessment will help establish a diagnosis. *(Photo by John Henley, The Stock Market. Reproduced by permission.)*

Substance use history

This portion of the psychological assessment details information on the patient's use of both illicit drugs (opiates, cocaine, alcohol, marijuana, hallucinogens, and depressants) and legally prescribed medications, as well as nicotine and caffeine. Questions usually focus on age of first use, age of last use, period of heaviest use, usage within the past 30 days, frequency, quantity, and route of usage. Tolerance and dependence, if present, are noted, as are the patient's treatment history, any medical complications (AIDS, for example), and legal problems associated with usage (such as driving or operating a vehicle or machine while impaired).

Mental Status Examination (MSE)

This assesses the patient's mental state, and begins by evaluating:

- Appearance—hygiene, general appearance, grooming, and attire.
- Behavior—abnormal movements, hyperactivity and eye contact with the interviewer.
- Speech—fluency, rate, clarity, and tone, all of which may indicate the patient's mental state. A fast-talking person, for example, may be anxious. Speech can also reveal intoxication or impairment as well as problems in the mouth (i.e. dentures, cleft palate) or speech impairment.

The examiner then goes on to assess other aspects of the patient's mental state, such as mood, thought process, and cognition, beginning with a question such as that suggested in the *Merck Manual of Geriatrics.* "I would like to ask you some questions about your feelings, your thinking, and your memory as a routine part of the examination. Is that all right with you?"

Mood and affect

These outward manifestations of the patient's mental state are important indicators. The clinician can ask the patient to describe his or her current mood ("How do you feel? Are you happy? Sad? Angry?"). The patient's affect, or emotional state, however, is observed and interpreted by the clinician throughout the interview, and described in standardized terms, such as excitable, flat, inappropriate, or labile (rapidly shifting).

Thought process and content

Thought process (or form) indicates whether or not the interviewee is properly oriented to time and place. Thought content reveals how connected, coherent, and logical the patient's thoughts are. The interviewer may ask the patient to identify themselves and loved ones, to name the current date, and/or to describe the route taken to the examiner's location. The patient's responses to questions can indicate disturbances in thought, such as circumstantial thinking (circuitous, persistent storytelling), tangential thinking (response not pertinent to the question) black/white (extreme) thinking, and impoverished (minimally responsive) thinking. Disturbed thought content can also indicate **delusions**, **hallucinations**, phobias, and obsessions. In addition, the examiner may question the patient about suicidal and/or homicidal thoughts.

Cognition

Cognition refers to the patient's attention, awareness, memory (long-, intermediate-, and short-term), general knowledge, abstract thinking ability, insight, and judgment. The interviewer may ask the patient to spell a word forward and backward, identify the current president, read and/or write something, compare two objects, and explain the meaning of common sayings.

Preparation

An evaluation session appointment is made with a qualified mental health practitioner. A specialist (someone specializing in anxiety/depressive disorders, pain management, **hypnotherapy**, or chemical dependency, for example) may be sought or recommended. A private,

quiet, nonthreatening, environment is recommended to ensure comfort and confidentiality.

Aftercare

Aftercare depends on the results of the evaluation. Treatment may be initiated and/or further tests may be required to confirm the diagnosis.

Risks

There are no known risks involved. A person seeking a mental health evaluation does so for a reason and may learn of an existing or potential mental problem.

Normal results

The patient does not require psychological therapy or psychotropic drug (medications beneficial to treat certain mental disorders) treatment.

Abnormal results

The person suffers from a mental disorder that may require psychotherapy or a combination of psychotherapy and medications.

Attention-deficit/ hyperactivity disorder

Definition

Attention-deficit/hyperactivity disorder (ADHD) is a developmental disorder characterized by distractibility, hyperactivity, impulsive behaviors, and the inability to remain focused on tasks or activities.

KEY TERMS

Antisocial personality disorder—Disorder characterized by behavior pattern of disregard for others' rights. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy or psychopathy.

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence in which children display physical aggression and infringe on or violate the rights of others. Youths diagnosed with conduct disorder may set fires, exhibit cruelty toward animals or other children, sexually assault others, or lie and steal for personal gain.

Nervous tic—A repetitive, involuntary action, such as the twitching of a muscle or repeated blinking.

Oppositional defiant disorder—An emotional and behavioral problem of children and adolescents characterized by defiant, hostile, or disobedient behavior that has lasted for longer than six months.

Description

ADHD, also known as hyperkinetic disorder (HKD) outside of the United States, is estimated to affect 3%-9% of children, and afflicts boys more often than girls. Although difficult to assess in infancy and toddlerhood, signs of ADHD may begin to appear as early as age two or three, but the symptom picture changes as adolescence approaches. Many symptoms, particularly hyperactivity, diminish in early adulthood, but impulsivity and problems focusing attention remain with up to 50% of individuals with ADHD throughout their adult life.

Children with ADHD have short attention spans, becoming easily bored and/or frustrated with tasks. Although they may be quite intelligent, their lack of focus frequently results in poor grades and difficulties in school. Children with ADHD act impulsively, taking action first and thinking later. They are constantly moving, running, climbing, squirming, and fidgeting, but often have trouble with gross and fine motor skills and, as a result, may be physically clumsy and awkward. In social settings, they are sometimes shunned due to their impulsive and intrusive behavior.

Causes and symptoms

Causes

The causes of ADHD are not known. However, it appears that heredity plays a major role in the development of ADHD. Children with an ADHD parent or sibling are more likely to develop the disorder themselves. Before birth, ADHD children may have been exposed to poor maternal nutrition, viral infections, or maternal substance abuse. In early childhood, exposure to lead or other toxins can cause ADHD-like symptoms. Traumatic **brain** injury or neurological disorders may also trigger ADHD symptoms. Although the exact cause of ADHD is not known, an imbalance of certain **neurotransmitters** (the chemicals in the brain that transmit messages between nerve cells) is believed to be the mechanism behind ADHD symptoms.

Symptoms

The **diagnosis** of ADHD requires the presence of at least six of the following symptoms of inattention, or six or more symptoms of hyperactivity and impulsivity combined:

Inattention:

- fails to pay close attention to detail or makes careless mistakes in schoolwork or other activities
- has difficulty sustaining attention in tasks or activities
- does not appear to listen when spoken to
- does not follow through on instructions and does not finish tasks
- has difficulty organizing tasks and activities
- avoids or dislikes tasks that require sustained mental effort (such as homework)
- is easily distracted
- is forgetful in daily activities

Hyperactivity:

- fidgets with hands or feet or squirms in seat
- does not remain seated when expected to
- runs or climbs excessively when inappropriate (in adolescents and adults, feelings of restlessness)
- has difficulty playing quietly
- is constantly on the move
- talks excessively

Impulsivity:

- blurts out answers before the question has been completed
- has difficulty waiting for his or her turn
- interrupts and/or intrudes on others

Further criteria to establish a diagnosis also require that some symptoms develop before age seven, and that they significantly impair functioning in two or more settings (home and school, for example) for a period of at least six months.

Many individuals with ADHD have symptoms from all three of the above categories. Some children, however, have behavior patterns in which inattention dominates, or hyperactivity and impulsivity dominate. For this reason, ADHD can be further categorized, or subdivided, into three subtypes. Children who have at least six symptoms from both of the inattention and hyperactivity-impulsivity categories above may be diagnosed with ADHD, combined type. Children who meet the symptom criteria for inattention, but not for hyperactivity/impulsivity are diagnosed with attention-deficit/hyperactivity disorder, predominantly inattentive type, commonly called ADD. Children who experience more symptoms from the hyperactivity and impulsivity categories, but fewer than six symptoms of inattention may be diagnosed with ADHD, predominantly hyperactive-impulsive type.

Diagnosis

The first step in determining if a child has ADHD is to consult with a pediatrician. The pediatrician can make an initial evaluation of the child's developmental maturity compared to other children in his or her age group. The physician should also perform a comprehensive physical examination to rule out any organic causes of ADHD symptoms, such as an overactive thyroid or vision or hearing problems.

If no organic problem can be found, a **psychologist**, **psychiatrist**, neurologist, neuropsychologist, or learning specialist is typically consulted to perform a comprehensive ADHD assessment. A complete medical, family, social, psychiatric, and educational history is compiled from existing medical and school records and from interviews with parents and teachers. Interviews may also be conducted with the child, depending on his or her age. Along with these interviews, several clinical questionnaires may also be used, such as the Conners Rating Scales (Teacher's Questionnaire and Parent's Questionnaire), Child Behavior Checklist (CBCL), and the Achenbach Child Behavior Rating Scales. These inventories provide valuable information on the child's behavior in different settings and situations. In addition, the Wender Utah Rating Scale has been adapted for use in diagnosing ADHD in adults.

It is important to note that mental disorders such as depression and anxiety disorder can cause symptoms similar to ADHD. (Depression can cause attention prob-

A special education teacher helps a student with attention-deficit/hyperactivity disorder with his math assignment. *(Photo Researchers, Inc. Reproduced by permission.)*

lems, and anxiety can cause symptoms similar to hyperactivity.) A complete and comprehensive psychological assessment is critical to differentiate ADHD from other possible mood and behavioral disorders. **Bipolar disorder**, for example, may be misdiagnosed as ADHD.

Public schools are required by federal law to offer free ADHD testing upon request. A pediatrician can also provide a referral to a psychologist or pediatric specialist for ADHD assessment. Parents should check with their insurance plans to see if these services are covered.

Treatment

Therapy that addresses both psychological and social issues (called psychosocial therapy), usually combined with medications, is the treatment approach of choice to alleviate ADHD symptoms.

Medications

Medications known as psychostimulants, such as dextroamphetamine (Dexedrine), **pemoline** (Cylert), and **methylphenidate** (Ritalin), are commonly prescribed to control hyperactive and impulsive behavior and increase attention span. These medications work by stimulating the production of certain neurotransmitters in the brain. These medications are usually well-tolerated and safe in most cases, but possible side effects of stimulants include nervous tics, irregular heartbeat, loss of appetite, and **insomnia**.

For children who do not respond well to stimulant therapy, and for children who clearly suffer from depression as well as ADHD, tricyclic antidepressants (a group of drugs used to treat depression) may be recommended. Examples of these antidepressants include **desipramine** (Norpramin, Pertofane) and **amitriptyline** (Elavil). Reported side effects of these drugs include persistent dry mouth, sedation, disorientation, and cardiac arrhythmia (an abnormal heart rate), particularly with desipramine. Other medications prescribed for ADHD therapy include buproprion (Wellbutrin), an antidepressant; **fluoxetine** (Prozac), an SSRI antidepressant (a group of medications used to treat depression by directing the flow of a neurotransmitter called serotonin); and **carbamazepine** (Tegretol, Atretol), an antiseizure drug. **Clonidine** (Catapres), a medication used to treat high blood pressure, has also been used to control aggression and hyperactivity in some ADHD children, although it should not be used with Ritalin. Because a child's

response to medication will change with age and maturation, ADHD symptoms should be monitored closely and prescriptions adjusted accordingly.

Psychosocial therapies

Behavior modification therapy uses a reward system to reinforce good behavior and task completion and can be implemented both in the classroom and at home. A tangible reward such as a sticker may be given to the child every time he completes a task or behaves in an acceptable manner. A chart may be used to display the stickers and visually illustrate the child's progress. When a certain number of stickers are collected, the child may trade them in for a bigger reward such as a trip to the zoo or a day at the beach. The reward system stays in place until the good behavior becomes ingrained.

A variation of this technique, **cognitive-behavioral therapy**, may work for some children to decrease impulsive behavior by getting the child to recognize the connection between thoughts and behavior, and to change behavior by changing negative thinking patterns.

Individual **psychotherapy** can help an ADHD child build self-esteem, provide a place to discuss worries and anxieties, and help him or her to gain insight into behavior and feelings.

Family therapy may also be beneficial in helping family members develop coping skills and in working through feelings of guilt or anger parents may be experiencing.

ADHD children perform better within a familiar, consistent, and structured routine with positive reinforcements for good behavior and real consequences for bad behavior. Family, friends, and caretakers should all be educated on the special needs and behaviors of the ADHD child so that they can act consistently. Communication between parents and teachers is especially critical to ensuring an ADHD child has an appropriate learning environment.

Alternative treatment

A number of alternative treatments exist for ADHD. Although there is a lack of controlled studies to prove their efficacy, proponents report that they are successful in controlling symptoms in some ADHD patients. Some of the more popular alternative treatments include:

- EEG (electroencephalograph) **biofeedback**. By measuring brainwave activity and teaching the ADHD patient which type of brainwave is associated with attention, EEG biofeedback attempts to train patients to generate the desired brainwave activity.
- Limited sugar intake. However, data indicate that this method does not actually reduce symptoms.
- Relaxation training.

Prognosis

Untreated, ADHD negatively affects a child's social and educational performance and can seriously damage his or her sense of self-esteem. ADHD children have impaired relationships with their peers, and may be looked upon as social outcasts. They may be perceived as slow learners or troublemakers in the classroom. Siblings and even parents may develop resentful feelings towards a child with ADHD.

Some ADHD children also develop a **conduct disorder** problem. For those adolescents who have both ADHD and a conduct disorder, up to 25% go on to develop **antisocial personality disorder** and the criminal behavior, substance abuse, and high rate of **suicide** attempts that can be symptomatic of that disorder. Children diagnosed with ADHD are also more likely to have a learning disorder, a mood disorder such as depression, or an anxiety disorder.

Approximately 70%-80% of ADHD patients treated with stimulant medication experience significant relief from symptoms, at least in the short term. Approximately half of ADHD children seem to "outgrow" the disorder in adolescence or early adulthood; the other half will retain some or all symptoms of ADHD as adults. With early identification and **intervention**, careful **compliance** with a treatment program, and a supportive and nurturing home and school environment, children with ADHD can flourish socially and academically.

Autism

Definition

The term "autism" refers to a cluster of conditions appearing early in childhood. All involve severe impairments in social interaction, communication, imaginative abilities, and rigid, repetitive behaviors. To be considered an autistic disorder, some of these impairments must be manifest before the age of three.

The reference book used by mental health professionals to diagnose mental disorders is the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM*. The 2000 edition of this reference book (the Fourth Edition Text Revision known as *DSM-IV-TR*) places autism in a category called **pervasive developmental disorders**. All of these disorders are characterized by ongoing problems with mutual social interaction and communication, or the presence of strange, repetitive behaviors, interests, and activities. People diagnosed with these disorders are affected in many ways for their entire lives.

KEY TERMS

Impulse control disorders—Group of disorders characterized by impulsive behavior, such as stealing.

Obsessive-compulsive disorder—Disorder in which the affected individual has an obsession (such as a fear of contamination, or thoughts he or she doesn't like to have and can't control) and feels compelled to perform a certain act to neutralize the obsession (such as repeated handwashing).

Phenylketonuria—(PKU) An inherited disease in which the body cannot metabolize the amino acid phenylalanine properly. If untreated, phenylketonuria can cause mental retardation.

Temporal lobe—Large lobe of each side of the brain that contains a sensory area associated with hearing.

Description

Each child diagnosed with an autistic disorder differs from every other, and so general descriptions of autistic behavior and characteristics do not apply equally to every child. Still, the common impairments in social interaction, communication and imagination, and rigid, repetitive behaviors make it possible to recognize children with these disorders, as they differ markedly from healthy children in many ways.

Many parents of autistic children sense that something is not quite right even when their children are infants. The infants may have feeding problems, dislike being changed or bathed, or fuss over any change in routine. They may hold their bodies rigid, making it difficult for parents to cuddle them. Or, they may fail to anticipate being lifted, lying passively while the parent reaches for them, rather than holding their arms up in return. Most parents of autistic children become aware of the strangeness of these and other behaviors only gradually.

Impairments in social interaction are usually among the earliest symptoms to develop. The most common social impairment is a kind of indifference to other people, or aloofness, even towards parents and close caregivers. The baby may fail to respond to his or her name being called and may show very little facial expression unless extremely angry, upset, or happy. Babies with autism may resist being touched, and appear to be lost in their own world, far from human interaction. Between

seven and 10 months of age, most infants often resist being separated from a parent or well-known caregiver, but these infants may show no disturbance when picked up by a stranger.

Other children with autism may be very passive, although less resistant to efforts by others to interact. However, they do not initiate social interaction themselves. Still others may attempt to engage with adults and peers, but in ways that strike others as inappropriate, or odd.

In adolescence and adulthood, some of the higher-functioning individuals with autistic disorders may appear overly formal and polite. They may react with little spontaneity, as if social interaction doesn't come naturally or easily to them, and so they are trying to follow a pre-determined set of rules.

Some individuals with autism have normal intelligence, and many have special talents in areas such as music or memory. However, individuals with autism may have other mental or emotional problems that co-exist with their autism. Some of these other disorders may include impulse control disorders, **obsessive-compulsive disorder**, mood and anxiety disorders, and **mental retardation**.

Causes and symptoms

Causes

PSYCHOLOGICAL AND FAMILY FACTORS. Although Henry Maudsley, in the late 1800s, was the first **psychiatrist** to focus on very young children with mental disorders, it was the psychiatrist Leo Kanner who coined the phrase "early infantile autism" in 1943. Kanner believed that the parents of children with autistic behaviors were emotionally cold and intellectually distant. He coined the term "refrigerator parents" to describe them. His belief that parental personality and behavior played a powerful role in the development of autistic behaviors left a devastating legacy of guilt and self-blame among parents of autistic children that continues to this day. Recent studies are unequivocal, however, in demonstrating that parents of autistic children are no different from parents of healthy children in their personalities or parenting behaviors. In fact, many families with an autistic child also have one or more perfectly healthy children.

Because autistic children can be extremely sensitive to change, any change within the family situation can be potentially traumatic to the autistic child. A move, divorce, birth of a sibling or other stressors that occur in the lives of most families may evoke a more extreme reaction from an autistic child.

NEUROLOGICAL AND BIOLOGICAL FACTORS. While there is no single neurological abnormality found in children with autistic disorders, some research using non-invasive **brain** imaging techniques such as **magnetic resonance imaging** (MRI) suggests that certain areas of the brain may be involved. Several of the brain areas being researched are known to control emotion and the expression of emotion. These areas include the temporal lobe (large lobe of each side of the brain that contains a sensory area associated with hearing), the limbic system, the cerebellum, the frontal lobe, the amygdala, and the brain stem, which regulates homeostasis (body temperature and heart rate). Recent research has focused particularly on the temporal lobe because of the finding that previously healthy people who sustain temporal lobe damage may develop autistic-like symptoms. In animal research, when the temporal lobe is damaged, social behavior declines, and restless, repetitive motor behaviors are common. When measured by MRI, total brain volume appears to be greater for those with autistic disorders.

Other neurological factors include lesions to the brain, congenital rubella, undiagnosed and untreated phenylketonuria (PKU), tuberous sclerosis, and **Rett's disorder** (a related condition in which the baby develops in an apparently normal manner through age five months, and then begins to lose communicative and social interaction skills). There is also evidence of a higher proportion of perinatal complications (complications arising around the time of giving birth) among children with autistic symptoms. These complications include maternal bleeding after the first trimester and meconium in the amniotic fluid. (Meconium is a substance that accumulates in the bowel of the developing fetus and is discharged shortly after birth.) Some evidence suggests that the use of medications during pregnancy may be related to the development of autistic symptoms. As newborns, children with autistic behaviors show a higher rate of respiratory illness and anemia than healthy children.

ALLERGIES, INFECTIONS, AND IMMUNIZATIONS. Some professionals believe that autistic disorders may be caused by allergies to particular fungi, viral infections, and various foods. No controlled studies have supported these beliefs, but some parents and professionals report improvement when allergens and/or certain foods are eliminated from the diet.

Viral infections of the mother, such as rubella, or of the young child, such as encephalitis, mumps, and measles, occasionally appear to cause autistic disorders. The common childhood immunization series known as MMR (measles, mumps, rubella) has recently come under scrutiny as a possible cause of some autistic conditions.

Teachers assist kindergarten students at a school for autistic children in Salt Lake City, Utah. *(AP/ Wide World Photos. Reproduced by permission.)*

Symptoms

DSM-IV-TR specifies three diagnostic categories, each with four components, that are used to make a **diagnosis** of autistic disorder. These diagnostic categories include impairments in social interaction, communication, and particular patterns of behavior. More information about the individual diagnostic categories and components follows.

SOCIAL INTERACTION. Qualitative impairment in social interaction, as demonstrated by at least two of the following:

- impairment in the use of nonverbal behaviors such as eye contact, facial expression, body posture, and gestures used for social interaction
- failure to develop age-appropriate peer relationships
- lack of attempts to share pleasure, activities, interests, or achievements with other people (by failing to bring items of interest to a parent, or pointing out animals or objects, for example)
- inability to respond to social situations or other people's emotions with empathy or a concerned attitude

COMMUNICATION. Qualitative impairments in communicating in at least one of the following four areas:

- lack of, or delay in development of spoken language, without attempts to communicate through alternative means such as gestures or mime
- in individuals who do speak, severe impairment in the ability to initiate or sustain a conversation with others
- repetitive and stereotyped use of language, or use of words in unusual, idiosyncratic ways
- failure to show imaginative play, such as make-believe or social imitative play appropriate to developmental level

BEHAVIOR. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, as demonstrated by at least one of the following:

- unusual and overly absorbing preoccupation with one or more interests or activities
- a need for rigid adherence to specific routines or rituals in daily life
- stereotyped and repetitive motor behaviors using parts of the body such as fingers or hands, or the whole body
- persistent preoccupation with parts of objects

Demographics

Autistic disorders strike families of all racial, ethnic, and social backgrounds. These disorders are estimated to affect approximately four children in 10,000. Other estimates place the number affected at between 1 in 500 and 1 in 2,500 Americans. Autistic disorder occurs four times more frequently in boys than girls. Several surveys have shown that between two and four percent of siblings of autistic children also have autistic disorder. This rate is 50 times greater than in the general population. Among pairs of identical twins in which one child has autism, in 36% of the pairs, the other twin has autism as well. Among fraternal twins, there is no similar correlation. Some studies indicate that even among family members who are not diagnosed as autistic, there tends to be a higher-than-average rate of language and other cognitive problems. As many as 25% of autistic children develop epileptic **seizures** later in life, usually during adolescence. This symptom appears mostly in those who are also mentally retarded.

Recently, professionals have reported observing increasing numbers of children with autistic disorders. While no studies confirm this observation, there are three possible reasons why it appears so. First, the definition of "autism" and "autistic disorders" has widened considerably since the first case reports by Leo Kanner in 1943. The *DSM-IV-TR* definition currently in use includes a far greater range of behaviors than earlier definitions of autism. Second, there has been an increasing awareness of the existence of autism and autistic disorders among the general public and among health professionals, making a child with symptoms of autism much more likely to be diagnosed than in years past. Finally, it is possible that there is an actual increase in the number of children born with one of these disorders.

Diagnosis

Because young infants are so limited in their range of behavior, autistic disorders are generally discovered gradually, and rarely diagnosed before the age of two or three. Parents may not realize that their baby's behavior is different from that of other infants until he or she reaches an age where a wide range of behaviors are typically displayed. Most doctors may attempt to reassure concerned parents of infants under two years that their children are "normal," or will "grow out of" a disturbing behavior, because many children do. At the time that speech and language usually develop, parents are more likely to observe that their autistic child is not at the same level as other children his age. Once the child is old enough to play with other children, it becomes more apparent that the autistic child either isn't interested in doing so, or does so in strange, unusual ways that differ from most children of the same age. Motor development may also appear unusual, with repetitive motions such as spinning, self-injurious behaviors such as headbanging, and rocking back and forth, giving the parents strong clues that their child behaves differently from others.

The child who continues to display unusual behaviors at about the age of two years would most likely receive a referral from the pediatrician to a child psychiatrist or to an early **intervention** program with a multidisciplinary staff including psychiatrists, psychologists, and **social workers**. These professionals would be the ones to diagnose autistic disorder, and, ideally, offer an early intervention program simultaneously. In order to reach the diagnosis, the professional(s) would observe the child both with and without parents present, interview the parents about the pregnancy, birth, siblings, family history, and early behaviors, and an assessment like the Bayley Scales of Infant Development might be administered.

Differential diagnosis

Differential diagnosis is the process of distinguishing one disorder from other similar disorders. Because there are currently no medical tests (such as a blood test) to detect autism, the diagnosis is often established by ruling out other disorders.

MENTAL RETARDATION. It is estimated that approximately 40% to 60% of children with autistic disorders show some degree of mental retardation ranging from mild to profound. It is possible for a child to have both conditions. What distinguishes children with mental retardation who do not have autistic symptoms from those who do is evenness of development. Children with mental retardation tend to exhibit a more even level of functioning in all areas, whereas autistic children tend to exhibit extreme variability within areas and between areas. Children with autistic disorders show uneven development in areas such as motor, language, and social skills. A child with autism may have high-level cognitive functioning in one area, but low-level cognitive functioning in another area, for example. Or a child with autism may exhibit delayed cognitive development, but normal motor skills development. For this reason, autism is often referred to as a "spectrum disorder" because of the large spectrum or range of variability in symptoms and functioning. Also, many children with mental retardation relate well to people and enjoy social connection, which is rare for autistic children.

LANGUAGE DISORDER. Children with autistic disorders may appear similar in some ways to children with language disorders. Unlike autistic children, however, children with language disorders have normal responses

to most people, situations, and objects. They make eye contact and show interest in peer and adult relationships.

CHILDHOOD SCHIZOPHRENIA. Schizophrenia is a disturbance of emotion and thought processes that rarely occurs in young children. When it does, it is characterized by **hallucinations** and **delusions**— seeing and hearing things that are not there, for example. These are not symptoms that appear among autistic children.

DEGENERATIVE ORGANIC BRAIN DISORDER. This is an extremely rare condition that may at first appear similar to autistic disorders. In degenerative organic brain disorder, the child begins to develop normally. But over time, speech, language, motor skills and other age-appropriate behaviors disintegrate and do not return. The disintegration is progressive. In children with autistic disorders, some children may begin to develop words and language and then lose them at around eighteen months. However, with appropriate education, these skills can be relearned and surpassed by the autistic child.

Treatments

Autistic disorders cannot be cured, but children who have these disorders can make considerable progress in all areas of life. Depending upon the level of intellectual function, it is possible for some children with autism to become functioning, semi-independent adults capable of working and enjoy some social relationships. Parenting a child with autism can be extremely challenging, however, and many families find **support groups** to be helpful. Both medication and psychosocial therapies (therapies that address both psychological and social issues) can help ameliorate troubling symptoms. Education is key for helping these children learn socially acceptable behaviors, decreasing odd mannerisms and behaviors, and increasing appropriate verbal and non-verbal language skills.

Education

Most educational programs for children with autistic disorders involve small, specialized classes with teachers specially trained to work with autistic children. Often, these children are educated in special schools that have extended school years rather than lengthy summer vacations. Research has shown that autistic children need regular, daily structure and routine, and they maintain their skills best when there are not frequent disruptions of their daily school program.

One method that has been used extensively both within the classroom and at home is a **behavior modification** method known as "Applied Behavior Analysis," or ABA. Specially trained teachers break down large goals into small steps that are taught and repeated until the child masters each one. Slowly, step by step, more appropriate patterns of behavior and communication are formed or "shaped" in this way. Positive **reinforcement** is used in many forms such as praise, for those children who are motivated by it, time permitted to engage in a favorite activity, or a small favored food item. For ABA to be most effective, parents need to be trained to use these same skills to continue the work at home.

Medications

Although no one drug is helpful to children with autistic disorders, several medications are currently used, along with education, to reduce severe temper tantrums and destructive aggression, self-injurious behaviors, hyperactivity, and strange, repetitive behaviors. Medications may also help the autistic child become more receptive to learning and relating to others. Some of the medications commonly used today include **risperidone** (Risperdal), and **haloperidol** (Haldol). Although there are side effects associated with these medications, careful dosing and use of other medications to counteract side effects often enable the autistic child to function more effectively.

Non-conventional treatments

One non-conventional and experimental treatment for autism is the use of secretin, a hormone produced in the small intestine that stimulates the pancreas to release sodium bicarbonate and other digestive enzymes. Some researchers think that children with autistic disorders do not produce enough of this hormone, and that the lack of sufficient secretin may be the reason why children with autistic disorders suffer so frequently from digestive problems. There are some reports of treating autistic children with secretin that indicate improvement not only in digestion, but in eye contact, alertness, and the ability to learn.

Another non-conventional, experimental treatment involves *Candida albicans*, the technical term for a common yeast that is found in the human body. Some scientists believe that an overgrowth of this yeast may cause or worsen autism. Some reports indicate that children treated with anti-yeast medications improve in eye contact, social abilities, language skills, concentration, and sleep, and that they show a reduction in aggressive and hyperactive behavior.

An additional non-conventional treatment being researched for autism is a nutritional supplement, Vitamin B6. Some experts believe that Vitamin B6 holds promise for reducing autistic symptoms and helping autistic children progress in all areas. It may be combined with magnesium and the combination appears to have no known side effects. Improvements attributed to these

supplements in some studies include enhanced language, eye-contact, and behaviors, as well as more normal brain activity and improved immune system functioning.

These treatments remain outside mainstream medicine, however, and research is ongoing as to their efficacy. Parents interested in these therapies may wish to discuss them with their child's health care team.

Prognosis

Autistic disorders follow a continuous course throughout life. Autistic individuals with higher levels of intelligence may become able to work and live independently or, more frequently, semi-independently. This is especially true for those with IQ scores of 70 or higher. One in six children with autism becomes a well-adjusted adult. Another one out of six achieves a fair degree of adjustment in adult life. Others may never be able to leave the structured environment of home or, later, special group home placement. During adolescence, sexual feelings emerge that cannot usually be handled appropriately by the autistic teen. Supervision throughout life is needed for the majority of individuals diagnosed with these disorders.

Prevention

At present, no specific means of preventing autistic disorders exist. Because of an elevated likelihood of giving birth to more than one autistic child exists, genetic counseling is recommended.

Aversion therapy

Definition

Aversion therapy is a form of behavior therapy in which an aversive (causing a strong feeling of dislike or disgust) stimulus is paired with an undesirable behavior in order to reduce or eliminate that behavior.

Purpose

As with other behavior therapies, aversion therapy is a treatment grounded in learning theory—one of its basic principles being that all behavior is learned and that undesirable behaviors can be unlearned under the right circumstances. Aversion therapy is an application of the branch of learning theory called classical conditioning. Within this model of learning, an undesirable behavior, such as a deviant sexual act, is matched with an unpleasant (aversive) stimulus. The unpleasant feelings or sensations become associated with that behavior, and the behavior will decrease in frequency or stop altogether. Aversion therapy differs from those types of behavior therapy based on principles of operant conditioning. In operant therapy, the aversive stimulus, usually called punishment, is presented after the behavior rather than together with it.

The goal of aversion therapy is to decrease or eliminate undesirable behaviors. Treatment focuses on changing a specific behavior itself, unlike insight-oriented approaches that focus on uncovering unconscious motives in order to produce change. The behaviors that have been treated with aversion therapy include such addictions as alcohol abuse, drug abuse, and smoking; pathological gambling; sexual deviations; and more benign habits— including writer's cramp. Both the type of behavior to be changed and the characteristics of the aversive stimulus influence the treatment—which may

be administered in either outpatient or inpatient settings as a self-sufficient **intervention** or as part of a multimodal program. Under some circumstances, aversion therapy may be self-administered.

Precautions

A variety of aversive stimuli have been used as part of this approach, including chemical and pharmacological stimulants as well as electric shock. Foul odors, nasty tastes, and loud noises have been employed as aversive stimuli somewhat less frequently. The chemicals and medications generate very unpleasant and often physically painful responses. This type of aversive stimulation may be risky for persons with heart or lung problems because of the possibility of making the medical conditions worse. Patients with these conditions should be cleared by their doctor first. Often, however, the more intrusive aversive stimuli are administered within inpatient settings under medical supervision. An uncomfortable but safe level of electric (sometimes called faradic) shock is often preferred to chemical and pharmacological aversants because of the risks that these substances involve.

In addition to the health precautions mentioned above, there are ethical concerns surrounding the use of aversive stimuli. There are additional problems with patient acceptance and negative public perception of procedures utilizing aversants. Aversion treatment that makes use of powerful substances customarily (and intentionally) causes extremely uncomfortable consequences, including nausea and vomiting. These effects may lead to poor **compliance** with treatment, high dropout rates, potentially hostile and aggressive patients, and public relations problems. Social critics and members of the general public alike often consider this type of treatment punitive and morally objectionable. Although the scenes were exaggerated, the disturbing parts of the Stanley Kubrick film *A Clockwork Orange* that depicted the use of aversion therapy to reform the criminal protagonist, provide a powerful example of society's perception of this treatment.

Parents and other advocates for the mentally retarded and developmentally disabled have been particularly vocal in their condemnation of behavior therapy that uses aversive procedures in general. Aversive procedures are used within a variety of **behavior modification** strategies and that term is sometimes confused with the more specific technique of aversion therapy. Aversive procedures are usually based on an operant conditioning model that involves punishment. Advocates for special patient populations believe that all aversive procedures are punitive, coercive, and use unnecessary amounts of control and manipulation to modify behavior. They call for therapists to stop using aversive stimuli, noting that positive, non-aversive, behavioral-change strategies are available. These strategies are at least as, if not more, effective than aversive procedures.

KEY TERMS

Aversion—A strong feeling of dislike or disgust. Aversion therapy makes use of this feeling to reduce or eliminate an undesirable behavior. Chemicals or medications used to produce unpleasant effects are called aversants.

Classical conditioning—In psychology, a process in which a previously neutral stimulus eventually produces a specific response by being paired repeatedly with another stimulus that produces that response. The best-known example of classical conditioning is Pavlov's dogs, who were conditioned to salivate when they heard a bell ring (the previously neutral stimulus) because the sound had been paired repeatedly with their feeding time.

Compliance—In medicine or psychiatry, cooperation with a treatment plan or schedule of medications.

Detoxification—A process in which the body is allowed to free itself of a drug while the symptoms of withdrawal are treated. It is the primary step in any treatment program for drug or alcohol abuse.

Emetic—A medication intended to cause vomiting. Emetics are sometimes used in aversion therapy in place of electric shock. Their most common use in mainstream medicine is in treating accidental poisoning.

Faradic—A type of discontinuous alternating electric current sometimes used in aversion therapy. It is named for Michael Faraday, an eminent British physicist.

Protocol—A plan for carrying out a scientific study or a patient's course of treatment.

Stimulus—Something that incites or moves a person to thought, emotion, or action. In mainstream psychotherapy, a stimulus can be anything from a certain picture or image to a smell, a sound, or a word or idea. In aversion therapy, the stimulus is typically a mild electric shock or a medication that produces unpleasant results.

Description

A patient who consults a behavior therapist for aversion therapy can expect a fairly standard set of procedures. The therapist begins by assessing the problem, most likely measuring its frequency, severity, and the environment in which the undesirable behavior occurs. Although the therapeutic relationship is not the focus of treatment for the behavior therapist, therapists in this tradition believe that good rapport will facilitate a successful outcome. A positive relationship is also necessary to establish the patient's confidence in the rationale for exposing him or her to an uncomfortable stimulus. The therapist will design a treatment protocol and explain it to the patient. The most important choice the therapist makes is the type of aversive stimulus to employ. Depending upon the behavior to be changed, the preferred aversive stimulus is often electric stimulation delivered to the forearm or leg. This aversive stimulus should not be confused with **electroconvulsive therapy** (ECT), which is delivered to the **brain** to treat depression. Mild but uncomfortable electric shocks have several advantages over chemical and pharmacological stimuli. A great many laboratory research studies using animal and human subjects have used electrical shock and its characteristics are well known. In addition, it has been widely used in clinical settings. Electric shock is easy to administer, and the level of intensity can be preselected by the patient. The stimulation can be precisely controlled and timed. The equipment is safe, battery-powered, suitable for outpatients, portable, easy to use, and can be self-administered by the patient when appropriate.

Case example #1: What would a treatment protocol look like for a relatively well-adjusted patient specifically requesting aversion therapy on an outpatient basis to reduce or eliminate problem gambling behavior? The therapist begins by asking the patient to keep a behavioral diary. The therapist uses this information both to understand the seriousness of the problem and as a baseline to measure whether or not change is occurring during the course of treatment. Because electric shock is easy to use and is acceptable to the patient, the therapist chooses it as the aversive stimulus. The patient has no medical problems that would preclude the use of this stimulus. He or she fully understands the procedure and consents to treatment. The treatment is conducted on an outpatient basis with the therapist administering the shocks on a daily basis for the first week in the office, gradually tapering to once a week over a month. Sessions last about an hour. A small, battery-powered electrical device is used. The electrodes are placed on the patient's wrist. The patient is asked to preselect a level of shock that is uncomfortable but not too painful. This shock is then briefly and repeatedly paired with stimuli (such as slides of the race track, betting sheets, written descriptions of gambling) that the patient has chosen for their association with his or her problem gambling. The timing, duration, and intensity of the shock are carefully planned by the therapist to assure that the patient experiences a discomfort level that is aversive and that the conditioning effect occurs.

After the first or second week of treatment, the patient is provided with a portable shocking device to use on a daily basis for practice at home to supplement office treatment. The therapist calls the patient at home to monitor compliance as well as progress between office sessions. The conditioning effect occurs, the discomfort from the electric shock becomes associated with the gambling behavior, the patient reports loss of desire and stops gambling. Booster sessions in the therapist's office are scheduled once a month for six months. A minor relapse is dealt with through an extra office visit. The patient is asked to administer his or her own booster sessions on an intermittent basis at home and to call in the future if needed.

Case example #2: What would the treatment protocol look like for an alcohol-dependent patient with an extensive treatment history including multiple prior life-threatening relapses? The patient who is motivated to change but has not experienced success in the past may be considered a candidate for aversion therapy as part of a comprehensive inpatient treatment program. The treating therapist assesses the extent of the patient's problem, including drinking history, prior treatments and response, physical health, and present drinking pattern. Patients who are physically addicted to alcohol and currently drinking may experience severe withdrawal symptoms and may have to undergo **detoxification** before treatment starts. When the detoxification is completed, the patient is assessed for aversion therapy. The therapist's first decision is what type of noxious stimulus to use, whether electrical stimulation or an emetic (a medication that causes vomiting). In this case, when the patient's problem is considered treatment-resistant and a medically-monitored inpatient setting is available, an emetic may be preferable to electric shock as the aversive stimulus. There is some research evidence that chemical aversants lead to at least short-term avoidance of alcohol in some patients. An emetic is "biologically appropriate" for the patient in that it affects him or her in the same organ systems that excessive alcohol use does. The procedure is fully explained to the patient, who gives **informed consent**.

During a ten-day **hospitalization**, the patient may receive aversion therapy sessions every other day as part of a comprehensive treatment program. During the treatment sessions, the patient is given an emetic intra-

venously under close medical supervision and with the help of staff assistants who understand and accept the theory. Within a few minutes following administration, the patient reports beginning to feel sick. To associate the emetic with the sight, smell and taste of alcohol, the patient is then asked to take a sip of the alcoholic beverage of his or her choice without swallowing. This process is repeated over a period of 30–60 minutes as nausea and vomiting occur. As the unpleasant effects of the emetic drug become associated with the alcoholic beverage, the patient begins to lose desire for drinking. Aversion therapy in an inpatient program is usually embedded within a comprehensive treatment curriculum that includes **group therapy** and such **support groups** as AA, couples/family counseling, **social skills training**, stress management, instruction in problem solving and conflict resolution, health education and other behavioral change and maintenance strategies. Discharge planning includes an intensive outpatient program that may include aversive booster sessions administered over a period of six to twelve months, or over the patient's lifetime.

Preparation

Depending upon his/her customary practice, a therapist administering aversion therapy may establish a behavioral contract defining the treatment, objectives, expected outcome, and what will be required of the patient. The patient may be asked to keep a behavioral diary to establish a baseline measure of the behavior targeted for change. The patient undergoing this type of treatment should have enough information beforehand to give full consent for the procedure. Patients with medical problems or who are otherwise vulnerable to potentially damaging physical side effects of the more intense aversive stimuli should consult their primary care doctor first.

Aftercare

Patients completing the initial phase of aversion therapy are often asked by the therapist to return periodically over the following six to twelve months or longer for booster sessions to prevent relapse.

Risks

Patients with cardiac, pulmonary, or gastrointestinal problems may experience a worsening of their symptoms, depending upon the characteristics and strength of the aversive stimuli. Some therapists have reported that patients undergoing aversion therapy, especially treatment that uses powerful chemical or pharmacological aversive stimuli, have become negative and aggressive.

Normal results

Depending upon the objectives established at the beginning of treatment, patients successfully completing a course of aversion therapy can expect to see a reduction or cessation of the undesirable behavior. If they practice relapse prevention techniques, they can expect to maintain the improvement.

Abnormal results

Some clinicians have reported that patients undergoing aversive treatment utilizing electric shocks have experienced increased anxiety and anxiety-related symptoms that may interfere with the conditioning process as well as lead to decreased acceptance of the treatment. As indicated above, a few clinicians have reported a worrisome increase in hostility among patients receiving aversion therapy, especially those undergoing treatment using chemical aversants. Although aversion therapy has some adherents, lack of rigorous outcome studies demonstrating its effectiveness, along with the ethical objections mentioned earlier, have generated numerous opponents among clinicians as well as the general public. These opponents point out that less intrusive alternative treatments, such as **covert sensitization**, are available.

Avoidant personality disorder

Definition

Avoidant personality disorder is one of several **personality disorders** listed in the newest edition of the standard reference guide to mental disorders ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR*. It is characterized by marked avoidance of both social situations and close interpersonal relationships due to an excessive fear of rejection by others. Persons with this disorder exhibit feelings of inadequacy, low self-esteem, and mistrust toward others.

Description

People who are diagnosed with avoidant personality disorder desire to be in relationships with others but lack the skills and confidence that are necessary in social interactions. In order to protect themselves from anticipated criticism or ridicule, they withdraw from other people. This avoidance of interaction tends to isolate them from meaningful relationships, and serves to reinforce their nervousness and awkwardness in social situations.

The behavior of people with avoidant personality disorder is characterized by social withdrawal, shyness, distrustfulness, and emotional distance. These people tend to be very cautious when they speak, and they convey a general impression of awkwardness in their manner. Most are highly self-conscious and self-critical about their problems relating to others.

Causes and symptoms

Causes

The cause of avoidant personality disorder is not clearly defined, and may be influenced by a combination of social, genetic, and biological factors. Avoidant personality traits typically appear in childhood, with signs of excessive shyness and fear when the child confronts new people and situations. These characteristics are also developmentally appropriate emotions for children, however, and do not necessarily mean that a pattern of avoidant personality disorder will continue into adulthood. When shyness, unfounded fear of rejection, hypersensitivity to criticism, and a pattern of social avoidance persist and intensify through adolescence and young adulthood, a **diagnosis** of avoidant personality disorder is often indicated.

Many persons diagnosed with avoidant personality disorder have had painful early experiences of chronic parental criticism and rejection. The need to bond with the rejecting parents makes the avoidant person hungry for relationships but their longing gradually develops into a defensive shell of self-protection against repeated parental criticisms. Ridicule or rejection by peers further reinforces the young person's pattern of social withdrawal and contributes to their fear of social contact.

Symptoms

DSM-IV-TR specifies seven diagnostic criteria for avoidant personality disorder:

- The person avoids occupational activities that require significant interpersonal contact. Job interviews or promotions may be turned down because the person's own perceptions of his or her abilities do not match the job description.
- The person is reluctant to participate in social involvement without clear assurance that they will be accepted. People with this disorder assume other people are not safe to trust until proven otherwise. Others must offer repeated support and encouragement in order to persuade them to participate in a social event.
- The person fears being shamed or ridiculed in close relationships. As a result, people with this disorder become overly alert to behavioral cues that may indicate disapproval or rejection. They will flee a situation in which they believe that others might turn against them.
- The person is preoccupied with being criticized or rejected. Much mental and physical energy is spent brooding about and avoiding situations perceived as "dangerous."
- The person is inhibited in unfamiliar social situations due to feelings of inadequacy. Low self-esteem undermines their confidence in meeting and conversing with new acquaintances.
- The person regards him- or herself as socially inept. This self-disparagement is especially apparent when the person must make social contacts with strangers. People with avoidant personality disorder perceive themselves as unappealing or inferior to others.
- The person is reluctant to take social risks, in order to avoid possible humiliation. Avoidant people seek interactions that promise the greatest amount of acceptance while minimizing the likelihood of embarrassment or rejection. They might go to a school dance, for example, but remain in one corner chatting with close friends rather than going out on the dance floor with someone they do not know well.

Demographics

Avoidant personality disorder appears to be as frequent in males as in females. It affects between 0.5% and 1.0% of adults in the general North American population, but it has been diagnosed in approximately 10% of clinical outpatients.

Diagnosis

Many individuals exhibit some avoidant behaviors at one point or another in their lives. Occasional feelings of self-doubt and fear in new and unfamiliar social or personal relationships are not unusual, nor are they unhealthy, as these situations may trigger feelings of inadequacy and the wish to hide from social contact in even the most self-confident individuals. An example would be the anxious hesitancy of a new immigrant in a country with a different language and strange customs. Avoidant characteristics are regarded as meeting the diagnostic criteria for a personality disorder only when they: begin to have a long-term negative impact on the affected person; lead to functional impairment by significantly altering occupational choice or lifestyle, or otherwise impacting quality of life; and cause significant emotional distress.

Avoidant personality disorder can occur in conjunction with other social phobias, mood and anxiety disorders, and personality disorders. The diagnosis may be complicated by the fact that avoidant personality disorder may be either the cause or result of other mood and anxiety disorders. For example, individuals who suffer from **major depressive disorder** may begin to withdraw from social situations and experience feelings of worthlessness, symptoms that are also prominent features of avoidant personality disorder. On the other hand, the insecurity and isolation that are symptoms of avoidant personality disorder can trigger feelings of depression.

The characteristics of avoidant personality disorder may resemble those found in both schizoid and schizotypal personality disorders. Persons with any of these disorders are prone to social isolation. Those diagnosed with avoidant personality disorder, however, differ from those with schizoid or schizotypal disorder, because they want to have relationships with others but are prevented by their social inadequacies. Persons diagnosed with schizoid and schizotypal personality disorders, on the other hand, usually prefer social isolation.

Personality disorders are usually diagnosed following a complete medical history and an interview with the patient. Although there are no laboratory tests for personality disorders, the doctor may give the patient a physical examination to rule out the possibility that a general medical condition is affecting the patient's behavior. For example, people with disorders of the digestive tract may avoid social occasions for fear of a sudden attack of diarrhea or the need to vomit. If the interview with the patient suggests a diagnosis of avoidant personality disorder, the doctor may administer a diagnostic questionnaire or another type of assessment tool.

KEY TERMS

Cognitive restructuring—An approach to psychotherapy that focuses on helping the patient examine distorted patterns of perceiving and thinking in order to change their emotional responses to people and situations.

Monoamine oxidase inhibitors (MAOIs)—A group of antidepressant drugs that decreases the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood. MAOIs are also used in the treatment of avoidant personality disorder.

Supportive—An approach to psychotherapy that seeks to encourage the patient or offer emotional support to him or her, as distinct from insight-oriented or educational approaches to treatment.

Assessment tools helpful in diagnosing avoidant personality disorder include:

- **Minnesota Multiphasic Personality Inventory** (MMPI-2)
- Millon Clinical Multiaxial Inventory (MCMI-II)
- Rorschach Psychodiagnostic Test
- **Thematic Apperception Test** (TAT)

Treatments

The general goal of treatment in avoidant personality disorder is improvement of self-esteem and confidence. As the patient's self-confidence and social skills improve, he or she will become more resilient to potential or real criticism by others.

Psychodynamically oriented therapies

These approaches are usually supportive; the therapist empathizes with the patient's strong sense of shame and inadequacy in order to create a relationship of trust. Therapy usually moves slowly at first because persons with avoidant personality disorder are mistrustful of others; treatment that probes into their emotional state too quickly may result in a more protective withdrawal by

the patient. As trust is established and the patient feels safer discussing details of his or her situations, he or she may be able to draw important connections between their deeply felt sense of shame and their behavior in social situations.

Cognitive-behavioral therapy

Cognitive-behavioral therapy (CBT) may be helpful in treating individuals with avoidant personality disorder. This approach assumes that faulty thinking patterns underlie the personality disorder, and therefore focuses on changing distorted cognitive patterns by examining the validity of the assumptions behind them. If a patient feels he is inferior to his peers, unlikable, and socially unacceptable, a cognitive therapist would test the reality of these assumptions by asking the patient to name friends and family who enjoy his company, or to describe past social encounters that were fulfilling to him. By showing the patient that others value his company and that social situations can be enjoyable, the irrationality of his social fears and insecurities are exposed. This process is known as "cognitive restructuring."

Group therapy

Group therapy may provide patients with avoidant personality disorder with social experiences that expose them to feedback from others in a safe, controlled environment. They may, however, be reluctant to enter group therapy due to their fear of social rejection. An empathetic environment in the group setting can help each member overcome his or her social anxieties. **Social skills training** can also be incorporated into group therapy to enhance social awareness and feedback.

Family and marital therapy

Family or couple therapy can be helpful for a patient who wants to break out of a family pattern that reinforces the avoidant behavior. The focus of marital therapy would include attempting to break the cycle of rejection, criticism or ridicule that typically characterizes most avoidant marriages. Other strategies include helping the couple to develop constructive ways of relating to one another without shame.

Medications

The use of monoamine oxidase inhibitors (MAOIs) has proven useful in helping patients with avoidant personality disorder to control symptoms of social unease and experience initial success. The major drawback of these medications is limitations on the patient's diet. People taking MAOIs must avoid foods containing a substance known as tyramine, which is found in most cheeses, liver, red wines, sherry, vermouth, beans with broad pods, soy sauce, sauerkraut, and meat extracts.

Prognosis

Higher-functioning persons with avoidant personality disorder can generally be expected to improve their social awareness and improve their social skills to some degree. But because of the significant social fear and deep-seated feelings of inferiority, these patterns usually do not change dramatically. Lower-functioning persons are likely to drop out of treatment if they become too anxious.

Prevention

Since avoidant personality disorder usually originates in the patient's family of origin, the only known preventive measure is a nurturing, emotionally stimulating and expressive family environment.

Barbiturates

Definition

Barbiturates are a large class of drugs, consisting of many different brand name products with generic equivalents, that are used primarily for mild sedation, general anesthesia, and as a treatment for some types of epilepsy. One barbiturate, butalbital, exists only as a component of several headache preparations. The most common members of the barbiturate family are phenobarbital (Luminal)), pentobarbital (Nembutal), amobarbital (Amytal), secobarbital (Seconal), thiopental (Pentothal), methohexital (Brevital), and butalbital (component of Fiorinal and Fioricet). They exist in numerous formulations and strengths.

Purpose

Barbiturates are used to sedate patients prior to surgery as well as to produce general anesthesia, to treat some forms of epilepsy, and to treat simple and migraine headache. These drugs are highly addictive and are often abused as recreational drugs. Although still commercially available, barbiturates such as secobarbital, pentobarbital, and amobarbital are no longer routinely recommended for the treatment of **insomnia** because of their ability to cause dependence, tolerance, and withdrawal. These drugs also have significant side effects when taken in large doses and can cause respiratory failure and death.

Description

The therapeutic effects of barbiturates as a class of drugs are all related to their ability to sedate and, at high enough doses and with certain preparations, to induce sleep. All barbiturates also have anticonvulsant properties although phenobarbital is the preferred barbiturate to treat epilepsy because it can produce anticonvulsant effects at levels low enough not to cause extreme sedation or sleep.

Recommended dosage

The typical dose of phenobarbital for use as an anticonvulsant in adults is 50–100 mg given two to three times per day. When a series of serious **seizures** known as status epilepticus occurs, adults are usually first given 300–800 mg intravenously (directly into the vein) followed by 120–240 mg every 20 minutes up to a maximum of 1000–2000 mg. For sedation, adults are given 30–120 mg per day divided into two or three doses. For sedation before surgery, 100–200 mg are given in an intramuscular injection (a shot) about one hour before the surgery.

The typical dose for an anticonvulsant effect in newborns is 2 mg to 4 mg of phenobarbital per kilogram of body weight per day. In infants, this dose is 5 mg to 8 mg per kilogram of body weight per day. In children one to five years of age, the dose is 6 mg to 8 mg per kilogram of body weight per day. In children aged five to 12 years, the dose is 4 mg to 6 mg per kilogram of body weight per day. All of these doses are given in one to two divided doses per day.

In newborns with status epilepticus, phenobarbital 15 mg to 20 mg per kilogram of body weight is given in a single or divided dose. Infants and children are given 10 mg to 20 mg per kilogram of body weight in a single or divided dose. They may also receive 5 mg per kilogram of body weight every 15 to 30 minutes up to a maximum of 40 mg per kilogram body weight. For anesthesia before surgery, 1 mg to 3 mg per kilogram of body weight is given about one hour before the surgery.

The typical dose of butalbital, as a component of headache preparations such as Fiorinal or Fioricet, is 50-100 mg administered every four to six hours as needed.

Precautions

Children who are hyperactive should not receive phenobarbital or other barbiturates. Some children paradoxically become stimulated and hyperactive after receiving barbiturates.

KEY TERMS

Addiction—A compulsive need for, and use of, a habit-forming substance or behavior.

Anticonvulsant—A medication used to control abnormal electrical activity in the brain that causes seizures.

Corticosteroids—Any one of a number of hormonal steroid compounds that are derived from the adrenal gland.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness.

Dependence—The adaptation of neurons and other physical processes to the use of a drug, followed by withdrawal symptoms when the drug is removed; physiological and/ or psychological addiction.

Hyperactive—Behavior disturbances, usually in children and adolescents, that involves impulsiveness, low levels of concentration, and distractibility.

Intramuscular—An injection that is given into a muscle.

Monoamine oxidase inhibitors (MAOIs)—A group of antidepressant drugs that decreases the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Status epilepticus—Series of grand mal epileptic seizures that may occur when the patient is asleep or awake and involves diminished consciousness.

Tolerance—Progressive decrease in the effectiveness of a drug with long-term use.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

The use of barbiturates in the elderly (over age 65) should be watched closely. Elderly patients must be carefully monitored for confusion, agitation, **delirium**, and excitement if they take barbiturates. Barbiturates should be avoided in elderly patients who are receiving drugs for other mental disorders such as **schizophrenia** or depression.

Women should not use barbiturates during pregnancy unless they are necessary to control seizures. In these cases, they should take the minimum amount to control the seizures. Barbiturate use by pregnant women has been associated with increased risk of fetal damage and bleeding during childbirth. Women who are breast-feeding should not take barbiturates because these drugs enter the breast milk and may cause serious side effects in the nursing baby.

Long-term barbiturate use should be avoided unless there is a strong medical need, as in the case of epilepsy, because of the potential for **addiction**, dependence, tolerance, and withdrawal. People should not drive, operate heavy equipment, or perform other hazardous activities requiring mental alertness while taking barbiturates.

Side effects

The most common side effect of barbiturate use is drowsiness. Less common side effects include agitation, confusion, breathing difficulties, abnormally low blood pressure, nausea, vomiting, constipation, lower body temperature, decreased heart rate, movement difficulty, nightmares, anxiety, nervousness, mental depression, and dizziness. Rare but reported side effects include fever, headache, anemia, allergic reactions, and liver damage.

Interactions

Patients should always tell their doctor and dentist when they are taking barbiturates. Barbiturates should generally not be taken with other drugs used to treat mental disorders.

There are a number of drugs that barbiturates should not be combined with because the barbiturates may increase the metabolism of these drugs and thus, reduce the amount of these drugs available to be of benefit. These drugs include oral corticosteroids such as prednisolone, methylprednisolone, prednisone, or dexamethasone, estrogen and oral contraceptives, blood-thinning medications such as warfarin (Coumadin), the antibiotic doxycycline (Vibramycin), and anticonvulsants such as phenytoin (Dilantin).

Barbiturates should not be combined with alcohol because the combination produces additive depressant effects in the central nervous system.

Barbiturates may lower the amount of absorption of the vitamins D and K.

Beck Depression Inventory

Definition

The Beck Depression Inventory (BDI) is a series of questions developed to measure the intensity, severity, and depth of depression in patients with psychiatric diagnoses. Its long form is composed of 21 questions, each designed to assess a specific symptom common among people with depression. A shorter form is composed of seven questions and is designed for administration by primary care providers. Aaron T. Beck, a pioneer in cognitive therapy, first designed the BDI.

Purpose

The BDI was originally developed to detect, assess, and monitor changes in depressive symptoms among people in a mental health care setting. It is also used to detect depressive symptoms in a primary care setting. The BDI usually takes between five and ten minutes to complete as part of a psychological or medical examination.

Precautions

The BDI is designed for use by trained professionals. While it should be administered by a knowledgeable mental health professional who is trained in its use and interpretation, it is often self-administered.

Description

The BDI was developed in 1961, adapted in 1969, and copyrighted in 1979. A second version of the inventory (BDI-II) was developed to reflect revisions in the Fourth Edition Text Revision of the ***Diagnostic and Statistical Manual of Mental Disorders*** (*DSM-IV-TR*, a handbook that mental health professionals use to diagnose mental disorders).

KEY TERMS

Reliability—The ability of a test to yield consistent, repeatable results.

Validity—The ability of a test to measure accurately what it claims to measure.

The long form of the BDI is composed of 21 questions or items, each with four possible responses. Each response is assigned a score ranging from zero to three, indicating the severity of the symptom. A version designed for use by primary care providers (BDI-PC) is composed of seven self-reported items, each correlating to a symptom of **major depressive disorder** experienced over the preceding two weeks.

Individual questions of the BDI assess mood, pessimism, sense of failure, self-dissatisfaction, guilt, punishment, self-dislike, self-accusation, suicidal ideas, crying, irritability, social withdrawal, body image, work difficulties, **insomnia**, **fatigue**, appetite, weight loss, bodily preoccupation, and loss of libido. Items 1 to 13 assess symptoms that are psychological in nature, while items 14 to 21 assess more physical symptoms.

Results

The sum of all BDI item scores indicates the severity of depression. The test is scored differently for the general population and for individuals who have been clinically diagnosed with depression. For the general population, a score of 21 or over represents depression. For people who have been clinically diagnosed, scores from 0 to 9 represent minimal depressive symptoms, scores of 10 to 16 indicate mild depression, scores of 17 to 29 indicate moderate depression, and scores of 30 to 63 indicate severe depression. The BDI can distinguish between different subtypes of depressive disorders, such as major depression and dysthymia (a less severe form of depression).

The BDI has been extensively tested for content validity, concurrent validity, and construct validity. The BDI has content validity (the extent to which items of a test are representative of that which is to be measured) because it was constructed from a consensus among clinicians about depressive symptoms displayed by psychiatric patients. Concurrent validity is a measure of the extent to which a test concurs with already existing standards; at least 35 studies have shown concurrent validity between the BDI and such measures of depression as the **Hamilton Depression Scale** and the **Minnesota**

Multiphasic Personality Inventory-D. Following a range of biological factors, attitudes, and behaviors, tests for construct validity (the degree to which a test measures an internal construct or variable) have shown the BDI to be related to medical symptoms, anxiety, **stress**, loneliness, sleep patterns, alcoholism, suicidal behaviors, and adjustment among youth.

Factor analysis, a statistical method used to determine underlying relationships between variables, has also supported the validity of the BDI. The BDI can be interpreted as one syndrome (depression) composed of three factors: negative attitudes toward self, performance impairment, and somatic (bodily) disturbance.

The BDI has also been extensively tested for reliability, following established standards for psychological tests published in 1985. Internal consistency has been successfully estimated by over 25 studies in many populations. The BDI has been shown to be valid and reliable, with results corresponding to clinician ratings of depression in more than 90% of all cases.

Higher BDI scores have been shown in a few studies to be inversely related to educational attainment; the BDI, however, does not consistently correlate with sex, race, or age.

Behavior modification

Definition

Behavior modification is a treatment approach, based on the principles of operant conditioning, that replaces undesirable behaviors with more desirable ones through positive or negative **reinforcement**.

Purpose

Behavior modification is used to treat a variety of problems in both adults and children. Behavior modification has been successfully used to treat **obsessive-compulsive disorder** (OCD), **attention-deficit/hyperactivity disorder** (ADHD), phobias, **enuresis** (bed-wetting), **generalized anxiety disorder**, and **separation anxiety disorder**, among others.

Description

Behavior modification is based on the principles of operant conditioning, which were developed by American behaviorist B. F. Skinner (1904-1990). Skinner formulated the concept of operant conditioning, through which behavior could be shaped by reinforcement or lack of it. Skinner considered his concept applicable to a wide range of both human and animal behaviors and introduced operant conditioning to the general public in his 1938 book, *The Behavior of Organisms*.

One behavior modification technique that is widely used is positive reinforcement, which encourages certain behaviors through a system of rewards. In behavior therapy, it is common for the therapist to draw up a contract with the client establishing the terms of the reward system.

In behavior modification, extinction eliminates the incentive for unwanted behavior by withholding the expected response. A widespread parenting technique based on extinction is the time-out, in which a child is separated from the group when he or she misbehaves. This technique removes the expected reward of parental attention. *(Cindy Roesinger. Photo Researchers, Inc. Reproduced by permission.)*

Another behavior modification technique is negative reinforcement. Negative reinforcement is a method of training that uses a negative reinforcer. A negative reinforcer is an event or behavior whose reinforcing properties are associated with its removal. For example, terminating an existing electric shock after a rat presses a bar is a negative reinforcer.

In addition to rewarding desirable behavior, behavior modification can also discourage unwanted behavior, through punishment. Punishment is the application of an aversive or unpleasant stimulus in reaction to a particular behavior. For children, this could be the removal of television privileges when they disobey their parents or teacher. The removal of reinforcement altogether is called extinction. Extinction eliminates the incentive for unwanted behavior by withholding the expected response. A widespread parenting technique based on extinction is the time-out, in which a child is separated from the group when he or she misbehaves. This technique removes the expected reward of parental attention.

Results

Normal results are that undesirable behaviors are replaced with more desirable ones.

Bender Gestalt Test

Definition

The Bender Gestalt Test, or the Bender Visual Motor Gestalt Test, is a psychological assessment instrument used to evaluate visual-motor functioning and visual perception skills in both children and adults. Scores on the test are used to identify possible organic **brain** damage and the degree maturation of the nervous system. The Bender Gestalt was developed by **psychiatrist** Lauretta Bender in the late nineteenth century.

Purpose

The Bender Gestalt Test is used to evaluate visual maturity, visual motor integration skills, style of responding, reaction to frustration, ability to correct mistakes, planning and organizational skills, and motivation. Copying figures requires fine motor skills, the ability to discriminate between visual stimuli, the capacity to integrate visual skills with motor skills, and the ability to shift attention from the original design to what is being drawn.

Precautions

The Bender Gestalt Test should not be administered to an individual with severe visual impairment unless his or her vision has been adequately corrected with eyeglass-

KEY TERMS

Psychometric testing—Pertaining to testing and measurement of mental or psychological abilities. Psychometric tests convert an individual's psychological traits and attributes into a numerical estimation or evaluation.

es. Additionally, the test should not be given to an examinee with a severe motor impairment, as the impairment would affect his or her ability to draw the geometric figures correctly. The test scores might thereby be distorted.

The Bender Gestalt Test has been criticized for being used to assess problems with organic factors in the brain. This criticism stems from the lack of specific signs on the Bender Gestalt Test that are definitively associated with brain injury, **mental retardation**, and other physiological disorders. Therefore, when making a **diagnosis** of brain injury, the Bender Gestalt Test should never be used in isolation. When making a diagnosis, results from the Bender Gestalt Test should be used in conjunction with other medical, developmental, educational, psychological, and neuropsychological information.

Finally, psychometric testing requires administration and evaluation by a clinically trained examiner. If a scoring system is used, the examiner should carefully evaluate its reliability and validity, as well as the normative sample being used. A normative sample is a group within a population who takes a test and represents the larger population. This group's scores on a test are then be used to create "norms" with which the scores of test takers are compared.

Description

The Bender Gestalt Test is an individually administered pencil and paper test used to make a diagnosis of brain injury. There are nine geometric figures drawn in black. These figures are presented to the examinee one at a time; then, the examinee is asked to copy the figure on a blank sheet of paper. Examinees are allowed to erase, but cannot use any mechanical aids (such as rulers). The popularity of this test among clinicians is most likely the short amount of time it takes to administer and score. The average amount of time to complete the test is five to ten minutes.

The Bender Gestalt Test lends itself to several variations in administration. One method requires that the examinee view each card for five seconds, after which the card is removed. The examinee draws the figure from memory. Another variation involves having the examinee draw the figures by following the standard procedure. The examinee is then given a clean sheet of paper and asked to draw as many figures as he or she can recall. Last, the test is given to a group, rather than to an individual (i.e., standard administration). It should be noted that these variations were not part of the original test.

Results

A scoring system does not have to be used to interpret performance on the Bender Gestalt Test; however, there are several reliable and valid scoring systems available. Many of the available scoring systems focus on specific difficulties experienced by the test taker. These difficulties may indicate poor visual-motor abilities that include:

- Angular difficulty: This includes increasing, decreasing, distorting, or omitting an angle in a figure.
- Bizarre doodling: This involves adding peculiar components to the drawing that have no relationship to the original Bender Gestalt figure.
- Closure difficulty: This occurs when the examinee has difficulty closing open spaces on a figure, or connecting various parts of the figure. This results in a gap in the copied figure.
- Cohesion: This involves drawing a part of a figure larger or smaller than shown on the original figure and out of proportion with the rest of the figure. This error may also include drawing a figure or part of a figure significantly out of proportion with other figures that have been drawn.
- Collision: This involves crowding the designs or allowing the end of one design to overlap or touch a part of another design.
- Contamination: This occurs when a previous figure, or part of a figure, influences the examinee in adequate completion of the current figure. For example, an examinee may combine two different Bender Gestalt figures.
- Fragmentation: This involves destroying part of the figure by not completing or breaking up the figures in ways that entirely lose the original design.
- Impotence: This occurs when the examinee draws a figure inaccurately and seems to recognize the error, then, he or she makes several unsuccessful attempts to improve the drawing.
- Irregular line quality or lack of motor coordination: This involves drawing rough lines, particularly when the examinee shows a tremor motion, during the drawing of the figure.
- Line extension: This involves adding or extending a part of the copied figure that was not on the original figure.

- Omission: This involves failing to adequately connect the parts of a figure or reproducing only parts of a figure.
- Overlapping difficulty: This includes problems in drawing portions of the figures that overlap, simplifying the drawing at the point that it overlaps, sketching or redrawing the overlapping portions, or otherwise distorting the figure at the point at which it overlaps.
- Perseveration: This includes increasing, prolonging, or continuing the number of units in a figure. For example, an examinee may draw significantly more dots or circles than shown on the original figure.
- Retrogression: This involves substituting more primitive figures for the original design—for example, substituting solid lines or loops for circles, dashes for dots, dots for circles, circles for dots, or filling in circles. There must be evidence that the examinee is capable of drawing more mature figures.
- Rotation: This involves rotating a figure or part of a figure by 45° or more. This error is also scored when the examinee rotates the stimulus card that is being copied.
- Scribbling: This involves drawing primitive lines that have no relationship to the original Bender Gestalt figure.
- Simplification: This involves replacing a part of the figure with a more simplified figure. This error is not due to maturation. Drawings that are primitive in terms of maturation would be categorized under "Retrogression."
- Superimposition of design: This involves drawing one or more of the figures on top of each other.
- Workover: This involves reinforcing, increased pressure, or overworking a line or lines in a whole or part of a figure.

Additionally, observing the examinee's behavior while drawing the figures can provide the examiner with an informal evaluation and data that can supplement the formal evaluation of the examinee's visual and perceptual functioning. For example, if an examinee takes a large amount of time to complete the geometric figures, it may suggest a slow, methodical approach to tasks, compulsive tendencies, or depressive symptoms. If an examinee rapidly completes the test, this could indicate an impulsive style.

Benztropine

Definition

Benztropine is classified as an antiparkinsonian agent. It is sold in the United States under the brand name Cogentin and is also available under its generic name.

Purpose

Benztropine is used to treat a group of side effects (called parkinsonian side effects) that include tremors, difficulty walking, and slack muscle tone. These side effects may occur in patients who are taking antipsychotic medications used to treat mental disorders such as **schizophrenia**.

Description

Some medicines, called antipsychotic drugs, that are used to treat schizophrenia and other mental disorders can cause side effects that are similar to the symptoms of Parkinson's disease. The patient does not have Parkinson's disease, but he or she may experience shaking in muscles while at rest, difficulty with voluntary movements, and poor muscle tone. These symptoms are similar to the symptoms of Parkinson's disease.

One way to eliminate these undesirable side effects is to stop taking the antipsychotic medicine. Unfortunately, the symptoms of the original mental disorder usually come back, so in most cases simply stopping the antipsychotic medication is not a reasonable option. Some drugs such as benztropine that control the symptoms of

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Catheterization—Placing a tube in the bladder so that it can be emptied of urine.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinsonian—Related to symptoms associated with Parkinson's disease, a nervous system disorder characterized by abnormal muscle movement of the tongue, face, and neck, inability to walk or move quickly, walking in a shuffling manner, restlessness, and/or tremors.

Parkinson's disease also control the parkinsonian side effects of antipsychotic medicines.

Benztropine works by restoring the chemical balance between dopamine and acetylcholine, two neurotransmitter chemicals in the **brain**. Taking benztropine along with the antipsychotic medicine helps to control symptoms of the mental disorder, while reducing parkinsonian side effects. Benztropine is in the same family of drugs (commonly known as anticholinergic drugs) as **biperiden** and **trihexyphenidyl**.

Recommended dosage

Benztropine is available in 0.5-, 1.0-, and 2.0-mg tablets and in an injectable form containing 2 mg of drug in each 2 mL glass container. For the treatment of tremor, poor muscle tone, and similar side effects, benztropine should be started at a dose of 1 to 2 mg orally. In cases of severe side effects, benztropine can be given as an intramuscular injection two to three times daily or as needed. Parkinson-like side effects caused by antipsychotic drugs may come and go, so benztropine may not be needed on a regular basis. Benztropine may also be prescribed to prevent these side effects before they actually occur. This is called as prophylactic (preventative) therapy.

Precautions

Benztropine should never be used in children under age three. It should be used cautiously and with close physician supervision in older children and in the elderly. Benztropine, like all anticholinergic drugs, decreases sweating and the body's ability to cool itself. People who are unaccustomed to being outside in hot weather should take care to stay as cool as possible and drink extra fluids. People who are chronically ill, have a central nervous system disease, or who work outside during hot weather may need to avoid taking benztropine.

People who have the following medical problems may experience increased negative side effects when taking benztropine. Anyone with these problems should discuss their condition with their physician before starting the drug:

- glaucoma, especially closed-angle glaucoma
- intestinal obstruction
- prostate enlargement
- urinary bladder obstruction

Although rare, some patients experience euphoria while taking benztropine and may abuse it for this reason. Euphoria can occur at doses only two to four times the normal daily dose. Patients with a history of drug abuse should be observed carefully for benztropine abuse.

Side effects

Although benztropine helps to control the side effects of antipsychotic drugs, it can produce side effects of its own. A person taking benztropine may have some of the following reactions, which may vary in intensity:

- dry mouth
- dry skin
- blurred vision
- nausea or vomiting
- constipation
- disorientation
- drowsiness
- irritability

- increased heart rate
- urinary retention

Dry mouth, if severe to the point of causing difficulty speaking or swallowing, may be managed by reducing or temporarily discontinuing benztropine. Chewing sugarless gum or sucking on sugarless candy may also help to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement may be especially prone to urinary retention. Symptoms of this problem include having difficulty starting a urine flow and more difficulty passing urine than usual. This side effect may be severe and require discontinuation of the drug. Urinary retention may require catheterization. People who think they may be experiencing any side effects from this or any other medication should tell their physician.

Patients who take an overdose of benztropine are treated with forced vomiting, removal of stomach contents and stomach washing, activated charcoal, and respiratory support if needed. They are also given physostigmine, an antidote for anticholinergic drug poisoning.

Interactions

When drugs such as benztropine are taken with antidepressants such as **amitriptyline**, **imipramine**, **trimipramine**, **desipramine**, **nortriptyline**, **protriptyline**, **amoxapine**, and **doxepin** or with many antihistamines that also have anticholinergic properties, the effects and side effects of benztropine are usually intensified.

Drugs such as benztropine decrease the speed with which food moves through the stomach and intestines. Because of this, the absorption of other drugs being taken may be enhanced by benztropine. Patients receiving benztropine should be alert to unusual responses to other drugs they might be taking and report any changes to their physician.

Beta blockers

Definition

Beta blockers, also known as beta antagonists, are a class of drugs that were first developed for the treatment of certain heart conditions and hypertension. Later, beta blockers were also found to be useful in glaucoma, migraine, and some psychiatric disorders such as performance anxiety, tremors secondary to lithium, and **movement disorders** that are caused by some drugs used in the treatment of **psychosis**. In the United States, the most commonly used beta blocker used in psychiatric practice is **propranolol** (Inderal). Nadolol (Corgard), metoprolol (Lopressor), and atenolol (Tenormin) are also used in psychiatric practice but to a lesser degree.

Purpose

Beta blockers are proven effective in the treatment of performance anxiety, lithium-induced tremor, and neuroleptic-induced akathisia (a physical condition caused by certain antipsychotic drugs). Beta blockers have sometimes been used with benzodiazepines in treating alcohol withdrawal.

Description

Beta blockers act on that part of the central nervous system that controls mental alertness, lung function, heart rate, and blood vessels. Although there is more than one mechanism by which beta blockers work in anxiety states, the most beneficial result probably arises from the fact that beta blockers slow the heart to a normal rate and rhythm. Therefore, persons with performance anxiety do not experience the usual chest tightness and rapid heart rate that is associated with such acts as public speaking or acting.

Certain antipsychotic medications known as neuroleptics can cause an unwanted effect called akathisia, which is the inability to sit, stand still, or remain inactive. Patients are restless, and in severe cases, may pace constantly and forcefully and repeatedly stomp their feet. Beta blockers can sometimes treat this condition with a lower incidence of side effects than any other drugs used to treat this condition.

Propranolol is available in 10- to 90-mg tablets. Nadolol is available in 20-, 40-, 80-, 120-, and 160-mg tablets. Atenolol is available in 50- and 100-mg tablets. Metoprolol is available in 50- and 100-mg tablets.

Recommended dosage

For the treatment of performance anxiety, sometimes called stage fright, a single dose of propranolol ranging

KEY TERMS

Akathisia—Agitated or restless movement, usually affecting the legs. Movement is accompanied by a sense of discomfort and an inability to sit, stand still, or remain inactive for periods of time. Akathisia is a common side effect of some neuroleptic (antipsychotic) medications.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Tremor—Involuntary shaking of the hands and arms.

from 10–40 mg is given 20–30 minutes before the event causing the unwanted reactions.

For lithium-induced tremors that cannot be controlled by reducing caffeine intake or administering the dosage of lithium at bedtime, propranolol at a dose of 20–160 mg daily can be given in two or three evenly divided doses.

For akathisia caused by antipsychotic medications, propranolol can be administered at doses of 10–30 mg three times daily.

Precautions

Because of their ability to narrow airways, beta blockers, especially propranolol, should not be taken by people with asthma and chronic obstructive pulmonary disease (COPD). If there is an urgent need to use beta blockers in persons with respiratory problems, atenolol or metoprolol are the beta-blockers of choice because they are less likely to have this side effect, although even these drugs should also be used with caution. Patients with congestive heart failure or certain cardiac conduction abnormalities such as a heart block, should also receive these drugs with caution.

Beta blockers should be used with close physician monitoring in people with diabetes, since the symptoms of low blood sugar (increased heart rate, lightheadedness, and abnormal perspiration) may be not be recognized by patients.

Side effects

Beta blockers can cause undesired decreases in blood pressure and are typically not given if blood pressure is 90/60 mm Hg or less.

Beta blockers can also cause an undesired drop in heart rate. People whose resting heart rate is less than 55 beats per minute should not take beta blockers.

Occasionally, beta blockers can cause rash, weakness, nausea, vomiting, and stomach discomfort.

Interactions

Each medication in the class of beta blockers has the potential to interact with a multitude of other medications. Anyone starting beta blocker therapy should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all their health care providers, including dentists, that they are taking beta blockers.

Bibliotherapy

Definition

Bibliotherapy is an adjunct to psychological treatment that incorporates appropriate books or other written materials, usually intended to be read outside of **psychotherapy** sessions, into the treatment regimen.

Purpose

The goal of bibliotherapy is to broaden and deepen the client's understanding of the particular problem that requires treatment. The written materials may educate the client about the disorder itself or be used to increase the client's acceptance of a proposed treatment. Many people find that the opportunity to read about their problem outside the therapist's office facilitates active participation in their treatment and promotes a stronger sense of personal responsibility for recovery. In addition, many are relieved to find that others have had the same disorder or problem and have coped successfully with it or recovered from it. From the therapist's standpoint, providing a client with specific information or assignments to be completed outside regular in-office sessions speeds the progress of therapy.

KEY TERMS

Adjunct—A form of treatment that is not strictly necessary to a therapy regimen but is helpful.

Cognitive-behavioral therapy—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Dyslexia—A type of reading disorder.

Regimen—A regulated course of treatment for a medical or mental disorder.

Bibliotherapy has been applied in a variety of settings to many kinds of psychological problems, including eating disorders, anxiety and mood disorders, and alcohol and substance abuse. Many people find that the opportunity to read about their problem outside the therapist's office facilitates active participation in their treatment. *(Joseph Nettis. Photo Researchers, Inc. Reproduced by permission.)*

Bibliotherapy has been applied in a variety of settings to many kinds of psychological problems. Practitioners have reported successful use of bibliotherapy in treating eating disorders, anxiety and mood disorders, **agoraphobia**, alcohol and substance abuse, and stress-related physical disorders.

Precautions

Bibliotherapy is not likely to be useful with clients suffering from thought disorders, psychoses, limited intellectual ability, dyslexia, or active resistance to treatment. In addition, some clients may use bibliotherapy as a form of do-it-yourself treatment rather than seeking professional help.

Description

In most settings, bibliotherapy is used as an adjunct to more traditional forms of psychotherapy. Practitioners of cognitive-behavioral therapies are among the most enthusiastic supporters of bibliotherapy, particularly in the development of individualized treatment protocols, including workbooks, for specific disorders. For example, clients with eating disorders, especially **bulimia nervosa**, often benefit from receiving educational information appropriate to their stage of recovery, such as books or articles about cultural biases regarding weight, attractiveness, and dieting. This information helps clients better understand the rationale for their treatment and to work on new skills or behavioral changes more effectively.

Aftercare

Unlike many standard forms of psychotherapy, bibliotherapeutic approaches often include specific examples of ways to deal with relapses or setbacks. As long as the client keeps these materials, he or she has easy access to resources for getting back on track.

Risks

People who use self-help manuals without professional guidance run the risk of misapplying techniques or misdiagnosing their problems.

Normal results

As with any form of treatment, bibliotherapy is effective only if it actively engages the client's desire for and belief in recovery. For many people, additional information or workbooks that can be used in private reinforce their commitment to getting better. People who lack the time or finances to attend regular psychotherapy sessions at a practitioner's office often find that bibliotherapy can bridge the gap between infrequent appointments. Likewise, the nature of the disorder itself may preclude in-office treatment for some people, such as persons suffering from agoraphobia. Current research indicates that a bibliotherapeutic approach can be highly effective in helping agoraphobics better understand and cope with their symptoms.

Binge eating

Description

Binge eating is a form of overeating in which a person ingests a large amount of food during a discrete period of time (within one or two hours, for example) and experiences feelings of being out of control and unable to stop eating during the episode. In practice, the duration of a binge may vary greatly from one event to the next, making it difficult to define the number of binges occurring in a given day. Binge eating often occurs in the absence of hunger and is characterized by eating very rapidly; eating alone (due to embarrassment over the amount being eaten); and having strong negative feelings, such as guilt, shame and depression, following the binge. Typically, a binge episode ends only when all the desirable binge foods have been consumed or when the person feels too full to continue eating.

While binge eating is a symptom of **bulimia nervosa**, it differs from this disorder in that behaviors intended to get rid of the food (fasting, excessive exercise, or using laxatives or inducing vomiting to "purge" the food from the system) are present among those with bulimia, but are generally absent among binge eaters. Binge eating may also occur in **anorexia nervosa**.

The clinician's diagnostic handbook, the ***Diagnostic and Statistical Manual of Mental Disorders*** (fourth edition, text revised, published in 2000) subsumes binge eating under the **diagnosis** of eating disorders not otherwise specified. Binge eating disorder is, however, under consideration as a separate diagnostic category, pending further study.

Symptoms and treatments

Binge eating episodes may occur in response to strong negative emotions, such as depression or anxiety, or to less defined feelings of distress or tension. The act of bingeing seems to alleviate these uncomfortable feelings temporarily and binge eaters typically describe themselves as "numb" or "spaced out" while engaged in these behaviors. Some people report that binges are related to the ingestion of certain "trigger foods," usually carbohydrates, but regardless of the stimulus, the feeling of eating without being able to control one's intake is a frightening experience for most people. The aftermath of a binge often includes an overwhelming sense of self-disgust, depression and anxiety.

While people who binge eat are clearly at high risk for becoming overweight, there are important differences between simple **obesity** and binge eating. People who binge eat are far more likely to report significant mood problems, especially depression, and to report greater dissatisfaction with their weight and shape than are comparably obese persons. They are also more likely to describe themselves as experiencing personal problems and work difficulties and to be hypersensitive to the thoughts and opinions of others. Like people with bulimia nervosa, they also have an increased likelihood of being diagnosed with major depression, substance-related disorders, and **personality disorders**, yet the overall rates of recovery for binge eating disorders are actually more favorable than those obtained in bulimia.

Binge eating is not common among the general public, but it is prevalent among persons attending weight loss clinics, where as many as half of the participants may fit this description. Both males and females develop binge-eating problems, but the rate of occurrence is 1.5 times greater among women. Age of onset is usually adolescence through young adulthood and the course of the disorder is often marked by a long history of on-again, off-again dieting.

As is the case with other forms of eating disorders, identification of specific causes for binge eating has been difficult. Since many people report relief from painful or uncomfortable mental states while bingeing, the behavior offers short-term emotional relief, making it likely to be repeated. Some investigators have considered genetic influences and personality variables. Still others have suggested that the "culture of thinness" in western societies contributes to the tendency toward harsh self-evaluation characterizing binge-eaters who then turn to food for solace.

At present, the most effective treatment approach to reducing the incidence of binge eating appears to be **cognitive-behavioral therapy** (CBT). The goal of this therapy is the development of skills for effectively coping with emotional distress rather than seeking to numb or disguise troubling feelings. This therapy focuses on helping the affected individual to decrease the binge eating behavior by recognizing the connection between thoughts and behavior, and to change behavior by changing negative thinking patterns. Follow-up research has

been very encouraging, documenting both a decrease in depressive symptoms and a corresponding likelihood of healthy weight loss as the individual achieves better control of eating behaviors.

KEY TERMS

Bruxism—Habitual, often unconscious, grinding of the teeth.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Incontinence—Inability to control the release of urine or feces.

Irritable bowel syndrome (IBS)—A condition affecting the small and large intestine, usually associated with emotional stress. There may be complaints of diarrhea and pain in the lower abdomen.

Raynaud's syndrome—A disorder of the circulatory or vascular system characterized by abnormally cold hands and feet because of constricted blood vessels in these areas.

Temporomandibular joint disorder (TMJ)—Inflammation, irritation, pain, limited range of motion, and clicking sounds in the jaw caused by improper opening and closing of the joint.

Biofeedback

Definition

Biofeedback is a technique that uses monitoring instruments to measure and feed back information about muscle tension, heart rate, sweat responses, skin temperature, or **brain** activity.

Terms associated with biofeedback include applied psychophysiology or behavioral physiology. It is also viewed as a mind-body therapy method used in complementary and alternative medicine. Biofeedback is an important part of understanding the relationship between physical state and thoughts, feelings, and behaviors.

Purpose

The purpose of biofeedback is to enhance an individual's awareness of physical reactions to physical, emotional, or psychological **stress**, and their ability to influence their own physiological responses. The overall purpose is to develop self-regulation skills that play a role in improving health and well-being.

Biofeedback has been used as a part of a comprehensive treatment approach with a number of conditions, including chronic pain, irritable bowel syndrome (IBS), temporomandibular joint disorder (TMJ), Raynaud's syndrome, epilepsy, **attention-deficit/hyperactivity disorder** (ADHD), anxiety, migraine headaches, depression, traumatic brain injury, and **sleep disorders**. There is some support for using biofeedback in the treatment of diabetes when self-monitoring of blood glucose levels is maintained and within the context of regular physician consultation and supervision.

Biofeedback has been a useful tool in helping individuals with urinary incontinence regain bladder control by controlling the muscles used in urination. Sensors are placed in the vaginal or anal canal to help individuals learn when the muscles are properly contracted. A recent study found that this type of biofeedback treatment was safe, effective, and well liked by women patients 55 years and older.

Conditions related to stress are also treated using biofeedback, such as certain types of headaches, high blood pressure, bruxism or teeth grinding, **post-traumatic stress disorder** (PTSD), eating disorders, substance abuse, and some anxiety disorders. In treatment of

stress-related conditions, biofeedback is often used in combination with relaxation training. Sometimes, biofeedback is used to help individuals learn how to experience deeper relaxation, such as in childbirth education programs or general stress management. This is referred to as biofeedback-assisted relaxation training. Even for individuals who can achieve relaxation through other strategies such as **meditation** or relaxation, biofeedback can be a valuable added technique. Biofeedback offers special advantages, such as allowing the clinician to track closely the places where an individual tenses up and helps the individual learn what thoughts and feelings are associated with the tension.

Precautions

Biofeedback depends on the motivation and active participation of an individual. Thus, it may not be suitable for individuals with low motivation who are not willing to take a highly active role in treatment, such as those suffering from depression. Also, since biofeedback focuses on initiating behavioral changes, individuals inclined to examine their past to alleviate problems and symptoms may benefit more from other treatment types, such as **psychotherapy**. Individuals with cognitive impairment may be unable to remain engaged in the treatment, depending on their level of functioning. Also, individuals with a pacemaker or other implanted electrical devices should inform their health care professional before entering biofeedback training, as certain types of biofeedback sensors may interfere with the devices. Patients with specific pain symptoms in which the cause is unknown should have a thorough medical examination to rule out any serious underlying disease before starting biofeedback training. Biofeedback can be used in combination with conventional therapies; however, while it can be used in combination with conventional medical treatment for illnesses such as cancer and diabetes, it should not replace those treatments.

Research on the success of biofeedback in treating certain conditions is inconclusive or needs to be validated. Some research studies use a small number of participants, which makes it difficult to generalize the results to a larger population. Also, many conditions have different subtypes with a variety of psychological, social, and physical causes. This fact, combined with research design concerns, makes it difficult to compare research studies. For example, while most studies have reported positive outcomes in the treatment of alcohol abuse and dependence, problems with methods and statistical analyses have called study results into question. Also, its effectiveness in treating opiate abuse or dependence has not been consistently shown, as with its use in treating menopausal hot flashes, and there are limitations in studies relating to its use in cancer treatment. Continued research is needed to further evaluate and improve different biofeedback techniques for various conditions.

Description

According to the Association for Applied Psychophysiology and Biofeedback, the technique was developed in the early 1970s by psychologists and physicians. These techniques continue to be used by psychologists, physicians, nurses, and other health care professionals such as physical therapists. Prior to beginning any biofeedback training, individuals may need a comprehensive psychological, educational, and/or medical assessment. Biofeedback can be used in conjunction with nonmedical treatments, such as psychotherapy, **cognitive-behavioral therapy**, and behavioral treatment strategies.

How biofeedback works

Biofeedback utilizes electronic sensors, or electrodes, attached to various parts of the body to detect changes in physical responses. Signals then inform the individual of these changes by means of visual or auditory signals such as a light display or a series of beeps. While the individual views or listens to feedback, he or she begins to recognize thoughts, feelings, and mental images that influence his or her physical reactions. By monitoring this mind-body connection, the individual can use the same thoughts, feelings, and mental images as cues or reminders to become more relaxed, or to change heartbeat, brain wave patterns, body temperature, and other body functions. The individual uses trial-and-error to change the signals change in the desired direction. For example, individuals trying to control their blood pressure levels may see a light flash whenever the pressure drops below a certain level. They may then try to remember what their thoughts and feelings were at the moment and deliberately maintain them to keep the blood pressure level low.

Through training, the individual learns to control the targeted physical response and, over time, is able to recognize what is required to reduce problematic symptoms. Eventually, the external biofeedback becomes unnecessary as the individual learns to perceive internal physical responses and make the desired changes. The individual then has a powerful, portable, and self-administered treatment tool to deal with problematic symptoms.

Three stages of biofeedback training

- Awareness of the problematic physical response: Individuals may complete a psychophysiological stress

profile (PSP) to identify how their bodies respond to a variety of stressors and determine their ability to overcome undesired physical reactions. This involves a period of rest, stress, and recovery. For example, various sensors are attached to various parts of the body, and a baseline measurement lasting from two to four minutes records physical responses. The individual then goes through a standard set of stressors (such as rapid math calculations or running in place) each lasting from two to four minutes. This is followed by another relaxation period to determine the length of the recovery period.

- Using signals from the biofeedback equipment to control physical responses: The individual is assisted in reaching certain goals related to managing a specific physical response.
- Transferring control from biofeedback equipment or the health care professional: Individuals learn to identify triggers that alert them to implement their new-found self-regulation skills.

Types of biofeedback equipment

- Electromyograph (EMG): Sensors (or electrodes) placed on the skin on pertinent parts of the body monitor electrical activity in muscles, specifically tension. This is the most frequently used biofeedback method in the treatment of various neurologic disorders such as **stroke**, cerebral palsy, traumatic brain injury, and multiple sclerosis. In children and adolescents, EMG may be used to treat tension headaches, **enuresis**, and **encopresis**. In treating TMJ or bruxism, EMG sensors are placed on jaw muscles. Chronic pain is treated by monitoring muscle tension in various places on the body.
- Galvanic skin response (GSR): Sensors on the fingers monitor perspiration or sweating. This is also referred to as obtaining a skin conductance level (SCL). GSR may be used in the treatment of anxiety, fears or phobias, stress, and sleep problems.
- Temperature or thermal sensors: Sensors monitor body temperature and changes in blood flow. Changes in hand temperature, for example, can indicate relaxation when there is increased blood flow to the skin. Temperature biofeedback may be useful for treating migraine headache, Raynaud's disorder, and anxiety disorders.
- Heart rate sensors: A pulse monitor placed on the fingertip monitors pulse rate. Increases in heart rate are associated with emotional arousal, such as being angry or fearful. Decreases in heart rate are associated with relaxation.
- Capnometry (CAP): Respiratory sensors monitor oxygen intake and carbon dioxide output. This differentiates correct breathing from problematic breathing practices. Breath control training may be used to treat panic attacks, asthma, and a variety of stress-related conditions.
- Electroencephalographs (EEG) or neurofeedback: Sensors attached to the scalp monitor brain wave activity in different parts of the brain. It may be used to treat conditions with proven or suspected impact on brain wave patterns such as seizure disorders or epilepsy, ADHD, learning disabilities, migraine headaches, traumatic brain injury, and sleep disorders.

A patient undergoes biofeedback monitoring for stress. *(Photo by Will and Deni McIntyre. Photo Researchers, Inc. Reproduced by permission.)*

Biofeedback is geared toward whatever a person finds most appealing and understandable and provided in several formats such as auditory, visual, or multimedia. Audio feedback, that may take the form of changes in tone and pitch, is useful because visual attention is not necessary. Visual feedback can be provided in various forms such as bar or line graphs on a computer screen. Initially, it was thought that—over time—computer signals could become boring or visually unappealing. In response to this, Barry Bittman developed Mindscope in 1992 that displays video scenes with realistic sounds on a high-definition television set connected to a computer. Physical responses detected by the biofeedback equipment control an engaging audiovisual environment of beautiful and realistic scenes. Clarity, perspective,

motion, and sounds improve as the individual deepens their relaxation. For children and adolescents, this may be described as a "video game for the body." Visual displays for EMG biofeedback may include sports such as basketball, baseball, and golf, where the individual plays against the computer.

The setting in which biofeedback training takes place can vary. Sometimes the clinician, client, and equipment are in the same room. Sometimes the client may sit in comfortable seating in a semi-dark, quiet room while the clinician is in another room with the equipment. In this arrangement, the clinician and client may communicate using an intercom.

In some cases, children and adolescents may reach the desired level of control in three to five sessions. Depending on the condition, biofeedback training may require a series of sessions for several days or weeks. In general, it may take 10 or 15 sessions at the lower end to 40 or 50 sessions at the higher end.

Preparation

Biofeedback is most successful when individuals are motivated to learn. It is useful for people who have difficulty relaxing, even when they make efforts to do so. A receptive and open attitude is important for attaining desired responses rather than actively focusing on attaining them. It is important that individuals are willing to practice regularly at home to apply the skill to everyday life. Establishing a foundation of trust and confidence in the health care professional is an important component of biofeedback training.

Before beginning biofeedback training, an initial consultation will be conducted to record medical history, treatment background, and biofeedback goals. The procedure will be explained to provide a clear understanding of how and why the training will be helpful. The individual may be shown the equipment and told where they will be placed and how they work.

Before electrodes are placed on the body, the skin surface must be adequately prepared by using alcohol preparation pads to remove oils, makeup, and dead skin cells that may interfere with the biofeedback signal. An electrode paste is then applied to the sensor, or a small adhesive pad is used to adhere the sensor to the skin. Heart rate, temperature, and GSR monitors may be placed on the fingertip with a Velcro or elastic band. With CAP, the tip of a small, flexible, plastic tube is positioned in the nostril using tape. An individual may be taught several forms of biofeedback initially, then the training may be tailored to the individual's preference.

The biofeedback trainer must have technical skill, an understanding of basic anatomy and physiology, knowledge of various conditions, and familiarity with computer hardware and software. The American Psychological Association views biofeedback as a proficiency area, master's and doctoral level training programs are available through a variety of sources, and certification is available through the Biofeedback Certification Institute of America.

Aftercare

One or two follow-up sessions may be arranged two to four months after the initial set of appointments. In this way, long-term progress can be assessed, support can be provided, and adjustments can be made, if needed.

Risks

There are no known side effects with properly administered biofeedback. Problems may occur if biofeedback is used to treat certain conditions where the use of biofeedback is not advised.

Normal results

A normal result may be indicated by achieving the desired changes in muscle tension, heart rate, sweat activity, respiration rate, temperate change, and brainwave activity. Health care professionals may use various criteria or normal values that have been developed for some biofeedback equipment. These values indicate levels that can be expected from normal physiological functioning or relaxation. Importantly, an individual learns to control their physical reactions, which may lead to feelings of empowerment and confidence.

Abnormal results

Unusual results may arise from a number of factors, including poor sensor or electrode contact with the skin and interference from other electrical signals or "noise." Some equipment may react to room temperature conditions, especially when the room is very hot or very cold. Although inexpensive monitoring equipment is available, such as watches that monitor heartbeat and handheld GSR devices, their results may not be accurate.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Catheterization—Placing a tube in the bladder so that it can be emptied of urine.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinsonian—Related to symptoms associated with Parkinson's disease, a nervous system disorder characterized by abnormal muscle movement of the tongue, face, and neck, inability to walk or move quickly, walking in a shuffling manner, restlessness, and/or tremors.

Biperiden

Definition

Biperiden is classified as an antiparkinsonian agent. It is sold in the United States under the brand name of Akineton.

Purpose

Biperiden is used to treat a group of side effects (called parkinsonian side effects) that include tremors, difficulty walking, and slack muscle tone. These side effects may occur in patients who are taking antipsychotic medications used to treat mental disorders such as **schizophrenia**.

Description

Some medicines, called antipsychotic drugs, that are used to treat schizophrenia and other mental disorders can cause side effects that are similar to the symptoms of Parkinson's disease. The patient does not have Parkinson's disease, but he or she may experience shaking in muscles while at rest, difficulty with voluntary movements, and poor muscle tone. These symptoms are similar to the symptoms of Parkinson's disease.

One way to eliminate these undesirable side effects is to stop taking the antipsychotic medicine. Unfortunately, the symptoms of the original mental disorder usually come back, so in most cases simply stopping the antipsychotic medication is not a reasonable option. Some drugs such as biperiden that control the symptoms of Parkinson's disease

also control the parkinsonian side effects of antipsychotic medicines.

Biperiden works by restoring the chemical balance between dopamine and acetylcholine, two neurotransmitter chemicals in the **brain**. Taking biperiden along with the antipsychotic medicine helps to control symptoms of the mental disorder, while reducing parkinsonian side effects. Biperiden is in the same family of drugs (commonly known as anticholinergic drugs) as **benztropine**, **amantadine**, and **trihexyphenidyl**.

Recommended dosage

Biperiden is available in 2-mg tablets. For the treatment of tremor, poor muscle tone, and similar parkinsonian side effects, the dose of biperiden is 2 mg orally one to three times daily. Parkinson-like side effects caused by antipsychotic drugs may come and go, so biperiden may not be needed on a regular basis. Biperiden may also be prescribed to prevent these side effects before they actually occur. This is called as prophylactic (preventative) therapy.

Precautions

Biperiden should never be used in children under age three. It should be used cautiously and with close physician supervision in older children and in the elderly. Biperiden, like all anticholinergic drugs, decreases sweating and the body's ability to cool itself. People who are unaccustomed to being outside in hot weather should take care to stay as cool as possible and drink extra fluids. People who are chronically ill, have a central nervous system disease, or who work outside during hot weather may need to avoid taking biperiden.

People who have the following medical problems may experience increased negative side effects when taking biperiden. Anyone with these problems should discuss their condition with their physician before starting the drug:

- glaucoma, especially closed-angle glaucoma
- intestinal obstruction
- prostate enlargement
- urinary bladder obstruction

Although rare, some patients experience euphoria while taking biperiden and may abuse it for this reason. Euphoria can occur at doses only two to four times the normal daily dose. Patients with a history of drug abuse should be observed carefully for biperiden abuse.

Side effects

Although biperiden helps control the side effects of antipsychotic drugs, it can produce side effects of its own. A person taking biperiden may have some of the following side effects, which may vary in intensity:

- dry mouth
- dry skin
- blurred vision
- nausea or vomiting
- constipation
- disorientation
- drowsiness
- irritability
- increased heart rate
- urinary retention

Dry mouth, if severe to the point of causing difficulty in speaking or swallowing, may be managed by dosage reduction or temporary discontinuation of the drug. Chewing sugarless gum or sucking on sugarless candy may also help to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement may be especially prone to urinary retention. Symptoms of this problem include having difficulty starting a urine flow and more difficulty passing urine than usual. This side effect may be severe and require discontinuation of the drug. Urinary retention may require catheterization. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Patients who take an overdose of biperiden are treated with forced vomiting, removal of stomach contents and stomach washing, activated charcoal, and respiratory support if needed. They are also given physostigmine, an antidote for anticholinergic drug poisoning.

Interactions

When drugs such as biperiden are taken with antidepressants such as **amitriptyline**, **imipramine**, **trimipramine**, **desipramine**, **nortriptyline**, **protriptyline**, **amoxapine**, and **doxepin**, as well as with many antihistamines that also have anticholinergic properties, the effects of biperiden are usually intensified.

Drugs such as biperiden decrease the speed with which food moves through the stomach and intestines. Because of this, it is possible that the absorption of some drugs may be enhanced by biperiden. Patients receiving biperiden should be observed for unusual responses to other drugs they might be taking.

Bipolar disorder

Definition

Bipolar, or manic-depressive, disorder is a mood disorder that causes radical emotional changes and mood swings, from manic highs to depressive lows. The majority of bipolar individuals experience alternating episodes of mania (an elevated or euphoric mood or irritable state) and depression.

Description

In the United States alone, bipolar disorder afflicts an estimated three million people. According to a report by the National Institutes of Mental Health, the disorder costs over $45 billion annually. The average age of onset of bipolar disorder is from adolescence through the early twenties. However, because of the complexity of the disorder, a correct **diagnosis** can be delayed for several years or more.

The Diagnostic and Statistical Manual of Mental Disorders, fourth edition text revised (*DSM-IV-TR*), the diagnostic standard for mental health professionals in the United States, defines four separate categories of bipolar disorder: bipolar I, bipolar II, cyclothymia, and bipolar not otherwise specified (NOS).

Bipolar I disorder is characterized by manic episodes, the "high" of the manic-depressive cycle. A bipolar patient experiencing mania often has feelings of self-importance, elation, talkativeness, increased sociability, and a desire to embark on goal-oriented activities, coupled with the characteristics of irritability, impatience, impulsiveness, hyperactivity, and a decreased need for sleep. Usually this manic period is followed by a period of depression, although a few bipolar I individuals may not experience a major depressive episode. Mixed states, where both manic or hypomanic symptoms and depressive symptoms occur at the same time, also occur frequently with bipolar I patients (for example, depression with the racing thoughts of mania). Also, dysphoric mania is common (mania characterized by anger and irritability).

Bipolar II disorder is characterized by major depressive episodes alternating with episodes of hypomania, a milder form of mania. Bipolar depression may be difficult to distinguish from unipolar depression (depression without mania, as found in **major depressive disorder**). Patients with bipolar depression tend to have extremely low energy, retarded mental and physical processes, and more profound **fatigue** (for example, hypersomnia—a sleep disorder marked by a need for excessive sleep or sleepiness when awake) than people with unipolar depression.

KEY TERMS

Anticonvulsant medication—A medication that prevents convulsions or seizures; often prescribed in the treatment of epilepsy. Several anticonvulsant medications have been found effective in the treatment of bipolar disorder.

Antipsychotic medication—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

ECT—Electroconvulsive therapy is sometimes used to treat depression or mania when pharmaceutical treatment fails.

Hypomania—A milder form of mania which is characteristic of bipolar II disorder.

Mania—An elevated or euphoric mood or irritable state that is characteristic of bipolar I disorder. This state is characterized by mental and physical hyperactivity, disorganization of behavior, and inappropriate elevation of mood.

Mixed mania/mixed state—A mental state in which symptoms of both depression and mania occur simultaneously.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells. Changes in the levels of certain neurotransmitters, such as serotonin, norepinephrine, and dopamine, are thought to be related to bipolar disorder.

Psychomotor retardation—Slowed mental and physical processes characteristic of a bipolar depressive episode.

Cyclothymia refers to the cycling of hypomanic episodes with depression that does not reach major depressive proportions. A third of patients with cyclothymia will develop bipolar I or II disorder later in life.

A phenomenon known as rapid cycling occurs in up to 20% of bipolar I and II patients. In rapid cycling, manic and depressive episodes must alternate frequently—at least four times in 12 months—to meet the diagnostic definition. In some cases of "ultra-rapid cycling," the patient may bounce between manic and depressive states several times within a 24-hour period. This condition is very hard to distinguish from mixed states.

Bipolar NOS is a category for bipolar states that do not clearly fit into the bipolar I, II, or cyclothymia diagnoses.

Causes and symptoms

The source of bipolar disorder has not been clearly defined. Because two-thirds of bipolar patients have a family history of emotional disorders, researchers have searched for a genetic link to the disorder. Several studies have uncovered a number of possible genetic connections to the predisposition for bipolar disorder. There is significant evidence that correlates bipolar II with genetic causes. Studies have shown that identical twins have an 80% concordance rate (presence of the same disorder). Additionally, studies have demonstrated that the disorder is transmitted to children by autosomal dominant inheritance. This means that either affected parent (father or mother) has a 50% chance of having a child (regardless if the child is male or female) with the disorder.

Further studies concerning the genetic correlations have revealed specific chromosomes (the structures that contain genes) that contain mutated genes. Susceptible genes are located in specific regions of chromosomes 13, 18, and 21. The building blocks of genes, called nucleotides, are normally arranged in a specific order and quantity. If these nucleotides are repeated, a genetic abnormality usually results. Recent evidence suggests that a special type of nucleotide repeat is observed in persons with bipolar II on chromosome 18. However, the presence of this sequence does not worsen the disorder or change the age of onset. It is currently thought that expression of bipolar II involves multiple mutated genes. Further research is ongoing to discover precise mechanisms and to develop genetic markers (gene tags) that would predict which individuals are at higher risk.

Another possible biological cause for bipolar disorder under investigation is the presence of an excessive calcium buildup in the cells. Also, dopamine and other neurochemical transmitters (the chemicals that transmit messages from nerve cell to nerve cell) appear to be implicated in bipolar disorder and these are under intense investigation.

Over half of patients diagnosed with bipolar disorder have a history of substance abuse. There is a high rate of association between cocaine abuse and bipolar disorder. Some studies have shown up to 30% of abusers meeting the criteria for bipolar disorder. The emotional and physical highs and lows of cocaine use correspond to the manic depression of the bipolar patient, making the disorder difficult to diagnose.

For some bipolar patients, manic and depressive episodes coincide with seasonal changes. Depressive episodes are typical during winter and fall, and manic episodes are more probable in the spring and summer months.

Symptoms of bipolar depressive episodes include low energy levels, feelings of despair, difficulty concentrating, extreme fatigue, and psychomotor retardation (slowed mental and physical capabilities). Manic episodes are characterized by feelings of euphoria, lack of inhibitions, racing thoughts, diminished need for sleep, talkativeness, risk taking, and irritability. In extreme cases, mania can induce **hallucinations** and other psychotic symptoms such as grandiose **delusions** (ideas that the person affected is extremely important or has some unrecognized talent or insight).

Demographics

Manic-depression is a common psychological disorder that is difficult to detect. As stated, it is estimated that about three million people in the United States are affected. The disorder is more common among women than men. Women have been observed at increased risk of developing subsequent episodes in the period immediately following childbirth.

Diagnosis

Bipolar disorder is usually diagnosed and treated by a **psychiatrist** and/or a **psychologist** with medical assistance. In addition to an interview, several clinical inventories or scales may be used to assess the patient's mental status and determine the presence of bipolar symptoms. These include the Millon Clinical Multiaxial Inventory III (MCMI-III), **Minnesota Multiphasic Personality Inventory** II (MMPI-2), the Internal State Scale (ISS), the Self-Report Manic Inventory (SRMI), and the Young Mania Rating Scale (YMRS). The tests are verbal and/or written and are administered in both hospital and outpatient settings.

Psychologists and psychiatrists typically use the criteria listed in the *DSM-IV-TR* as a guideline for diagnosis of

bipolar disorder and other mental illnesses. *DSM-IV-TR* describes a **manic episode** as an abnormally elevated or irritable mood lasting a period of at least one week that is distinguished by at least three of the mania symptoms: inflated self-esteem, decreased need for sleep, talkativeness, racing thoughts, distractibility, increase in goal-directed activity, or excessive involvement in pleasurable activities that have a high potential for painful consequences. If the mood of the patient is irritable and not elevated, four of the symptoms are required.

Although many clinicians find the criteria too rigid, a hypomanic diagnosis requires a duration of at least four days with at least three of the symptoms indicated for manic episodes (four if mood is irritable and not elevated). *DSM-IV-TR* notes that unlike manic episodes, hypomanic episodes do not cause a marked impairment in social or occupational functioning, do not require **hospitalization**, and do not have psychotic features (no delusions or hallucinations). In addition, because hypomanic episodes are characterized by high energy and goal-directed activities and often result in a positive outcome, or are perceived in a positive manner by the patient, bipolar II disorder can go undiagnosed.

Bipolar symptoms often appear differently in children and adolescents than they appear in adults. Manic episodes in these age groups are typically characterized by more psychotic features than in adults, which may lead to a misdiagnosis of **schizophrenia**. Children and adolescents also tend toward irritability and aggressiveness instead of elation. Further, symptoms tend to be chronic, or ongoing, rather than acute, or episodic. Bipolar children are easily distracted, impulsive, and hyperactive, which can lead to a misdiagnosis of **attention-deficit/hyperactivity disorder** (ADHD). Furthermore, their aggression often leads to violence, which may be misdiagnosed as a **conduct disorder**.

Substance abuse, thyroid disease, and use of prescription or over-the-counter medication can mask or mimic the presence of bipolar disorder. In cases of substance abuse, the patient must ordinarily undergo a period of **detoxification** and abstinence before a mood disorder is diagnosed and treatment begins.

Treatment

Bipolar disorder is usually treated with both medical and psychosocial interventions. Psychosocial therapies address both psychological and social issues.

Medical interventions

A combination of mood-stabilizing agents with antidepressants, antipsychotics, and anticonvulsants is used to regulate manic and depressive episodes.

MOOD-STABILIZING AGENTS. Mood-stabilizing agents such as lithium, **carbamazepine**, and **valproic acid** (valproate) are prescribed to regulate the manic highs and lows of bipolar disorder:

- Lithium (**lithium carbonate**, Cibalith-S, Eskalith, Lithane, Lithobid, Lithonate, Lithotabs) is one of the oldest and most frequently prescribed drugs available for the treatment of bipolar mania and depression. Because the drug takes four to ten days to reach a therapeutic level in the bloodstream, it is sometimes prescribed in conjunction with neuroleptics (other psychiatric drugs) and/or benzodiazepines (medications that ease tension by slowing down the central nervous system) to provide more immediate relief of a manic episode. Lithium has also been shown to be effective in regulating bipolar depression, but is not recommended for mixed mania. Lithium may not be an effective long-term treatment option for rapid cyclers, who typically develop a tolerance for it, or may not respond to it. Possible side effects of the drug include weight gain, thirst, nausea, and hand tremors. Prolonged lithium use may also cause hyperthyroidism (a disease of the thryoid marked by heart palpitations, nervousness, the presence of goiter, sweating, and a wide array of other symptoms.)
- Carbamazepine (Tegretol, Atretol) is an anticonvulsant drug (a drug to treat **seizures**) usually prescribed in conjunction with other mood-stabilizing agents. The drug is often used to treat bipolar patients who have not responded well to lithium therapy. Blurred vision and abnormal eye movement are two possible side effects of carbamazepine therapy.
- Valproic acid (**divalproex sodium**, or Depakote; valproate, or Depakene) is one of the few drugs available that has been proven effective in treating rapid cycling bipolar and mixed states patients. Valproate is prescribed alone or in combination with carbamazepine and/or lithium. Stomach cramps, indigestion, diarrhea, hair loss, appetite loss, nausea, and unusual weight loss or gain are some of the common side effects of valproate.

ANTIDEPRESSANTS. Because antidepressants may stimulate manic episodes in some bipolar patients, their use is typically short-term. Selective serotonin reuptake inhibitors (SSRIs) or, less often, monoamine oxidase inhibitors (MAO inhibitors) are prescribed for episodes of bipolar depression. Tricyclic antidepressants used to treat unipolar depression may trigger rapid cycling in bipolar patients and are, therefore, not a preferred treatment option for bipolar depression.

- SSRIs, such as **fluoxetine** (Prozac), **sertraline** (Zoloft), and **paroxetine** (Paxil), regulate depression by regulating levels of serotonin, a neurotransmitter. Anxiety, diarrhea, drowsiness, headache, sweating,

nausea, sexual problems, and **insomnia** are all possible side effects of SSRIs.

- MAOIs such as **tranylcypromine** (Parnate) and **phenelzine** (Nardil) block the action of monoamine oxidase (MAO), an enzyme in the central nervous system. Patients taking MAOIs must cut foods high in tyramine (found in aged cheeses and meats) out of their diet.
- **Bupropion** (Wellbutrin) is a heterocyclic antidepressant. The exact neurochemical mechanism of the drug is not known, but it has been effective in regulating bipolar depression in some patients. Side effects of bupropion include agitation, anxiety, confusion, tremor, dry mouth, fast or irregular heartbeat, headache, and insomnia.

ADJUNCT TREATMENTS. Adjunct treatments are used in conjunction with a long-term pharmaceutical treatment plan:

- Long-acting benzodiazepines (medications that ease tension by slowing the central nervous system) such as **clonazepam** (Klonapin) and **alprazolam** (Xanax) are used for rapid treatment of manic symptoms to calm and sedate patients until mania or hypomania have waned and mood-stabilizing agents can take effect. Sedation is a common effect, and clumsiness, lightheadedness, and slurred speech are other possible side effects of benzodiazepines.
- Neuroleptics (antipsychotic medications) such as **chlorpromazine** (Thorazine) and **haloperidol** (Haldol) are also used to control mania while a mood stabilizer such as lithium or valproate takes effect. Because neuroleptic side effects can be severe (difficulty in speaking or swallowing, paralysis of the eyes, loss of balance control, muscle spasms, severe restlessness, stiffness of arms and legs, tremors in fingers and hands, twisting movements of body, and weakness of arms and legs), benzodiazepines are generally preferred over neuroleptics.
- ECT, or **electroconvulsive therapy**, has a high success rate for treating both unipolar and bipolar depression, and mania. However, because of the convenience of drug treatment and the **stigma** sometimes attached to ECT therapy, ECT is usually employed after all pharmaceutical treatment options have been explored. ECT is given under anesthesia and patients are given a muscle relaxant medication to prevent convulsions. The treatment consists of a series of electrical pulses that move into the **brain** through electrodes on the patient's head. Although the exact mechanisms behind the success of ECT therapy are not known, it is believed that this electrical current alters the electrochemical processes of the brain, consequently relieving depression. Headaches, muscle soreness, nausea, and confusion are possible side effects immediately following an ECT procedure. Temporary memory loss has also been reported in ECT patients. In bipolar patients, ECT is often used in conjunction with drug therapy.

Calcium channel blockers (nimodipine, or Nimotop), typically used to treat angina and hypotension (low blood pressure), have been found effective, in a few small studies, for treating rapid cyclers. Calcium channel blockers stop the excess calcium buildup in cells that is thought to be a cause of bipolar disorder. They are usually used in conjunction with other drug therapies such as carbamazepine or lithium.

Clozapine (Clozaril) is an antipsychotic medication used to control manic episodes in patients who have not responded to typical mood-stabilizing agents. The drug has also been a useful prophylactic, or preventative treatment, in some bipolar patients. Common side effects of clozapine include tachycardia (rapid heart rate), hypotension, constipation, and weight gain. Agranulocytosis, a potentially serious but reversible condition in which the white blood cells that typically fight infection in the body are destroyed, is a possible side effect of clozapine. Patients treated with the drug should undergo weekly blood tests to monitor white blood cell counts.

Risperidone (Risperdal) is an antipsychotic medication that has been successful in controlling mania in several clinical trials when low doses were administered. The side effects of risperidone are mild compared to many other antipsychotics (constipation, coughing, diarrhea, dry mouth, headache, heartburn, increased length of sleep and dream activity, nausea, runny nose, sore throat, fatigue, and weight gain).

A new potential treatment for bipolar II disorder may be **gabapentin**, an anticonvulsant that may help treat mania. Recent reports indicate that gabapentin is effective for treating sudden onset bipolar II. Very recent evidence suggests, however, that gabapentin can potentially induce aggressive and disruptive behavior in children treated with this drug for seizures.

rTMS, or repeated transcranial magnetic stimulation is a new and still experimental treatment for the depressive phase of bipolar disorder. In rTMS, a large magnet is placed on the patient's head and magnetic fields of different frequency are generated to stimulate the left front cortex of the brain. Unlike ECT, rTMS requires no anesthesia and does not induce seizures.

Psychosocial interventions

Because bipolar disorder is thought to be biological in nature, psychological therapy is recommended as a companion to, but not a substitute for, pharmaceutical treatment of the disease. **Psychotherapy**, such as **cogni-**

tive-behavioral therapy, can be a useful tool in helping patients and their families adjust to the disorder, in encouraging **compliance** to a medication regimen, and in reducing the risk of **suicide**. Also, educative counseling is recommended for the patient and family.

In educative counseling, patients (and their families) learn of the high rates of social dysfunction and marital discord associated with this disorder. Patients also learn how their treatment will progress, which factors can affect treatment, and what kind of follow-up after treatment will be implemented. Genetic counseling should be a part of **family education** programs since this disorder is more prevalent among first-degree relatives of individuals with the disorder.

Social support for individuals with bipolar disorder is also important. Some people with the disorder, as well as their families, may find **support groups** helpful.

Alternative treatment

General recommendations include maintaining a calm environment, avoiding over-stimulation, getting plenty of rest, regular exercise, and proper diet. Some Chinese herbs may soften mood swings, but care must be taken (and good communication with the physician is essential) when combining herbal therapies with medications. **Biofeedback** is effective in helping some patients control symptoms such as irritability, poor self-control, racing thoughts, and sleep problems. A diet low in vanadium (a mineral found in meats and other foods) and high in vitamin C may be helpful in reducing depression.

Prognosis

While most patients will show some positive response to treatment, response varies widely, from full recovery to a complete lack of response to all drugs and/or ECT therapy. Drug therapies frequently need adjustment to achieve the maximum benefit for the patient. Bipolar disorder is a chronic recurrent illness in over 90% of those afflicted, and one that requires lifelong observation and treatment after diagnosis. Patients with untreated or inadequately treated bipolar disorder have a suicide rate of 15-25% and a nine-year decrease in life expectancy. With proper treatment, the life expectancy of the bipolar patient increases by nearly seven years and work productivity increases by ten years.

Prevention

The ongoing medical management of bipolar disorder is critical to preventing relapse (recurrence) of manic episodes. Even in carefully controlled treatment programs, bipolar patients may experience recurring episodes of the disorder. Patient education in the form of psychotherapy or **self-help groups** is crucial for training bipolar patients to recognize signs of mania and depression and to take an active part in their treatment program.

Bipolar disorders

Definition

Bipolar disorders is the name given to a group of mental disorders characterized by extreme fluctuations in

KEY TERMS

Bipolar disorder not otherwise specified—Disorder of mood involving mood swings that do not meet criteria for other disorders specified above.

Bipolar disorders—Disorders characterized by wide fluctuations in mood.

Bipolar I disorder—A major mood disorder characterized by full-blown manic episodes, often interspersed with episodes of major depression.

Bipolar II disorder—Disorder with major depressive episodes and mild manic episodes known as hypomania.

Cyclothymic disorder—A relatively mild mood disorder characterized by mood swings between mild depression to mild mania.

Depression—A mental state characterized by excessive sadness. Other symptoms include altered sleep patterns, thoughts of suicide, difficulty concentrating, agitation, lack of energy, and loss of enjoyment in activities that are usually pleasurable.

Hypomania—A milder form of mania which is characteristic of bipolar II disorder.

Mania—An elevated or euphoric mood or irritable state that is characteristic of bipolar I disorder. This state is characterized by mental and physical hyperactivity, disorganization of behavior, and inappropriate elevation of mood.

mood. People diagnosed with bipolar disorders experience moods ranging from deepest depression to mania, often with periods of less extreme moods, or even emotional stability, in between.

Description

Individuals diagnosed with bipolar disorders experience fluctuations in mood over which they have no control. All of the bipolar disorders cause great emotional distress. Even the state of elevated mood, or "mania," might sound as if it would feel good; but it is, in fact, a painful, pressured feeling that is not at all pleasurable. People with mania find their thoughts running at an unstoppable pace; they cannot sleep, often for many nights at a time. Their speech may become rapid, and they may have grandiose ideas. Often people in manic states spend money they do not have, and make important but disastrous life decisions.

Individuals in the depressed mood state experience loss of interest in activities and people. They also experience loss of appetite, difficulty sleeping, lack of sexual desire, and an extreme loss of general energy. The ability to concentrate and think clearly is also compromised. Work, social, and family relationships are always impaired. Feelings of worthlessness and helplessness are common, as is the feeling that nothing will every improve. While depressed individuals may or may not report feeling "down" or "depressed," the feelings they do experience are very painful.

The handbook used by mental health professionals to diagnose mental disorders is the *Diagnostic and Statistical Manual of Mental Disorders,* 4th Edition, Text Revision, also known as the *DSM-IV-TR.* It includes four basic types of **bipolar disorder**: Bipolar I Disorder, Bipolar II Disorder, Cyclothymia, and Bipolar Disorder Not Otherwise Specified.

Bipolar I disorder is characterized by one or more manic episodes, or so-called "mixed" episodes, which involve both manic and depressive feelings alternating rapidly, often within the same day or week. Individuals with Bipolar I disorder may also experience one or more major depressive episodes. **Suicide** occurs in 10-15% of individuals with this disorder.

Bipolar II disorder is characterized by the occurrence of one or more major depressive episodes, interspersed with periods of mild manic episodes referred to as "hypomania." Hypomanic episodes are similar to manic ones, but are far less intense and less severe in their consequences. In fact, individuals may not see their hypomanic episodes as a problem, feeling, instead, that they have bursts of energy in which they can accomplish a great deal.

Cyclothymic disorder is a chronic, low-level disturbance of mood, punctuated by periods of depressive symptoms and periods of hypomanic symptoms. Cyclothymia often begins early in life, and people with the disorder may not know they have it; they may simply think of themselves as sadder and/or less energetic than other people, with occasional bursts of energy.

Bipolar disorder not otherwise specified is the term used in the *DSM-IV-TR* for individuals who do not meet the criteria for one of the other three diagnoses, but who nevertheless experience patterns of mood swings alternating between depression and mania.

KEY TERMS

Body image—A term that refers to a person's inner picture of his or her outward appearance. It has two components: perceptions of the appearance of one's body, and emotional responses to those perceptions.

Comorbidity—Association or presence of two or more mental disorders in the same patient. A disorder that is said to have a high degree of comorbidity is likely to occur in patients diagnosed with other disorders that may share or reinforce some of its symptoms.

Delusion—A false belief that is resistant to reason or contrary to actual fact. Common delusions include delusions of persecution, delusions about one's importance (sometimes called delusions of grandeur), or delusions of being controlled by others. In BDD, the delusion is related to the patient's perception of his or her body.

Displacement—A psychological process in which feelings originating from one source are expressed outwardly in terms of concern or preoccupation with an issue or problem that the patient considers more acceptable. In some BDD patients, obsession about the body includes displaced feelings, often related to a history of childhood abuse.

Muscle dysmorphia—A subtype of BDD, described as excessive preoccupation with muscularity and bodybuilding to the point of interference with social, educational, or occupational functioning.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Somatoform disorders—A group of psychiatric disorders in the *DSM-IV-TR* classification that are characterized by external physical symptoms or complaints. BDD is classified as a somatoform disorder.

Body dysmorphic disorder

Definition

Body dysmorphic disorder (BDD) is defined by the *DSM-IV-TR* (a handbook for mental health professionals) as a condition marked by excessive preoccupation with an imaginary or minor defect in a facial feature or localized part of the body. The diagnostic criteria specify that the condition must be sufficiently severe to cause a decline in the patient's social, occupational, or educational functioning. The most common cause of this decline is the time lost in obsessing about the "defect." The *DSM-IV-TR* assigns BDD to the larger category of somatoform disorders, which are disorders characterized by physical complaints that appear to be medical in origin but that cannot be explained in terms of a physical disease, the results of substance abuse, or by another mental disorder.

Although cases of BDD have been reported in the psychiatric literature from a number of different countries for over a century, the disorder was first defined as a formal diagnostic category by the *DSM-III-R* in 1987. The word *dysmorphic* comes from two Greek words, *dys* that means "bad," or "ugly;" and, *morphos,* that means "shape," or "form." BDD was previously known as dysmorphophobia.

Description

BDD is characterized by an unusually exaggerated degree of worry or concern about a specific part of the face or body, rather than the general size or shape of the body. It is distinguished from **anorexia nervosa** and **bulimia nervosa**, to the extent that patients with these disorders are preoccupied with their overall weight and body shape. For example, an adolescent who thinks that her breasts are too large and wants to have plastic surgery to reduce their size but is otherwise unconcerned about her weight and is eating normally would be diagnosed with BDD, not anorexia or bulimia. As many as 50% of patients diagnosed with BDD undergo plastic surgery to correct their perceived physical defects.

Since the publication of *DSM-IV* in 1994, some psychiatrists have suggested that a subtype of BDD exists, which they term muscle dysmorphia. Muscle dysmorphia is marked by excessive concern with one's muscularity and/or fitness. Persons with muscle dysmorphia spend unusual amounts of time working out in gyms or exercising rather than dieting obsessively or looking into plastic surgery. Although gender stereotypes would suggest that women are more likely to develop BDD while men are more vulnerable to developing muscle dysmorphia, surveys indicate that both disorders have approximately equal gender ratios. *DSM-IV-TR* has additional references regarding body build and excessive weight lifting to *DSM-IV*'s description of BDD to accommodate muscle dysmorphia.

BDD and muscle dysmorphia can both be described as disorders resulting from the patient's distorted body image. Body image refers to the mental picture individuala have of their outward appearance, including size, shape, and form. It has two major components: how the people perceive their physical appearance, and how they feel about their body. Significant distortions in self-perception can lead to intense dissatisfaction with one's body and dysfunctional behaviors aimed at improving one's appearance. Some patients with BDD are aware that their concerns are excessive; others do not have this degree of insight. About 50% of patients diagnosed with BDD also meet the criteria for a **delusional disorder**, which is characterized by beliefs that are not based in reality.

The usual age of onset of BDD is late childhood or early adolescence; the average age of patients diagnosed with the disorder is 17. Ironically, even though BDD begins in childhood or adolescence, most research and treatment studies to date have been done on adults aged 35 and older.

BDD has a high rate of comorbidity, which means that people diagnosed with the disorder are highly likely to have been diagnosed with another psychiatric disorder— most commonly major depression, **social phobia**, or **obsessive-compulsive disorder** (OCD).

Causes and symptoms

Causes

The causes of BDD fall into two major categories, neurobiological and psychosocial.

NEUROBIOLOGICAL CAUSES. Research indicates that patients diagnosed with BDD have serotonin levels that are lower than normal. Serotonin is a neurotransmitter—a chemical produced by the **brain** that helps to transmit nerve impulses across the junctions between nerve cells. Low serotonin levels are associated with depression and other mood disorders.

PSYCHOSOCIAL CAUSES. Another important factor in the development of BDD is the influence of the mass media in developed countries, particularly the role of advertising in spreading images of physically "perfect" men and women. Impressionable children and adolescents absorb the message that anything short of physical perfection is unacceptable. They may then develop distorted perceptions of their own faces and bodies.

A young person's family of origin also has a powerful influence on his or her vulnerability to BDD. Children whose parents are themselves obsessed with appearance, dieting, and/or bodybuilding; or who are highly critical of their children's looks, are at greater risk of developing BDD.

An additional factor in some young people is a history of childhood trauma or abuse. Buried feelings about the abuse or traumatic incident emerge in the form of **obsession** about a part of the face or body. This "reassignment" of emotions from the unacknowledged true cause to another issue is called displacement. For example, an adolescent who frequently felt overwhelmed in childhood by physically abusive parents may develop a preoccupation at the high school level with muscular strength and power.

Symptoms

The central symptom of BDD is excessive concern with a specific facial feature or body part. Research done in the United Kingdom and the United States indicates that the features most likely to be the focus of the patient's attention are (in order of frequency) complexion flaws (acne, blemishes, scars, wrinkles); hair (on the head or the body, too much or too little); and facial features (size, shape, or lack of symmetry). The patient's concerns may, however, involve other body parts, and may shift over time from one feature to another.

Other symptoms of body dysmorphic disorder include:

- Ritualistic behavior. Ritualistic behavior refers to actions that the patient performs to manage anxiety and that take up excessive amounts of his or her time. Patients are typically upset if someone or something interferes with or interrupts their ritual. In the context of BDD, ritualistic behaviors may include exercise or makeup routines, assuming specific poses or postures in front of a mirror, etc.
- Camouflaging the "problem" feature or body part with makeup, hats, or clothing. Camouflaging appears to be

the single most common symptom among patients with BDD; it is reported by 94%.

- Abnormal behavior around mirrors, car bumpers, large windows, or similar reflecting surfaces. A majority of patients diagnosed with BDD frequently check their appearance in mirrors or spend long periods of time doing so. A minority, however, react in the opposite fashion and avoid mirrors whenever possible.
- Frequent requests for reassurance from others about their appearance.
- Frequently comparing one's appearance to others.
- Avoiding activities outside the home, including school and social events.

The loss of functioning resulting from BDD can have serious consequences for the patient's future. Adolescents with BDD often cut school and may be reluctant to participate in sports, join church- or civic-sponsored youth groups, or hold part-time or summer jobs. Adults with muscle dysmorphia have been known to turn down job promotions in order to have more time to work out in their gym or fitness center. Economic consequences of BDD also include overspending on cosmetics, clothing, or plastic surgery.

Demographics

As was mentioned earlier, BDD is primarily a disorder of young people. Its true incidence in the general population is unknown; however, it has been diagnosed in 1.9% of nonclinical patients and 12% of psychiatric outpatients. The *DSM-IV-TR* gives a range of 5%–40% for patients in clinical mental health settings diagnosed with anxiety or depressive disorders to be diagnosed with BDD. One community study published in 2001 found that 0.7% of women between the ages of 36 and 44 met the criteria for BDD. The disorder appears to be equally common in men and women.

As a result of gaps in research, little is known as of 2002 about the lifetime course of BDD or its prevalence in different ethnic or racial groups. The majority of patients in research studies to date have been Caucasians, but it is not clear whether this reflects racial patterns in the wider society or whether it represents referral bias, in that most study subjects are patients in private psychiatric hospitals. Anecdotal evidence, however, indicates that Asian Americans and African Americans with BDD are more likely to obsess about facial features or skin color that conflict with appearance ideals that dominate the mass media and have been derived from Caucasian people. Information through research done on the history of the American cosmetics industry reveals the startling statistic that African Americans spend three to five times as much money on personal care products as Caucasian Americans. In addition, successful African American and Asian American models, male as well as female, tend to resemble the Caucasian appearance ideal more than they deviate from it.

Diagnosis

The **diagnosis** of BDD in children and adolescents is often made by physicians in family practice because they are more likely to have developed long-term relationships of trust with the young people. With adults, it is often specialists in dermatology, cosmetic dentistry, or plastic surgery who may suspect that the patient suffers from BDD because of frequent requests for repeated or unnecessary procedures. Reported rates of BDD among dermatology and cosmetic surgery patients range between 6% and 15%. The diagnosis is made on the basis of the patient's history together with the physician's observations of the patient's overall mood and conversation patterns. People with BDD often come across to others as generally anxious and worried. In addition, the patient's dress or clothing styles may suggest a diagnosis of BDD.

As of 2002, there are no diagnostic questionnaires specifically for BDD, although a semi-structured interview called the BDD Data Form is sometimes used by researchers to collect information about the disorder from patients. The BDD Data Form includes demographic information, information about body areas of concern and the history and course of the illness, and the patient's history of **hospitalization** or **suicide** attempts, if any. The diagnostic questionnaire most frequently used to identify BDD patients is the Structured Clinical Interview for DSM-III-R Disorders, or SCID-II.

There are no brain **imaging studies** or laboratory tests as of 2002 that can be used to diagnose BDD.

Treatments

The standard treatment regimen for body dysmorphic disorder is a combination of medications and **psychotherapy**. Surgical, dental, or dermatologic treatments have been found to be ineffective.

Medications

The medications most frequently prescribed for patients with BDD are the selective serotonin reuptake inhibitors, most commonly **fluoxetine** (Prozac) or **sertraline** (Zoloft). Other SSRIs that have been used with this group of patients include **fluvoxamine** (Luvox) and **paroxetine** (Paxil). In fact, it is the relatively high rate of positive responses to SSRIs among BDD patients that led to the hypothesis that the disorder has a neurobiological

component related to serotonin levels in the body. An associated finding is that patients with BDD require higher dosages of SSRI medications to be effective than patients who are being treated for depression with these drugs.

Psychotherapy

The most effective approach to psychotherapy with BDD patients is **cognitive-behavioral therapy**, of which cognitive restructuring is one component. Since the disorder is related to **delusions** about one's appearance, cognitive-oriented therapy that challenges inaccurate self-perceptions is more effective than purely supportive approaches. Relaxation techniques also work well with BDD patients when they are combined wih cognitive restructuring.

Hospitalization

BDD patients have high rates of self-destructive behavior, including performing surgery on themselves at home (liposuction followed by skin stapling, sawing down teeth, and removing facial scars with sandpaper) and attempted or completed suicide. Many are unable to remain in school, form healthy relationships, or keep steady jobs. In one group of 100 patients diagnosed with BDD, 48% had been hospitalized for psychiatric reasons, and 30% had made at least one suicide attempt.

Alternative treatments

Although no alternative or complementary form of treatment has been recommended specifically for BDD, herbal remedies for depressed feelings, such as **St. John's wort**, have been reported as helping some BDD patients. **Aromatherapy** appears to be a useful aid to relaxation techniques as well as a pleasurable physical experience for BDD patients. **Yoga** has helped some persons with BDD acquire more realistic perceptions of their bodies and to replace obsessions about external appearance with new respect for the inner structure and functioning of their bodies.

Prognosis

As of 2002, researchers do not know enough about the lifetime course of body dysmorphic disorder to offer a detailed prognosis. The *DSM-IV-TR* notes that the disorder "has a fairly continuous course, with few symptom-free intervals, although the intensity of symptoms may wax and wane over time."

Prevention

Given the pervasive influence of the mass media in contemporary Western societies, the best preventive strategy involves challenging those afflicted with the disorder and who consequently have unrealistic images of attractive people. Parents, teachers, primary health care professionals, and other adults who work with young people can point out and discuss the pitfalls of trying to look "perfect." In addition, parents or other adults can educate themselves about BDD and its symptoms, and pay attention to any warning signs in their children's dress or behavior.

Bodywork therapies

Definition

Bodywork therapies is a general term that refers to a group of body-based approaches to treatment that emphasize manipulation and realignment of the body's structure in order to improve its function as well as the client's mental outlook. These therapies typically combine a relatively passive phase, in which the client receives deep-tissue bodywork or postural correction from an experienced instructor or practitioner, and a more active period of movement education, in which the client practices sitting, standing, and moving about with better alignment of the body and greater ease of motion.

Bodywork should not be equated with massage simply speaking. Massage therapy is one form of bodywork, but in massage therapy, the practitioner uses oil or lotion to reduce the friction between his or her hands and the client's skin. In most forms of body work, little if any lubrication is used, as the goal of this type of hands-on treatment is to warm, relax and stretch the fascia (a band or sheath of connective tissue that covers, supports, or connects the muscles and the internal organs) and underlying layers of tissue.

Purpose

The purpose of bodywork therapy is the correction of problems in the client's overall posture, connective tissue, and/or musculature in order to bring about greater ease of movement, less discomfort, and a higher level of energy in daily activity. Some forms of bodywork have as a secondary purpose the healing or prevention of repetitive stress injuries, particularly for people whose occupations require intensive use of specific parts of the body (such as dancers, musicians, professional athletes, opera singers, etc.) Bodywork may also heal or prevent specific musculoskeletal problems, such as lower back pain or neck pain.

KEY TERMS

Bodywork—Any technique involving hands-on massage or manipulation of the body.

Endorphins—A group of peptide compounds released by the body in response to stress or traumatic injury. Endorphins react with opiate receptors in the brain to reduce or relieve pain sensations. Shiatsu is thought to work by stimulating the release of endorphins.

Fascia (plural, fasciae)—A band or sheath of connective tissue that covers, supports, or connects the muscles and the internal organs.

Ki—The Japanese spelling of qi, the traditional Chinese term for vital energy or the life force.

Meridians—In traditional Chinese medicine, a network of pathways or channels that convey qi (also sometimes spelled "ki"), or vital energy, through the body.

Movement education—A term that refers to the active phase of bodywork, in which clients learn to move with greater freedom and to maintain the proper alignment of their bodies.

Repetitive stress injury (RSI)—A type of injury to the musculoskeletal and nervous systems associated with occupational strain or overuse of a specific part of the body. Bodywork therapies are often recommended to people suffering from RSIs.

Somatic education—A term used in both Hellerwork and the Feldenkrais method to describe the integration of bodywork with self-awareness, intelligence, and imagination.

Structural integration—The term used to describe the method and philosophy of life associated with Rolfing. Its fundamental concept is the vertical line.

Tsubo—In shiatsu, a center of high energy located along one of the body's meridians. Stimulation of the tsubos during a shiatsu treatment is thought to rebalance the flow of vital energy in the body.

Bodywork therapies are holistic in that they stress increased self-awareness and intelligent use of one's body as one of the goals of treatment. Some of these therapies use verbal discussion, visualization or guided imagery along with movement education to help clients break old patterns of moving and feeling. Although most bodywork therapists do not address mental disorders

Shiatsu, or acupressure, resembles acupuncture in its use of the basic concepts of ki, the vital energy that flows throughout the body, and the meridians, or 12 major pathways that channel ki to the various organs of the body. The shiatsu practitioner seeks out the meridians in the client's body through finger pressure, and stimulates points along the meridians, releasing energy that rebalances the body's energy level. *(Photo Researchers, Inc. Reproduced by permission.)*

directly in their work with clients, they are often knowledgeable about the applications of bodywork to such specific emotions as depession, anger, or fear.

Although some bodywork therapies, such as Rolfing or Hellerwork, offer programs structured around a specific number or sequence of lessons, all therapies of this type emphasize individualized treatment and respect for the uniqueness of each individual's body. Bodywork instructors or practitioners typically work with clients on a one-to-one basis, as distinct from a group or classroom approach.

Precautions

Persons who are seriously ill, acutely feverish, or suffering from a contagious infection should wait until they have recovered before beginning a course of bodywork. As a rule, types of bodywork that involve intensive manipulation or stretching of the deeper layers of body tissue are not suitable for persons who have undergone recent surgery or have recently suffered severe injury. In the case of Tragerwork, shiatsu, and trigger point therapy, clients should inform the therapist of any open wounds, bruises, or fractures so that the affected part of the body can be avoided during treatment. Craniosacral therapy, the Feldenkrais method, and the Alexander technique involve gentle touch and do not require any special precautions.

Persons who are recovering from **abuse** or receiving treatment for any post-traumatic syndrome or dissociative disorder should consult their therapist before undertaking bodywork. Although bodywork is frequently recommended as an adjunctive treatment for these disorders, it can also trigger flashbacks if the bodywork therapist touches a part of the patient's body associated with the abuse or trauma. Many bodywork therapists, however, are well informed about post-traumatic symptoms and disorders, and able to adjust their treatments accordingly.

Description

The following are brief descriptions of some of the more popular bodywork therapies.

Alexander technique

The Alexander technique was developed by an Australian actor named F. Matthias Alexander (1869-1955), who had voice problems that were not helped by any available medical treatments. Alexander decided to set up a number of mirrors so that he could watch himself during a performance from different angles. He found that he was holding his head and neck too far forward, and that these unconscious patterns were the source of the tension in his body that was harming his voice. He then developed a method for teaching others to observe the patterns of tension and stress in their posture and movement, and to correct these patterns with a combination of hands-on guidance and visualization exercises. As of 2002, the Alexander technique is included in the curricula of the Juilliard School of Music and many other drama and music schools around the world, because performing artists are particularly vulnerable to repetitive stress injuries if they hold or move their bodies incorrectly.

In an Alexander technique session, the client works one-on-one with an instructor who uses verbal explanations as well as guided movement. The sessions are usually referred to as "explorations" and last about 30 minutes. Although most clients see positive changes after only two or three sessions, teachers of the technique recommend a course of 20–30 sessions so that new movement skills can be learned and changes maintained.

Rolfing

Rolfing, which is also called Rolf therapy or structural integration, is a holistic system of bodywork that uses deep manipulation of the body's soft tissue to realign and balance the body's myofascial (muscular and connective tissue) structure. It was developed by Ida Rolf (1896-1979), a biochemist who became interested in the structure of the human body after an accident damaged her health. She studied with an osteopath as well as with practitioners of other forms of alternative medicine, and developed her own technique of body movement that she

called structural integration. Rolfing is an approach that seeks to counteract the effects of gravity, which tends to pull the body out of alignment over time and cause the connective tissues to stiffen and contract.

Rolfing treatment begins with the so-called "Basic Ten," a series of ten sessions each lasting 60–90 minutes, spaced a week or longer apart. After a period of integration, the client may undertake advanced treatment sessions. "Tune-up" sessions are recommended every six months. In Rolfing sessions, the practitioner uses his or her fingers, hands, knuckles, or elbows to rework the connective tissue over the client's entire body. The deep tissues are worked until they become pliable, which allows the muscles to lengthen and return to their proper alignment. Rolfing treatments are done on a massage table, with the client wearing only undergarments.

Hellerwork

Hellerwork is a bodywork therapy developed by Joseph Heller, a former NASA engineer who became a certified Rolfer in 1972 and started his own version of structural integration, called Hellerwork, in 1979. Heller describes his program as "a powerful system of somatic education and structural bodywork" based on a series of eleven sessions. Hellerwork is somewhat similar to Rolfing in that it begins with manipulation of the deep tissues of the body. Heller, however, decided that physical realignment of the body by itself is insufficient, so he extended his system to include movement education and "self-awareness facilitated through dialogue."

The bodywork aspect of Hellerwork is intended to release the tension that exists in the fascia, which is the sheath or layer of connective tissue that covers, supports, or connects the muscles and internal organs of the body. Fascia is flexible and moist in its normal state, but the effects of gravity and ongoing physical stresses lead to misalignments that cause the fascia to become stiff and rigid. The first hour of a Hellerwork session is devoted to deep connective tissue bodywork in which the Hellerwork practitioner uses his or her hands to release tension in the client's fascia. The bodywork is followed by movement education, which includes the use of video feedback to help clients learn movement patterns that will help to keep their bodies in proper alignment. The third component of Hellerwork is verbal dialogue, which is intended to help clients become more aware of the relationships between their emotions and attitudes and their body.

Tragerwork

Trager psychophysical integration, which is often called simply Tragerwork, was developed by Milton Trager (1908-1977), a man who was born with a spinal deformity and earned a medical degree in his middle age after working out an approach to healing chronic pain. Tragerwork is based on the theory that many illnesses are caused by tension patterns that are held in the unconscious mind as much as in the tissues of the body; clients are advised to think of Tragerwork sessions as "learning experiences" rather than "treatments." Tragerwork sessions are divided into bodywork, which is referred to as tablework, and an exercise period. Trager practitioners use their hands during tablework to perform a variety of gentle motions—rocking, shaking, vibrating, and gentle stretching—intended to help the client release their patterns of tension by experiencing how it feels to move freely and effortlessly on one's own. Following the tablework, clients are taught how to perform simple dance-like exercises called Mentastics, for practice at home. Tragerwork sessions take between 60–90 minutes, while clients are advised to spent 10–15 minutes three times a day doing the Mentastics exercises.

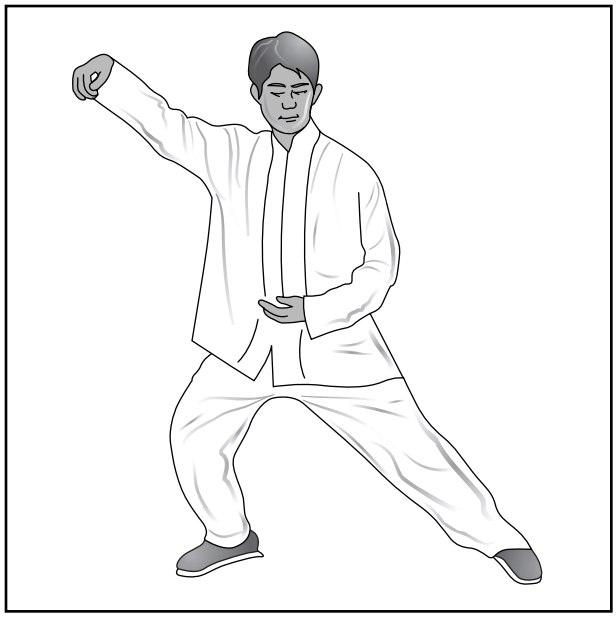
Feldenkrais method

The Feldenkrais method, like Hellerwork, refers to its approach as "somatic education." Developed by Moshe Feldenkrais (1904-1984), a scientist and engineer who was also a judo instructor, the Feldenkrais method consists of two major applications— Awareness Through Movement (ATM) lessons, a set of verbally directed exercise lessons intended to engage the client's intelligence as well as physical perception; and Functional Integration (FI), in which a Feldenkrais practitioner works with the client one-on-one, guiding him or her through a series of movements that alter habitual patterns and convey new learning directly to the neuromuscular system. Functional Integration is done with the client fully clothed, lying or sitting on a low padded table.

Perhaps the most distinctive feature of the Feldenkrais method is its emphasis on new patterns of thinking, attention, cognition, and imagination as byproducts of new patterns of physical movement. It is the most intellectually oriented of the various bodywork therapies, and has been described by one observer as "an unusual melding of motor development, biomechanics, psychology, and martial arts." The Feldenkrais method is the form of bodywork that has been most extensively studied by mainstream medical researchers.

Trigger point therapy

Trigger point therapy, which is sometimes called myotherapy, is a treatment for pain relief in the musculoskeletal system based on the application of pressure to trigger points in the client's body. Trigger points are defined as hypersensitive spots or areas in the muscles



T'ai chi is an ancient Chinese form of meditation with slow, smooth movements. The posture above is part of the single whip sequence of t'ai chi motions.

that cause pain when subjected to stress, whether the stress is an occupational injury, a disease, or emotional stress. Trigger points are not necessarily in the same location where the client feels pain.

Myotherapy is a two-step process. In the first step, the therapist locates the client's trigger points and applies pressure to them. This step relieves pain and also relaxes the muscles associated with it. In the second part of the therapy session, the client learns a series of exercises that progressively stretch the muscles that have been relaxed by the therapist's pressure. Most clients need fewer than 10 sessions to benefit from myotherapy. One distinctive feature of trigger point therapy is that clients are asked to bring a relative or trusted friend to learn the pressure technique and the client's personal trigger points. This "buddy system" helps the client to maintain the benefits of the therapy in the event of a relapse.

Shiatsu

Shiatsu is the oldest form of bodywork therapy, having been practiced for centuries in Japan as part of traditional medical practice. As of 2002, it is also the type of bodywork most commonly requested by clients in Western countries as well as in East Asia. The word *shiatsu* itself is a combination of two Japanese words that mean "pressure" and "finger." Shiatsu resembles **acupuncture** in its use of the basic concepts of ki, the vital energy that flows throughout the body, and the meridians, or 12 major pathways that channel ki to the various organs of the body. In Asian terms, shiatsu works by unblocking and rebalancing the distribution of ki in the body. In the categories of Western medicine, shiatsu may stimulate the release of endorphins, which are chemical compounds that block the receptors in the **brain** that perceive pain.

A shiatsu treatment begins with the practitioner's assessment of the client's basic state of health, including posture, vocal tone, complexion color, and condition of hair. This evaluation is used together with ongoing information about the client's energy level gained through the actual bodywork. The shiatsu practitioner works with the client lying fully clothed on a futon. The practitioner seeks out the meridians in the client's body through finger pressure, and stimulates points along the meridians known as tsubos. The tsubos are centers of high energy where the ki tends to collect. Pressure on the tsubos results in a release of energy that rebalances the energy level throughout the body.

Craniosacral therapy

Craniosacral therapy, or CST, is a form of treatment that originated with William Sutherland, an American osteopath of the 1930s who theorized that the manipulative techniques that osteopaths were taught could be applied to the skull. Sutherland knew from his medical training that the skull is not a single piece of bone, but consists of several bones that meet at seams; and that the cerebrospinal fluid that bathes the brain and spinal cord has a natural rise-and-fall rhythm. Sutherland experimented with gentle manipulation of the skull in order to correct imbalances in the distribution of the cerebrospinal fluid. Contemporary craniosacral therapists practice manipulation not only of the skull, but of the meningeal membranes that cover the brain and the spinal cord, and sometimes of the facial bones. Many practitioners of CST are also osteopaths, or DOs.

In CST, the patient lies on a massage table while the therapist gently palpates, or presses, the skull and spine. If the practitioner is also an osteopath, he or she will take a complete medical history as well. The therapist also "listens" to the cranial rhythmic impulse, or rhythmic pulsation of the cerebrospinal fluid, with his or her hands. Interruptions of the normal flow by abnormalities caused by tension or by injuries are diagnostic clues to the practitioner. Once he or she has identified the cause of the abnormal rhythm, the skull and spinal column are gently manipulated to restore the natural rhythm of the cranial impulse. Craniosacral therapy appears to be particularly useful in treating physical disorders of the head, including migraine headaches, ringing in the ears, sinus problems, and injuries of the head, neck, and spine. In addition, patients rarely require extended periods of CST treatments.

Preparation

Bodywork usually requires little preparation on the client's or patient's part, except for partial undressing for Rolfing, trigger point therapy, and Hellerwork.

Aftercare

Aftercare for shiatsu, trigger point therapy, and craniosacral therapy involves a brief period of rest after the treatment.

Some bodywork approaches involve various types of long-term aftercare. Rolfing clients return for advanced treatments or tune-ups after a period of integrating the changes in their bodies resulting frm the Basic Ten sessions. Tragerwork clients are taught Mentastics exercises to be done at home. The Alexander technique and the Feldenkrais approach assume that clients will continue to practice their movement and postural changes for the rest of their lives. Trigger point therapy clients are asked to involve friends or relatives who can help them maintain the benefits of the therapy after the treatment sessions are over.

Risks

The deep tissue massage and manipulation in Rolfing and Hellerwork are uncomfortable for many people, particularly the first few sessions. There are, however, no serious risks of physical injury from any form of bodywork that is administered by a trained practitioner of the specific treatment. As mentioned, however, bodywork therapies that involve intensive manipulation or stretching of the deeper layers of body tissue are not suitable for persons who have undergone recent surgery or have recently suffered severe injury.

Normal results

Normal results from bodywork include deep relaxation, improved posture, greater ease and spontaneity of movement, greater range of motion for certain joints, greater understanding of the structures and functions of the body and their relationship to emotions, and release of negative emotions.

Many persons also report healing or improvement of specific conditions, including migraine headaches, repetitive stress injuries, osteoarthritis, **insomnia**, sprains and bruises, sports injuries, stress-related illnesses, sciatica, postpregnancy problems, menstrual cramps, temporomandibular joint disorders, lower back pain, whiplash injuries, disorders of the immune system, asthma, depression, digestive problems, chronic **fatigue**, and painful scar tissue. The Alexander technique has been reported to ease the process of childbirth by improving the mother's postural alignment prior to delivery.

Some studies of the Feldenkrais method have found that its positive effects on subjects' self-esteem, mood, and anxiety sympoms are more significant than its effects on body function.

Abnormal results

Abnormal results from bodywork therapies would include serious physical injury or trauma-based psychological reactions.; Acupuncture; Energy therapies

Borderline personality disorder

Definition

Borderline personality disorder (BPD) is a mental disorder characterized by disturbed and unstable interpersonal relationships and self-image, along with impulsive, reckless, and often self-destructive behavior.

Description

Individuals with BPD have a history of unstable interpersonal relationships. They have difficulty interpreting reality and view significant people in their lives as either completely flawless or extremely unfair and uncaring (a phenomenon known as "splitting"). These alternating feelings of idealization and devaluation are the hallmark feature of borderline personality disorder. Because borderline patients set up such excessive and unrealistic expectations for others, they are inevitably disappointed when their expectations aren't realized.

The term "borderline" was originally used by **psychologist** Adolf Stern in the 1930s to describe patients whose condition bordered somewhere between **psychosis** and **neurosis**. It has also been used to describe the borderline states of consciousness these patients sometimes feel when they experience dissociative symptoms (a feeling of disconnection from oneself).

Causes and symptoms

Causes

Adults with borderline personalities often have a history of significant childhood traumas such as emotional, physical, and/or sexual **abuse** and parental **neglect** or loss. Feelings of inadequacy and self-loathing that arise from these situations may be key in developing the borderline personality. It has also been theorized that these patients try to compensate for the care they were denied in childhood through the idealized demands they now make on themselves and on others as adults. Some studies suggests that this disorder is associated with mood or impulse control problems, others implicate malfunctioning **neurotransmitters** (the chemicals that send messages to nerve cells). The disorder has a genetic correlation since it occurs more commonly among first-degree relatives.

Symptoms

The handbook used by mental health professionals to diagnose mental disorders is the *Diagnostic and Statistical Manual of Mental Disorders (DSM).* The 2000 edition of this manual (fourth edition, text revised) is known as the *DSM-IV-TR.* Published by the American Psychiatric Association, the *DSM* contains diagnostic criteria, research findings, and treatment information for mental disorders. It is the primary reference for mental health professionals in the United States. BPD was first listed as a disorder in the third edition *DSM-III,* which was published in 1980, and has been revised in subsequent editions.

The *DSM-IV-TR* requires that at least five of the following criteria (or symptoms) be present in an individual for a **diagnosis** of borderline disorder:

- frantic efforts to avoid real or perceived abandonment
- pattern of unstable and intense interpersonal relationships, characterized by alternating between idealization and devaluation ("love-hate" relationships)
- extreme, persistently unstable self-image and sense of self
- impulsive behavior in at least two areas (such as spending, sex, substance abuse, reckless driving, binge eating)

- recurrent suicidal behavior, gestures, or threats, or recurring acts of self-mutilation (such as cutting or burning oneself)
- unstable mood caused by brief but intense episodes of depression, irritability, or anxiety
- chronic feelings of emptiness
- inappropriate and intense anger, or difficulty controlling anger displayed through temper outbursts, physical fights, and/or sarcasm
- stress-related **paranoia** that passes fairly quickly and/or severe dissociative symptoms— feeling disconnected from one's self, as if one is an observer of one's own actions

Demographics

Borderline personality disorder accounts for 30–60% of all **personality disorders**, and is present in approximately 2% of the general population. The disorder appears to affect women more frequently than men—as many as 75% of all diagnosed patients are female.

Diagnosis

Borderline personality disorder typically first appears in early adulthood. Although the disorder may occur in adolescence, it may be difficult to diagnose, since borderline symptoms such as impulsive and experimental behaviors, insecurity, and mood swings are common—even developmentally appropriate—occurrences at this age.

Borderline symptoms may also be the result of chronic substance abuse and/or medical conditions (specifically, disorders of the central nervous system). These should be ruled out before making the diagnosis of borderline personality disorder.

BPD commonly occurs with mood disorders (i.e., depression and anxiety), **post-traumatic stress disorder** (PTSD), eating disorders, attention deficit/hyperactivity disorder (ADHD), and other personality disorders. It has also been suggested by some researchers that borderline personality disorder is not a true pathological condition in and of itself, but rather a number of overlapping personality disorders; it is, however, commonly recognized as a separate and distinct disorder by the American Psychiatric Association and by most mental health professionals. It is diagnosed by interviewing the patient, and matching symptoms to the *DSM* criteria. Supplementary testing may also be necessary.

Treatment

Individuals with borderline personality disorder seek psychiatric help and **hospitalization** at a much higher rate than people with other personality disorders, probably due to their fear of abandonment and their need to seek idealized interpersonal relationships. These patients represent the highest percentage of diagnosed personality disorders (up to 60%).

Providing effective therapy for the borderline personality patient is a necessary, but difficult, challenge. The therapist-patient relationship is subject to the same inappropriate and unrealistic demands that borderline personalities place on all their significant interpersonal relationships. They are chronic "treatment seekers" who become easily frustrated with their therapist if they feel they are not receiving adequate attention or empathy, and symptomatic anger, impulsivity, and self-destructive behavior can impede the therapist-patient relationship. However, their fear of abandonment, and of ending the therapy relationship, may actually cause them to discontinue treatment as soon as progress is made.

Psychotherapy, typically in the form of **cognitive-behavioral therapy**, is usually the treatment of choice for borderline personalities. Dialectical behavior therapy (DBT), a cognitive-behavioral technique, has emerged as an effective therapy for borderline personalities with suicidal tendencies. The treatment focuses on giving the borderline patient self-confidence and coping tools for life outside of treatment through a combination of social skill training, mood awareness and meditative exercises, and education on the disorder. **Group therapy** is also an option for some borderline patients, although some may feel threatened by the idea of "sharing" a therapist with others.

Medication is not considered a first-line treatment choice, but may be useful in treating some symptoms of the disorder and/or the mood disorders that have been diagnosed in conjunction with BPD. Recent clinical studies indicate that **naltrexone** may be helpful in relieving physical discomfort related to dissociative episodes.

Prognosis

The disorder usually peaks in young adulthood and frequently stabilizes after age 30. Approximately 75–80% of borderline patients attempt or threaten **suicide**, and between 8–10% are successful. If the borderline patient suffers from depressive disorder, the risk of suicide is much higher. For this reason, swift diagnosis and appropriate interventions are critical.

Prognosis

Prevention recommendations are scarce. The disorder may be genetic and not preventable. The only known

prevention would be to ensure a safe and nurturing environment during childhood.

Brain

Definition

The brain is the part of the central nervous system located in the skull. It controls the mental processes and physical actions of a human being.

Description

The brain, along with the spinal cord and network of nerves, controls information flow throughout the body, voluntary actions such as walking, reading, and talking, and involuntary reactions such as breathing and digestion.

The human brain is a soft, shiny, grayish-white, mushroom-shaped structure. The brain of an average adult weighs about 3 lb (1.4 kg). At birth, the average infant's brain weighs 13.7 oz (390 g); by age 15, it has nearly reached full adult size. The brain is protected by the skull and a three-layered membrane called the meninges. The brain's surface is covered with many bright red arteries and bluish veins that penetrate inward. Glucose, oxygen, and certain ions pass easily across the blood-brain barrier into the brain, although other substances, such as antibiotics, do not.

The four principal sections of the human brain are: the brain stem, the diencephalon, the cerebrum (divided into two large paired cerebral hemispheres), and the cerebellum.

The brain stem

The brain stem connects the brain with the spinal cord. Every message transmitted between the brain and spinal cord passes through the *medulla oblongata*—a part of the brain stem—via nerve fibers. The fibers on the right side of the medulla cross to the left and those on the left cross to the right. As a result, each side of the brain controls the opposite side of the body. The medulla regulates the heartbeat, breathing rate, and blood-vessel diameters; it also helps coordinate swallowing, vomiting, hiccuping, coughing, and sneezing.

Another brain stem component, the *pons* (meaning "bridge"), conducts messages between the spinal cord and the rest of the brain, and between the different parts of the brain. The *midbrain* conveys impulses between the cerebral cortex, pons, and spinal cord, and also contains visual and audio reflex centers involving the movement of the eyeballs and head.

Twelve pairs of *cranial nerves* originate in the underside of the brain, mostly from the brain stem. They leave the skull through openings and extend as peripheral nerves to their destinations. Among these cranial nerves are the olfactory nerves that bring messages about smell and the optic nerves that conduct visual information.

The diencephalon

The diencephalon lies above the brain stem and embodies the *thalamus* and *hypothalamus.* The thalamus is an important relay station for sensory information, interpreting sound, smell, taste, pain, pressure, temperature, and touch; it also regulates some emotions and memory. The hypothalamus controls a number of body functions, such as heartbeat and digestion, and helps regulate the endocrine system (hormonal system) and normal body temperature. The hypothalamus signals hunger and thirst, and also helps regulate sleep, anger, and aggression.

The cerebrum

Constituting nearly 90% of the brain's weight, the cerebrum is divided into specific areas that interpret sensory impulses. For example, spoken and written languages are transmitted to a part of the cerebrum called Wernicke's area where meaning is constructed. Motor areas control muscle movements. Broca's area translates thoughts into speech, and coordinates the muscles needed for speaking. Impulses from other motor areas direct hand muscles for writing and eye muscles for physical movement necessary for reading. The cerebrum is divided into left and right hemispheres. A deep fissure separates the two, with the corpus callosum, a large bundle of fibers, connecting them.

By studying patients whose corpora callosa had been destroyed, scientists realized that differences existed between the left and right sides of the cerebral cortex. The left side of the brain functions mainly in speech, logic, writing, and arithmetic. The right side, on the other hand, is more concerned with imagination, art, symbols, and spatial relations. In general, the left half of the brain controls the right side of the body, and vice versa. For most right-handed people (and many left-handed people as well), the left half of the brain is dominant.

The cerebrum's outer layer, the *cerebral cortex,* is composed of gray matter, which is made up of nerve cell bodies. About 0.08 in (2 mm) thick with a surface area about 5 sq ft (0.5 sq m), it's nearly half the size of an office desk. White matter, composed of nerve fibers covered with myelin sheaths, lies beneath the gray matter. During embryonic development, the gray matter grows faster than the white and folds in on itself, giving the brain its characteristic wrinkles, called *convolutions,* or *gyri;* the grooves between them are known as *sulci.*

The cerebellum

The cerebellum is located below the cerebrum and behind the brain stem. It is butterfly-shaped, with the "wings" known as the *cerebellar hemispheres;* the two halves are connected by the *vermis.* The cerebellum coordinates many neuromuscular functions, such as balance and coordination. Disorders related to damage of the cerebellum often result in ataxia (problems with coordination), dysarthria (unclear speech resulting from problems controlling the muscles used in speaking), and nystagmus (uncontrollable jerking of the eyeballs). A brain tumor that is relatively common in children known as medulloblastoma grows in the cerebellum.

KEY TERMS

Corpus callosum—(plural, corpora callosa) A thick bundle of nerve fibers lying deep in the brain that connects the two cerebral hemispheres and coordinates their functions.

Meninges—A membrane covering the brain and spinal cord that consists of three layers: the *pia mater,* the innermost layer; the *arachnoid,* in the middle; and the *dura mater,* the outermost layer.

Myelin sheaths—A fatty layer around nerve cells that aids the transmission of nerve impulses.

Peripheral nerve—A nerve in a distant location from the brain that receives information in the form of an impulse from the brain and spinal cord.

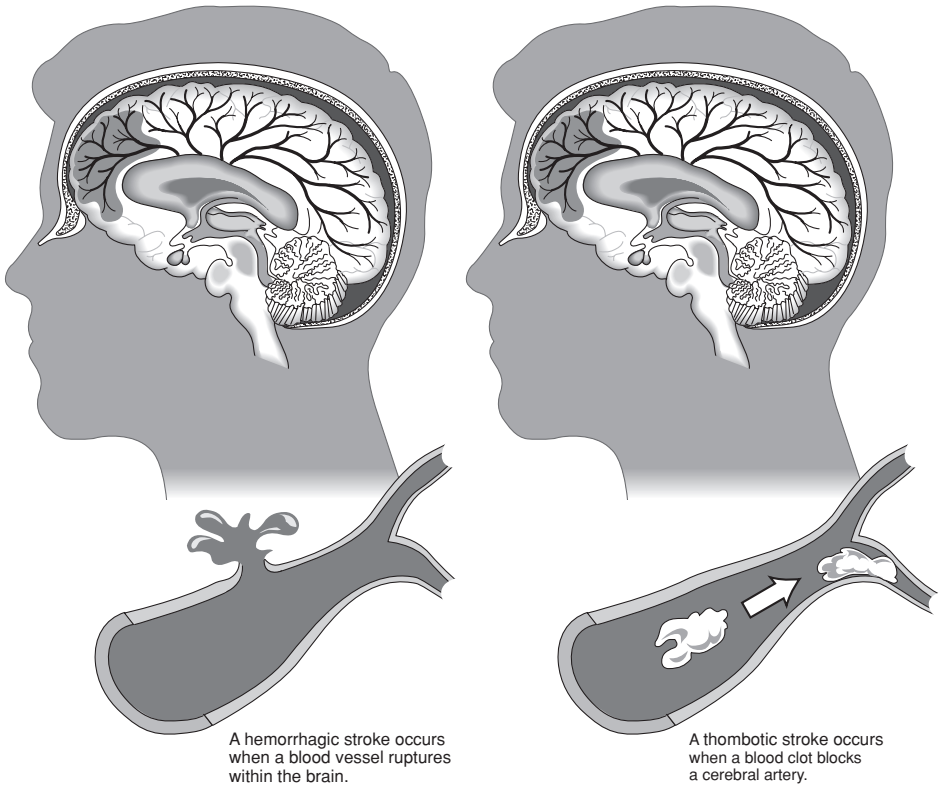
Studying the brain

Neurons carry information through the nervous system in the form of brief electrical impulses called *action potentials.* When an impulse reaches the end of an axon, **neurotransmitters** are released at junctions called *synapses.* The neurotransmitters are chemicals that bind to receptors on the receiving neurons, triggering the continuation of the impulse. Fifty different neurotransmitters have been discovered since the first was identified in 1920. By studying the chemical effects of neurotransmitters in the brain, scientists have developed treatments for mental disorders and are learning more about how drugs affect the brain.

Scientists once believed that brain cells do not regenerate, thereby making brain injuries and brain diseases untreatable. Since the late 1990s, however, researchers have been testing treatment for such patients with neuron transplants, which introduce nerve tissue into the brain, with promising results. They have also been investigating substances such as nerve growth factor (NGF), which may someday help regenerate nerve tissue.

Computerized brain imaging

Technology provides useful tools for researching the brain and helping patients with brain disorders. An electroencephalogram (EEG) records brain waves, which are produced by electrical activity in the brain. It is obtained by positioning electrodes on the head and amplifying the waves with an electroencephalograph. EEGs are valuable in diagnosing brain diseases such as epilepsy and tumors.



The human brain. *(Illustration by Hans & Cassady.)*

Scientists use three other techniques to study and understand the brain and diagnose disorders:

MAGNETIC RESONANCE IMAGING (MRI). Using a magnetic field to display the living brain at various depths, MRI can produce very clear and detailed pictures of brain structures. These images, which often appear as cross-sectional slices, are obtained by altering the main magnetic field of a specific brain area. MRI is particularly valuable in diagnosing damage to soft tissues, such as areas affected by head trauma or **stroke**. This is crucial when early **diagnosis** improves the chances of successful treatment. MRI also reveals tumors and other types of brain lesions.

POSITRON EMISSION TOMOGRAPHY (PET). During this test, a technician injects the patient with a small amount of a substance, such as glucose, that is marked with a radioactive tag. By tracking the radioactive substance as it travels to the brain, physicians can see almost immediately where glucose is consumed in the brain. This indicates brain activity, an important factor in diagnosing epilepsy, Alzheimer's, or Parkinson's. PET is also valuable in locating tumors and brain areas that have been affected by a stroke or blood clot.

MAGNETOENCEPHALOGRAPHY (MEG). Magnetoencephalography measures the electromagnetic fields created between neurons as electrochemical information is passed along. Of all brain-scanning methods, MEG provides the most accurate indicator of nerve cell activity, which can be measured in milliseconds. By combining an MRI with MEG, clinicians can get a noninvasive look at the brain that is especially useful in diagnosing epilepsy or migraines, for example. MEG also helps identify specific brain areas involved with different tasks. Any movement by the patient—wiggling the toes, for example—appears on the computer screen immediately as concentric colored rings. This pinpoints brain signals even before the toes are actually wiggled. Researchers foresee that these techniques could someday help paralysis victims move by supplying information on how to stimulate their muscles or indicating the signals needed to control an artificial limb.

KEY TERMS

Alveolar—Pertaining to alveoli, which are tiny air sacs at the ends of the small air passages in the lungs.

Apnea—A brief suspension or interruption of breathing.

Dyssomnia—A type of sleep disorder characterized by a problem with the amount, quality, or timing of the patient's sleep.

Hypoventilation—An abnormally low level of blood oxygenation in the lungs.

Polysomnogram—A machine that is used to diagnose sleep disorders by measuring and recording a variety of body functions related to sleep, including heart rate, eye movements, brain waves, muscle activity, breathing, changes in blood oxygen concentration, and body position.

Syndrome—A group of symptoms that together characterize a disease or disorder.

Tracheostomy—A surgical procedure in which an artificial opening is made in the patient's windpipe to relieve airway obstruction.

Breathing-related sleep disorder

Definition

Breathing-related sleep disorder is marked by sleep disruption caused by abnormal breathing during sleep. The most common complaint of individuals with breathing-related sleep disorder is excessive daytime sleepiness, brought on by frequent interruptions of nocturnal, or nighttime, sleep. A less frequent complaint is **insomnia** or inability to sleep.

Mental health professionals use the ***Diagnostic and Statistical Manual of Mental Disorders*** also known as the *DSM* to diagnose mental disorders. In the 2000 edition of this manual (the fourth edition, text revision, also known as *DSM-IV-TR*) breathing-related sleep disorder is listed as one of several different primary **sleep disorders**. Within the category of primary sleep disorders, it is classified as one of the dyssomnias, which are characterized by irregularities in the quality, timing, and amount of sleep.

The *DSM-IV-TR* lists three types of breathing-related sleep disorder: obstructive sleep apnea syndrome (the most common type); central sleep apnea syndrome; and central alveolar hypoventilation syndrome.

Description

The most common feature of any breathing-related sleep disorder is interruption of the person's sleep leading to excessive daytime sleepiness. When the regular nighttime sleep of individuals is frequently interrupted, sleepiness at other times of the day is the usual result. People with breathing-related sleep disorder often find that they feel sleepy during such relaxing activities as reading or watching a movie. With extreme cases, the person may feel so sleepy that he or she falls asleep during activities that require alertness, such as talking, walking, or driving.

Other people with breathing-related sleep disorder report having insomnia, or the inability to sleep. Patients also find that their sleep does not refresh them; they may awaken frequently during sleep, or have difficulty breathing while sleeping or lying down.

The two sleep apnea syndromes that are listed as subtypes of breathing-related sleep disorder are characterized by episodes of airway blockage or stopping of breathing during sleep. Sleep apnea is potentially deadly. The other type of breathing-related sleep disorder, central alveolar hypoventilation syndrome, is distinguished from the other two subtypes by the fact that the reduced oxygen content of the blood is caused by shallow breathing. The alveoli, which are the tiny air sacs in the lung tissue, are not able to oxygenate the blood efficiently because the person is not breathing deeply enough. Shallow breathing often occurs when people are awake and is common in severely overweight individuals.

A patient suffering from acute sleep apnea is hooked up to monitors in preparation for a night's sleep at a Stanford University lab. *(Russell D. Curtis. National Audubon Society Collection/ Photo Researchers, Inc. Reproduced by permission.)*

Causes and symptoms

Causes

Many persons with the obstructive sleep apnea syndrome subtype of breathing-related sleep disorder are overweight. The symptoms often grow worse as the person's weight increases. Persons who have obstructive sleep apnea and are not overweight often have breathing passages that are narrowed by swollen tonsils, abnormally large adenoids, or other abnormalities of the various structures of the mouth and throat.

Central sleep apnea syndrome is often associated with cardiac or neurological conditions affecting airflow regulation. It is a disorder that occurs most frequently in elderly patients.

Patients diagnosed with central alveolar hypoventilation syndrome experience a breathing impairment related to abnormally low arterial oxygen levels.

Symptoms

Obstructive sleep apnea syndrome, which is the most common type of breathing-related sleep disorder, is marked by frequent episodes of upper-airway obstruction during sleep. Patients with this syndrome alternate between loud snores or gasps and silent periods that usually last for 20–30 seconds. The snoring is caused by the partial blockage of the airway. The silent periods are caused by complete obstruction of the airway, which makes the patient's breathing stop.

Obstructive sleep apnea syndrome is also common in children with enlarged tonsils. The symptoms of any breathing-related sleep disorder in children are often subtle and more difficult to diagnose. Children under five are more likely to demonstrate such nighttime symptoms as apnea and breathing difficulties. Children over five are more likely to demonstrate such daytime symptoms as sleepiness and attention difficulties.

Persons with central sleep apnea syndrome experience periods when the oxygenation of blood in the lungs temporarily stops during sleep; but they do not suffer airway obstruction. Although these patients may snore, their snoring is usually mild and not a major complaint.

Central alveolar hypoventilation syndrome is characterized by excessive sleepiness and insomnia.

Demographics

The majority of patients with the obstructive sleep apnea type of breathing-related sleep disorder are overweight, middle-aged males. Adult males are two to four times as likely as adult females to experience obstructive sleep apnea syndrome. Among children the male: female ratio is 1:1.

Central sleep apnea syndrome is most common in the elderly.

Diagnosis

A **diagnosis** of breathing-related sleep disorder usually requires a thorough physical examination of the patient. The patient may be referred to an otorhinolaryngologist (a doctor who specializes in disorders of the ear, nose, and throat) for a detailed evaluation of the upper respiratory tract. The physical examination is followed by observation of the patient in a sleep clinic or laboratory. Breathing patterns, including episodes of snoring and apnea, are evaluated when the patient is connected to a device called a polysomnogram. The polysomnogram uses a set of electrodes to measure several different body functions associated with sleep, including heart rate, eye movements, **brain** waves, muscle activity, breathing, changes in blood oxygen concentration, and body position. Interviews are also conducted with the patient and his or her partner.

To meet criteria for the diagnosis of breathing-related sleep disorder, the patient must experience interruptions of sleep leading to insomnia or excessive sleepiness that have been determined to result from one of the following sleep-related breathing conditions: obstructive sleep apnea syndrome; central sleep apnea syndrome; or central alveolar hypoventilation syndrome.

The disturbance in sleep must also not be better accounted for by another mental disorder or by a general medical condition not related to breathing.

The disturbance in sleep must not be due to the direct effects on the body of a prescription medication or drug of abuse.

Treatments

Weight loss is a key to effective treatment of overweight people with breathing-related sleep disorder. It is often considered the first step in treating any disorder involving sleep apnea. Increased exercise and reduced-calorie **diets** are the most important components of an effective weight loss regimen.

Nasal continuous positive airway pressure therapy, also known as nasal CPAP therapy, is a popular form of treatment for the obstructive sleep apnea subtype of breathing-related sleep disorder. Nasal CPAP therapy, which has been in use since 1981, involves the use of a high-pressure blower that delivers continuous air flow to a mask worn by the patient during sleep. The airflow from the nasal CPAP blower is often very effective in reducing or eliminating sleep apnea episodes. Nasal CPAP treatment is, however, inconvenient and somewhat noisy for anyone who must share a bedroom with the patient. Patients do not always comply with this form of treatment; one study indicated that about 25% of patients who are treated with nasal CPAP therapy stop using it within a year.

Medications for patients with the sleep apnea subtype of breathing-related sleep disorder are most commonly such respiratory stimulants as medroxyprogesterone acetate (Depo-Provera) and acetazolamide (Diamox). **Protriptyline** (Vivactil), which is a tricyclic antidepressant, is also used for some patients.

Surgery to relieve airway obstruction is increasingly preferred by many patients. If the airway obstruction is related to anatomical structures that are narrowing the airway, surgical reshaping of the soft palate and uvula (a small, conical-shaped piece of tissue attached to the middle of the soft palate) may be performed. Another surgical procedure that is sometimes done in very obese patients with obstructive sleep apnea is a tracheostomy, or an artificial opening made in the windpipe. This operation has a number of unpleasant side effects, however, and so is usually reserved for patients whose breathing-related disorder is life-threatening.

Patients with sleep apnea are advised to abstain from alcohol and sedative medications, which are often given to patients who display any type of sleeping irregularities. Alcohol and sedatives often increase the likelihood of upper airway problems during sleep.

Prognosis

Breathing-related sleep disorder often has a gradual long-term progression and a chronic course. For this reason, many people have the disorder for years before seeking treatment. For many, symptoms worsen during middle age, causing people to seek treatment at that point.

Successful treatment of other conditions, such as **obesity**, cardiac or neurological conditions in the elderly, or enlarged tonsils in children often aids in the treatment of breathing-related sleep disorder. Weight loss often leads to spontaneous resolution of the disorder.

Prevention

Because overweight people are more likely to develop the more common obstructive sleep apnea type of breathing-related sleep disorder, a good preventive measure is effective weight management. Good general health and treatment of related physiological conditions are also effective in preventing the disorder.

Brief psychotic disorder

Definition

Brief psychotic disorder is a short-term, time-limited disorder. An individual with brief psychotic disorder has experienced at least one of the major symptoms of **psychosis** for less than one month. **Hallucinations**, **delusions**, strange bodily movements or lack of movements (catatonic behavior), peculiar speech and bizarre or markedly inappropriate behavior are all classic psychotic symptoms that may occur in brief psychotic disorder.

The cause of the symptoms helps to determine whether or not the sufferer is described as having brief psychotic disorder. If the psychotic symptoms appear as a result of a physical disease, a reaction to medication, or intoxication with drugs or alcohol, then the unusual behaviors are not classified as brief psychotic disorder. If hallucinations, delusions, or other psychotic symptoms occur at the same time that an individual is experiencing major clinical depression or bipolar (manic-depressive) disorder, then the brief psychotic disorder **diagnosis** is not given. The decision rules that allow the clinician to identify this cluster of symptoms as brief psychotic disorder are outlined in the ***Diagnostic and Statistical Manual of Mental Disorders*** Fourth Edition Text Revision, produced by the American Psychiatric Association. This manual is referred to by most mental health professionals as *DSM-IV-TR*.

Description

Positive symptoms

The person experiencing brief psychotic disorder always has one or more "positive" psychotic symptoms. The psychotic symptoms are not "positive" in the everyday sense of something being good or useful. Positive in this context is used with the medical meaning: a factor is present that is not normally expected, or a normal type of behavior is experienced in its most extreme form. **Positive symptoms** of psychosis include hallucinations, delusions, strange bodily movements or lack of movements (catatonic behavior), peculiar speech and bizarre or primitive behavior.

HALLUCINATIONS. Hallucinations involve experiencing sensations that have no corresponding objective reality. Hallucinations can occur in various forms that parallel the human senses. Visual hallucinations involve the sense of sight, or "seeing things." Auditory hallucinations generally involve hearing voices, and are the most common of the hallucinations. Sometimes, a hallucination can include both voices and some visual experience; mental health professionals describe this as an "auditory-visual hallucination." Smelling non-existent smells or feeling things on or under one's skin that do not actually exist are forms of somatic hallucinations. Somatic comes from *soma*, the Greek word for body; thus, somatic hallucinations are bodily hallucinations.

DELUSIONS. Delusions are also a classic psychotic feature. Delusions are strongly held irrational and unrealistic beliefs that are extremely difficult to change, even

when the person is exposed to evidence that contradicts the delusion. The layperson typically thinks of delusions as being "paranoid," or "persecutory" wherein the delusional person is excessively suspicious and continually feels at the mercy of conspirators who are "out to get" him or her. However, delusions can also be unjustified beliefs that are grandiose, involve elaborate love fantasies ("erotomanic" delusions), or extreme and irrational jealousy. Grandiose delusions are persistent irrational beliefs that somehow exaggerate the person's importance, such as believing oneself to be a famous person, or having an enviable position such as being the Prime Minister or President. Often grandiose delusions take on religious overtones; for instance, a person might become convinced that she is the Virgin Mary. Furthermore, delusions can be somatic. Somatic delusions are erroneous but strongly held beliefs about the characteristics or functioning of one's body; an example is a mental health consumer who refuses to eat because of a conviction that the throat muscles are completely paralyzed and that only liquids can be swallowed, when there is no actual physical reason to be unable to swallow.

OTHER PSYCHOTIC SYMPTOMS. Other psychotic symptoms that may occur in brief psychotic disorder are strange bodily movements or lack of movements (catatonic behavior), peculiar speech, and bizarre or child-like behavior. Catatonic behavior or **catatonia** involves both possible extremes related to movement. Catalepsy is the motionless aspect of catatonia—a person with catalepsy may remain fixed in the same position for hours on end. Rapid or persistently repeated movements, frequent grimacing and strange facial expressions, and unusual gestures are the opposite end of the catatonia phenomenon. Peculiar speech is also seen in some cases of brief psychotic disorder. Speech distortions can involve words mixed together in no coherent order, responses that are irrelevant and strange in the context of the conversation in which they occur, or echolalia, the repetition of another person's exact spoken words, repeated either immediately after the speaker or after a delay of minutes to hours. Bizarre behavior can range from child-like behaviors such as skipping, singing, or hopping in inappropriate circumstances to unusual practices such as hoarding food or covering one's head and clothing with aluminum foil wrappings.

Of course, not all of these psychotic symptoms will be observed simultaneously in the person with brief psychotic disorder. Any constellation of these positive psychotic symptoms that occurs for one entire day up to one month is considered to be brief psychotic disorder, unless there is some other syndrome or biological cause that caused the symptoms to appear.

Causes and symptoms

Causes

Brief psychotic disorder is not a simple or consistent disorder with a single cause. Because many phenomena can prompt a short-term experience of psychotic symptoms, there are several ways of viewing the causes of the disorder.

AN EARLY PHASE OF SCHIZOPHRENIA. Because of the similarities between brief psychotic disorder, **schizophreniform disorder** and **schizophrenia**, many clinicians have come to think of brief psychotic disorder as being the precursor to a lengthier psychotic disorder. Although this can only be identified retrospectively, brief psychotic disorder is often the diagnosis that was originally used when an individual (who later develops schizophrenia) experiences a first "psychotic break" from more typical functioning.

A STRESS RESPONSE. At times, under severe **stress**, temporary psychotic reactions may appear. The source of stress can be from typical events encountered by many people in the course of a lifetime, such as being widowed or divorced. The severe stress may be more unusual, such as being in combat, enduring a natural disaster, or being taken hostage. The person generally returns to a normal method of functioning when the stress decreases or more support is available, or better coping skills are learned.

POSTPARTUM PSYCHOSIS. In some susceptible women, dramatic hormonal changes in childbirth and shortly afterward can result in a form of brief psychotic disorder often referred to as *postpartum psychosis*. Unfortunately, postpartum conditions are often misidentified and improperly treated. In many cases of a mother killing her infant or committing **suicide**, postpartum psychosis is involved.

DEFENSE MECHANISM IN PERSONALITY DISORDER. Persons with **personality disorders** appear to be more susceptible to developing brief psychotic reactions in response to stress. Individuals with personality disorders have not developed effective adult mechanisms for coping with life. When life becomes more demanding and difficult than can be tolerated, the person may lapse into a brief psychotic state.

CULTURALLY DEFINED DISORDER. Culture is a very important factor in understanding mental health and psychological disturbance, and brief psychotic disorder is an excellent example. The types of behavior that occur during brief psychotic disorder are very much shaped by the expectations and traditions of the individual's culture. Many cultures have some form of mental disorder that would meet criteria for brief psychotic disorder the features of which are unique to that culture, wherein most

KEY TERMS

Psychosis—Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an over-arching disorder, not a disorder in itself. (Plural: psychoses)

sufferers have similar behaviors that are attributed to causes that are localized to that community. The *DSM-IV-TR* calls disorders unique to certain societies or groups "culture-bound." An example of a culture-bound syndrome is *koro*, a syndrome observed in Japan and some other areas of Asia but not elsewhere. Koro is an **obsession** to the point of delusion with the possibility that the genitals will retract or shrink into the body and cause death.

Conversely, while culture shapes the form a psychotic reaction may take, culture also determines what is *not* to be considered psychotic. Behaviors that in one culture would be thought of as bizarre or psychotic, may be acceptable in another. For example, some cultural groups and religions view "speaking in tongues" as a valuable expression of the gifts of God, whereas viewed out of context, the unrecognizable speech patterns might be viewed as psychotic. If the behaviors shown are culturally acceptable in the person's society or religion, and happen in an approved setting such as a religious service, then brief psychotic disorder would not be diagnosed.

Symptoms

DSM-IV-TR provides three major criteria for brief psychotic disorder:

- At least one positive symptom of psychosis, from the following symptoms: delusions; hallucinations; disorganized speech which is strange, peculiar, difficult to comprehend; disorganized (bizarre or child-like) behavior; or catatonic behavior.
- Limited duration. The psychotic symptoms have occurred for at least one day but less than one month. There is an eventual return to normal level of functioning.
- The symptoms are not biologically influenced or attributable to another disorder. In other words, the symptoms cannot be occurring as part of a mood disorder, **schizoaffective disorder**, or schizophrenia, and they cannot be due to intoxication with drugs or alcohol. Further, the symptoms cannot be an adverse reaction to a medication, and they cannot be caused by a physical injury or medical illness.

Demographics

The actual rate of brief psychotic disorder is unknown, although it appears to be fairly rare in the United States and other developed countries. While psychotic reactions that occur and subside in under a month are more common in non-industrialized nations, the mental disorders wherein psychotic symptoms last longer than one month are more prevalent in developed countries. The disorder appears to be more common in adolescents and young adults than in those of middle age or older.

Diagnosis

Using the *DSM-IV-TR* criteria previously listed makes identification of the disorder relatively clear-cut. However, an unusual aspect to this diagnosis is the emphasis on the length of time that symptoms have been evident. Most mental health disorder diagnoses do not include the duration of the symptoms as part of their definitions. However, the length of time the person has had psychotic symptoms is one of the major distinctions among three different psychotic disorders. Brief psychotic disorder involves the shortest duration of suffering psychotic symptoms: one day to one month. Schizophreniform disorder also involves the individual showing signs of psychosis, but for a longer period (one month or more, but less than six months). Schizophrenia is diagnosed in individuals who have evidenced psychotic symptoms that are not associated with physical disease, mood disorder or intoxication, for six months or longer. Another complicating factor in making the diagnosis is the context in which the "psychotic symptoms" are experienced. If the psychotic-like behaviors evidenced are acceptable in the person's culture or religion and these behaviors happen in a traditionally expected context such as a religious service or **meditation**, then brief psychotic disorder would not be diagnosed.

The disorder is usually diagnosed by obtaining information in interview from the client and possibly from immediate family. Also, the diagnostician would be likely to perform a semi-structured interview called a mental status examination, which examines the person's ability to concentrate, to remember, to realistically understand the situation, and to think logically.

Treatments

Antipsychotic medications are very effective in ending a brief psychotic episode. A number of different antipsychotics are used for the purpose of terminating

acute psychotic episodes. **Haloperidol** (Haldol) is most commonly used if the psychotic symptoms are accompanied by *agitation*. Agitation is a state of frantic activity that is often accompanied by anger or fearfulness; when in an agitated state, the client is more likely to cause harm to self or others. In agitated psychotic states, the haloperidol is often given as an injection, accompanied by other medications that decrease anxiety (**lorazepam**, also known as Ativan) and slow behavior (**diphenhydramine**, also known as Benadryl). If the client is not agitated, usually a newer-generation antipsychotic is used, given daily as tablets, capsules or liquid, for a lengthier period of time. The novel antipsychotic that would be used is likely to be one of the following: **olanzapine** (Zyprexa), **quetiapine** (Seroquel), or **risperidone** (Risperdal). Hormones may also be prescribed for postpartum psychosis. Supportive therapy may also prove helpful in some situations, in decreasing the client's anxiety and educating the client about the psychiatric illness. In culture-bound syndromes, the most effective treatment is often the one that is societally expected; for example, bathing in a river viewed as sacred might be a usual method of curing the psychotic-like state, in a particular culture.

Prognosis

The prognosis is fairly positive in brief psychotic disorder because by its own definition, a return to normal functioning is expected. If there is a major life event as a stress or an unusual traumatic experience that initiated the episode, chances are very good that there will be no recurrence. If there is not a particular triggering event or if the episode occurred in an individual with a personality disorder, the likelihood of recurrence is higher. If an episode is a recurrence without a specific triggering event, then the beginnings of the development of schizophrenia or **bipolar disorder** may be at hand, in which case the prognosis is poor. In the individual with personality disorder, the pattern may recur in response to stress, so that there are intermittent experiences of brief psychotic disorder over the course of a lifetime.

Prevention

In women who have experienced brief postpartum psychosis, one prevention option is to forgo having additional children. If a postpartum psychosis has occurred in the past, in subsequent pregnancies the physician may be proactive in prescribing an antipsychotic medication regimen to be taken in the postpartum period in order to prevent psychotic symptoms from recurring. Severe stressors can be a trigger for brief psychotic disorder in many cases. Therefore, in response to identifiable extreme stressors, such as natural disasters or terrorist attacks, strong social support and immediate post-crisis counseling could possibly prevent the development of brief psychotic disorder in susceptible persons.

Bulimia nervosa

Definition

Bulimia nervosa is an eating disorder characterized by **binge eating** and engaging in inappropriate ways of counteracting the bingeing (using laxatives, for example) in order to prevent weight gain. The word "bulimia" is the Latin form of the Greek word *boulimia*, which means "extreme hunger." A binge is consuming a larger amount of food within a limited period of time than most people would eat in similar circumstances. Most people with bulimia report feelings of loss of control associated with bingeing, and some have mildly dissociative experiences in the course of a binge, which means that they feel disconnected from themselves and from reality when they binge.

KEY TERMS

Binge—An excessive amount of food consumed in a short period of time. Usually, while a person binge eats, he or she feels disconnected from reality, and feels unable to stop. The bingeing may temporarily relieve depression or anxiety, but after the binge, the person usually feels guilty and depressed.

Body image—A term that refers to a person's inner picture of his or her outward appearance. It has two components: perceptions of the appearance of one's body, and emotional responses to those perceptions.

Comorbidity—Association or presence of two or more mental disorders in the same patient. A disorder that is said to have a high degree of comorbidity is likely to occur in patients diagnosed with other disorders that may share or reinforce some of its symptoms.

Cortisol—A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress.

Diuretic—A medication or substance given to increase the amount of urine excreted.

Dysthymic disorder—A mood disorder that is less severe than depression but usually more chronic.

Electrolytes—Substances or elements that dissociate into electrically charged particles (ions) when dissolved in the blood. The electrolytes in human blood include potassium, magnesium, and chloride.

Hypokalemia—Abnormally low levels of potassium in the blood. Hypokalemia is a potential medical emergency, as it can lead to disturbances in of the heart rhythm. Muscle cramps and pain are a common symptom of hypokalemia in bulimic patients.

Incisors—The four teeth in the front of each jaw in humans. The incisors of patients with bulimia frequently show signs of erosion from stomach acid.

Ipecac—The dried root of *Caephalis ipecacuanha*, a South American plant. Given in syrup form, ipecac is most commonly used to induce vomiting in cases of accidental poisoning.

Petechiae—Pinpoint-sized hemorrhages in the skin or a mucous membrane. In bulimia, petechiae may appear in the skin around the eyes as a result of increased pressure in the capillaries caused by vomiting.

Purging—Inappropriate actions taken to prevent weight gain, often after bingeing, including self-induced vomiting or the misuse of laxatives, diuretics, enemas, or other medications.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

The handbook for mental health professionals to aid in **diagnosis** is the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR*. This book categorizes bulimia nervosa as an eating disorder, along with **anorexia nervosa**.

Description

Bulimia nervosa is classified into two subtypes according to the methods used by the patient to prevent weight gain after a binge. The purging subtype of bulimia is characterized by the use of self-induced vomiting, laxatives, enemas, or diuretics (pills that induce urination); in the nonpurging subtype, fasting or overexercising is used to compensate for binge eating.

The onset of bulimia nervosa is most common in late adolescence or early adult life. Dieting efforts and body dissatisfaction, however, often occur in the teenage years. For these reasons, it is often described as a developmental disorder. Although genetic researchers have identified specific genes linked to susceptibility to eating disorders, the primary factor in the development of bulimia nervosa is environmental **stress** related to the onset of puberty. Girls who have strongly negative feelings about their bodies in response to puberty are at high risk for developing bulimia.

The binge eating associated with bulimia begins most often after a period of strict dieting. Most people with bulimia develop purging behaviors in response to the bingeing. Vomiting is used by 80%–90% of patients

diagnosed with bulimia. The personal accounts of recovered bulimics suggest that most "discover" vomiting independently as a way of ridding themselves of the food rather than learning about it from other adolescents. Vomiting is often done to relieve an uncomfortable sensation of fullness in the stomach following a binge as well as to prevent absorption of the calories in the food. Vomiting is frequently induced by touching the gag reflex at the back of the throat with the fingers or a toothbrush, but a minority of patients use syrup of ipecac to induce vomiting. About a third of bulimics use laxatives after binge eating to empty the digestive tract, and a minority use diuretics or enemas. Purging behaviors lead to a series of digestive and metabolic disturbances that then reinforce the behaviors.

A small proportion of bulimics exercise excessively or fast after a binge instead of purging.

Patients with bulimia may come to the attention of a **psychiatrist** because they develop medical or dental complications of the eating disorder. In some cases, the adolescent's dentist is the "case finder." In many cases, however, the person with bulimia seeks help.

Causes and symptoms

Causes

As of 2002, bulimia nervosa is understood to be a complex disorder with multiple factors contributing to its development. Researchers presently disagree about the degree of influence exerted by genetic factors, psychological patterns in the family of origin, and social trends.

GENETIC. Two recently published reviews (in 1999 and 2000) suggest that there is some heritability for bulimia. In other words, these articles suggest that there is a genetic component to bulimia. **Neurotransmitters** are chemicals that pass chemical messages along from nerve cell to nerve cell, and people with bulimia have abnormal levels of certain neurotransmitters. Some observers have suggested that these abnormalities in the levels of central nervous system neurotransmitters may also be influenced by genetic factors.

FAMILY OF ORIGIN. A number of recent studies point to the interpersonal relationships in the family of origin (the patient's family while growing up) as a factor in the later development of bulimia. People with bulimia are more likely than people with anorexia to have been sexually abused in childhood; studies have found that abnormalities in blood levels of serotonin (a neurotransmitter associated with mood disorders) and cortisol (the primary stress hormone in humans) in bulimic patients with a history of childhood sexual **abuse** resemble those in patients with **post-traumatic stress disorder**. Post-traumatic stress disorder is a mental disorder that can develop after someone has experienced a traumatic event (horrors of war, for example) and is unable to put that event behind him or her— the disorder is characterized by very realistic flashbacks of the traumatic event.

A history of eating conflicts and struggles over food in the family of origin is also a risk factor for the development of bulimia nervosa. Personal accounts by recovered bulimics frequently note that one or both parents were preoccupied with food or dieting. Fathers appear to be as influential as mothers in this regard.

An additional risk factor for early-onset bulimia is interest in or preparation for a sport or occupation that requires strict weight control, such as gymnastics, figure skating, ballet, and modeling.

SOCIOCULTURAL CAUSES. Emphasis in the mass media on slenderness in women as the primary criterion of beauty and desirability is commonly noted in studies of bulimia. Historians of fashion have remarked that the standard of female attractiveness has changed over the past half century in the direction of greater slenderness; some have commented that Marilyn Monroe would be considered "fat" by contemporary standards. The ideal female figure is not only unattainable by the vast majority of women, but is lighter than the standards associated with good health by insurance companies. In 1965 the average model weighed 8% less than the average American woman; as of 2001 she weighs 25% less.

Another factor mentioned by intellectual historians is the centuries-old split in Western philosophy between mind and body. Instead of regarding a human person as a unified whole comprised of body, soul, and mind, Western thought since Plato has tended to divide human nature in a dualistic fashion between the life of the mind and the needs of the body. Furthermore, this division was associated with gender symbolism in such a way that the life of the mind was associated with masculinity and the needs of the body with femininity. The notion that the "superior" mind should control the "inferior" physical dimension of human life was correlated with men's physical, legal, and economic domination of women. Although this dualistic pattern of symbolic thought is no longer a conscious part of the Western mindset, it appears to influence Western culture on a subterranean level.

A number of different theories have been put forward to explain the connections between familial and social factors and bulimia. Some of these theories maintain that:

- Bulimia results from a conflict between mother and daughter about nurturing and dependency. Girls are typically weaned earlier than boys and fed less. The bulimic's bingeing and purging represent a conflict

The cuts on the knuckles shown in this photograph are due to the teeth breaking the skin during self-induced vomiting. *(B. Bodine/Custom Medical Stock Photo, Inc. Reproduced by permission.)*

between wanting comfort and believing that she does not deserve it.

- Bulimia develops when an adolescent displaces larger conflicts about being a woman in a hypersexualized society onto food. Many writers have commented about the contradictory demands placed on women in contemporary society— for example, to be sexually appealing yet "untouchable" at the same time. Controlling body size and food intake becomes a simplified solution to a very complex problem of personal identity and moral standards.
- Bulimia is an **obsession** with food that the culture encourages in order to protect men from competition from intellectually liberated women. Women who are spending hours each day thinking about food, or bingeing and purging, do not have the emotional and intellectual energy to take their places in the learned professions and the business world.
- Bulimia expresses a fear of fat rooted in childhood memories of mother's size relative to one's own.
- Bulimia results from intensified competition among women for professional achievement (getting a desirable job or a promotion, or being accepted into graduate or professional school) as well as personal success (getting a husband), because studies have indicated that businesses and graduate programs discriminate against overweight applicants.
- Bulimia results from attempts to control emotional chaos in one's interpersonal relationships by imposing rigid controls on food intake.

Nutrition experts have pointed to the easy availability of foods high in processed carbohydrates in developed countries as a social factor that contributes to the incidence of bulimia. One study found that subjects who were given two slices of standard mass-produced white bread with some jelly had their levels of serotonin increased temporarily by 450%. This finding suggests that bulimics who binge on ice cream, bread, cookies, pizza, and fast food items that are high in processed carbohydrates are simply manipulating their neurochemistry in a highly efficient manner. The incidence of bulimia may be lower in developing countries because **diets** that are high in vegetables and whole-grain products but low in processed carbohydrates do not affect serotonin levels in the **brain** as rapidly or as effectively.

Symptoms

The *DSM-IV-TR* specifies that bingeing and the inappropriate attempts to compensate for it must occur twice a week for three months on average to meet the diagnostic criteria for bulimia nervosa.

A second criterion of bulimia nervosa is exaggerated concern with body shape and weight. Bulimia can be distinguished from **body dysmorphic disorder** (BDD) by the fact that people with BDD usually focus on a specific physical feature— most commonly a facial feature— rather than overall shape and weight. Bulimics do, however, resemble patients with BDD in that they have distorted body images.

Bulimia is associated with a number of physical symptoms. Binge eating by itself rarely causes serious medical complications, but it is associated with nausea, abdominal distension and cramping, slowed digestion, and weight gain.

Self-induced vomiting, on the other hand, may have serious medical consequences, including:

- Erosion of tooth enamel, particularly on the molars and maxillary incisors. Loss of tooth enamel is irreversible.
- Enlargement of the salivary glands.
- Scars and calloused areas on the knuckles from contact with the teeth.

- Irritation of the throat and esophagus from contact with stomach acid.
- Tearing of mucous membranes in the upper gastrointenstinal tract or perforation of the esophagus and stomach wall. Perforation of part of the digestive tract is a rare complication of bulimia but is potentially fatal.
- Electrolyte imbalances. The loss of fluids from repeated vomiting and laxative abuse can deplete the body's stores of hydrogen chloride, potassium, sodium, and magnesium. Hypokalemia (abnormally low levels of potassium in the blood) is a potential medical emergency that can lead to muscle cramps, **seizures**, and heart arrhythmias.

Other physical symptoms associated with bulimia include irregular menstrual periods or amenorrhea; petechiae (pinhead-sized bruises from capillaries ruptured by increased pressure due to vomiting) in the skin around the eyes and rectal prolapse (the lowering of the rectum from its usual position).

Demographics

Bulimia nervosa affects between 1% and 3% of women in the developed countries; its prevalence is thought to have increased markedly since 1970. The rates are similar across cultures as otherwise different as the United States, Japan, the United Kingdom, Australia, South Africa, Canada, France, Germany, and Israel. About 90% of patients diagnosed with bulimia are female as of 2002, but some researchers believe that the rate of bulimia among males is rising faster than the rate among females.

The average age at onset of bulimia nervosa appears to be dropping in the developed countries. A study of eating disorders in Rochester, Minnesota over the 50 years between 1935 and 1985 indicated that the incidence rates for women over 20 remained fairly constant, but there was a significant rise for women between 15 and 20 years of age. The average age at onset among women with bulimia was 14 and among men, 18.

In terms of sexual orientation, gay men appear to be as vulnerable to developing bulimia as heterosexual women, while lesbians are less vulnerable.

Recent studies indicate that bulimia in the United States is no longer primarily a disorder of Caucasian women; the rates among African American and Hispanic women have risen faster than the rate of bulimia for the female population as a whole. One report indicates that the chief difference between African American and Caucasian bulimics in the United States is that the African American patients are less likely to eat restricted diets between episodes of binge eating.

Diagnosis

The diagnosis of bulimia nervosa is made on the basis of a physical examination, a psychiatric assessment, the patient's eating history, and the findings of laboratory studies. Patients who do not meet the full criteria for bulimia nervosa may be given the diagnosis of subsyndromal bulimia or of eating disorder not otherwise specified (EDNOS).

Physical examination

Patients suspected of having bulimia nervosa should be given a complete physical examination because the disorder has so many potential medical complications. In addition, most bulimics are close to normal weight or only slightly overweight, and so do not look outwardly different from most people of their sex in their age group. The examination should include not only vital signs and an assessment of the patient's height and weight relative to age, but also checking for such signs of bulimia as general hair loss, abdominal soreness, swelling of the parotid glands, telltale scars on the back of the hand, petechiae, edema, and teeth that look ragged or "moth-eaten."

Psychiatric assessment

Psychiatric assessment of patients with bulimia usually includes four components:

- A thorough history of body weight, eating patterns, diets, typical daily food intake, methods of purging (if used), and concept of ideal weight.
- A history of the patient's significant relationships with parents, siblings, and peers, including present or past physical, emotional, or sexual abuse.
- A history of previous psychiatric treatment (if any) and assessment of comorbid (occurring at the same time as the bulimia) mood, anxiety, substance abuse, or **personality disorders**.
- Administration of standardized instruments that measure attitudes toward eating, body size, and weight. Common tests for eating disorders include the Eating Disorder Examination; the Eating Disorder Inventory; the Eating Attitude Test, or EAT; and the Kids Eating Disorder Survey.

Laboratory findings

Laboratory tests ordered for patients suspected of having bulimia usually include a complete blood cell count, blood serum chemistry, thyroid tests, and urinalysis. If necessary, the doctor may also order a chest x ray and an electrocardiogram (EKG). Typical findings in

patients with bulimia include low levels of chloride and potassium in the blood, and higher than normal levels of amylase, a digestive enzyme found in saliva.

Treatments

Treatment for bulimia nervosa typically involves several therapy approaches. It is, however, complicated by several factors.

First, patients diagnosed with bulimia nervosa frequently have coexisting psychiatric disorders that typically include major depression, **dysthymic disorder**, anxiety disorders, substance abuse disorders, or personality disorders. In the case of depression, the mood disorder may either precede or follow the onset of bulimia, and, with bulimia, the prevalence of depression is 40%–70%. With regard to substance abuse, about 30% of patients diagnosed with bulimia nervosa abuse either alcohol or stimulants over the course of the eating disorder. The personality disorders most often diagnosed in bulimics are the so-called Cluster B disorders— borderline, narcissistic, histrionic, and antisocial. **Borderline personality disorder** is a disorder characterized by stormy interpersonal relationships, unstable self-image, and impulsive behavior. People with **narcissistic personality disorder** believe that they are extremely important and are unable to have empathy for others. Individuals with **histrionic personality disorder** seek attention almost constantly and are very emotional. **Antisocial personality disorder** is characterized by a behavior pattern of a disregard for others' rights— people with this disorder often deceive and mainpulate others. A number of clinicians have noted that patients with bulimia tend to develop impulsive and unstable personality disturbances whereas patients with anorexia tend to be more obsessional and perfectionistic. Estimates of the prevalence of personality disorders among patients with bulimia range between 2% and 50%. The clinician must then decide whether to treat the eating disorder and the comorbid conditions concurrently or sequentially. It is generally agreed, however, that a substance abuse disorder, if present, must be treated before the bulimia can be effectively managed. It is also generally agreed that mood disorders and bulimia can be treated concurrently, often using antidepressant medication along with therapy.

Second, the limitations on treatment imposed by **managed care** complicate the treatment of bulimia nervosa. When the disorder first received attention in the 1970s, patients with bulimia were often hospitalized until the most significant physical symptoms of the disorder could be treated. As of 2002, however, few patients with bulimia are hospitalized, with the exception of medical emergencies related to electrolyte imbalances and gastrointestinal injuries associated with the eating disorder. Most treatment protocols for bulimia nervosa now reflect cost-containment measures.

Medications

The most common medications given to patients are antidepressants, because bulimia is so closely associated with depression. Short-term medication trials have reported that tricyclic antidepressants— **desipramine**, **imipramine**, and **amitriptyline** — reduce episodes of binge eating by 47%–91% and vomiting by 45%–78%. The monoamine oxidase inhibitors are not recommended as initial medications for patients diagnosed with bulimia because of their side effects. The most promising results have been obtained with the selective serotonin reuptake inhibitors, or SSRIs. **Fluoxetine** (Prozac) was approved in 1998 by the Food and Drug Administration (FDA) for the treatment of bulimia nervosa. Effective dosages of fluoxetine are higher for the treatment of bulimia than they are for the treatment of depression. Although a combination of medication and **cognitive-behavioral therapy** is more effective in treating most patients with bulimia than medication alone, one team of researchers reported success in treating some bulimics who had not responded to **psychotherapy** with fluoxetine by itself.

A newer type of medication that shows promise in the treatment of bulimia nervosa is ondansetron, a drug that was originally developed to control nausea from chemotherapy and radiation therapy for cancer. Ondansetron acts to control the transmission of signals in nerves leading to the vagus nerve, which in turn governs feelings of fullness and the vomiting reflex. A British study reported that ondansetron normalized several aspects of eating behaviors in all the patients who received it during the study.

In addition to antidepressant or antinausea medications, such acid-reducing medications as cimetidine and ranitidine, or antacids, may be given to patients with bulimia to relieve discomfort in the digestive tract associated with irritation caused by stomach acid.

Psychotherapy

Cognitive-behavioral therapy (CBT) is regarded as the most successful psychotherapeutic approach to bulimia nervosa. CBT is intended to interrupt the faulty thinking processes associated with bulimia, such as preoccupations with food and weight, black-white thinking ("all or nothing" thinking, or thinking thoughts only at extreme ends of a spectrum) and low self-esteem, as well as such behaviors as the binge-purge cycle. Patients are first helped to regain control over their food intake by keeping

food diaries and receiving feedback about their meal plans, symptom triggers, nutritional balance, etc. They are then taught to challenge rigid thought patterns as well as receiving **assertiveness training** and practice in identifying and expressing their feelings in words rather than through distorted eating patterns. About 50% of bulimic patients treated with CBT are able to stop bingeing and purging. Of the remaining half, some show partial improvement and a small minority do not respond at all.

Family therapy is sometimes recommended as an additional mode of treatment for patients with bulimia who come from severely troubled or food-obsessed families that increase their risk of relapsing.

Other mainstream therapies

Medical nutrition therapy, or MNT, is a recognized component of the treatment of eating disorders. Effective MNT for patients with bulimia involves an understanding of cognitive-behavioral therapy as well as the registered dietitian's usual role of assisting the physician with monitoring the patient's physical symptoms, laboratory values, and vital signs. In the treatment of bulimia, the dietitian's specialized knowledge of nutrition may be quite helpful in dealing with the myths about food and fad diets that many bulimic patients believe. The dietitian's most important task, however, is helping the patient to normalize her or his eating patterns in order to break the deprivation/bingeing cycle that is characteristic of bulimia nervosa. Calorie intake is usually based on retaining the patient's weight in order to prevent hunger, since hunger increases susceptibility to bingeing.

Recent studies in upstate New York have found that bright **light therapy**, of the type frequently prescribed for **seasonal affective disorder** (SAD), appears to be effective in reducing binge eating in patients diagnosed with bulimia. It also significantly relieved depressive symptoms, as measured by the patients' scores on the **Beck Depression Inventory**.

Alternative and complementary treatments

Alternative therapies that have been shown to be helpful for some patients in relieving the anxiety and muscular soreness associated with bulimia nervosa include **acupuncture**, massage therapy, hydrotherapy, and shiatsu.

Herbal remedies that have been used to calm digestive upsets in bulimic patients include teas made from **chamomile** or peppermint. Peppermint helps to soothe the intestines by slowing down the rate of smooth muscle contractions (peristalsis). Chamomile has been used to help expel gas from the digestive tract, a common complaint of bulimics. Both herbs have a wide margin of safety.

Some bulimic patients have responded well to **yoga** because its emphasis on focused breathing and **meditation** calls attention to and challenges the distorted thought patterns that characterize bulimia. In addition, the stretching and bending movements that are part of a yoga practice help to displace negative thoughts focused on the body's outward appearance with positive appreciation of its strength and agility. Lastly, since yoga is noncompetitive, it allows bulimics to explore the uniqueness of their bodies rather than constantly comparing themselves to other people.

Prognosis

The prognosis of bulimia depends on several factors, including age at onset, types of purging behaviors used (if any), and the presence of other psychiatric conditions or disorders. In many cases, the disorder becomes a chronic (long-term) condition; 20%–50% of patients have symptoms for at least five years in spite of treatment. The usual pattern is an alternation between periods of remission and new episodes of bingeing. Patients whose periods of remission last for a year or longer have a better prognosis; patients diagnosed with major depression or a personality disorder have a less favorable prognosis. Overall, however, the prognosis for full recovery from bulimia nervosa is considered relatively poor compared to other eating disorders.

Bulimia nervosa appears to produce changes in the functioning of the serotonin system in the brain. Serotonin is a neurotransmitter. A team of researchers at the University of Pittsburgh who compared brain images taken by **positron emission tomography** (PET) from bulimic women who had been in remission for a year or longer with brain images from healthy women found that the recovered bulimics did not have a normal age-related decline in serotonin binding. Since serotonin helps to regulate mood, appetite, and impulse control, the study may help to explain why some women may be more susceptible to developing bulimia than others.

Prevention

As of 2002, the genetic factors in bulimia are not well understood. With regard to family influences, an important study published in December 2001 reported that the presence of eating problems in early childhood is a strong predictor of eating disorders in later life. The longitudinal study of 800 children and their mothers was based on psychiatric assessments of the subjects made in 1975, 1983, 1985, and 1992. The researchers found that a diagnosis of bulimia nervosa in early adolescence is associated with a nine-fold increase in risk for late adolescent bulimia and a 20-fold increase in risk for adult bulimia. Late adolescent

bulimia nervosa is associated with a 35-fold increase in risk for adult bulimia nervosa. Given these findings, the most important preventive measure that can be taken in regard to bulimia nervosa is the establishment of healthful eating patterns and attitudes toward food in the family of origin.

Bupropion

Definition

Bupropion is an antidepressant drug used to elevate mood and promote recovery of a normal range of emotions in patients with depressive disorders. In addition, bupropion is used to as an aid in smoking cessation treatment. In the United States, bupropion is sold as an antidepressant under the brand name Wellbutrin. As a smoking cessation treatment, the drug is marketed under the brand name Zyban.

Purpose

Bupropion is principally known as an antidepressant drug used to promote recovery of depressed patients. It also has therapeutic uses in smoking cessation treatment, **panic disorder**, and **attention-deficit/hyperactivity disorder** (ADHD).

Description

Bupropion is a non-tricyclic antidepressant drug. Tricyclic antidepressants, which have a three-ring chemical structure, may cause troublesome side effects, including sedation, dizziness, faintness, and weight gain. Until the 1980s, such drugs were the mainstay of the pharmacological treatment of depression. Bupropion was one of the first antidepressants with a significantly different chemical structure to be developed by pharmaceutical researchers seeking drugs effective in treating depression but without the unwanted actions of the tricyclic antidepressants.

The exact way that bupropion works in the **brain** is not understood. Its mechanism of action appears to be different from that of most other antidepressant drugs, although bupropion does act on some of the same **neurotransmitters** and neurotransmission pathways. Neurotransmitters are naturally occurring chemicals that regulate the transmission of nerve impulses from one cell to another. Mental well-being is partially dependent on maintaining the proper balance among the various neurotransmitters in the brain. Bupropion may restore normal emotional feelings by counteracting abnormalities of neurotransmission that occur in depressive disorders.

In contrast to the drowsiness frequently caused by other antidepressants, bupropion is a mild stimulant. Bupropion is also less likely to cause weight gain and adverse effects on blood pressure and the heart. However, it is more likely to trigger epileptic **seizures**.

KEY TERMS

Antipsychotic drug—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Neurotransmission—The conduction of a nerve impulse along a chain of nerve cells, which occurs when a cell in the chain secretes a chemical substance, called a neurotransmitter, onto a subsequent cell.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Recommended dosage

The usual adult dose of bupropion (Wellbutrin) is 100 mg, taken three times per day, with at least six hours between doses. The extended release form of the drug (Wellbutrin SR) is taken as 150 mg twice a day with at least eight hours between doses. For smoking cessation, bupropion (Zyban) is taken as 150-mg extended release tablets twice a day, with at least eight hours between doses. Bupropion treatment should be started at a lower dose, then gradually increased to a therapeutic dosage, as directed by the physician. Generally, the total dosage should not exceed 300 mg per day, except as directed by the physician.

The therapeutic effects of bupropion, like other antidepressants, appear slowly. Maximum benefit is often not evident for several weeks after starting the drug. People taking bupropion should be aware of this and continue taking the drug as directed even if they do not see immediate improvement in mood.

Since higher doses of bupropion increase the risk of seizures, no more than 150 mg should be given at any one time, and the total daily dosage should not be increased by more than 100 mg every three days.

Increasing the dosage gradually also minimizes agitation, restlessness, and **insomnia** that may occur.

Healthy elderly patients do not appear to be more sensitive to side effects of bupropion than younger adults and do not require reduced doses. Certain medical conditions, especially liver and kidney disease, may necessitate dose reduction. Although bupropion has been taken by children and adolescents under age 18, it has not been systematically studied in these age groups.

Precautions

Bupropion is more likely to trigger epileptic seizures than other antidepressants. The drug should not be given to patients who have a history of epilepsy, take other medication to help control seizures, or have some other condition associated with seizures, such as head trauma or alcoholism. Nevertheless, in fewer than 1% of healthy people taking bupropion at the recommended dose have seizures. The possibility of seizures is increased at higher doses and following a sudden increase in dose. Patients should minimize alcohol intake while taking bupropion, since alcohol consumption increases the chance of seizures.

Because of the possibility of overdose, potentially suicidal patients should be given only small quantities of the drug at one time. Increases in blood pressure have occurred in patients taking bupropion along with nicotine treatment for smoking cessation. Monitoring blood pressure is recommended in such cases. Excessive stimulation, agitation, insomnia, and anxiety have been troublesome side effects for some patients, especially when treatment is first begun or when the dose is increased. Such adverse effects may be less intense and less frequent when the dose is increased gradually.

It has not been determined whether bupropion is safe to take during pregnancy. Pregnant women should take bupropion only if necessary. The drug is secreted in breast milk. Women taking bupropion should consult their physicians about breast-feeding.

Side effects

Bupropion is a mild stimulant and may cause insomnia, agitation, confusion, restlessness, and anxiety. These effects may be more pronounced at the beginning of therapy and after dose increases. Headache, dizziness, and tremor may occur. Despite stimulating effects, bupropion may also cause sedation.

Weight loss is more common with bupropion than weight gain, but both have been reported. Excessive sweating, dry mouth, sore throat, nausea, vomiting, decreased appetite, constipation, blurred vision, and rapid heart rate may occur.

Interactions

Bupropion should not be administered along with other medications that lower the seizure threshold, such as steroids and the asthma medication theophylline. Many psychiatric medications also lower the seizure threshold. Monoamine oxidase inhibitors (MAOs), another type of antidepressant medication, should not be taken with bupropion. Adverse effects may increase in patients taking levodopa and other medications for Parkison's disease along with bupropion. Patients should inform their doctors about all other medications they are taking before starting this drug.

Nicotine patch therapy may be administered concurrently with bupropion in smoking cessation treatment. If this is done, blood pressure must be monitored, since increased blood pressure has been reported with this combination of medications.

Certain drugs, especially those eliminated by the liver, may interfere with the elimination of bupropion from the body, causing higher blood levels and increased side effects. Conversely, bupropion may retard the elimination of other medicines, including many antidepressants, antipsychotic drugs, and heart medications, resulting in higher blood levels and potentially increased side effects.

BuSpar *see* **Buspirone**

Buspirone

Definition

Buspirone is an anti-anxiety (anxiolytic) drug sold in the United States under the brand name of BuSpar. It is also available under its generic name.

Purpose

Buspirone is used for the treatment of generalized anxiety disorders and for short term relief of symptoms of anxiety.

Description

Buspirone's mechanism of action is unclear but probably involves actions on such central nervous system chemicals as dopamine, serotonin, acetylcholine, and norepinephrine. These chemicals are called **neurotransmitters** and are involved in the transmission of nervous impulses from cell to cell. Mental well-being is partially dependent on maintaining a balance among different neurotransmitters.

Buspirone's actions are different from a common class of sedatives called benzodiazepines. The primary action of benzodiazepines is to reduce anxiety, relax skeletal muscles, and induce sleep. The earliest drugs in this class were **chlordiazepoxide** (Librium) and **diazepam** (Valium). Buspirone also acts through a different mechanism than **barbiturates** such as phenobarbital. Unlike benzodiazepines, buspirone has no anticonvulsant or muscle-relaxant properties, and unlike benzodiazepines or barbiturates, it does not have strong sedative properties. If **insomnia** is a component of the patient's anxiety disorder, a sedative/hypnotic drug may be taken along with buspirone at bedtime. Buspirone also diminishes anger and hostility for most people. Unlike benzodiazepines, which may aggravate anger and hostility in some patients, (especially older patients), buspirone may help patients with anxiety who also have a history of aggression.

The benefits of buspirone take a long time to become evident. Unlike benzodiazepines, where onset of action and time to maximum benefit are short, patients must take buspirone for three to four weeks before feeling the maximum benefit of the drug. In some cases, four to six weeks of treatment may be required. Patients should be aware of this and continue to take the drug as prescribed even if they think they are not seeing any improvement.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anxiolytic—A preparation or substance given to relieve anxiety; a tranquilizer.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Buspirone is available in 5-, 10-, 15-, and 30-mg tablets.

Recommended dosage

The usual starting dose of buspirone is 10 to 15 mg per day. This total amount is divided into two or three doses during the day. For example, a dose of 5 mg may be given two or three times per day to make a total dose of 10 to 15 mg per day. The dose may be increased in increments of 5 mg daily every two to four days. Most patients will respond to a dose of 15 to 30 mg daily. Patients should not take a total dose of more than 60 mg daily. When patients are receiving certain other drugs (see below) in addition to buspirone, starting doses of buspirone may need to be lowered (for example, 2.5 mg twice daily), and any dosage increases should be done with caution and under close physician supervision. Dosages may need to be reduced in patients with kidney or liver problems.

Precautions

Buspirone is less sedating (causes less drowsiness and mental sluggishness) than other anti-anxiety drugs. However, some patients may still experience drowsiness and mental impairment. Because it is impossible to predict which patients may experience sedation with buspirone, those starting this drug should not drive or operate dangerous machinery until they know how the drug will affect them.

Patients who have been taking benzodiazepines for a long time should be gradually withdrawn from them while they are being switched over to buspirone. They should also be observed for symptoms of benzodiazepine withdrawal.

Patients with kidney damage should take buspirone with caution in close consultation with their physician. They may require a lower dosage of buspirone to prevent buildup of the drug in the body. Patients with severe kidney disease should not take buspirone. Patients with liver damage should likewise be monitored for a buildup of buspirone and have their doses lowered if necessary.

Side effects

The most common side effects associated with buspirone involve the nervous system. Ten percent of patients may experience dizziness, drowsiness, and headache, and another 5% may experience **fatigue**, nervousness, insomnia, and light-headedness. Patients may also experience excitement, depression, anger, hostility, confusion, nightmares, or other **sleep disorders**, lack of coordination, tremor, and numbness of the extremities. Although buspirone is considered non-sedating, some patients will experience drowsiness and lack of mental alertness at higher doses and especially early in therapy. In most patients, these side effects decrease with time.

The following side effects have also been associated with buspirone:

- nausea (up to 8% of patients)
- dry mouth, abdominal distress, gastric distress, and diarrhea, constipation (up to 5% of patients)
- rapid heart rate and palpitations (up to 2% of patients)
- blurred vision (up to 2% of patients)
- increased or decreased appetite
- flatulence
- non-specific chest pain
- rash
- irregular menstrual periods and/or breakthrough bleeding

Interactions

Dangerously high blood pressure has resulted from the combination of buspirone, and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Because of this, buspirone should never be taken in combination with MAO inhibitors. Patient taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor then wait at least 10 days before starting buspirone. The same holds true when discontinuing buspirone and starting an MAO inhibitor.

Certain drugs may inhibit the enzyme system in the liver that breaks down buspirone. Examples of drugs that might inhibit this system are erythromycin, a broad-spectrum antibiotic, itraconazole, an oral antifungal agent, and **nefazodone**, an antidepressant. When these drugs are combined with buspirone, buspirone concentrations may increase to the point of toxicity (poisoning). These combinations should either be avoided or doses of buspirone decreased to compensate for this interaction.

Caffeine-related disorders

Definition

Caffeine is a white, bitter crystalline alkaloid derived from coffee or tea. It belongs to a class of compounds called xanthines, its chemical formula being 1,3,7-trimethylxanthine. Caffeine is classified together with cocaine and **amphetamines** as an analeptic, or central nervous system stimulant. Coffee is the most abundant source of caffeine, although caffeine is also found in tea, cocoa, and cola beverages as well as in over-the-counter and prescription medications for pain relief.

In the clinician's handbook for diagnosing mental disorders (the ***Diagnostic and Statistical Manual of Mental Disorders***, known as the *DSM-IV-TR*), caffeine-related disorders are classified under the rubric of substance-related disorders. *DSM-IV-TR* specifies four caffeine-related disorders: caffeine intoxication, caffeine-induced anxiety disorder, caffeine-induced sleep disorder, and caffeine-related disorder not otherwise specified. A fifth, caffeine withdrawal, is listed under the heading of "Criteria Sets and Axes Provided for Further Study."

Caffeine-related disorders are often unrecognized for a number of reasons:

- Caffeine has a "low profile" as a drug of abuse. Consumption of drinks containing caffeine is unregulated by law and is nearly universal in the United States; one well-known textbook of pharmacology refers to caffeine as "the most widely used psychoactive drug in the world." In many countries, coffee is a social lubricant as well as a stimulant; the "coffee break" is a common office ritual, and many people find it difficult to imagine eating a meal in a fine restaurant without having coffee at some point during the meal. It is estimated that 10–12 billion pounds of coffee are consumed worldwide each year.
- People often underestimate the amount of caffeine they consume on a daily basis because they think of caffeine only in connection with coffee as a beverage. Tea, cocoa, and some types of soft drink, including root beer and orange soda as well as cola beverages, also contain significant amounts of caffeine. In one British case study, a teenager who was hospitalized with muscle weakness, nausea, vomiting, diarrhea, and weight loss was found to suffer from caffeine intoxication caused by drinking 8 liters (about 2 gallons) of cola on a daily basis for the previous two years. She had been consuming over a gram of caffeine per day. Chocolate bars and coffee-flavored yogurt or ice cream are additional sources of measurable amounts of caffeine.
- Caffeine has some legitimate medical uses in athletic training and in the relief of tension-type headaches. It is available in over-the-counter (OTC) preparations containing aspirin or acetaminophen for pain relief as well as in such OTC stimulants as NoDoz and Vivarin.
- Caffeine is less likely to produce the same degree of physical or psychological dependence as other drugs of abuse. Few coffee or tea drinkers report loss of control over caffeine intake, or significant difficulty in reducing or stopping consumption of beverages and food items containing caffeine.
- The symptoms of caffeine intoxication are easy to confuse with those of an anxiety disorder.

The *DSM-TR-IV* states that it is unclear as of 2000 whether the tolerance, withdrawal symptoms, and "some aspects of dependence on caffeine" seen in some people who drink large amounts of coffee "are associated with clinically significant impairment that meets the criteria for Substance Abuse or Substance Dependence." On the other hand, a research team at Johns Hopkins regards caffeine as a model drug for understanding substance abuse and dependence. The team maintains that 9%–30% of caffeine consumers in the United States may be caffeine-dependent according to *DSM* criteria for substance dependency.

KEY TERMS

Adenosine—A compound that serves to modulate the activities of nerve cells (neurons) and to produce a mild sedative effect when it activates certain types of adenosine receptors. Caffeine is thought to produce its stimulating effect by competing with adenosine for activation of these receptors.

Analeptic—A substance that acts as a stimulant of the central nervous system. Caffeine is classified as an analeptic.

Caffeinism—A disorder caused by ingesting very high doses of caffeine (10g or more per day) and characterized by seizures and respiratory failure.

Dependence—The adaptation of neurons and other physical processes to the use of a drug, followed by withdrawal symptoms when the drug is removed; physiological and/ or psychological addiction.

Hematemesis—Vomiting blood. Hematemesis is a symptom that sometimes occurs with gastrointestinal ulcers made worse by high levels of caffeine consumption.

Norepinephrine—A catecholamine neurotransmitter that acts to constrict blood vessels, raise blood pressure, and dilate the bronchi of the respiratory system. Caffeine increases the secretion of norepinephrine.

Reinforcement—A term that refers to the ability of a drug or substance to produce effects that will make the user want to take it again.

Tolerance—Progressive decrease in the effectiveness of a drug with long-term use.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

Xanthine—A class of crystalline nitrogenous compounds that includes caffeine, which is 1,3,7-trimethylxanthine.

Description

Pharmacological aspects of caffeine

An outline of the effects of caffeine on the central nervous system (CNS) and other organ systems of the body may be helpful in understanding its potential for physical dependence. When a person drinks a beverage containing caffeine (or eats coffee-flavored ice cream), the caffeine is absorbed from the digestive tract without being broken down. It is rapidly distributed throughout the tissues of the body by means of the bloodstream. If a pregnant woman drinks a cup of coffee or tea, the caffeine in the drink will cross the placental barrier and enter the baby's bloodstream.

When the caffeine reaches the **brain**, it increases the secretion of norepinephrine, a neurotransmitter that is associated with the so-called fight or flight **stress** response. The rise in norepinephrine levels and the increased activity of the neurons, or nerve cells, in many other areas of the brain helps to explain why the symptoms of caffeine intoxication resemble the symptoms of a **panic attack**.

The effects of caffeine are thought to occur as a result of competitive antagonism at adenosine receptors. Adenosine is a water-soluble compound of adenine and ribose; it functions to modulate the activities of nerve cells and produces a mild sedative effect when it activates certain types of adenosine receptors. Caffeine competes with adenosine to bind at these receptors and counteracts the sedative effects of the adenosine. If the person stops drinking coffee, the adenosine has no competition for activating its usual receptors and may produce a sedative effect that is experienced as **fatigue** or drowsiness.

Caffeine content of food items and OTC preparations

The caffeine content of various food items and medications is as follows:

- Brewed coffee, 8-oz cup: 135–150 mg
- Instant coffee, 8-oz cup: 95 mg
- Powdered cappuccino beverage, 8-oz cup: 45–60 mg
- Tea brewed from leaves or bag, 8-oz cup: 50 mg
- Iced tea from mix, 8-oz glass: 25–45 mg
- Snapple iced tea, 8-oz glass: 21 mg
- Mountain Dew, 8-oz glass: 38 mg
- Dr. Pepper, 8-oz. glass: 28 mg
- Diet cola, 8-oz glass: 31 mg
- Root beer, 8-oz glass: 16 mg
- Coffee ice cream, 8-oz serving: 60–85 mg
- Coffee yogurt, 8-oz serving: 45 mg.
- Dark chocolate candy bar, 1.5 oz: 31 mg
- NoDoz, regular strength, 1 tablet: 100 mg

- NoDoz, maximum strength, 1 tablet: 200 mg
- Excedrin, 2 tablets: 130 mg

Caffeine can produce a range of physical symptoms following ingestion of as little as 100 mg, although amounts of 250 mg or higher are usually needed to produce symptoms that meet the criteria of caffeine intoxication.

Caffeine intoxication

To meet *DSM-IV-TR* criteria for caffeine intoxication, a person must develop five or more of the twelve symptoms listed below; the symptoms must cause significant distress or impair the person's social or occupational functioning; and the symptoms must not be caused by a medical disorder or better accounted for by an anxiety disorder or other mental disorder.

Because people develop tolerance to caffeine fairly quickly with habitual use, caffeine intoxication is most likely to occur in those who consume caffeine infrequently or who have recently increased their intake significantly.

Caffeine-induced anxiety and sleep disorders

DSM-IV-TR criteria for caffeine-induced anxiety and **sleep disorders** specify that the symptoms of anxiety and **insomnia** respectively must be more severe than the symptoms associated with caffeine intoxication. In addition, the anxiety or insomnia must be severe enough to require separate clinical attention.

Causes and symptoms

Causes

The immediate cause of caffeine intoxication and other caffeine-related disorders is consumption of an amount of caffeine sufficient to produce the symptoms specified by *DSM-IV-TR* as criteria for the disorder. The precise amount of caffeine necessary to produce symptoms varies from person to person depending on body size and degree of tolerance to caffeine. Tolerance of the stimulating effects of caffeine builds up rapidly in humans; mild withdrawal symptoms have been reported in persons who were drinking as little as one to two cups of coffee per day.

Some people may find it easier than others to consume large doses of caffeine because they are insensitive to its taste. Caffeine tastes bitter to most adults, which may serve to limit their consumption of coffee and other caffeinated beverages. Slightly more than 30% of the American population, however, has an inherited inability to taste caffeine.

Symptoms

The symptoms of caffeine intoxication include:

- restlessness
- nervousness
- excitement
- insomnia
- flushed face
- diuresis (increased urinary output)
- gastrointestinal disturbance
- muscle twitching
- talking or thinking in a rambling manner
- tachycardia (speeded-up heartbeat) or disturbances of heart rhythm
- periods of inexhaustibility
- psychomotor agitation

People have reported ringing in the ears or seeing flashes of light at doses of caffeine above 250 mg. Profuse sweating and diarrhea have also been reported. Doses of caffeine higher than 10 g may produce respiratory failure, **seizures**, and eventually death.

Side effects and complications

High short-term consumption of caffeine can produce or worsen gastrointestinal problems, occasionally leading to peptic ulcers or hematemesis (vomiting blood).

In addition to the symptoms produced by high short-term doses, long-term consumption of caffeine has been associated with fertility problems and with bone loss in women leading to osteoporosis in old age. Some studies have found that pregnant women who consume more than 150 mg per day of caffeine have an increased risk of miscarriage and low birth weight babies, but the findings are complicated by the fact that most women who drink large amounts of coffee during pregnancy are also heavy smokers. Some researchers believe that long-term consumption of caffeine is implicated in cardiovascular diseases, but acknowledge that further research is required.

On the other hand, moderate doses of caffeine improve athletic performance as well as alertness. Caffeine in small doses can relieve tension headaches, and one study found that a combination of ibuprofen and caffeine was more effective in relieving tension headaches than either ibuprofen alone or a placebo. Coffee consumption also appears to lower the risk of alcoholic and nonalcoholic cirrhosis of the liver.

Coffee is the most abundant source of caffeine, although caffeine is also found in tea, cocoa, and cola beverages as well as in over-the-counter and prescription medications for pain relief. *(Patrik Giardino/ CORBIS. Photo reproduced by permission.)*

Drug interactions

Caffeine is often combined with aspirin or acetaminophen in over-the-counter and prescription analgesics (pain relievers). It can also be combined with ibuprofen. On the other hand, certain groups of drugs should not be combined with caffeine or taken with beverages containing caffeine. Oral contraceptives, cimetidine (Tagamet), mexiletine (Mexitil), and **disulfiram** (Antabuse) interfere with the breakdown of caffeine in the body. Caffeine interferes with the body's absorption of iron, and with drugs that regulate heart rhythm, including quinidine and **propranolol** (Inderal). Caffeine may produce serious side effects when taken together with monoamine oxidase inhibitors or with certain decongestant medications.

Combinations of ephedra and caffeine have been used in weight-loss programs because they produce greater weight loss than can be achieved by caloric restriction alone. Major studies were underway as of 2001 at Harvard and Vanderbilt to determine the safety of these regimens.

Practitioners of homeopathy have traditionally advised patients not to drink beverages containing caffeine in the belief that caffeine "antidotes" homeopathic remedies. Contemporary homeopaths disagree on the antidoting effects of caffeine, observing that homeopathy is used widely and effectively in Europe and that Europeans tend to drink strong espresso coffee more frequently than Americans.

Demographics

The general population of the United States has a high level of caffeine consumption, with an average intake of 200 mg per day. About 85% of the population uses caffeine in any given year. Among adults in the United States, about 30% consume 500 mg or more each day. These figures are lower, however, than the figures for Sweden, the United Kingdom, and other parts of Europe, where the average daily consumption of caffeine is 400 mg or higher. In developing countries, the average consumption of caffeine is much lower— about 50 mg per day.

In the United States, levels of caffeine consumption among all races and ethnic groups are related to age, with usage beginning in the late teens and rising until the early 30s. Caffeine consumption tapers off in adults over 40 and decreases in adults over 65. Caffeine intake is higher among males than among females in North America.

The prevalence of caffeine-related disorders in the United States is not known as of 2002.

Diagnosis

Diagnosis of a caffeine-related disorder is usually based on the patient's recent history, a physical examination, or laboratory analysis of body fluids. In addition to medical evidence, the examiner will rule out other mental disorders, particularly manic episodes, **generalized anxiety disorder**, **panic disorder**, amphetamine intoxication, or withdrawal from sedatives, tranquilizers, sleep medications, or nicotine. All of these disorders or syndromes may produce symptoms resembling those of caffeine intoxication. In most cases, the temporal relationship of the symptoms to high levels of caffeine intake establishes the diagnosis.

In some cases, the examiner may consider the possibility of depression during the differential diagnosis, as many people with depression and eating disorders self-medicate with caffeine.

Treatments

Treatment of caffeine-related disorders involves lowering consumption levels or abstaining from beverages containing caffeine. Some people experience mild withdrawal symptoms that include headaches, irritability, and occasionally nausea, but these usually resolve quickly.

Caffeine consumption has the advantage of having relatively weak (compared to alcohol or cigarettes) social **reinforcement**, in the sense that one can easily choose a noncaffeinated or decaffeinated beverage in a restaurant or at a party without attracting comment. Thus physical dependence on caffeine is less complicated by the social factors that reinforce nicotine and other drug habits.

Prognosis

With the exception of acute episodes of caffeinism, people recover from caffeine intoxication without great difficulty.

Prevention

Prevention of caffeine-related disorders requires awareness of the caffeine content of caffeinated beverages, OTC drugs, and other sources of caffeine; monitoring one's daily intake; and substituting decaffeinated coffee, tea, or soft drinks for the caffeinated versions of these beverages.

Cannabis and related disorders

Definition

Cannabis, more commonly called marijuana, refers to the several varieties of *Cannabis sativa*, or Indian hemp plant, that contains the psychoactive drug delta-9-tetrahydrocannabinol (THC). Cannabis-related disorders refer to problems associated with the use of substances derived from this plant.

KEY TERMS

Amotivational syndrome—Loss of ambition associated with chronic cannabis (marijuana) use.

Anandamide—One type of endocannabinoid that appears to help regulate early pregnancy.

Cannabis—The collective name for several varieties of Indian hemp plant. Also known as marijuana.

Cannabis abuse—Periodic use of cannabis, less serious than dependence, but still capable of causing problems for the user.

Cannabis dependence—The compulsive need to use cannabis, leading to problems.

Cannabis intoxication—The direct effects of acute cannabis use and the reactions that accompany those effects.

Delta-9-tetrahydrocannabinol(THC)—The primary active ingredient in marijuana.

Endocannabinoids—Cannabis-like compounds produced naturally in the human body.

Hashish—The dark, blackish resinous material that exudes from the leaves of the Indian hemp plant.

Marijuana—The dried and shredded or chopped leaves of the Indian hemp plant.

Description

Cannabis—in the form of marijuana, hashish (a dried resinous material that seeps from cannabis leaves and is more potent than marijuana), or other cannabinoids—is considered the most commonly used illegal substance in the world. Its effects have been known for thousands of years, and were described as early as the fifth century B.C., when the Greek historian Herodotus told of a tribe of nomads who, after inhaling the smoke of roasted hemp seeds, emerged from their tent excited and shouting for joy.

Cannabis is the abbreviation for the Latin name for the hemp plant—*Cannabis sativa*. All parts of the plant contain psychoactive substances, with THC making up the highest percentage. The most potent parts are the flowering tops and the dried, blackish-brown residue that comes from the leaves known as hashish, or "hash."

There are more than 200 slang terms for marijuana, including "pot," "herb," "weed," "Mary Jane," "grass," "tea," and "ganja." It is usually chopped and/or shredded and rolled into a cigarette, or "joint," or placed in a pipe (sometimes called a "bong") and smoked. An alternative method of using marijuana involves adding it to foods and eating it, such as baking it into brownies. It can also be brewed as a tea. Marijuana has appeared in the form of "blunts"—cigarettes emptied of their tobacco content and filled with a combination of marijuana and another drug such as crack cocaine.

Between 1840 and 1900, European and American medical journals published numerous articles on the therapeutic uses of marijuana. It was recommended as an appetite stimulant, muscle relaxant, painkiller, sedative, and anticonvulsant. As late as 1913, Sir William Osler recommended it highly for treatment of migraine. Public opinion changed, however, in the early 1900s, as alternative medications such as aspirin, opiates, and **barbiturates** became available. In 1937, the United States passed the Marijuana Tax Act, which made the drug essentially impossible to obtain for medical purposes.

By the year 2000, the debate over the use of marijuana as a medicine continued. THC is known to successfully treat nausea caused by cancer treatment drugs, stimulate the appetites of persons diagnosed with acquired immune deficiency syndrome (AIDS), and possibly assist in the treatment of glaucoma. Its use as a medicinal agent is still, however, highly controversial. Even although the states of Arizona and California passed laws in 1996 making it legal for physicians to prescribe marijuana in the form of cigarettes for treatment of the diseases listed above, governmental agencies continue to oppose strongly its use as a medicine, and doctors who do prescribe it may find their licenses at risk.

Cannabis-related disorders reflect the problematic use of cannabis products to varying degrees. These disorders include:

- Cannabis dependence: The compulsive need to use the drug, coupled with problems associated with chronic drug use.
- Cannabis abuse: Periodic use that may cause legal problems, problems at work, home, or school, or danger when driving.
- Cannabis intoxication: The direct effects of acute cannabis use and reactions that accompany it such as feeling "high," euphoria, sleepiness, lethargy, impairment in short-term memory, stimulated appetite, impaired judgment, distorted sensory perceptions, impaired motor performance, and other symptoms.

Causes and symptoms

Causes

Cannabis-related disorders share many of the same root causes with other addictive substances. The initial desire for a "high," combined with the widely held perception that cannabis use is not dangerous, often leads to experimentation in the teen years.

Recent research challenges the notion that cannabis use is not physically addictive. According to the National Institute of Drug Abuse (NIDA), daily cannabis users experience withdrawal symptoms including irritability, stomach pain, aggression, and anxiety. Many frequent cannabis users are believed to continue using in order to avoid these unpleasant symptoms. Long-term use may lead to changes in the **brain** similar to those seen with long-term use of other addictive substances. It is believed that the greater availability, higher potency, and lower price for cannabis in recent years all contribute to the increase in cannabis-related disorders.

Beginning in the 1990s, researchers began to discover that cannabis-like compounds are naturally produced in various parts of the human body. These compounds, called "endocannabinoids," appear to suppress inflammation and other responses of the immune system. One of these endocannabinoids— anandamide—appears to help regulate the early stages of pregnancy.

Symptoms

CANNABIS DEPENDENCE AND ABUSE. The handbook used by mental health professionals to diagnose mental disorders is the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR*. This manual states that the central features of cannabis dependence are compulsive use, tolerance of its effects, and withdrawal symptoms. Use may interfere with family, school, and work, and may cause legal problems.

Regular cannabis smokers may show many of the same respiratory symptoms as tobacco smokers. These include daily cough and phlegm, chronic bronchitis, and more frequent chest colds. Continued use can lead to abnormal functioning of the lung tissue, which may be injured or destroyed by the cannabis smoke.

Recent research indicates that smoking marijuana has the potential to cause severe increases in heart rate and blood pressure, particularly if combined with cocaine use. Even with marijuana use alone, however, the heart rate of subjects increased an average of 29 beats per minute when smoking marijuana.

A study of heavy marijuana users has shown that critical skills related to attention, memory, and learning can be impaired, even after use is discontinued for at least 24 hours. Heavy users, compared to light users, made more errors on tasks and had more difficulty sustaining attention and shifting attention when required. They also had more difficulty in registering, processing, and using information. These findings suggest that the greater impairment in mental functioning among heavy users is most likely due to an alteration of brain activity directly produced by the marijuana use.

Recent studies have found that babies born to mothers who used marijuana during pregnancy were smaller than those born to nonusing mothers. Smaller babies are more likely to develop health problems. Additionally, nursing mothers who use marijuana pass some of the THC to the baby in their breast milk. Research shows that use of marijuana during the first month of breastfeeding can impair an infant's motor development.

Cannabis abuse is characterized by less frequent use and less severe problems. However, as with cannabis dependence, abuse can interfere with performance at school or work, cause legal problems, and interfere with motor activities such as driving or operating machinery.

CANNABIS INTOXICATION. Cannabis intoxication refers to the occurrence of problematic behaviors or psychological changes that develop during, or shortly after, cannabis use. Intoxication usually starts with a "high" feeling followed by euphoria, inappropriate laughter, and feelings of grandiosity. Other symptoms include sedation, lethargy, impaired short-term memory, difficulty with motor tasks, impaired judgment, distorted sensory perceptions, and the feeling that time is passing unusually slowly. Sometimes severe anxiety, feelings of depression, or social withdrawal may occur. Along with these symptoms, common signs of cannabis intoxication include reddening of the membranes around the eyes, increased appetite, dry mouth, and increased heart rate.

Demographics

The NIDA conducts an annual nationwide study of twelfth-, tenth-, and eighth-grade students and young adults. This study is known as the *Monitoring the Future Study*, or *MTF*. Results show that after a decade of decreased use in the 1980s, marijuana use among students began to rise in the early 1990s. Data show that, between 1998 and 1999, marijuana use continued to increase among twelfth and tenth graders. For twelfth graders, the lifetime rate (use of marijuana at least one or more times) is higher than for any year since 1987. However, these rates remain well below those seen in the late 1970s and early 1980s. Daily marijuana use among students in all three grades also showed a slight increase.

Another method by which the government measures marijuana use is the *Community Epidemiology Work Group*, or *CEWG*. This method examines rates of emergency room admissions related to marijuana use in 20 major metropolitan areas. In 1998, use of marijuana showed an upward trend in most of the areas monitored, with the largest increases occurring in Dallas, Boston, Denver, San Diego, and Atlanta. The highest percentage increase in emergency room visits related to marijuana was among 12- to 17-year-olds.

Treatment data for marijuana abuse increased in six of the metropolitan areas surveyed but remained stable elsewhere. Marijuana treatment admissions were highest in Denver, Miami, New Orleans, and Minneapolis/St. Paul. Half of the admissions in Minneapolis/St. Paul were under the age of 18 years.

Marijuana remains the most commonly used illicit drug in the United States. As with most other illicit drugs, cannabis use disorders appear more often in males and is most common among people between the ages of 18 and 30 years.

An estimated 2.1 million people started using marijuana in 1998. According to data from a study released in the late 1990s called the *National Household Survey on Drug Abuse*, or *NHSDA*, more than 72 million Americans ages 12 years and older (33%) tried marijuana at least once during their lifetime, while almost 18.7 million (8.6%) used marijuana in the previous year. The reader can compare these figures to the figures from 1985, when 56.5 million Americans (29.4%) had tried marijuana at least once in their life, and 26.1 million (13.6%) had used marijuana within the past year.

Diagnosis

Diagnosis of cannabis-related disorders is made in a number of ways. Intoxication is easiest to diagnose because of clinically observable signs, including reddened eye membranes, increased appetite, dry mouth, and increased heart rate. It is also diagnosed by the presence of problematic behavioral or psychological changes such as impaired motor coordination, judgment, anxiety, euphoria, and social withdrawal. Occasionally, panic attacks may occur, and there may be impairment of short-term memory. Lowered immune system resistance, lowered testosterone levels in males, and chromosomal damage may also occur. Psychologically, chronic use of marijuana has been associated with a loss of ambition known as the "amotivational syndrome."

Cannabis use is often paired with the use of other addictive substances, especially nicotine, alcohol, and cocaine. Marijuana may be mixed and smoked with opiates, phencyclidine ("PCP" or "angel dust"), or hallucinogenic drugs. Individuals who regularly use cannabis often report physical and mental lethargy and an inability to experience pleasure when not intoxicated (known as "anhedonia"). If taken in sufficiently high dosages, cannabinoids have psychoactive effects similar to hallucinogens such as lysergic acid diethylamide (LSD), and individuals using high doses may experience adverse effects that resemble hallucinogen-induced "bad trips." Paranoid ideation is another possible effect of heavy use, and, occasionally, **hallucinations** and **delusions** occur. Highly intoxicated individuals may feel as if they are outside their body ("depersonalization") or as if what they are experiencing isn't real ("derealization"). Fatal traffic accidents are more common among individuals testing positive for cannabis use.

Urine tests can usually identify metabolites of cannabinoids. Because cannabinoids are fat soluble, they remain in the body for extended periods. Individuals who have used cannabis may show positive urine tests for as long as two to four weeks after using.

Examination of the nasopharynx and bronchial lining may also show clinical changes due to cannabis use. Marijuana smoke is known to contain even larger amounts of carcinogens than tobacco smoke. Sometimes cannabis use is associated with weight gain.

Treatments

Treatment options for individuals with cannabis-related disorders are identical to those available for people with alcohol and other substance abuse disorders. The goal of treatment is abstinence. Treatment approaches range from in-patient **hospitalization**, drug and alcohol rehabilitation facilities, and various outpatient programs. Twelve-step programs such as Narcotics Anonymous are also treatment options. For heavy users suffering from withdrawal symptoms, treatment with anti-anxiety and/or antidepressant medication may assist in the treatment process.

Prognosis

According to the *DSM-IV-TR*, cannabis dependence and abuse tend to develop over a period of time. It may, however, develop more rapidly among young people with other emotional problems. Most people who become dependent begin using regularly. Gradually, over time, both frequency and amount increase. With chronic use, there can sometimes be a decrease in or loss of the pleasurable effects of the substance, along with increased feelings of anxiety and/or depression. As with alcohol and nicotine, cannabis use tends to begin early in the course of

substance abuse and many people later go on to develop dependence on other illicit substances. Because of this, cannabis has been referred to as a "gateway" drug, although this view remains highly controversial. There is much that remains unknown about the social, psychological, and neurochemical basis of drug use progression, and it is unclear whether marijuana use actually causes individuals to go on to use other illicit substances.

One long-term effect of chronic use has been termed the "amotivational syndrome." This refers to the observation that many heavy, chronic users seem unambitious in relation to school and/or career.

Prevention

Many drug education programs focus strongly on discouraging marijuana experimentation among young teenagers. Recent research reported by the NIDA indicates that high-sensation-seekers—that is, individuals who seek out new, emotionally intense experiences and are willing to take risks to obtain these experiences—are at greater risk for using marijuana and other drugs, and for using them at an earlier age. As a result, the NIDA developed a series of public service announcements (PSAs) for national television. These PSAs were dramatic and attention getting, and were aired during programs that would appeal to high sensation-seekers, such as action-oriented television shows. These PSAs were aired in a limited television area and the results monitored. Marijuana use declined substantially among teens during the PSA campaigns, and long-term effects were shown for several months afterwards. In one county, marijuana use decreased by 38%, and in another, by 26.7%.

Drug education programs such as the "DARE" (Drug Awareness and Resistance Education) programs target fifth graders. These and other antidrug programs focus on peer pressure resistance and the use of older teens who oppose drug use as models of a drug-free lifestyle. These programs show mixed results.

Carbamazepine

Definition

Carbamazepine is an anticonvulsant that is structurally related to tricyclic antidepressants such as **amitriptyline** and **imipramine**. In the United States, carbamazepine is sold under the trade names Tegretol and Carbatrol.

Purpose

Carbamazepine is effective in the treatment of psychomotor and grand mal **seizures** and a type of facial pain called trigeminal neuralgia and, in combination with other drugs, for psychiatric disorders such as mania and extreme aggression. Carbamazepine is also occasionally used to control pain in persons with cancer.

Description

Carbamazepine was first marketed as an anti-seizure medication and as a first-line treatment for trigeminal

KEY TERMS

Absence seizure—An epileptic seizure characterized by a sudden, momentary loss of consciousness, occasionally accompanied by some minor, jerky movements in the neck or upper arms, a twitching of the face, or a loss of muscle tone.

Aplastic anemia—A form of anemia in which the bone marrow does not produce adequate amounts of peripheral blood components such as red cells, white cells and platelets.

Bipolar disorder—A mental disorder characterized by dramatic, and sometimes rapid mood swings, resulting in both manic and depressive episodes; formerly called manic-depressive disorder.

Convulsion—A violent, involuntary contraction or series of contractions of muscles.

Grand mal seizure—A seizure characterized by a sudden loss of consciousness that is immediately followed by generalized convulsions. Such a seizure is usually preceded by a sensory experience, called an aura, which provides a warning as to an impending convulsion.

Psychomotor seizure—A seizure characterized by electrical activity that is characterized by variable degrees of loss of consciousness and often accompanied by bizarre behavior.

neuralgia. Because it was later noted to be effective in patients with certain psychiatric disorders, psychiatrists began combining it with other drugs such as lithium and major tranquilizers in severe cases of bipolar disease and aggressive behavior that could not be managed with single-drug therapy.

Carbamazepine is available in 100-mg chewable tablets, 200-mg capsules and a suspension at 100 mg per 5 ml of liquid.

Recommended dosage

When used to treat seizure disorders or psychiatric disease, the recommended initial dosage of carbamazepine is 200 mg two times each day. If needed, the daily dosage may be increased by 200 mg once each week. Total daily dosages should not exceed 1,000 mg in children between the ages of 12 and 15 years. Total daily dosages for adults should not exceed 1,200 mg. Carbamazepine should be taken with meals.

Precautions

Carbamazepine should be used with caution in persons who also experience other types of seizure disorders such as atypical absence seizures. Among such individuals, carbamazepine usage has been associated with an increased risk of initiating, rather than controlling, generalized convulsions.

Carbamazepine should never be discontinued abruptly unless another treatment for seizures is initiated at the same time. If this does not happen, acute withdrawal of carbamazepine may result in seizures.

Patients should be alert for signs and symptoms of bone marrow toxicity such as fever, sore throat, infection, mouth sores, easy bruising, or bleeding which occurs just under the skin.

Because carbamazepine may affect mental alertness, especially early in therapy, patients receiving this drug should not operate dangerous machinery or drive a car until they understand how the drug will affect them.

Side effects

The most commonly reported adverse reactions to carbamazepine include dizziness, drowsiness, unsteadiness, nausea and vomiting. These are more common when therapy is just beginning.

Carbamazepine has been reported to cause aplastic anemia. This is a form of anemia that is generally does not respond to treatment. The bone marrow of persons with aplastic anemia does not produce adequate amounts of red blood cells, white blood cells, and platelets. Blood counts should be monitored for individuals using this drug. Some people with previously diagnosed depression of the bone marrow should not take carbamazepine.

Carbamazepine may cause birth defects and should be avoided by women who are pregnant. An effective contraceptive method should be used while taking carbamazepine. It is important to note that this medication may decrease the effectiveness of oral contraceptives.

The drug can cross into breast milk and should be avoided by women who are breast-feeding.

Carbamazepine may also cause a skin rash or sensitivity to the sun.

Interactions

Blood levels of carbamazepine may be reduced when it is used in combination with other drugs such as phenobarbitol, phenytoin or primidone. This means that inadequate amounts of carbamazepine are available to the body, limiting the ability of the drug to control seizure

activity or treat psychiatric disease. Carbamazepine also causes reductions in the blood levels of the following drugs when they are used simultaneously: phenytoin, warfarin, doxycycline, **haloperidol**, **valproic acid**, and theophylline.

The simultaneous administration of carbamazepine with erythromycin, cimetidine, propoxyohene, isoniacid, **fluoxetine** and calcium channel blockers such as nifedipine or verapamil may increase the blood level of carbamazepine to a toxic range.

The simultaneous use of carbamazepine and oral contraceptives may increase the possibility that the oral contraceptive won't be effective in preventing pregnancy. Some physicians recommend that a different method of contraception be used while carbamazepine is being used.

People taking carbamazepine should not drink grapefruit juice. Grapefruit juice slows the breakdown of carbamazepine, increasing the concentration of carbamazepine in the bloodstream.

Due to the potential of many interactions with other drugs, individuals should consult with a physician or pharmacist prior to starting any new medications either bought over the counter or initiated by another physician.

Case management

Definition

Case management assigns the administration of care for an outpatient individual with a serious mental illness to a single person (or team); this includes coordinating all necessary medical and mental health care, along with associated supportive services.

Purpose

Case management tries to enhance access to care and improve the continuity and efficiency of services. Depending on the specific setting and locale, case managers are responsible for a variety of tasks, ranging from linking clients to services to actually providing intensive clinical or rehabilitative services themselves. Other core functions include outreach to engage clients in services, assessing individual needs, arranging requisite support services (such as housing, benefit programs, job training), monitoring medication and use of services, and advocating for client rights and entitlements.

Case management is not a time-limited service, but is intended to be ongoing, providing clients whatever they need whenever they need it, for as long as necessary.

KEY TERMS

Medicaid—A program jointly funded by state and federal governments that reimburses hospitals and physicians for the care of individuals who cannot pay for their own medical expenses. These individuals may be in low-income households or may have chronic disabilities.

Medicare—A federally funded health insurance program for individuals age 65 and older, and certain categories of younger persons with disabilities.

Meta-analysis—The statistical analysis of a large collection of analyses from individual studies for the purpose of integrating the findings.

Neuroleptic—Another name for the older antipsychotic medications, such as haloperidol (Haldol) and chlorpromazine (Thorazine).

Psychosis—Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an over-arching disorder, not a disorder in itself. (Plural: psychoses)

Supplemental Security Income—A federal program that provides cash to meet basic needs for food, shelter and clothing for aged, blind, and disabled individuals who have little or no income.

Historical background

Over the past 50 years, there have been fundamental changes in the system of mental health care in America. In the 1950s, mental health care for persons with severe and persistent mental illnesses (like **schizophrenia**, **bipolar disorder**, severe depression, and **schizoaffective disorder**) was provided almost exclusively by large public mental hospitals. Created as part of a reform movement, these state hospitals provided a wide range of basic life supports in addition to mental health treatment, including housing, meals, clothing and laundry services, and varying degrees of social and **vocational rehabilitation**.

During the latter half of the same decade, the introduction of neuroleptic medication provided symptomatic management of seriously disabling psychoses. This breakthrough, and other subsequent reforms in mental health policy (including the introduction of Medicare and Medicaid in 1965 and the Supplemental Security Income [SSI] program in 1974), provided incentives for policy makers to discharge patients to the community and transfer state mental health expenditures to the federal government.

These advances—coupled with new procedural safeguards for involuntary patients, court decisions establishing the right to treatment in the least restrictive setting, and changed philosophies of care—led to widespread **deinstitutionalization**. In 1955 there were 559,000 persons in state hospitals; by 1980, that number had dropped to 132,000. According to the most recent data from the U.S. Center for Mental Health Services, while the number of mental health organizations providing 24-hour services (hospital inpatient and residential treatment) more than doubled in the United States from 1970 to 1998, the number of psychiatric beds provided by these organizations decreased by half.

As a result of deinstitutionalization policies, the number of patients discharged from hospitals has risen, and the average length of stay for newly admitted patients has decreased. An increasing number of patients are never admitted at all, but are diverted to a more complex and decentralized system of community-based care. Case management was designed to remedy the confusion created by multiple care providers in different settings, and to assure accessibility, continuity of care, and accountability for individuals with long-term disabling mental illnesses.

Models of case management

The two models of case management mentioned most often in the mental health literature are assertive community treatment (ACT) and intensive case management.

A third model, clinical case management, refers to a program where the case manager assigned to a client also functions as their primary therapist.

Assertive community treatment

The ACT model originated in an inpatient research unit at Mendota State Hospital in Madison, Wisconsin in the late 1960s. The program's architects, Arnold Marx, M.D., Leonard Stein, M.D. and Mary Ann Test, Ph.D., sought to create a "hospital without walls." In this model, teams of 10–12 professionals— including case managers, a **psychiatrist**, nurses, **social workers**, and vocational specialists—are assigned ongoing responsibility 24 hours a day, seven days a week, 365 days a year, for a caseload of approximately 10 clients with severe and persistent mental illnesses.

ACT uses multidisciplinary teams, low client-to-staff ratios, an emphasis on assertive outreach, provision of in-vivo services (in the client's own setting), an

emphasis on assisting the client in managing their illness, assistance with ADL (activities of daily living) skills, emphasis on relationship building, and emotional support, **crisis intervention** (as necessary) and an orientation, whenever possible, towards providing clients with services rather than linking them to other providers.

Compared to other psychosocial interventions the program has a remarkably strong evidence base. Twenty-five randomized controlled clinical trials have demonstrated that these programs reduce **hospitalization**, **homelessness**, and inappropriate hospitalization; increase housing stability; control psychiatric symptoms; and improve quality of life, especially among individuals who are high users of mental health services. The ACT model has been implemented in 33 states.

Intensive case management

Intensive case management practices are typically targeted to individuals with the greatest service needs, including individuals with a history of multiple hospitalizations, persons dually diagnosed with substance abuse problems, individuals with mental illness who have been involved with the criminal justice system, and individuals who are both homeless and severely mentally ill.

A recent (2002) mail survey of 22 experts found that while intensive case management shares many critical ingredients with ACT programs, its elements are not as clearly articulated. Another distinction between intensive case management and ACT appears to be that the latter relies more heavily on a team versus individual approach. In addition, intensive case managers are more likely to "broker" treatment and rehabilitation services rather than provide them directly. Finally, intensive case management programs are more likely to focus on client strengths, empowering clients to fully participate in all treatment decisions.

Clinical case management

A meta-analytic study comparing ACT and clinical case management found that while the generic approach resulted in increased hospital admissions, it significantly decreased the length of stay. This suggests that the overall impact of clinical case management is positive. Consistent with prior research, the study concluded that both ACT and high-quality clinical case management should be essential features of any mental health service system. One of the greatest tragedies of deinstitutionalization has been that most families, without any training or support, often become de facto case managers for their family members.

Case management for children and adolescents

Case management is also used to coordinate care for children with serious emotional disturbances—diagnosed mental health problems that substantially disrupt a child's ability to function socially, academically, and emotionally. Although not a formal **diagnosis** in the ***Diagnostic and Statistical Manual of Mental Disorders*** *(DSM),* the handbook published by the American Psychiatric Association used by mental health professionals to diagnose mental disorders, the term "serious emotional disturbance" is commonly used by states and the federal government to identify children with the greatest service needs. While the limited research on case management for children and youth with serious emotional disturbances has been primarily focused on service use rather than clinical outcomes, there is growing evidence that case management is an effective **intervention** for this population.

Case management models used for children vary considerably. One model, called "wraparound," helps families develop a plan to address the child's individual needs across multiple life domains (home and school, for example). Research on the effectiveness of this model is still in an early stage. Another model, known as the children and youth intensive case management or expanded broker model had been evaluated in two controlled studies. Findings suggest that this broker/advocacy model results in behavioral improvements and fewer days in hospital settings.

Conclusion

In recent years, many case management programs have expanded their teams to successfully utilize consumers as peer counselors and family members as outreach workers. The programs have also been adapted to serve older individuals with severe and persistent mental illnesses. While the ACT model offers the strongest evidential base for its effectiveness, research into the clinical and service system outcomes of this and other models of case management is ongoing.

The effectiveness of any case management program depends upon the availability of high-quality treatment and support services in a given community, the structure and coordination of the service system, and on the ability of an individual or family to pay for care either through private insurance or (more often) through public benefit and entitlement programs. With recent policy directives from the Centers for Medicaid and Medicare Services (formerly the Health Care Financing Administration or HCFA) promoting the use of Medicaid funds

for ACT, more states are funding case management through Medicaid. While some policy makers express concern about costs, the expense of these programs is usually offset by the savings realized from keeping patients out of jails, hospitals, and emergency rooms. Compared to traditional outpatient programs, case management also offers a level of care that is far more comprehensive and humane for a disabled population.

Catatonia

Definition

Catatonia is a disturbance of motor behavior that can have either a psychological or neurological cause. Its most well-known form involves a rigid, immobile position that is held by a person for a considerable length of time—often days, weeks, or longer. It can also refer to agitated, purposeless motor activity that is not stimulated by something in the environment. A less extreme form of catatonia involves very slowed motor activity. Often, the physical posture of a catatonic individual is unusual and/or inappropriate, and the individual may hold a posture if placed in it by someone else. According to the handbook used by mental health professionals to diagnose mental disorders, the *Diagnostic and Statistical Manual of the American Psychiatric Association*, 4th Edition, Text Revision, also known as the *DSM-IV-TR*, some 5–9% of all psychiatric inpatients show some catatonic symptoms. Of these, 25–50% are associated with mood disorders, 10–15% are associated with **schizophrenia**, and the remainder are associated with other mental disorders.

Description

Types of catatonia

CATATONIC SCHIZOPHRENIA. As with all types of schizophrenia, the catatonic type, fortunately rare today, involves a marked disturbance in all spheres of life. As a schizophrenic disorder, the individual shows disturbances in thinking, feeling, and behavior. Most schizophrenics are unable to form meaningful intimate relationships or train for and sustain meaningful employment.

The catatonic type of schizophrenia is characterized by severe psychomotor disturbance. Individuals with this disorder show extreme immobility. They may stay in the same position for hours, days, weeks, or longer. The position they assume may be unusual and appear uncomfortable to the observer. If another person moves part of the catatonic individual's body, such as a limb, he or she may maintain the position into which they are placed, a condition known as "waxy flexibility." Sometimes catatonia presents itself as excessive motor activity, but the activity seems purposeless, and does not appear to fit with what is happening in the environment. In its most severe forms, whether stupor or agitation, the individual may need close supervision to keep from injuring him- or herself, or others.

DEPRESSION WITH CATATONIC FEATURES. Individuals who are severely depressed may show disturbances of motor behavior that is similar to that of catatonic schizophrenics, as previously described. They may be essential-

KEY TERMS

Catatonia—Disturbance of motor behavior with either extreme stupor or random, purposeless activity.

Catatonic schizophrenia—A subtype of a severe mental disorder that affects thinking, feeling and behavior, and that is also characterized by catatonic behaviors—either extreme stupor or random, purposeless activity.

Echolalia—Meaningless repetition of words or phrases spoken by another.

Echopraxia—Imitation of another person's physical movements in a repetitious or senseless manner.

Waxy flexibility—A condition in which a person can be molded into a strange position and hold that position for a long period of time.

ly immobile, or exhibit excessive but random-seeming motor activity. Extreme negativism, elective mutism (choosing not to speak), peculiar movements, mimicking words or phrases (known as "echolalia") or mimicking movements (known as "echopraxia") may also be part of the picture. Again, in its most extreme forms, catatonic stupor (not moving for hours, days, weeks, or longer), and catatonic activity (random-seeming activity) may necessitate supervision so that the individual does not hurt him- or herself, or others. Catatonic behaviors may also be seen in persons with other mood disorders, such as manic or mixed-mood states; these are also known as Bipolar I and Bipolar II disorders.

CATATONIC DISORDER DUE TO GENERAL MEDICAL CONDITION. Individuals with catatonia due to a medical condition may show symptoms similar to persons with catatonic schizophrenia and catatonic depression. However, the cause is believed to be physiological. Certain neurologic diseases, such as encephalitis, may cause catatonic symptoms that can be either temporary, or lasting.

Catatonic disorders

Definition

Catatonic disorders are a group of symptoms characterized by disturbances in motor (muscular movement) behavior that may have either a psychological or a physiological basis. The best-known of these symptoms is immobility, which is a rigid positioning of the body held for a considerable length of time. Patients diagnosed with a catatonic disorder may maintain their body position for hours, days, weeks or even months at a time. Alternately, catatonic symptoms may look like agitated, purposeless movements that are seemingly unrelated to the person's environment. The condition itself is called **catatonia**.

A less extreme symptom of catatonic disorder is slowed-down motor activity. Often, the body position or posture of a catatonic person is unusual or inappropriate; in addition, he or she may hold a position if placed in it by someone else.

Description

Types of catatonic disorder

CATATONIC SCHIZOPHRENIA. Schizophrenia is a severe, usually life-long mental illness that affects every aspect of human functioning. Thinking, feeling, and behavior are all affected by the disorder; and the person with schizophrenia usually has difficulties in interpersonal relationships as well as in obtaining and keeping meaningful employment. The catatonic subtype of schizophrenia is, fortunately, rare today in North America and Europe. It is characterized by severe disturbances in motor behavior. Individuals with catatonic schizophrenia often show extreme immobility. They may stay in the same position for hours, days, weeks, or longer. The position they assume may be unusual and appear uncomfortable to the observer; for example, the person may stand on one leg like a stork, or hold one arm outstretched for a long time. If an observer moves a hand or limb of the catatonic person's body, he or she may maintain the new

KEY TERMS

Akinesia—Absence of physical movement.

Catalepsy—An abnormal condition characterized by postural rigidity and mental stupor, associated with certain mental disorders.

Catatonic disorder—A severe disturbance of motor behavior characterized by either extreme immobility or stupor, or by random and purposeless activity.

Catatonic schizophrenia—A subtype of a severe mental disorder that affects thinking, feeling and behavior, and that is also characterized by catatonic behaviors—either extreme stupor or random, purposeless activity.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Echolalia—Meaningless repetition of words or phrases spoken by another.

Echopraxia—Imitation of another person's physical movements in a repetitious or senseless manner.

Hypomania—A milder form of mania which is characteristic of bipolar II disorder.

Mutism—Inability to speak due to conscious refusal or psychological inhibition.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Stupor—A trance-like state that causes a person to appear numb to their environment.

Waxy flexibility—A condition in which a person's body part, usually a limb, can be moved by others into diffferent positions, where it remains for long periods of time.

position. This condition is known as waxy flexibility. In other situations, a person with catatonic schizophrenia may be extremely active, but the activity appears bizarre, purposeless, and unconnected to the situation or surroundings. The patient may, for example, run up and down a flight of stairs repeatedly. Catatonic stupor is characterized by extremely slowed motor activity, often to the point of being motionless and appearing unaware of surroundings. The patient may exhibit negativism, which means that he or she resists all attempts to be moved, or all instructions or requests to move, without any apparent motivation.

Catatonic symptoms were first described by the **psychiatrist** Karl Ludwig Kahlbaum in 1874. Kahlbaum described catatonia as a disorder characterized by unusual motor symptoms. His description of individuals with catatonic behaviors remains accurate to this day. Kaulbaum carefully documented the symptoms and the course of the illness, providing a natural history of this unusual disorder.

DEPRESSION WITH CATATONIC FEATURES. People who are severely depressed may show disturbances of motor behavior resembling those of patients diagnosed with catatonic schizophrenia. These depressed persons may remain virtually motionless, or move around in an extremely vigorous but apparently random fashion. Extreme negativism, elective mutism (choosing not to speak), peculiar movements, and imitating someone else's words or phrases (echolalia) or movements (echopraxia) may also be part of the symptomatic picture. These behaviors may require caregivers to supervise the patient, to insure that he or she does not hurt him- or herself or others.

Catatonic behaviors may also occur in persons with other mood disorders. Persons experiencing manic or mixed mood states (a simultaneous combination of manic and depressive symptoms) may at times exhibit either the immobility or agitated random activity seen in catatonia. A severely depressed person may experience intense emotional pain from simply moving a finger. Even getting up out of a chair can be a painful chore that may take hours for the severely depressed individual. As the depression begins to lift, the catatonic symptoms diminish.

CATATONIC DISORDER DUE TO A GENERAL MEDICAL CONDITION. Persons with catatonic disorder due to a medical condition show symptoms similar to those of catatonic schizophrenia and catatonic depression, except that the cause is believed to be physiological. Such neurological diseases as encephalitis may cause catatonic symptoms that can be temporary or lasting.

Psychiatric symptoms caused by physiological illnesses can appear early in the course of an illness. For this reason, it is important to consider possible physical causes when catatonic symptoms appear. Persons with catatonic symptoms of physical origin generally show

greater self-awareness or insight, and more distress about their symptoms than those suffering from schizophrenia. This difference can help clinicians distinguish between patients whose catatonic symptoms stem from psychiatric causes versus those whose symptoms have a medical origin.

Causes and symptoms

Causes

CATATONIC SCHIZOPHRENIA. The cause of schizophrenia remains unknown. During the past decade, however, research has pointed to abnormalities in structure or function of certain areas of the **brain**, including the limbic system, the frontal cortex, and the basal ganglia. These three regions are interconnected, so that dysfunction in one area may be related to structural problems in another. Brain imaging of living people and studies of the brains of deceased persons point to the limbic system as the potential site of pathology in at least some, if not most, schizophrenic patients.

DEPRESSION WITH CATATONIC FEATURES. Mood disorders are believed to be at least partially caused by irregularities in production of **neurotransmitters** within the brain. Neurotransmitters are chemicals that conduct impulses along a nerve from one nerve cell to another. Two of the most important neurotransmitters associated with depression are norepinephrine and serotonin. In animal studies, virtually all effective antidepressant medications affect the receptors for these neurotransmitters. Dopamine is another neurotransmitter that plays a role in the development of depressive disorders.

CATATONIC DISORDER DUE TO A GENERAL MEDICAL CONDITION. Numerous medical conditions can cause psychiatric symptoms. Some of the more common are infectious, metabolic, and neurological conditions. Catatonic symptoms have been linked to earlier infection with encephalitis and to Parkinson's disease. Although the appearance of patients with post-encephalitis catatonia may be similar to that of catatonic schizophrenic patients, the majority of post-encephalitic patients are not psychotic. Oliver Sacks vividly describes catatonic disorder due to encephalitis and Parkinson's disease in his 1973 book *Awakenings*.

Symptoms

CATATONIC SCHIZOPHRENIA. Catatonic schizophrenia is a form of thought disorder with prominent motor symptoms and abnormalities. These symptoms include:

- Catalepsy, or motionlessness maintained over a long period of time.
- Catatonic excitement, marked by agitation and seemingly pointless movement.
- Catatonic stupor, with markedly slowed motor activity, often to the point of immobility and seeming unawareness of the environment.
- Catatonic rigidity, in which the person assumes a rigid position and holds it against all efforts to move him or her.
- Catatonic posturing, in which the person assumes a bizarre or inappropriate posture and maintains it over a long period of time.
- Waxy flexibility, in which the limb or other body part of a catatonic person can be moved into another position that is then maintained. The body part feels to an observer as if it were made of wax.
- Akinesia, or absence of physical movement.

DEPRESSION WITH CATATONIC FEATURES. Within the category of mood disorders, catatonic symptoms are most commonly associated with bipolar I disorder. Bipolar I disorder is a mood disorder involving periods of mania interspersed with depressive episodes. Symptoms of catatonic excitement, such as random activity unrelated to the environment or repetition of words, phrases and movements may occur during manic phases. Catatonic immobility may appear during the most severe phase of the depressive cycle. The actual catatonic symptoms are indistinguishable from those seen in catatonic schizophrenia. It is also possible for catatonic symptoms to occur in conjunction with other mood disorders, including bipolar II disorder (in which a milder form of mania called hypomania occurs); mixed disorders (in which mania and depression occur at the same time); and major depressive disorders.

CATATONIC DISORDER DUE TO A GENERAL MEDICAL CONDITION. Symptoms of catatonic disorder caused by medical conditions are indistinguishable from those that occur in schizophrenia and mood disorders. Unlike persons with schizophrenia, however, those with catatonic symptoms due to a medical condition demonstrate greater insight and awareness into their illness and symptoms. They have periods of clear thinking, and their affect (emotional response) is generally appropriate to the circumstances. Neither of these conditions is true of patients with schizophrenia or severe depression.

Demographics

According to the handbook used by mental health professionals to diagnose mental disorders, the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, Text Revision, also known as the *DSM-IV-*

A patient suffering from catatonic schizophrenia. *(Grunnitus Studios. Photo Researchers, Inc. Reproduced by permission.)*

TR, between 5% and 9% of all psychiatric inpatients show some catatonic symptoms. Of these, 25%–50% are associated with mood disorders, 10%–15% are associated with schizophrenia, and the remainder are associated with other mental disorders. Catatonic symptoms can also occur in a wide variety of general medical conditions, including infectious, metabolic and neurological disorders. They may also appear as side effects of various medications, including several drugs of abuse.

Diagnosis

Catatonic symptoms are quite noticeable. Important diagnostic distinctions, however, must be made to determine their cause. Catatonic schizophrenia is diagnosed when the patient's other symptoms include thought disorder, inappropriate affect, and a history of peculiar behavior and dysfunctional relationships. Catatonic symptoms associated with a mood disorder are diagnosed when there is a prior history of mood disorder, or after careful psychiatric evaluation. Medical tests are necessary to determine the cause of catatonic symptoms caused by infectious diseases, metabolic abnormalities, or neurological conditions. The patient should be asked about recent use of both prescribed and illicit drugs in order to determine whether the symptoms are drug-related.

Treatment

Treatment for catatonic symptoms depends on the underlying cause. Catatonic schizophrenia is treated by a variety of pharmacological and psychotherapeutic methods. **Hospitalization** may be necessary to protect the patient's safety. Supportive **psychotherapy** and **family education** can help persons with schizophrenia and their families adjust to problems created by the illness. Such other supportive services as sheltered workshops and special education may also be necessary.

Treatment of catatonic symptoms due to mood disorder involves therapy directed at the underlying mood disorder. Manic episodes are treated with such mood stabilizers as lithium and **valproic acid** (Depakote). Depressive episodes are treated with antidepressant medications or, if necessary, electroconvulsive treatment (ECT).

Catatonic symptoms caused by a medical disorder require correct **diagnosis** of the underlying medical condition, followed by appropriate treatment. Levodopa and **amantadine** (Symmetrel) have shown some effectiveness in reducing catatonic symptoms due to post-encephalitic Parkinson'sdisease. Hospitalization and careful supervision of persons with catatonic symptoms may be necessary to insure that they do not hurt themselves or others.

Prognosis

Catatonic schizophrenia is usually a debilitating lifelong illness. Symptoms typically emerge in adolescence. Social and environmental stressors, such as leaving home for college or military service, use of an illicit drug, or the death of a close friend or relative may trigger the initial symptoms of schizophrenia. The classic pattern is one of worsened symptoms alternating with remissions rather than cure, although about 20% of patients eventually resume their previous level of functioning. Following the initial episode, most patients suffer a relapse within five years of the diagnosis. The course of the disorder varies, with women having a somewhat better prognosis, but persons with schizophrenia remain vulnerable to **stress** for their lifetime.

Catatonia associated with mood disorders is somewhat more treatable, although it may also recur from time to time throughout the patients life.

Catatonic symptoms caused by medical conditions can be treated and sometimes cured. Infections are the most completely curable. Metabolic and neurological

conditions may be treatable, but various degrees of impairment may remain throughout the patient's life.

Prevention

There are no specific preventive measures for most causes of catatonia. Infectious disease can sometimes be prevented. Catatonic symptoms caused by medications or drugs of abuse can be reversed by suspending use of the drug.

Chamomile

Definition

Chamomile is a plant that has been used since ancient Egypt in a variety of healing applications. Chamomile is a native of the Old World; it is related to the daisy family, having strongly scented foliage and flowers with white petals and yellow centers. The name chamomile is derived from two Greek words that mean "ground" and "apple," because chamomile leaves smell somewhat like apples, and because the plant grows close to the ground.

There are two varieties of chamomile commonly used in herbal preparations for internal use and for **aromatherapy**. One is called Roman chamomile (*Anthemis nobilis*), with contemporary sources in Belgium and southern England. Roman chamomile grows to a height of 9 in (23 cm) or less, and is frequently used as a ground cover along garden paths because of its pleasant apple scent. German chamomile (*Matricaria recutita*) is grown extensively in Germany, Hungary, and parts of the former Soviet Union. German chamomile grows to a height of about 3 ft (1 m) and is the variety most commonly cultivated in the United States, where it is used medicinally.

Purpose

Chamomile has been used internally for a wide variety of complaints. The traditional German description of chamomile is *alles zutraut*, which means that the plant "is good for everything."

Chamomile has been used internally for the following purposes:

- Antispasmodic: A preparation given to relieve intestinal cramping and relax the smooth muscles of the internal organs. Chamomile is used as an antispasmodic to relieve digestive disorders, menstrual cramps, premenstrual syndrome (PMS), headache, and other stress-related disorders.
- Anthelminthic: Chamomile has been used to expel parasitic worms from the digestive tract.
- Carminative: Chamomile is given to help expel gas from the intestines.
- Sedative: Perhaps the most frequent internal use of chamomile is in teas prepared to relieve anxiety and insomnia.
- Anti-inflammatory: Roman chamomile has been used to soothe the discomfort of gingivitis (inflamed gums), earache, and arthritis. German chamomile is used in

KEY TERMS

Anthelminthic—A type of medication given to expel or eliminate intestinal worms.

Antispasmodic—A medication or preparation given to relieve muscle or digestive cramps.

Carminative—A substance or preparation that relieves digestive gas.

Essential oil—The product of special ducts or cells in the tissues of aromatic plants (or the sap of certain trees) that gives the plant its characteristic aroma and therapeutic properties. Essential oils are sometimes called volatile oils because they evaporate readily at room temperature.

Flavonoids—Plant pigments that have a variety of effects on human physiology. Some of these pigments have anti-inflammatory, anti-carcinogenic, and antioxidant effects, for example.

Middle note—A term used in perfumery and aromatherapy to designate essential oils whose odors emerge later than top notes but evaporate more rapidly than bottom notes. Chamomile is considered a middle note in aromatherapy.

Tannin—An astringent compound found in chamomile, oak bark, and certain other plants. Tannin in large quantities can interfere with iron absorption.

Topical—A type of medication or preparation intended for use on the skin or external surface of the body. Chamomile is commonly used in topical preparations for acne, open skin irritations, and similar conditions because of its antibacterial properties.

Europe to treat oral mucosities in cancer patients following chemotherapy treatment.

- Antiseptic: Chamomile has mild antibacterial properties, and is sometimes used as a mouthwash or eyewash. It can be applied to compresses to treat bruises or small cuts.
- Other: Mexican Americans, especially the elderly, have been reported to use chamomile for the treatment of asthma and urinary incontinence. It is one of the two most popular herbs in use among this population.

The external uses of chamomile include blending its essential oil with **lavender** or rose for scenting perfumes, candles, creams, or other aromatherapy products intended to calm or relax the user. Chamomile is considered a middle note in perfumery, which means that its scent lasts somewhat longer than those of top notes but is less long lasting than scents extracted from resinous or gum-bearing plants. Chamomile is also a popular ingredient in shampoos, rinses, and similar products to add highlights to blonde or light brown hair.

Other external uses of chamomile include topical preparations for the treatment of bruises, scrapes, skin irritations, and joint pain. The antibacterial and anti-inflammatory properties of chamomile make it a widely used external treatment for acne, arthritis, burns, ulcerated areas of skin, and even diaper rash. The German E Commission, regarded as an authority on herbal treatments, has recommended chamomile to "combat inflammation, stimulate the regeneration of cell tissue, and promote the healing of refractory wounds and skin ulcers."

Description

The flowers are the part of the chamomile plant that are harvested for both internal and external use. Chamomile flowers can be dried and used directly for teas and homemade topical preparations, but they are also available commercially in prepackaged tea bags and in capsule form. The essential oil of chamomile is pressed from the leaves as well as the flowers of the plant; it costs about $22–$35 for 5 ml. Chamomile is also available as a liquid extract.

The chemically active components of chamomile include alpha bisabobol, chamozulene, polyines, tannin, coumarin, flavonoids, and apigenin. However, no single factor has been credited with all the major healing properties of whole chamomile; it is assumed that the various components work together to produce the plant's beneficial effects.

Recommended dosage

Children may be given 1–2 ml of a glycerine preparation of German chamomile three times a day for colic; or 2–4 oz (57–100 g) of tea, one to three times a day, depending on the child's weight.

Adults may take a tea made from 0.7–1 oz (2–3 g) of dried chamomile steeped in hot water, three to four times daily for relief of heartburn, gas, or stomach cramps. Alternately, adults may take 5 ml of 1:5 dilution of chamomile tincture three times daily.

For use as a mouthwash, one may prepare a tea from 0.7–1 oz (2–3 g) of dried chamomile flowers, allow the tea to cool, and then gargle as often as desired. To soothe an irritated upper respiratory tract during cold season, adults may pour a few drops of essential oil of

chamomile on top of steaming water and inhale the fragrant vapors.

For relief of eczema, insect bites, and other skin irritations, adults may add 4 oz (110 g) of dried chamomile flowers to a warm bath. Topical ointments containing 3–10% chamomile may be used for psoriasis, eczema, or dry, irritated skin.

Precautions

Because chamomile is related botanically to the ragweed plant, persons who are highly allergic to ragweed should use chamomile with caution.

Chamomile is generally safe to drink when prepared using the recommended quantity of dried flowers. Highly concentrated tea made from Roman chamomile has been reported to cause nausea; this reaction is caused by a compound found in Roman chamomile called anthemic acid.

Women who are pregnant or lactating should not use chamomile.

Persons taking warfarin or similar blood-thinning medications should use chamomile only after consulting their physician, as it may intensify the effects of anticoagulant drugs.

Side effects

Chamomile can cause allergic reactions in people who are sensitive to ragweed.

Interactions

Chamomile can increase the effects of anticoagulant medications. In addition, its tannin content may interfere with iron absorption. Chamomile may also add to the effects of benzodiazepines, including Valium, Ativan, and Versed. No other noteworthy medication interactions have been reported.

Child Depression Inventory

Definition

The Child Depression Inventory (CDI) is a symptom-oriented instrument for assessing depression in children between the ages of seven and 17 years. The basic CDI consists of 27 items, but a 10-item short form is also available for use as a screener.

Purpose

The CDI was first published by Maria Kovacs in 1992. It was developed because depression in young children is often difficult to diagnose, and also because depression was regarded as an adult disorder until the 1970s. It was thought that children's nervous systems were not sufficiently mature to manifest the neurochemical changes in **brain** function associated with depression.

In 2002 the National Institute of Mental Health (NIMH) estimated that as many as 2.5% of children and 8.3% of adolescents under the age of 18 in the United States suffer from depression. A study sponsored by the NIMH of 9- to 17-year-olds found that 6% developed depression in a six-month period, with 4.9% diagnosed as having major depression. Research also indicates that children and adolescents experience the onset of depression at earlier ages than previous generations, are more likely to experience recurrences, and are more likely to experience severe depression as adults.

KEY TERMS

Dysthymic disorder—A mood disorder that is less severe than depression but usually more chronic. Dysthymic disorder is diagnosed in children and adolescents when a depressed mood persists for a least one year and is accompanied by at least two other symptoms of major depression.

Epidemiology—The study of the causes, incidence, transmission, and control of diseases.

Frequency distribution—In statistics, the correspondence between a set of frequencies and the set of categories used to classify the group being tested.

Psychometric—Pertaining to testing and measurement of mental or psychological abilities. Psychometric tests convert an individual's psychological traits and attributes into a numerical estimation or evaluation.

Self-rated—A term in psychological testing that means that the person taking the test is the one who decides whether a question applies to them and records the answer, as distinct from an examiner's evaluating and recording answers.

Standard deviation—A measure of variability in a set of scores. The standard deviations are based on a comparison to others in the same age group. Standardizing the scores in this way allows scores across age groups to be compared.

The CDI is intended to detect and evaluate the symptoms of a **major depressive disorder** or **dysthymic disorder** in children or adolescents, and to distinguish between children with those disorders and children with other psychiatric conditions. The CDI can be administered repeatedly in order to measure changes in the depression over time and to evaluate the results of treatment for depressive disorders. It is regarded as adequate for assessing the severity of the depressive symptoms.

The CDI has also been used in research studies of the epidemiology of depression in children as well as studies of dissociative symptoms and post-traumatic syndromes in children. It has been rated as having adequate to excellent psychometric properties by research psychologists.

Precautions

The CDI shares certain drawbacks with other self-report measures used in children, namely that children do not have the same level of ability as adults to understand and report strong internal emotions. On the other hand, children have the same ability as adults to modify their answers on the CDI and similar tests to reflect what they think are the desired answers rather than what they actually feel. This phenomenon is variously known as "faking good" or "faking bad," depending on the bias of the modified answers. Some researchers have also observed that children who do not have age-appropriate reading skills may receive an inaccurate **diagnosis** on the basis of their CDI score.

The results of the CDI should be evaluated only by a trained professional **psychologist** or **psychiatrist**, not by a parent, teacher, or school nurse.

Because depressive symptoms fluctuate somewhat in children as well as in adults, the author of the test recommends retesting children who score positive on the CDI, with a two- to four-week interval between the test and the retest. A child who screens positive on the CDI should receive a comprehensive diagnostic evaluation by a licensed mental health professional. The evaluation should include interviews with the child or adolescent; the parents or other caregivers; and, when possible, such other observers as teachers, social service personnel, or the child's primary care physician.

Description

The CDI is self-rated, which means that the child or adolescent being evaluated records their answers to the questions on the test sheet, as distinct from giving verbal answers to questions that are then analyzed and recorded by the examiner. Other self-rated instruments for assessing depression in children include the **Beck Depression Inventory** (BDI) and the Weinberg Screening Affective Scale (WSAS).

Each question on the CDI consists of three possible responses; the child or adolescent being evaluated selects the response that most closely describes him or her over the preceding two weeks. The CDI is designed to make quantitative measurements of the following symptoms of depression: mood disturbances; capacity for enjoyment; depressed self-evaluation; disturbances in behavior toward other people; and vegetative symptoms, which include **fatigue**, oversleeping, having difficulty with activities requiring effort, and other symptoms of passivity or inactivity.

Results

The test administrator totals the responses and plots them onto a profile form. A score that falls below a cut-

off point, or is 1.0 to 2.0 standard deviations above the mean, is considered to be positive for depression.

Childhood disintegrative disorder

Definition

Childhood disintegrative disorder (CDD) is a developmental disorder that resembles **autism**. It is characterized by at least two years of normal development, followed by loss of language, social skills, and motor skills before age ten. Other names for childhood disintegrative disorder are Heller's syndrome, **dementia** infantilis, and disintegrative **psychosis.**

Description

Thomas Heller, an Austrian educator, first described childhood disintegrative disorder in 1908. It is a complex disorder that affects many different areas of the child's development. It is grouped with the **pervasive developmental disorders** (PDDs) and is related to the better known and more common disorder of autism.

Initially CDD was considered strictly a medical disorder and was believed to have identifiable medical causes. After researchers reviewed the reported cases of CDD, however, no specific medical or neurological cause was found to account for all occurrences of the disorder. For that reason, CDD was included in the fourth edition of the ***Diagnostic and Statistical Manual of Mental Disorders***, or *DSM-IV*, in 1994. The *Diagnostic and Statistical Manual* is the standard reference work consulted by mental health professionals in the United States and Canada.

Causes and symptoms

Causes

The cause of childhood disintegrative disorder is unknown. Research findings suggest, however, that it may arise in the neurobiology of the **brain**. About half the children diagnosed with CDD have an abnormal electroencephalogram (EEG). EEGs measure the electrical activity in the brain generated by nerve transmission (brain waves). CDD is also sometimes associated with **seizures**, another indication that the neurobiology of the brain may be involved. CDD is occasionally associated with such diagnosed medical disorders of the brain as leukodystrophy and Schilder's disease; but no one disease, brain defect, disorder, or condition can account for all symptoms and all cases. Research is hampered by the rarity of this disorder.

Symptoms

Children with CDD have at least two years of normal development in all areas—language understanding, speech, skill in the use of large and small muscles, and social development. After this period of normal growth, the child begins to lose the skills he or she has acquired. This loss usually takes place between ages three and four, but it can happen any time up to age ten.

KEY TERMS

Autism—A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

Dementia infantilis—Another term for childhood disintegrative disorder, used more frequently in the European medical literature. The Latin name literally means "early childhood dementia."

Leukodystrophy—A disturbance of the white matter of the brain

Schilder's disease—A disturbance of the white matter of the brain that causes blindness, deafness, and mental deterioration

Sensory integration therapy—A treatment that was originally designed for children with autism. Sensory integration therapy is often performed by occupational or physical therapists; its goal is to help the child with autism or CDD process information acquired through the senses (hearing, touch, taste, and smell as well as sight) more effectively.

The loss of skills may be gradual, but more often occurs rapidly over a period of six to nine months. The transition may begin with unexplained changes in behavior, such as anxiety, unprovoked anger, or agitation. Behavioral changes are followed by loss of communication, social, and motor skills. Children may stop speaking or revert to single words. They often lose bowel or bladder control and withdraw into themselves, rejecting social interaction with adults or other children. They may perform repetitious activities and often have trouble moving from one activity to the next.

In this way CDD resembles autism. In autism, however, previously acquired skills are not usually lost. According to the *Handbook of Autism and Pervasive Developmental Disorders*, virtually all children with CDD lose speech and social skills. About 90% lose self-help skills (the ability to feed, wash, and toilet themselves); and about the same number develop non-specific overactivity. After a time, the regression stops, but the child does not usually regain the skills that were lost.

Demographics

CDD is a rare disease, much less common than autism. About 1 in 100,000 children are thought to have CDD. It is possible, however, that the disorder is underdiagnosed. For a long time, it was thought that CDD occurred equally among boys and girls. Newer research suggests that it is about four times more common in boys, and that many girls who were diagnosed with CDD actually had **Rett's disorder**, a disorder that shares many of the symptoms of CDD but occurs almost always in girls.

Diagnosis

CDD is most commonly diagnosed when the parents of the affected child consult the pediatrician about the child'sloss of previously acquired skills. The doctor will first give the child a medical examination to rule out epilepsy or other medical conditions. The child'shead may also be x rayed to rule out head trauma or a brain tumor. Following the medical examinations and tests, the child will be referred to a **psychiatrist** who specializes in treating children and adolescents. The psychiatrist will then make the differential **diagnosis** of CDD.

To be diagnosed with CDD, a child must show loss or regression in at least two of the areas listed below. Usually regression occurs in more than two areas. These are:

- receptive language skills (language understanding)
- expressive language skills (spoken language)
- social or self-help skills
- play with peers
- motor skills
- bowel or bladder control, if previously established

Children with CDD are unable to start conversations with other people and often do not communicate with nonverbal signals (smiles, gestures, nodding the head, etc.) either. They also lose interest in playing games and in relationships with other people. They may engage in strange repetitive behavior, such as bobbing the head up and down, or other repeated movements. These changes must not be caused by a general medical condition or another diagnosed mental disorder.

CDD must be differentiated from autism and such other specific pervasive developmental disorders as Rett's disease. It also must be differentiated from **schizophrenia**. One of the differences between CDD and other PDDs is that to be diagnosed with CDD, a child must develop normally for at least two years before loss of skills occurs, and the loss must occur before age ten. Parents' reports of the child's development, records in baby books, medical records kept by the child's pediatrician, and home movies are often used to document normal development through the first two years of life.

Treatments

Treatment for CDD is very similar to treatment for autism. The emphasis falls on early and intense educational interventions. Most treatment is behavior-based and highly structured. Educating the parents so that they can support the child'streatments at home is usually part of the overall treatment plan. Speech and language therapy, occupational therapy, social skills development, and sensory integration therapy may all be used according to the needs of the individual child

Families with a child who has CDD often find themselves highly stressed. Practical demands on caregivers are high, and CDD takes an emotional toll on family members. Finding appropriate providers with experience delivering services for a child with CDD is sometimes difficult, especially outside large cities. **Support groups** for families can help reduce their isolation and frustration. Because CDD is rare, autism support groups and organizations include families of children with CDD in their services.

Prognosis

The prognosis for children with CDD is very poor; it is worse than the prognosis for children with autism. Once skills are lost, they are not usually regained. Only about 20% of children diagnosed with the disorder reacquire the ability to speak in sentences. Most adults with CDD remain dependent on full-time caregivers or are institutionalized.

Prevention

Since the causes of CDD are unknown, there are no known ways to prevent this disorder.

Children's Apperception Test

Definition

The Children's Apperception Test, often abbreviated as CAT, is an individually administered projective personality test appropriate for children aged three to 10 years.

Purpose

The CAT is intended to measure the personality traits, attitudes, and psychodynamic processes evident in prepubertal children. By presenting a series of pictures and asking a child to describe the situations and make up stories about the people or animals in the pictures, an examiner can elicit this information about the child.

The CAT was originally developed to assess psychosexual conflicts related to certain stages of a child's development. Examples of these conflicts include relationship issues, sibling rivalry, and aggression. Today, the CAT is more often used as an assessment technique in clinical evaluation. Clinical diagnoses can be based in part on the Children's Apperception Test and other projective techniques.

Precautions

A **psychologist** or other professional person who is administering the CAT must be trained in its usage and interpretation, and be familiar with the psychological theories underlying the pictures. Because of the subjective nature of interpreting and analyzing CAT results, caution should be used in drawing conclusions from the test results. Most clinical psychologists recommend using the CAT in conjunction with other psychological tests designed for children.

The CAT is frequently criticized for its lack of objective scoring, its reliance on the scorer's own scoring method and bias, and the lack of accepted evidence for its reliability (consistency of results) and validity (effectiveness in measuring what it was designed to measure). For example, no clear evidence exists that the test measures needs, conflicts, or other processes related to human motivations in a valid and reliable way.

KEY TERMS

Apperception—The process of understanding through linkage with previous experience. The term was coined by one of the authors of the TAT to underscore the fact that people don't "perceive" the story cards in a vacuum; rather, they construct their stories on the basis of past experiences as well as present personality traits.

Defense—An unconscious mental process that protects the conscious mind from unacceptable or painful thoughts, impulses, or desires. Examples of defenses include denial, rationalization, projection, and repression. Some defenses are considered to represent lower levels of maturation than others; thus identifying a child's defenses may be helpful in evaluating his or her level of psychological maturity.

Ego—In Freudian psychology, the conscious, rational part of the mind that experiences and reacts to the outside world.

Projective test—A psychological test in which the test taker responds to or provides ambiguous, abstract, or unstructured stimuli, often in the form of pictures or drawings.

Psychodynamic—Referring to the motivational forces, unconscious as well as conscious, that form human attitudes and behavior.

Psychosexual conflicts—In Freudian categories, internal conflicts related to problems at a particular stage of childhood development. Freud associated each developmental stage with a particular part of the human body, such as the mouth or the phallus.

Reliability—The ability of a test to yield consistent, repeatable results.

Sibling rivalry—Competition among brothers and sisters in a nuclear family. It is considered to be an important influence in shaping the personalities of children who grow up in middle-class Western societies but less relevant in traditional African and Asian cultures.

Superego—According to Freud, the part of the mind that represents traditional parental and societal values. The superego is the source of guilt feelings.

Validity—The ability of a test to measure accurately what it claims to measure.

Older children between the ages of seven and 10 years may feel that the animal pictures in the original version of the CAT are too childish for them. They may respond better to the pictures of human beings available in the Children's Apperception Test-Human Figures (CAT-H), a version of the CAT in which human beings replace animals in the pictures.

Description

The Children's Apperception Test was developed in 1949 by Leopold Bellak and Sonya Sorel Bellak. It was an offshoot of the widely used **Thematic Apperception Test** (TAT), which was based on Henry Murray's need-based theory of personality. Bellak and Bellak developed the CAT because they saw a need for an apperception test specifically designed for children. The most recent revision of the CAT was published in 1993.

The original CAT featured ten pictures of animals in such human social contexts as playing games or sleeping in a bed. Today, this version is known as the CAT or the CAT-A (for animal). Animals were chosen for the pictures because it was believed that young children relate better to animals than humans. Each picture is presented by a test administrator in the form of a card. The test is always administered to an individual child; it should never be given in group form. The test is not timed but normally takes 20–30 minutes. It should be given in a quiet room in which the administrator and the child will not be disturbed by other people or activities.

The second version of the CAT, the CAT-H, was developed in 1965 by Bellak and Bellak. The CAT-H includes ten pictures of human beings in the same situations as the animals in the original CAT. The CAT-H was designed for the same age group as the CAT-A but appeals especially to children aged seven to 10, who may prefer pictures of humans to pictures of animals.

The pictures on the CAT were chosen to draw out children's fantasies and encourage storytelling. Descriptions of the ten pictures are as follows: baby chicks seated around a table with an adult chicken appearing in the background; a large bear and a baby bear playing tug-of-war; a lion sitting on a throne being watched by a mouse through a peephole; a mother kangaroo with a joey (baby kangaroo) in her pouch and an older joey beside her; two baby bears sleeping on a small bed in front of a larger bed containing two bulges; a cave in which two large bears are lying down next to a baby bear; a ferocious tiger leaping toward a monkey who is trying to climb a tree; two adult monkeys sitting on a sofa while another adult monkey talks to a baby monkey; a rabbit sitting on a child's bed viewed through a doorway; and a puppy being spanked by an adult dog in front of a bathroom. The cards

in the human version substitute human adults and children for the animals but the situations are the same. Gender identity, however, is more ambiguous in the animal pictures than in the human ones. The ambiguity of gender can allow for children to relate to all the child animals in the pictures rather than just the human beings of their own sex.

The pictures are meant to encourage the children to tell stories related to competition, illness, injuries, body image, family life, and school situations. The CAT test manual suggests that the administrator should consider the following variables when analyzing a child's story about a particular card: the protagonist (main character) of the story; the primary needs of the protagonist; and the relationship of the main character to his or her personal environment. The pictures also draw out a child's anxieties, fears, and psychological defenses.

One theoretical basis for the CAT and other apperception tests is Murray's theory of personality. Murray is credited with clarifying the concept of human needs. He believed that a person's needs affect the way in which he or she interacts with the environment. The pictures on the CAT often address the manner in which individuals interact with their environment in terms of need fulfillment. Murray developed the Thematic Apperception Test, or TAT, in order to assess the relative strength of a person's needs. The needs that Murray particularly emphasized include the need for achievement and the need for recognition.

Because the primary content of the CAT consists of pictures, it is widely used in countries outside the United States.

Results

Scoring of the Children's Apperception Test is not based on objective scales; it must be performed by a trained test administrator or scorer. The scorer's interpretation should take into account the following variables: the story's primary theme; the story's hero or heroine; the needs or drives of the hero or heroine; the environment in which the story takes place; the child's perception of the figures in the picture; the main conflicts in the story; the anxieties and defenses expressed in the story; the function of the child's superego; and the integration of the child's ego.

Consider, for example, the card in which a ferocious tiger leaps toward a monkey who is trying to climb a tree. A child may talk about his or her fears of aggression or punishment. The monkey may be described as a hero escaping punishment from the evil tiger. This story line may represent the child's perceived need to escape punishment from an angry parent or a bully. Conversely, a child may perceive the picture in a relatively harmless way, perhaps seeing the monkey and tiger playing an innocent game.

A projective test like the CAT allows for a wide variety of acceptable responses. There is no "incorrect" response to the pictures. The scorer is responsible for interpreting the child's responses in a coherent way in order to make the test useful as a clinical assessment technique. It is recommended practice for the administrator to obtain the child's personal and medical history before giving the CAT, in order to provide a context for what might otherwise appear to be abnormal responses. For example, it would be normal under the circumstances for a child whose pet has just died to tell stories that include themes of **grief** or loss even though most children would not respond to the cards in that way.

A person scoring the CAT has considerable flexibility in interpretation. He or she can use the analysis of a child's responses to support a psychological **diagnosis**, provide a basis for a clinical evaluation, or gain insight into the child's internal psychological structure.

Chloral hydrate

Definition

Chloral hydrate is a drug that is used to help sedate persons before and after surgery, to help relieve anxiety or tension, and to help promote sleep in persons with **insomnia**. It is sold in the United States under the brand names Aquachloral and Noctec. It is also available under its generic name.

KEY TERMS

Hydrated—Combining a substance with water.

Hypnotic—A type of medication that induces sleep.

Porphyria—A group of disorders that arise from changes in the metabolism of porphyrin, a naturally occurring compound in the body, and that are characterized by acute abdominal pain and neurological problems.

Sedative—A medication that induces relaxation and sleep.

Purpose

Chloral hydrate is primarily used to help sedate persons, especially children, before and after surgery. It has a calming effect on persons as they prepare for surgery. It is also used to help persons who have sleep difficulties fall asleep. Chloral hydrate can be used to help calm tense or nervous persons.

Description

Chloral hydrate is classified as a sedative-hypnotics drug. The entire mechanism by which chloral hydrate works is not completely understood. It is believed that a chemical produced by chloral hydrate called trichloroethanol causes a mild depressive effect on the **brain**.

Recommended dosage

Chloral hydrate is available in oral and suppository forms. The oral form includes both capsules and a syrup. Adults usually receive 500 mg–1000 mg taken 15–30 minutes before bedtime or one to two hours before surgery. These dosages are for hypnotic effects. For sedative effects, 250 mg is usually taken three times daily after meals. Total daily dosage should not be more than 2 g (2000 mg). The hypnotic dose for children is usually 50 mg for every kilogram of body weight. The maximum amount per single dose is 1 g. Daily dosage is usually divided into several smaller doses and taken throughout the day. The sedative dose is typically one-half of the hypnotic dose. The syrup form should be combined with a half glass of fruit juice or water. The capsules should be taken with a full glass of water or juice to help prevent stomach upset.

The typical hypnotic dose using suppositories is 10–20 grains before bedtime in adults. The sedative dose for adults is 5–10 grains three times daily. The total maximum suppository dose should not be more than 30 grains per day. The hypnotic suppository dose in children is 5 grains for every 40 pounds (18.2 kg) of body weight. The sedative dose is one-half of this amount. The amount of absorption of these suppositories is primarily based on how well the body is hydrated and not on body temperature. It helps to moisten the suppository and finger before inserting the suppository.

Precautions

The treating doctor needs to check the progress of any patients taking this drug for more than a few days to ensure significant side effects are not developing. Patients should not stop taking chloral hydrate suddenly. Instead, the dosage should be gradually decreased over time. Chloral hydrate can produce increased effects when combined with other central nervous depressants such as alcohol, antihistamines, and tranquilizers. The combination of chloral hydrate with these agents can cause significant drowsiness. Chloral hydrate can sometimes cause persons to become drowsy, lightheaded, or dizzy. Chloral hydrate should generally not be used in patients with a history of severe kidney disease, severe liver disease, or those with a history of significant heart disease.

Chloral hydrate should be used with great caution only where necessary in persons with a history of heart disease, gastrointestinal problems, porphyria, drug abuse, and in the elderly. Chloral hydrate should be used with caution in pregnant women and in women who are nursing. Chloral hydrate, as with most drugs, can be taken in excess to the point of overdose. Signs of overdose include difficulty in swallowing, extreme weakness, confusion, **seizures**, extreme drowsiness, low body temperature, staggering, changes in heart rate, and breathing problems.

Side effects

Uncommon but serious side effects of chloral hydrate use include skin rash or hives. Even more rare side effects include confusion, hallucination, and excessive excitement. The development of any of these side effects should be promptly reported to a doctor.

Less serious but more common side effects of chloral hydrate use include nausea, stomach pain, and vomiting. Less common and not particularly serious side effects include diarrhea, lightheadedness, drowsiness, and clumsiness.

Interactions

Chloral hydrate should not be combined with alcohol because of additive depressant effects on the central nervous system. This combination can lead to significant drowsiness. Likewise, chloral hydrate should not be combined with the antidepressants drugs called tricyclic antidepressants because of the additive depressive effect. Chloral hydrate should not be combined with the blood-thinning drug called warfarin. The combination of these drugs may require adjustments in the amount of the warfarin taken.

Chlordiazepoxide

Definition

Chlordiazepoxide is used for the treatment of anxiety. It is a member of the benzodiazepine family of compounds, which slow the central nervous system in order to ease tension or nervousness. In the United States, it is sold under the trade name of Librium.

Purpose

Chlordiazepoxide is used for the short-term relief of symptoms of anxiety and management of anxiety disorders. It is also used for treating symptoms of withdrawal from acute alcoholism and alcoholic intoxication.

Description

Chlordiazepoxide is useful when treating anxiety for short periods of time. It has sedative properties that are useful for brief periods of use. It is occasionally used to stimulate appetites and is a weak analgesic. The precise mechanism of action is not known. Several hours are needed for peak levels of the drug to be achieved. Chlordiazepoxide is available in 5-, 10-, and 25-mg capsules.

KEY TERMS

Analgesic—A substance that provides relief from pain.

Edema—Abnormal accumulation of fluid in the interstitial spaces of bodily tissue.

Libido—Psychic energy or instinctual drive associated with sexual desire, pleasure, or creativity.

Porphyria—A group of disorders that arise from changes in the metabolism of porphyrin, a naturally occurring compound in the body, and that are characterized by acute abdominal pain and neurological problems.

Porphyrin—Any iron- or magnesium-free pyrrole derivative occurring in many plant and animal tissues.

Recommended dosage

Recommended dosage varies with **diagnosis**. The lowest possible dosage that provides relief from symptoms should be used as the drug has a high potential to cause physiological and psychological dependence. When used in adults for the treatment of moderate anxiety, the usual oral dosage is 5–10 mg three or four times per day. When used for the treatment of more severe **anxiety and anxiety disorders**, the usual oral dosage is 20–25 mg three or four times per day. When used by older persons, or to relieve symptoms of preoperative apprehension or anxiety, the usual oral dosage is 5 mg two to four times per day. If used as a preoperative medication, the usual dosage is 50–100 mg via intramuscular (IM) injection. When used to treat symptoms of acute alcoholism, the usual initial oral dosage is 50–100 mg, repeated as needed until agitation is adequately controlled. The recommended maximum dosage is 300 mg per day. The usual dosage for children is 5 mg two to four times per day.

Precautions

Persons with suicidal tendencies should be closely monitored, as chlordiazepoxide may lower the threshold for action and attempting **suicide**. The drug has a high

potential to cause physiological or psychological dependence.

Side effects

Other than physiological and psychological dependence, few adverse effects have been reported. The most commonly reported include drowsiness, confusion, and difficulty in moving. These are most common among older persons. Occasionally, transient loss of consciousness has been reported.

Other adverse effects include edema (abnormal accumulation of fluid in bodily tissues), minor menstrual irregularities, nausea, constipation and, infrequently, changes in libido (sex drive). Also, it may impair mental or physical skills needed to perform complex motor tasks. For this reason, persons using this drug are advised not to drive automobiles or operate machinery.

Interactions

Chlordiazepoxide may increase the effect of alcohol or other substances that depress central nervous system functions. For this reason, they should not be used at the same time. A small number of reports of interaction with oral anticoagulants have been received, and it may exacerbate porphyria—a group of inherited disorders in which there is abnormally increased production of substances called porphyrins.

Chlorpromazine

Definition

Chlorpromazine is an antipsychotic drug. It is a member of the phenothiazine family of compounds and is used to alleviate the symptoms and signs of **psychosis**. Psychosis is a form of severe mental illness, which is characterized by loss of contact with reality, **hallucinations**, **delusions**, agitation, and unusual behavior. In the United States, chlorpromazine is also sold under the brand name Thorazine.

Purpose

Chlorpromazine is principally used to reduce the signs and symptoms of psychosis. For this purpose, the drug is used in **schizophrenia** and the manic phase of bipolar (formerly manic-depressive) disorder. The drug is also used in the management of severe behavioral disorders with aggression, combativeness, or excessive excitability. Chlorpromazine may sometimes be used as a sedative in non-psychotic patients with excessive anxiety and agitation. In addition, the drug has been used to relieve nausea, vomiting, and persistent hiccups.

Description

Chlorpromazine was the first antipsychotic drug. It is not an exaggeration to say that the development of this medication began a revolution in the treatment of severe mental illness, which continues to this day. Patients with schizophrenia and other psychoses, who once would have been considered hopelessly untreatable and relegated to the back wards of state institutions, are often able today, as a result of treatment with chlorpromazine or similar medications, to live in the community and lead fuller lives.

The discovery of chlorpromazine resulted from efforts of pharmaceutical researchers in the first half of the twentieth century to develop sedative medications. Several drugs of a chemical class known as phenothiazines were investigated and shown to be effective sedatives, but they had little effect on agitated patients with psychosis. A new phenothiazine drug, chlorpromazine, was synthesized in France in 1950 and was tested on such patients. In 1952, two French psychiatrists, Delay and Deniker, announced that the drug exerted a specific effect in diminishing the symptoms and signs of psychosis in patients with severe mental illnesses.

The mechanism of action of chlorpromazine is not completely understood. Its antipsychotic effects are believed to be related to its action in selectively blocking the transmission of nerve impulses from cell to cell in a region of the **brain** called the limbic system. This part of the brain is involved with emotions and motivation.

Chlorpromazine, when sold under the name Thorazine, is available in many forms: tablets of 10, 25, 50, 100, and 200 mg; spansules (sustained release capsules) of 30, 75, and 150 mg; ampules for injection of 25 and 50 mg; multidose vial of 10 mL of 25 mg/mL; syrup 10mg/5mL, 4 fl oz.; suppositories of 25 and 100 mg. Generic chlorpromazine manufacturers may supply a somewhat different set of dosages and products.

KEY TERMS

Antipsychotic drug—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (is a neurotransmitter) and helps to regulate movement and emotions.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Neurotransmission—The conduction of a nerve impulse along a chain of nerve cells, which occurs when one cell in the chain secretes a chemical substance, called a neurotransmitter, onto a subsequent cell.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Phenothiazine—A class of drugs widely used in the treatment of psychosis.

Recommended dosage

For acutely disturbed adult patients suffering from a psychosis, such as schizophrenia or mania, the usual daily dosage ranges from 100 mg to 1000 mg per day. Some patients may require a higher dosage. There is great variation in individual dosage requirements for chlorpromazine and for other antipsychotic medications. It is usually advisable to begin with a lower dosage, and increase the dosage until sufficient reduction of symptoms is achieved. Maximum reduction of symptoms may take many weeks of continued treatment. Because of the possibility of side effects, which may be severe, lower dosages should be used in outpatients, children, the elderly, and patients with serious health problems. For nonpsychotic patients with excessive anxiety or agitation, amounts used are generally less than 200 mg per day, divided among two or three doses.

For nausea and vomiting in adults, the usual dosage is 10–25 mg every four to six hours as needed, given by injection. Alternatively, doses of 50–100 mg may be given rectally. Persistent hiccups may be treated with 25–50 mg three or four times per day, orally or by injection.

Precautions

Elderly patients (those over age 65), especially women, and patients receiving long-term antipsychotic treatment are prone to develop **tardive dyskinesia**. This syndrome consists of involuntary, uncoordinated movements that may not disappear or may only partially improve after the drug is stopped. Tardive dyskinesia involves involuntary movements of the tongue, jaw,

mouth or face or other groups of skeletal muscles. Tardive dyskinesia may also appear after chlorpromazine use has stopped. There is no known effective treatment for tardive dyskinesia, although gradual (but rarely complete) improvement may occur over a long period. The need for long-term antipsychotic medication should be weighed against the risk of tardive dyskinesia, which increases with duration of treatment.

Neuroleptic malignant syndrome (NMS), a dangerous condition with high fever, muscular rigidity, rapid pulse, sweating, and altered mental state, may occur with antipsychotic medication. NMS requires immediate medical treatment.

Phenothiazine drugs, such as chlorpromazine, may cause sedation and may interfere with driving and other tasks requiring alertness. They may increase the effects of alcohol and sedatives. The adverse effects of chlorpromazine may be increased in people with diseases of the heart, liver, or kidney, or other debilitating illnesses. Phenothiazines may lower the seizure threshold, making it more likely that a seizure will occur in people who have a history of **seizures**. People with epilepsy may require adjustment of their anti-seizure medications. Chlorpromazine may cause acute muscle spasms, particularly of the head and neck, and sudden decreases of blood pressure. Patients may need to be hospitalized during the initial phase of treatment, particularly when receiving high doses or treatment by injection.

Chlorpromazine reduces the body's ability to sweat, thus interfering with the regulation of body temperature. This may be a problem for some people in very hot weather. The problem most commonly occurs in elderly people in hot buildings without air conditioning. Body temperature may reach fatal levels. People taking chlorpromazine should be aware of the possibility of developing hyperthermia (high body temperature) in very hot weather. They should seek cool places in very hot weather.

Children may especially susceptible to neurologic reactions to phenothiazines, such as muscle spasms. Elderly patients may be particularly sensitive to sedation, low blood pressure, and other side effects. These patients should start with lower doses and increase their dosage gradually under physician supervision. Chlorpromazine may decrease salivation in older patients, predisposing to tooth decay, gum disease and mouth infections. Candy and other sugary foods should be limited, and oral hygiene should be maintained.

Chlorpromazine, like all phenothiazines, should not be taken by pregnant women because they harm the developing fetus. Breast-feeding is not recommended while taking the drug. Phenothiazines are secreted in breast milk and may cause harm to nursing infants.

Side effects

Chlorpromazine and other phenothiazines may cause many side effects. The following more common side effects are grouped by the body system affected:

- Cardiovascular: decreases of blood pressure, especially on arising, which may cause dizziness or fainting; rapid heart rate, changes in heart rhythm and electrocardiogram.
- Nervous system: sedation, muscle spasms of the head and neck, muscle rigidity, restlessness, tremors, slowed movement, shuffling gait, increased seizure tendency.
- Digestive system: dry mouth, nausea, constipation, abnormal liver tests.
- Autonomic: blurred vision, nasal congestion, reduced sweating, difficulty urinating, problems with ejaculation, impotence.
- Hormonal: lactation, breast enlargement.
- Skin: rashes, sensitivity to sunlight.
- Body as a whole: weight gain.

Interactions

Chlorpromazine interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Chlorpromazine and other phenothiazines may intensify the effects of drugs causing sedation, including alcohol, **barbiturates**, narcotic pain medications, minor tranquilizers, and antihistamines. Similarly, chlorpromazine may cause excessive reductions of blood pressure in patients taking other medicines that lower blood pressure. Chlorpromazine may also intensify side effects of drugs that also cause blurred vision, dry mouth, diminished sweating in hot weather, and constipation. Many other antipsychotics and antidepressants cause such effects.

Chlorpromazine may enhance the effects of medications that lower the seizure threshold, such as steroid drugs, the asthma medication theophylline, and many other psychiatric drugs. Patients with epilepsy may require dosage adjustments of their anti-seizure medications. The effectiveness of medications for Parkinson's disease may be reduced by chlorpromazine and other antipsychotics. The likelihood of changes in heart rhythm may be increased when the drug is taken with other medications that have the same effect, including other antipsychotic drugs, antidepressants, certain heart medicines, and erythromycin.

Certain drugs that are eliminated by the liver may interfere with the elimination of chlorpromazine from the

body, causing higher blood levels and increased side effects. Chlorpromazine may retard the elimination of other medicines, including many antidepressants, antipsychotic drugs, and heart medications, resulting in higher levels of these other medications and possibly increased side effects.

Circadian rhythm sleep disorder

Definition

Circadian rhythm sleep disorder is a persistent or recurring pattern of sleep disruption resulting either from an altered sleep-wake schedule or an inequality between a person's natural sleep-wake cycle and the sleep-related demands placed on him or her. The term circadian rhythm refers to a person's internal sleep and wake-related rhythms that occur throughout a 24-hour period. The sleep disruption leads to **insomnia** or excessive sleepiness during the day, resulting in impaired functioning.

The Fourth Edition Text Revision of the ***Diagnostic and Statistical Manual of Mental Disorders*** (*DSM-IV-TR*, a handbook used by mental health professionals to diagnose mental disorders) defines circadian rhythm sleep disorder as one of several primary **sleep disorders**. Within the category of primary sleep disorders, it is classified as one of the dyssomnias, characterized by irregularities in an individual's quality, timing, and amount of sleep. In earlier versions of the *DSM*, the disorder is called sleep-wake schedule disorder.

Description

Circadian rhythm sleep disorder involves an alteration of an individual's circadian system or a mismatch between a person's natural, or endogenous, circadian system and the external, or exogenous, demands placed on it. It can lead to insomnia at certain times of the day or excessive sleepiness throughout the day. The insomnia or excessive sleepiness results in impaired functioning in social, occupational, or other environments.

The *DSM-IV-TR* lists four types of circadian rhythm sleep disorder: delayed sleep phase type, jet lag type, shift work type, and unspecified type.

Causes and symptoms

Causes

The delayed sleep phase type of circadian rhythm sleep disorder is marked by a delay of the sleep-wake cycle as it relates to the demands of society. It is often due to a psychosocial stressor (an event in a person's environment that causes **stress** or discomfort), especially for adolescents. The delayed sleep-wake cycle leads to chronic sleep deprivation and habitually late sleeping hours. Individuals with this type often have difficulty changing their sleeping patterns to an earlier and more socially acceptable time. Their actual sleep, once it begins, is normal. It is the timing of their sleeping and waking that is persistently delayed.

The jet lag type of circadian rhythm sleep disorder is characterized by disruptions arising from a mismatch between a person's circadian cycle and the cycle required by a different time zone. The more time zones that are traveled, the greater the disruption. Eastbound travel, in which sleep-wake hours are advanced, typically causes more problems than westbound travel, in which sleep-wake hours are delayed. People who travel often and cross many time zones when they travel are most susceptible to this type.

The shift work type of circadian rhythm sleep disorder is distinguished by disruptions due to a conflict

The jet lag type of circadian rhythm sleep disorder is characterized by disruptions arising from a mismatch between a person's circadian cycle and the cycle required by a different time zone. People who travel often and cross many time zones when they travel are most susceptible to this type of circadian rhythm sleep disorder. *(Will McIntyre. Photo Researchers, Inc. Reproduced by permission.)*

between a person's endogenous circadian cycle and the cycle required by shift work. Individuals who work the night shift often experience this problem, especially those people who switch to a normal sleep schedule on days off. Also, people who work rotating shifts experience this problem because of the changing sleep-wake schedules they experience. The disruptions caused by shift work result in inconsistent circadian schedules and an inability to adjust to the changes consistently.

The unspecified type of circadian rhythm sleep disorder is characterized by a pattern of sleep-wake disturbance and circadian mismatch that is not due to the causes of the other three types. Examples of other causes include irregular sleep-wake patterns and non-24-hour sleep-wake patterns. If an individual's sleep-wake pattern is based on a period of time of slightly more than 24 hours, their circadian rhythm can become progressively delayed.

Symptoms

Individuals with the delayed sleep phase type of the disorder exhibit habitually late sleep hours and an inability to change their sleeping schedule consistently. They often show sleepiness during the desired wake period of their days. Their actual phase of sleep is normal. Once they fall asleep, they stay asleep for a normal period of time, albeit a period of time that starts and stops at an abnormally late time.

Individuals with the jet lag type of circadian rhythm sleep disorder demonstrate sleepiness during the desired wake portion of the day due to the change in time zone. They have difficulty sleeping during the desired sleep portion of the day. They also have difficulty altering their sleep-wake schedule to one appropriate to the new time zone.

Individuals with the shift work type of the disorder feel sleepy or fall asleep during the desired wake period, which includes the time spent at work. People with rotating shift schedules, especially schedules that gradually change, exhibit sleep disturbance and wake period sleepiness. Insufficient sleep time, family and social expectations, and alcohol use worsen this problem.

Individuals with the unspecified type of circadian rhythm sleep disorder also exhibit daytime and evening sleepiness or insomnia, especially those people who have a non-24-hour sleep pattern. People with irregular sleep patterns have difficulty knowing when they will fall asleep and wake up.

Demographics

The delayed sleep phase type of the disorder usually begins during adolescence and can continue without treatment through adulthood. People with this type may have a family history of delayed sleep phase. The delayed sleep phase type of the disorder is thought to impact up to 4% of adults and up to 7% of adolescents.

The shift work and jet lag types of the disorder often result in more severe symptoms for late-middle-aged and elderly people. It is estimated that up to 60% of night shift workers have the shift work type of circadian rhythm sleep disorder.

Diagnosis

In order to diagnose circadian rhythm sleep disorder, patients are often asked for records of their sleep and wake times in order to determine if a **diagnosis** is warranted. Interviews and direct observation in a sleep lab may also be utilized. A diagnosis requires a pattern of sleep disruption caused by a mismatch between a person's circadian sleep-wake pattern and the pattern required by that person's environment. The disruption can be persistent or recurrent and leads to impaired functioning, often in a social or occupational context.

To differentiate circadian rhythm sleep disorder from other diagnoses, the sleep disruption must not occur exclusively during the cause of another sleep disorder or other disorder. The disturbance in sleep must not be due

to the direct physiological effects of a substance, whether used for medication or abuse, or to a general medical condition.

The delayed sleep phase type of the disorder requires a persistent pattern of delayed sleeping and awakening and an inability to change the pattern. The jet lag type requires sleepiness and wakefulness at inappropriate times relative to the local time zone; there must be repeated travel more than one time zone away. The shift work type requires excessive sleepiness during the desired wake period and an inability to sleep during the desired sleep period, both due to changing shift work or night shift work.

Diagnosis of any type of circadian rhythm sleep disorder must be distinguished from normal adjustments a person makes in reaction to a schedule change. The sleep disruptions must be persistent and recurring and lead to social or occupational problems. People who prefer unusually late or early sleep schedules or people adjusting to a new sleep schedule should not receive this diagnosis unless they meet the other criteria.

Treatments

Treatment of the delayed sleep phase type depends on the severity of the case. Mild cases may be addressed by an individual simply adhering to strict sleep and wake times. Severe cases may require incremental changes in sleep time, where a person sleeps 15 to 30 minutes earlier each day until an appropriate pattern is reached. Other methods of altering delayed sleep patterns include prescribing a night of sleep deprivation or the use of chronotherapy, a method in which sleep is delayed for three hours each night until the sleep pattern is rotated around the clock.

Often, treatment is ignored for persons with the jet lag type because people eventually return to their regular time zone and normal sleep-wake cycle and no longer exhibit symptoms. For people who travel often, it is preferable to adjust to the new time zone by sleeping at times appropriate to that zone if they intend to be there for one week or longer. **Diets** that target jet lag are also effective for some people, and **light therapy**, which involves exposure to a lighted device to simulate daytime, may be helpful to some people to adjust to new time zones.

People with the shift work type of the disorder benefit most from a non-changing work schedule. If rotating or changing shifts are unavoidable, rotations that occur in a clockwise direction, where shifts get progressively later and later, are preferable to those in a counter-clockwise direction. Also, when attempting to sleep, it is a good idea to create a comfortable sleeping environment by eliminating daytime noise and light.

Prognosis

Individuals with delayed sleep phase type often have great difficulty changing their sleep patterns and when they are able to change their circadian cycle, they have difficulty maintaining the changes.

People with jet lag type or shift work type can reduce symptoms often by simply decreasing the amount of travel or returning to a normal work schedule. When these changes are not possible, these individuals have trouble making the constant adjustments required to sleep and wake. People with the shift work type often report a reversal of symptoms two weeks after returning to a normal work and sleep schedule.

Prevention

Because circadian rhythm sleep disorder is usually related to environmental stressors, avoidance of these stressors (such as long-distance travel, shift work, and sleep-disrupting lifestyles) can prevent the disorder from beginning or continuing. People who are able to adhere strictly to a normal sleep-wake schedule can also offset circadian rhythm-related problems.

Citalopram

Definition

Citalopram is a selective serotonin reuptake inhibitor (SSRI) antidepressant drug that is sold in the United States under brand name Celexa.

Purpose

Citalopram is approved by the United States Food and Drug Administration (FDA) for the treatment of depression. It appears to be very effective in the treatment of **panic disorder** and is being evaluated for the treatment of **obsessive-compulsive disorder**, alcohol abuse, headache, **post-traumatic stress disorder**, and premenstrual syndrome.

Description

Serotonin is a **brain** chemical that carries nerve impulses from one nerve cell to another. Researchers think that depression and certain other mental disorders may be caused, in part, because there is not enough serotonin being released and transmitted in the brain. Like the other SSRI antidepressants, **fluoxetine** (Prozac), **sertraline** (Zoloft), and **paroxetine** (Paxil), citalopram increases the level of brain serotonin (also known as 5-HT). Increased serotonin levels in the brain may be beneficial in patients with obsessive-compulsive dirder, alcoholism, certain types of headaches, post-traumatic stress disorder (PTSD), premenstrual tension and mood swings, and panic disorder.

Citalopram is available in 20-mg, 40-mg, and 60-mg tablets.

Recommended dosage

The daily dosage of citalopram for depression ranges from 20–60 mg. The initial dosage is usually 20 mg per day. This dosage may then be increased to 40 mg per day at an interval of no less than one week. Most patients experience relief from depression at this dosage and do not require more than 40 mg per day. The dosage is taken once daily, either in the morning or in the evening.

Patients who are being treated for panic disorder receive doses ranging from 20–60 mg daily. A dosage of 20–30 mg daily appears to be optimal for the treatment of most panic disorders.

KEY TERMS

Obsessive-compulsive disorder—Disorder in which the affected individual has an obsession (such as a fear of contamination, or thoughts he or she doesn't like to have and can't control) and feels compelled to perform a certain act to neutralize the obsession (such as repeated handwashing).

Panic disorder—An anxiety disorder in which an individual experiences sudden, debilitating attacks of intense fear.

Post-traumatic stress disorder—A disorder caused by an extremely stressful or traumatic event (such as rape, act of war, or natural disaster) in which the trauma victim is haunted by flashbacks. In the flashbacks, the event is re-experienced in the present. Other symptoms include nightmares and feelings of anxiety.

Premenstrual syndrome—A severe change in mood that occurs in women immediately prior to, and during, their menstrual period.

Precautions

Patients who are allergic to citalopram, any other SSRI drug, or any component of the preparation should not take citalopram.

Patients with liver problems and elderly patients (over age 65) need to take smaller amounts of the drug. Dosage for these patients should start at 20 mg but can be increased to 40 mg daily if needed. Patients with kidney problems do not need dosage adjustments. Patients with history of mania, **suicide** attempts, or seizure disorders should start citalopram with caution and only under close physician supervision. There is no clinical data available on the use of citalopram in children and adolescents.

Side effects

More than 15% of patients develop **insomnia** while taking citalopram. Nausea and dry mouth occur in about 20% patients being treated with citalopram. Patients also experience tremor, anxiety, agitation, yawning, headaches, dizziness, restlessness, and sedation with citalopram therapy. These side effects usually diminish or disappear with continued use of the drug, although it may take up to four weeks for this to occur.

A drop in blood pressure and increased heart rate have been associated with citalopram use. In general,

patients do not experience weight gain or loss after starting citalopram.

Sexual dysfunction, which includes decreased sex drive in women and difficulty ejaculating in men, is also associated with the use of citalopram. In some patients, it may take up to 12 weeks for these side effects to disappear. In some patients these sexual side effects never resolve. If sexual side effects continue, the dose of citalopram may be reduced, patients can also have drug holidays where the weekend dose is either decreased or skipped, or they can discuss with their physician the risks and benefits of switching to another antidepressant.

Interactions

Citlopram interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all their health care providers, including dentists, that they are taking citalopram.

Certain antifungal medications such as itraconazole, fluconazole, ketoconazole, as well as the antibiotic erythromycin, can increase the levels of citalopram in the body. This can cause increased side effects. Levomethadyl, a medication used to treat opioid dependence, may cause toxicity to the heart if used together with citalopram.

Serious side effects called serotonin syndrome have resulted from the combination of antidepressants such as citalopram and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Serotonin syndrome usually consists of at least three of the following symptoms: diarrhea, fever, sweatiness, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking. Because of this, citalopram should never be taken in combination with MAO inhibitors. MAO inhibitors include isocarboxazid, nialamide, pargyline, selegiline, **phenelzine**, procarbazine, iproniazid, and clorgyline. Patient taking any MAO inhibitors, should stop the MAO inhibitor then wait at least 14 days before starting citalopram or any other antidepressant. The same holds true when discontinuing citalopram and starting an MAO inhibitor.

Buspirone, an anti-anxiety medication, should not be used together with citalopram. **Ginkgo biloba** and **St. John's Wort**, herbal supplements that are common in the United States, should not be taken together with citalopram.

Clinical Assessment Scales for the Elderly

Definition

The Clinical Assessment Scales for the Elderly, often abbreviated as CASE, is a diagnostic tool used to determine the presence of mental disorders and other conditions in elderly adults.

Purpose

The CASE is used to determine the presence of mental disorders in an elderly person as defined by the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revision (2000), which is also called *DSM-IV-TR*. The *DSM-IV-TR* is the basic reference work consulted by mental health professionals when making a **diagnosis**. The CASE, which is used with adults between the ages of 55 and 90, consists of a self-report form in which the person answers questions about himself or herself related to various scales. If the elderly adult is unable to complete the form because of cognitive or physical deficiencies, an other-rating form is provided for use by a knowledgeable caregiver, such as a spouse, child, or health care worker.

The CASE is not always used specifically for diagnosing mental disorders. It may be administered simply as a general assessment tool to gain insight about an elderly person. It may serve as a neurological screening tool to rule out other problems. The test makers also claim that it can be used as an early screening tool for **dementia** and thus allow elderly adults to receive medications to slow the progress of **Alzheimer's disease**.

KEY TERMS

Alzheimer's disease—An incurable dementia marked by the loss of cognitive ability and memory over a period of 10–15 years. Usually affects elderly people.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Reliability—The ability of a test to yield consistent, repeatable results.

Standardization—The administration of a test to a sample group of people for the purpose of establishing test norms.

Validity—The ability of a test to measure accurately what it claims to measure.

Description

The Clinical Assessment Scales for the Elderly were written by Cecil Reynolds and Erin Bigler. The most recent version of the test was published in 2001. The CASE consists of 10 clinical scales that measure the following: Anxiety; Cognitive Competence; Depression; Fear of Aging; Obsessive-Compulsiveness; **Paranoia**; Psychoticism; Somatization; Mania; and Substance Abuse. The degree to which an elderly person exhibits symptoms in these areas can help a mental health professional with the process of differential diagnosis for a mental disorder.

The CASE also includes three validity scales. These are helpful in evaluating the consistency of a person's responses and whether the person is faking his or her answers.

The person who is completing the CASE, whether they are using the self-rating or the other-rating form, responds to the test's written items. The test usually takes between 20–40 minutes to finish, but it is not timed. People are generally given as much time as they need to complete it.

A shorter version of the test, called the Clinical Assessment Scales for the Elderly-Short Form (CASE-SF) is also available. The CASE-SF takes about 20 minutes to complete and includes all 10 of the clinical scales.

Results

Scoring for the CASE is relatively simple. Scores are calculated for each scale and then compared to age-appropriate scores to determine the presence or severity of symptoms. For example, if a person scores high on the Depression scale, this information could be used as part of an overall diagnosis for a *DSM-IV* depressive disorder. A person scoring high in Psychoticism may have a psychotic disorder. For any specific *DSM-IV* diagnosis to be made, however, all of the required criteria for that disorder must be met. The results from the CASE may satisfy only some of the requirements.

The Fear of Aging scale assesses the person's degree of apprehension or concern about the aging process. It is not necessarily related to a particular *DSM-IV* disorder. Information about a person's fear of aging, however, may be helpful during the diagnostic process. It may also be useful information for a psychotherapist or other counselor, to understand the patient's concerns or to measure progress in therapy.

The CASE was standardized using a sample of 2000 adults in the United States, 1000 for each of the two test forms. The test has been shown to have good reliability and validity. For example, scores from the CASE Depression scale have been shown to correlate very well with scores on the widely used **Beck Depression Inventory**, or BDI.

Clomipramine

Definition

Clomipramine is an antidepressant drug used primarily to alleviate obsessions and compulsions in patients with **obsessive-compulsive disorder**. Clomipramine is also used in the treatment of depressive disorders and in

a number of other psychiatric and medical conditions. In the United States, the drug has also been known by the brand name Anafranil.

Purpose

Clomipramine is principally used in the treatment of the obsessions and compulsions of obsessive-compulsive disorder (OCD), when these symptoms greatly disrupt the patient's daily activities. Obsessions are repetitive thoughts and impulses, and compulsions are repetitive behaviors. Patients with OCD find these experiences inappropriate, distressing, and time-consuming.

Clomipramine may also be used in the treatment of depressive disorders, especially when associated with obsessions and compulsions, in **panic disorder**, pain management, sleep attacks (**narcolepsy** and cataplexy), and **anorexia nervosa**. The drug may help to reduce compulsive behaviors in a variety of disorders with such symptoms, including **trichotillomania** (hair-pulling), onychophagia (nail-biting), Tourette's disorder (tics and vocalizations), and childhood **autism**.

Description

Clomipramine is one of the tricyclic antidepressants, so-called because of the three-ring chemical structure common to these drugs. In the 1940s and 1950s, pharmaceutical researchers synthesized a number of new compounds for possible medical use as antihistamines and sedatives. After testing in animal experiments, a few of these substances were selected for human study. One potential drug, a tricyclic compound called **imipramine**, was not useful in calming agitation, but it had a striking effect in improving the mood of certain patients with depression.

Since the discovery of imipramine, many other tricyclic antidepressants have been developed with somewhat differing pharmacological activities and side effect profiles. Within this group of drugs, clomipramine is exceptionally potent in affecting levels of serotonin in the **brain**. In this action, it is similar to serotonin-selective antidepressant drugs, like **fluoxetine** (Prozac), which act specifically on serotonin levels and are effective in OCD. Serotonin is a messenger chemical (neurotransmitter) involved in transmitting signals between nerve cells. Clomipramine reduces the effects on serotonin neurotransmission in depression and OCD symptoms.

Recommended dosage

For adults, clomipramine is administered in dosages up to a maximum of 250 mg per day. Starting with a dose of 25 mg, the dosage is increased during the first two weeks to 100 mg per day. If needed, it is further increased gradually over the next several weeks. The initial dose is low to avoid side effects, and it is increased slowly to permit the patient to develop tolerance or adapt to side effects that may occur.

Older patients (over age 65), children, and adolescents are more sensitive to the side effects and toxicities of tricyclic antidepressants such as clomipramine. The maximum daily dose is usually lower for elderly patients than younger adults. For children and adolescents, the maximum recommended daily dose is the lesser of 100 mg or 3 mg per kg of body weight.

KEY TERMS

Autonomic—The part of the nervous system that governs the heart, involuntary muscles, and glands.

Cataplexy—A symptom of narcolepsy marked by a sudden episode of muscle weakness triggered by strong emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to minutes.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Kilogram—A metric unit of weight. It equals 2.2 lbs.

Monoamine oxidase (MAO) inhibitors—A group of antidepressant drugs that decreases the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Precautions

Epileptic **seizures** are the most important risk associated with clomipramine. Among patients taking the drug for six months or more, more than 1% may experience seizures. The risk of seizure increases with larger doses, and seizures have been reported to occur following abrupt discontinuation of the medication. Caution and physician supervision is required if the patient has a history of epilepsy or some other condition associated with seizures, such as brain damage or alcoholism.

Clomipramine and other tricyclic antidepressants often cause drowsiness. Activities requiring alertness, such as driving, should be avoided until patients understand how the drug affects them. Dizziness or lightheadedness may occur on arising from a seated position, due to sudden decreases in blood pressure. Fainting may also occur. Some patients, especially men with prostate enlargement, may experience difficulty urinating. Glaucoma may be worsened. Sensitivity to ultraviolet light may increase, and sunburns may occur more easily.

Tricyclic antidepressants, including clomipramine, should be used with caution and physician supervision in patients with heart disease, because of the possibility of adverse effects on heart rhythm. Adverse effects on the heart occur frequently when tricyclics are taken in overdose. Only small quantities of these drugs should be given to patients who may be suicidal.

Tricyclic antidepressants may cause dry mouth, due to decreased saliva, possibly contributing to the development of tooth decay, gum disease, and mouth infections. Patients should avoid sweets, sugary beverages, and chewing gum containing sugar.

It has not been determined whether clomipramine is safe to take during pregnancy, and the patient's need for this medicine should be balanced against the possibility of harm to the fetus. Tricyclic antidepressants may be secreted in breast milk and may cause sedation and depress breathing of a nursing infant.

Side effects

Clomipramine may cause many side effects. Initially, the side effects of tricyclic drugs may be more pronounced, but sensitivity often decreases with continued treatment.

The following more common side effects are grouped by the body system affected:

- Cardiovascular: decreases of blood pressure on arising, which may cause dizziness or fainting, increases of blood pressure, rapid heart rate, pounding heart, altered heart rhythm.
- Nervous system: sedation, dizziness, headache, confusion, nervousness, restlessness, sleep difficulties, numbness, tingling sensations, tremors, twitches, increased seizure tendency.
- Digestive system: dry mouth, nausea, loss of appetite, indigestion, and constipation.
- Autonomic: blurred vision, increased sweating.
- Genital/urinary: difficulty urinating, menstrual pain, ejaculatory difficulty, impotence, decreased sex drive.
- Skin: rashes, sensitivity to sunlight.
- Body as a whole: **fatigue**, weight gain, flushing.

Less commonly, tricyclic drugs may cause adverse effects on almost any organ or system of the body, particularly the blood, hormones, kidney, and liver. Patients should consult their physicians if symptoms develop or bodily changes appear.

Interactions

Tricyclic antidepressants, such as clomipramine, may interact with many other drugs. Patients should inform their physicians about all other drugs they are taking before starting treatment.

Clomipramine may intensify the effects of other drugs that act on serotonin levels, possibly producing serotonin syndrome, a rare but dangerous condition with fever, sweating, tremors, and changes in mental state. Drugs that may interact this way include other antidepressants, especially selective serotonin re-uptake inhibitor (SSRI) drugs and monoamine oxidase (MAO) inhibitors. These drugs should not be taken within two weeks of taking clomipramine. Other drugs to avoid include lithium, **alprazolam** (Xanax), fenfluramine (Pondimin), amphetamine, dextromethorphan (used in cough suppressants), meperidine (Demerol), and tramadol (Ultram).

Tricyclic drugs may intensify the effects of other drugs causing sedation, including alcohol, **barbiturates**, narcotic pain medications, minor tranquilizers, and antihistamines. Tricyclics may cause excessive reductions of blood pressure in patients taking blood pressure medicine, especially on arising or standing up. Conversely, these drugs may interfere with the pressure-reducing effects of certain other blood pressure medicines and may necessitate an adjustment in dosage. Tricyclics may interact with thyroid medications to produce abnormalities of heart rhythm. Concurrent use of tricyclic antidepressants with other psychiatric medicines may result in intensification of certain side effects.

Certain drugs may interfere with the elimination of tricyclic antidepressants from the body, causing higher blood levels and increased side effects. This effect may occur with cimetidine (Tagamet), other antidepressants, **methylphenidate** (Ritalin, Concerta), and some antipsychotic medications.

Clonazepam

Definition

Clonazepam belongs to a group of drugs called benzodiazepines. Benzodiazepines are medications that help relieve nervousness, tension, symptoms of anxiety, and some types of **seizures** by slowing the central nervous system. In the United States, clonazepam is sold under brand name Klonopin.

Purpose

Although clonazepam is approved by the United States Food and Drug Administration (FDA) for the treatment of **panic disorder** and some types of epilepsy, it is also used to treat **social phobia**, mania, and **post-traumatic stress disorder**.

KEY TERMS

Anorexia—Loss of appetite or unwillingness to eat. Can be caused by medications, depression, or many other factors.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Description

Clonazepam belongs to a group of drugs called benzodiazepines. Benzodiazepines are sedative-hypnotic drugs that help to relieve nervousness, tension, anxiety symptoms, and seizures by slowing the central nervous system. To do this, they block the effects of a specific chemical involved in the transmission of nerve impulses in the **brain**, decreasing the excitement level of the nerve cells.

When clonazepam is used to treat panic disorder, it is more sedating than **alprazolam**, another benzodiazepine drug used to treat panic disorder. However, unlike alprazolam, clonazepam may trigger depressive episodes in patients with a previous history of depression. In people who experience social phobia, treatment with clonazepam reduces the rate of depression. The use of clonazepam for social phobia is considered off-label use—a use that is legal, but not specifically approved by the FDA.

Clonazepam comes in 0.5 mg-, 1 mg-, and 2 mg-tablets.

Recommended dosage

For panic disorder, the initial recommended dose is 0.25 mg twice daily. This dose can be increased every three days in increments of 0.125–0.25 mg twice daily. The target dose for panic disorder is 1.0 mg per day, although some people benefit from doses up to a maximum of 4 mg per day. When a person stops taking clonazepam, the drug should be gradually discontinued by decreasing the dose by 0.125 mg twice daily every three days.

Although clonazepam is not FDA-approved for the treatment of post-traumatic stress disorder, doses in the range of 0.25–3 mg daily appears to help treat symptoms of this disorder. Daily dosages for the treatment of social

phobia range from 1.0–2.5 mg, while the dosage to control mania may be as high as 10 mg daily.

Precautions

Women who are pregnant should not use clonazepam, because it may harm the developing fetus. Clonazepam should never be taken by people who have had an allergic reaction to it or another benzodiazepine drug such as **diazepam** (Valium). People with narrow-angle glaucoma or severe liver disease should not take clonazepam. People who have kidney disease may need to take a reduced dosage of the drug. Saliva production may increase while taking clonazepam. Because of this, people with respiratory disease or an impaired gag reflex should use clonazepam with close physician supervision.

Because clonazepam is a nervous system depressant, it should not be taken with other such depressants, such as alcohol, other sedatives, sleeping pills, or tranquilizers. People taking clonazepam may feel unusually drowsy and mentally sluggish when they first start taking the drug. They should not drive, operate dangerous machinery, or engage in hazardous activities that require mental alertness until they see how clonazepam affects them. This excessive sedation usually goes away after a short time on the drug.

People who have underlying depression should be closely monitored while taking clonazepam, especially if they are at risk for attempting **suicide**.

Side effects

The main side effects of clonazepam are sedation, dizziness, impaired coordination, depression, and **fatigue**. Some people experience decreased sex drive while taking clonazepam.

A small number of people develop sinus problems and upper respiratory tract infections while taking clonazepam. One of the side effects of clonazepam may be increased salivation. This may cause some people to start coughing while taking clonazepam. Clonazepam may also cause anorexia and dry mouth. It may cause either constipation or diarrhea. There are a few reports of clonazepam causing menstrual irregularities or blurred vision.

Interactions

Clonazepam may increase the sedative effects of other drugs that depress the central nervous system such as certain pain strong medicines (opiates such as codeine, oxycodone, hydromorphone) and antihistamines (found in many cold and allergy medications). The sedative effect is also increased if clonazepam is taken with alcohol.

Disulfiram (Antabuse), a medication used to treat alcohol dependence, increases the effect of clonazepam. Medications that make clonazepam ineffective include phenobarbital, phenytoin, **carbamazepine**, theophylline, rifampin, and rifabutin.

Clonidine

Definition

Clonidine belongs to a class of drugs called central alpha-adrenergic agonists. In the United States, clonidine tablets are sold under the brand name Catapres and clonidine skin patches are sold under the brand name Catapres-TTS. The tablets are also available generically. There is also an injectable form that is administered directly into the spinal cord for the treatment of postoperative pain.

Purpose

Clonidine tablets and patches are approved by the United States Food and Drug Administration (FDA) for the treatment of high blood pressure. However, clonidine has been found to be useful in the treatment of alcohol, opiate, and nicotine withdrawal syndromes, **attention-deficit/hyperactivity disorder** (ADHD), and Tourette's syndrome, one of the **tic disorders**.

Description

Clonidine was synthesized in 1960s and was initially tested as a nasal decongestant. In the United States, clonidine was first used to treat hypertension although it has also been investigated for treatment of different neuropsychiatric disorders. Clonidine works on specific nerve cells in the **brain** that are responsible for lowering blood pressure, slowing heart rate, and decreasing the body's reaction to the withdrawal of chemicals like alco-

hol, opiates, cocaine, and nicotine. Because of this, clonidine is often used to treat the symptoms of drug, alcohol, and nicotine withdrawal.

Clonidine is beneficial in opiate withdrawal because it treats symptoms that are commonly associated with that condition (watery eyes and nose, diarrhea, irritability). For this condition, clonidine is often used alone. For the treatment of alcohol withdrawal, clonidine is usually combined with benzodiazepine tranquilizers such as Librium, Valium, Xanax, or Ativan.

Several studies of treatment for smoking cessation showed patients treated with clonidine had decreased nicotine craving. Clonidine skin patches appear to be more effective than tablets in this condition. Both dermal patches and tablets are effective in the treatment of Tourette's syndrome and ADHD.

Clonidine tablets are available in 0.1-mg, 0.2-mg, and 0.3-mg strengths. Clonidine skin patches are available in 0.1-mg, 0.2-mg, and 0.3-mg per day patches. Each patch lasts seven days.

Recommended dosage

Dosages of 0.4–0.6 mg have been used for the treatment of alcohol withdrawal. Total daily dosage for the treatment of opiate withdrawal range between 0.5 and 1.4 mg, depending on the stage as well as the severity of withdrawal symptoms. If the clonidine patch is used to treat nicotine withdrawal symptoms, dosages that deliver 0.1–.2 mg daily are used. For oral therapy (tablets), a total dosage of 0.2–0.4 mg daily is taken in divided doses.

Pediatric doses of clonidine are calculated based on the child's body weight. Clonidine dosage for ADHD in children is 5 micrograms per kilogram of body weight per day orally in four divided doses. Children who require a daily dosage of 0.2 mg usually can use the 0.3 mg dermal patch. If ADHD is associated with sleep disturbances, low to moderate doses of clonidine can be taken at bedtime. Oral doses in children with Tourette's syndrome range from 3 to 6 micrograms per kilogram of body weight per day divided into two to four even doses.

Precautions

Clonidine should not be used by people who have a known allergy to this drug. If a person has underlying depression, clonidine should be used with caution and under close physician supervision.

Clonidine should not be abruptly withdrawn but rather, slowly decreased over several days to avoid withdrawal symptoms. Withdrawal symptoms include increases in blood pressure, irritability, nervousness, **insomnia**, and headache. Because of the possibility of withdrawal, clonidine should not be used in patients who are unwilling or unable to follow the prescribing information.

Clonidine should be used only with caution and close physician supervision in patients with chronic renal failure, coronary artery disease, and in patients with preexisting eye problems. Often people with kidney disease should take a reduced dosage. Clonidine should not be used by pregnant women, except in the rare case where the benefits of taking clonidine outweigh the risks to the developing fetus.

Side effects

The most common side effect associated with clonidine is dizziness associated with sudden changes in position such as standing up rapidly. In order to avoid this, patients should stand up slowly. People using the dermal patch may develop rash, hair loss, a burning sensation on the skin, or other skin irritations where the patch is applied. Switching to tablets may not completely eliminate these skin problems, however.

Clonidine can cause dry mouth, constipation, nausea, daytime sleepiness, weakness, and lethargy. These side effects may take several weeks to disappear. In some cases, these side effects can be eliminated with dosage readjustment. In addition, clonidine may cause eye dryness, loss of sex drive, and decreased sexual activity.

If patients experience weight gain in the beginning of therapy, they can expect this side effect to decline over a period of several days to weeks.

KEY TERMS

Attention-deficit/hyperactivity disorder (ADHD)—A learning and behavioral disorder characterized by difficulty in sustaining attention, impulsive behavior, and excessive activity.

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Tourette syndrome—Neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics that come and go over years, usually beginning in childhood and becoming chronic. Sometimes the tics include inappropriate language.

Interactions

Clonidine's blood pressure-lowering effects may be enhanced by other drugs that lower blood pressure. Conversely, the blood pressure-lowering effects of clonidine may be negated by many antidepressants.

Clorazepate

Definition

Clorazepate is a medication that belongs to a family of drugs called benzodiazepines—a group of pharmacologically active compounds used to produce a calming effect by relieving anxiety and tension. In the United States, clorazepate is sold under brand names Tranxene and Gen-XENE.

Purpose

Clorazepate is used for the treatment of anxiety and alcohol withdrawal. Moreover, clorazepate is an adjunct in the management of partial **seizures**.

Description

Clorazepate binds to different sites in the **brain**, causing them to shift into a state that is less excitable. It is very effective in treating **anxiety and anxiety disorders**. Moreover, anxiety associated with undergoing surgical procedures is controlled with clorazepate. Clorazepate alone is not efficacious in treating seizures; however, if used along with other standard seizure medications, such as phenobarbital, primidone, phenytoin, **carbamazepine**, and **valproic acid**, better seizure control may be achieved. Convulsions and anxiety associated with alcohol withdrawal are controlled with clorazepate.

KEY TERMS

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Clorazepate is available in two different formulations. Clorazepate tablets come in 3.75-, 7.5-, and 15-mg doses, while slow-release tablets, administered once daily, are available in 11.25- and 22.5-mg strengths. Capsules are available in 3.75-, 7.5-, and 15-mg strengths.

Recommended dosage

If used for anxiety, the dose of clorazepate usually ranges anywhere from 15 mg to 60 mg daily in divided dose intervals. Usually, however, the average dose is 30 mg daily given in two to four doses. If slow-release formulation is used, the dose of either 11.25 mg or 22.5 mg is usually administered at bedtime. Slow-release products should not be used to initiate therapy.

Doses of clorazepate for the management of seizures differ in adult and pediatric populations. Patients who are nine to 12 years of age should be started on 3.75–7.5 mg twice daily. This dose should be increased by no more than 3.75 mg weekly. The maximum dose per day is 60 mg administered in two to three divided doses. Children older than 12 and adults should receive 7.5 mg two to three times daily. This can be increased to a higher dose by adding 7.5 mg at weekly intervals. The total daily dose should not exceed 90 mg daily administered in two to three doses. In patients undergoing alcohol withdrawal, the first dose is 30 mg. Treatment is continued with 15 mg two to four times daily for the maximum dose of 90 mg in one day. Once maximum dose is achieved, the dose is gradually decreased over subsequent days.

Precautions

Pregnant women should not take clorazepate. Patients who have narrow-angle glaucoma should not take clorazepate, as this may worsen their condition. Clorazepate should not be used in patients younger than nine years of age.

If depression coexists with anxiety, clorazepate should be used with caution as suicidal tendencies may be present. (One of the side effects with this medication is depression; if a patient has an underlying problem with depression, that problem can be exacerbated with clorazepate.) Patients should be cautioned against engaging in hazardous occupations requiring mental alertness, since clorazepate causes drowsiness and dizziness. Abrupt discontinuation of clorazepate has been associated with withdrawal symptoms and seizures. Hence, doses of clorazepate should be slowly decreased in patients who have been taking clorazepate continuously over several weeks. Other withdrawal symptoms may include nervousness, **insomnia**, irritability, diarrhea, and muscle aches. The doses for elderly patients, as well as patients with liver or kidney problems, may need to be decreased.

Side effects

The most common side effects include drowsiness, dizziness, and confusion. There are a few reports about behavioral changes associated with the use of clorazepate and they include rage, depression, irritability, and aggression.

Other side effects include vision disturbances—such as blurred and double vision—decreased libido, nausea, vomiting, either decreased or increased appetite, and diarrhea or constipation. In a few cases, clorazepate has been associated with liver toxicity where patients developed jaundice or fever. It is also known to cause a rash.

Interactions

Simultaneous use of clorazepate and dong quai, a Chinese herb, has been associated with excessive muscle relaxation and central nervous system depression. Other herbs that should not be used with clorazepate include **ginkgo biloba** and **kava kava**.

Omeprazole, a medication used to treat heartburn, should not be used together with clorazepate. Medicines to treat disorders associated with increased acid secretions—such as ranitidine, sucralfate, and pantoprazole—are not contraindicated with clorazepate. **Valerian**, an herb used as a sleep aid, binds to the same receptors in the brain as clorazepate; thus, the desired effects of clorazepate may not be seen in patients taking it and valerian at the same time.

Clorazepate may increase the effects of other drugs that cause drowsiness,. These drugs include antihistamines (such as Benadryl), sedatives (usually used to treat insomnia), pain relievers, anxiety and seizure medicines, and muscle relaxants. Alcohol combined with clorazepate also causes excessive drowsiness.

Clozapine

Definition

Clozapine is an antipsychotic drug used to alleviate the symptoms and signs of schizophrenia—a form of severe mental illness— which is characterized by loss of contact with reality, **hallucinations**, **delusions**, and unusual behavior. In the United States, the drug is also known by the brand name Clozaril.

Purpose

Clozapine is principally used to reduce the signs and symptoms of severe schizophrenic illness. The drug is intended for use in patients with severe **schizophrenia** who have not responded to any other antipsychotic drug. Clozapine is also used in patients with severe schizophrenia when other antipsychotic medications have caused intolerable side effects.

Description

Clozapine is considered an atypical antipsychotic drug. Atypical antipsychotics differ from typical antipsychotics in their effectiveness in schizophrenia and their profile of side effects. Clozapine may reduce the signs and symptoms of schizophrenia in a large proportion of treatment-resistant schizophrenic patients who do not respond to typical antipsychotics. Moreover, the drug is less likely than typical antipsychotics to cause **tardive dyskinesia** and other extrapyramidal side effects. Tardive dyskinesia is a syndrome of involuntary, uncoordinated movements that may not disappear or may only partially improve after the drug is stopped. Tardive dyskinesia involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles. The incidence of tardive dyskinesia increases with increasing age and with increasing dosage. It

KEY TERMS

Agranulocytosis—A blood disorder characterized by a reduction in the number of circulating white blood cells (granulocytes). White blood cells defend the body against infections. Agranulocytosis is a potential side effect of some of the newer antipsychotic medications used to treat schizophrenia.

Antipsychotic drug—A medication used to treat psychotic symptoms of schizophrenia such as hallucinations, delusions and delirium. May be used to treat symptoms in other disorders, as well.

Autonomic—The part of the nervous system that governs the heart, involuntary muscles, and glands.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Extrapyramidal side effects—A group of neurological side effects including muscle spasms, involuntary movements, and symptoms that resemble Parkinson's disease (also called drug-induced Parkinsonism).

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Tardive dyskinesia—A condition that involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles that usually occurs either late in antipsychotic therapy or even after the therapy is discontinued. It may be irreversible.

may also appear after use of the antipsychotic has stopped. Women are at greater risk than men for developing tardive dyskinesia. There is no known effective treatment for this syndrome, although gradual (but rarely complete) improvement may occur over a long period.

Clozapine was the first atypical antipsychotic drug to be developed. In the late 1980s, clozapine was tested in severely ill schizophrenic patients who had been treated with a typical antipsychotic drug but had not shown much improvement. A significant proportion of these patients improved as a result of treatment with clozapine.

The superiority of clozapine in treatment-resistant patients is considered an important advance, but the drug is not without problems. Clozapine is generally considered the most toxic of the antipsychotic drugs. It causes agranulocytosis, a life-threatening depletion of white blood cells, in 1-2% of patients. It also causes epileptic **seizures** and adverse effects on the heart and blood pressure more frequently than other antipsychotic medicines. Clozapine is usually reserved for the most severely ill schizophrenic patients who have not responded to other treatments. Other atypical antipsychotic drugs have been developed in recent years, and they are considered safer to use than clozapine.

The mechanisms of action of antipsychotic drugs are not completely understood. The effect of clozapine is believed to be related to its actions in blocking neurotransmission due to the **neurotransmitters** dopamine and serotonin in a region of the **brain** called the limbic system, which is involved with emotions and motivation. The actions of clozapine may target the limbic system more specifically than those of typical antipsychotic drugs.

Clozapine is available as Clozaril, the only brand, as 25- and 100-mg tablets.

Recommended dosage

The usual dosage of clozapine is 300–600 mg per day; however, some patients may require daily dosages of up to 900 mg. To minimize side effects, the initial dose of clozapine is 12.5 mg (one-half tablet) twice a day, and the dose is increased by 25–50 mg each day, until the dose reaches 300–450 mg per day. The daily dosage of the drug is then determined based on the individual patient's response, but increases should not exceed 100 mg once or twice a week.

Precautions

Clozapine may cause agranulocytosis, a life-threatening depletion of white blood cells. The blood cells affected by clozapine defend the body against infections by bacteria and other microorganisms, and patients with agranulocytosis are subject to severe infections. Clozapine treatment is reserved for the most severely ill schizophrenic patients who have not responded to other treatments. Clozapine is available only through a distribution system that assures close monitoring of white blood cells. Patients must have white blood cell counts determined before starting treatment, once every week for the first six months, once every other week after that,

and once a week for the first month after clozapine treatment is stopped.

Clozapine may cause epileptic seizures in about 5% of patients. The frequency of seizures goes up as the dose of the drug is increased. Patients who experience seizures on clozapine should usually have the drug discontinued or the dose reduced. Neuroleptic malignant syndrome (NMS), a dangerous condition with high fever, muscular rigidity, rapid pulse, sweating, and altered mental state, may occur with all antipsychotic medications, including clozapine. NMS requires immediate medical treatment.

Clozapine frequently causes sedation and may interfere with driving and other tasks requiring alertness. The drug may increase the effects of alcohol and sedatives. Clozapine may cause low blood pressure and sudden drops in blood pressure on standing up, which may cause dizziness or fainting. Elevated heart rate may occur in 25% of patients; this effect may be a serious risk for patients with heart disease. Clozapine-induced fever, unrelated to any illness, may occur. The fever usually subsides within a few days, but it may require stopping the drug.

The safety and effectiveness of clozapine in children under 16 years old have not been established. Elderly patients may be particularly sensitive to sedation, low blood pressure, and other side effects. The drug should be used with caution in older patients. Clozapine should be used in pregnant women only when strictly necessary. The drug has not been adequately studied in pregnancy. In animal studies, however, clozapine has not produced harmful effects on the fetus. Clozapine may be secreted in breast milk, and breast-feeding may not be advisable.

Side effects

Clozapine may cause many side effects. The following side effects are grouped by the body system affected:

- Cardiovascular: decreases of blood pressure, especially on arising from a seated or lying position, which may cause dizziness or fainting; rapid heart rate, changes in heart rhythm and electrocardiogram.
- Nervous system: sedation, increased seizure tendency.
- Digestive system: increased appetite, excessive salivation, nausea, constipation, abnormal liver tests, elevated blood sugar.
- Autonomic: blurred vision, exacerbation of glaucoma, dry mouth, nasal congestion, decreased sweating; difficulty urinating, particularly in men with enlarged prostate.
- Skin: rashes.
- Body as a whole: weight gain, fever.

Interactions

Clozapine may interact with many other drugs. Patients should inform their physicians about all other drugs they are taking before starting treatment. Because of the risk of agranulocytosis, clozapine should not be given along with medications that suppress production of blood cells.

Clozapine may intensify the effects of drugs causing sedation, including alcohol, **barbiturates**, narcotic pain medications, minor tranquilizers, and antihistamines. Similarly, clozapine may cause excessive reductions of blood pressure in patients taking other medicines that lower blood pressure. Clozapine may also intensify side effects of drugs that cause blurred vision, dry mouth, diminished sweating in hot weather, and constipation. Many other antipsychotics and antidepressants cause such side effects.

Clozapine may potentiate (increase) the effects of other medications that also lower seizure threshold (make it more likely to have seizure), such as steroid drugs, the asthma medication theophylline, and many other psychiatric drugs. Patients with epilepsy may require adjustment in their dosage of anti-seizure medications. Lithium may increase the risk of seizures and other nervous system adverse effects when given with clozapine.

Certain drugs that are eliminated by the liver may interfere with the elimination of clozapine from the body, causing higher blood levels and increased side effects. Conversely, clozapine may interfere with the elimination of other drugs that are eliminated by the liver. Antidepressants that affect brain serotonin levels may increase blood levels of clozapine, possibly causing increased side effects.

Cocaine and related disorders

Definition

Cocaine is extracted from the coca plant, which grows in Central and South America. The substance is processed into many forms for use as an illegal drug of abuse. Cocaine is dangerously addictive, and users of the drug experience a "high"—a feeling of euphoria or intense happiness, along with hypervigilance, increased sensitivity, irritablity or anger, impaired judgment, and anxiety.

Forms of the drug

In its most common form, cocaine is a whitish crystalline powder that produces feelings of euphoria when ingested. In powder form, cocaine is known by such street names as "coke," "blow," "C," "flake," "snow" and "toot." It is most commonly inhaled or "snorted." It may also be dissolved in water and injected.

Crack is a form of cocaine that can be smoked and that produces an immediate, more intense, and more short-lived high. It comes in off-white chunks or chips called "rocks."

In addition to their stand-alone use, both cocaine and crack are often mixed with other substances. Cocaine may be mixed with methcathinone to create a "wildcat." Cigars may be hollowed out and filled with a mixture of crack and marijuana. Either cocaine or crack used in conjunction with heroin is called a "speedball." Cocaine used together with alcohol represents the most common fatal two-drug combination.

Description

Cocaine-related disorders is a very broad topic. According to the mental health clinician's handbook, ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revised (also known as the *DSM-IV-TR*), the broad category of cocaine-related disorders can be subdivided into two categories: cocaine use disorders and cocaine-induced disorders. Cocaine use disorders include cocaine dependence and cocaine abuse. Cocaine-induced disorders include:

- cocaine intoxication
- cocaine withdrawal
- cocaine intoxication **delirium**
- cocaine-induced psychotic disorder, with **delusions**
- cocaine-induced psychotic disorder, with **hallucinations**
- cocaine-induced mood disorder
- cocaine-induced anxiety disorder
- cocaine-induced sexual dysfunction
- cocaine-induced sleep disorder
- cocaine-related disorder not otherwise specified

Cocaine use disorders

COCAINE ABUSE. For the cocaine abuser, the use of the substance leads to maladaptive behavior over a 12-month period. The person may fail to meet responsibilities at school, work, or home. The cocaine abuse impairs the affected person's judgment, and he or she puts him- or herself in physical danger to use the substance. For example, the individual may use cocaine in an unsafe environment. The person who abuses cocaine may be arrested or charged with possession of the substance, yet will continue to use cocaine despite all of the personal and legal problems that may result.

COCAINE DEPENDENCE. Cocaine dependence is even more serious than cocaine abuse. Dependence is a maladaptive behavior that, over a three-month period, has caused the affected individual to experience tolerance for and withdrawal symptoms from cocaine. Tolerance is the need to increase the amount of cocaine intake to achieve the same desired effect. In other words, someone who is dependent on cocaine needs more cocaine to produce the same "high" that a lesser amount produced in the past. The dependent person also experiences cocaine withdrawal. Withdrawal symptoms develop within hours or days after cocaine use that has been heavy and prolonged and then abruptly stopped. The symptoms include irritable mood and two or more of the following symptoms: **fatigue**, nightmares, difficulty sleeping or too much sleep, elevated appetite, agitation (restlessness), or slowed physical movements. The onset of withdrawal symptoms can cause a person to use more cocaine to avoid these painful and uncomfortable symptoms. The dependent person uses larger amounts of cocaine for longer periods of time than intended. He or she cannot cut back on the use of the substance, often has a difficult time resisting cocaine

when it is available, and may abandon work or school to spend more time acquiring and planning to acquire more cocaine. The individual continues to use the cocaine despite the negative effects it has on family life, work, and school.

KEY TERMS

Amygdala—An almond-shaped brain structure in the limbic system that is activated in acute stress situations to trigger the emotion of fear.

Coca plant—The plant that is the source of cocaine.

Crack—A slang term for a form of cocaine that is smokable.

Craving—An overwhelming need to seek out more drugs.

Physical dependence—A maladaptive behavior that over a three-month period has caused the individual to experience tolerance and withdrawal symptoms.

Tolerance—Progressive decrease in the effectiveness of a drug with long-term use.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

Cocaine-induced disorders

COCAINE INTOXICATION. Cocaine intoxication occurs after recent cocaine use. The person experiences a feeling of intense happiness, hypervigilance, increased sensitivity, irritability or anger, with impaired judgment, and anxiety. The intoxication impairs the person's ability to function at work, school, or in social situations. Two or more of the following symptoms are present immediately after the use of the cocaine:

- enlarged pupils
- elevated heart rate
- elevated or lowered blood pressure
- chills and increased sweating
- nausea or vomiting
- weight loss
- agitation or slowed movements
- weak muscles
- chest pain
- coma
- confusion
- irregular heartbeat
- depressed respiration
- seizures
- odd postures
- odd movements

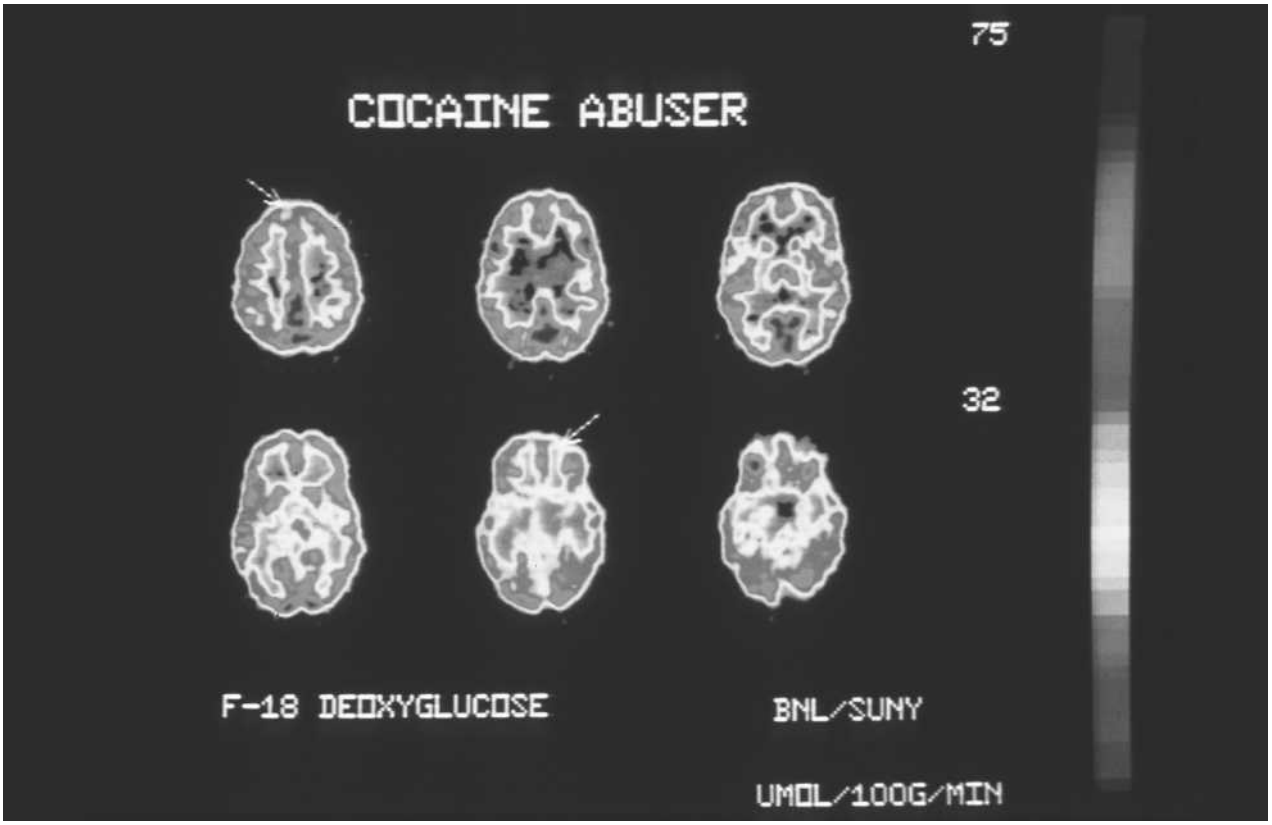
COCAINE WITHDRAWAL. As mentioned, withdrawal symptoms develop within hours or days after cocaine use that has been heavy and prolonged and then abruptly stopped. The symptoms include irritable mood and two or more of the following symptoms: fatigue, nightmares, difficulty sleeping or too much sleep, elevated appetite, agitation (restlessness), or slowed physical movements.

COCAINE-INDUCED DELIRIUM. According to the *DSM-IV-TR*, several criteria must be met in order for a health care professional to establish the **diagnosis** of cocaine-induced delirium. Patients have a disturbance of their level of consciousness or awareness, evidenced by drowsiness or an inability to concentrate or pay attention. Patients also experience a change in their cognition (ability to think) evidenced by a deficit in their language or their memory. For example, these patients may forget where they have placed an item, or their speech is confusing. These symptoms have rapid onset within hours or days of using cocaine and the symptoms fluctuate throughout the course of the day. These findings cannot be explained by **dementia** (state of impaired thought processes and memory that can be caused by various diseases and conditions) and the doctor must not be able to recognize some other physical reason that can account for the symptoms other than cocaine intoxication.

COCAINE-INDUCED PSYCHOTIC DISORDER, WITH DELUSIONS. The person suffering from this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience delusions (beliefs that the person continues to maintain, despite evidence to the contrary). In order for this state to be considered cocaine-induced psychotic disorder, these symptoms cannot be due to another condition or substance.

COCAINE-INDUCED PSYCHOTIC DISORDER, WITH HALLUCINATIONS. This condition is the same as cocaine-induced psychotic disorder with delusions, except that this affected individual experiences hallucinations instead of delusions. Hallucinations can be described as hearing and seeing things that are not real.

COCAINE-INDUCED MOOD DISORDER. The person suffering from this disorder has experienced intoxication or withdrawal from cocaine within a month from the time



Colored positron emission tomography (PET) brain scans of a cocaine user. *(Photo Researchers, Inc. Reproduced by permission.) See color insert for color version of photo.*

he or she begins to experience depressed, elevated, or irritable mood with **apathy** (lack of empathy for others, and lack of showing a broad range of appropriate emotions).

COCAINE-INDUCED ANXIETY DISORDER. The person suffering from this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience anxiety, panic attacks, obsessions, or compulsions. Panic attacks are discrete episodes of intense anxiety. Persons affected with panic attacks may experience accelerated heart rate, shaking or trembling, sweating, shortness of breath, or fear of going crazy or losing control, as well as other symptoms. An **obsession** is an unwelcome, uncontrollable, persistent idea, thought, image, or emotion that a person cannot help thinking even though it creates significant distress or anxiety. A **compulsion** is a repetitive, excessive, meaningless activity or mental exercise which a person performs in an attempt to avoid distress or worry.

COCAINE-INDUCED SEXUAL DYSFUNCTION. The person suffering from this disorder has experienced intoxication or withdrawal from cocaine within a month from the time he or she begins to experience sexual difficulties, and these difficulties are deemed by the clinician to be due directly to the cocaine use. Substance-induced sexual difficulties can range from impaired desire, impaired arousal, impaired orgasm, or sexual pain.

COCAINE-INDUCED SLEEP DISORDER. This disorder is characterized by difficulty sleeping (**insomnia**) during intoxication or increased sleep duration when patients are in withdrawal.

COCAINE-RELATED DISORDER NOT OTHERWISE SPECIFIED. This classification is reserved for clinicians to use when a cocaine disorder that the clinician sees does not fit into any of the above categories.

Causes and symptoms

Causes

BIOCHEMICAL/PHYSIOLOGICAL CAUSES. Twin studies have demonstrated that there is a higher rate of cocaine abuse in identical twins as compared to fraternal twins. This indicates that genetic factors contribute to the development of cocaine abuse. This finding also indicates, however, that unique environmental factors contribute to the development of cocaine abuse, as well. (If genes alone determined who would develop cocaine dependence,

100% of the identical twins with the predisposing genes would develop the disorder. However, because the results show only a relationship, or a correlation, between genetics and cocaine use among twins, these results indicate that other factors must be at work, as well.) Studies have also shown that disorders like **attention-deficit/hyperactivity disorder** (ADHD), **conduct disorder**, and **antisocial personality disorder** all have genetic components, and since patients who abuse cocaine have a high incidence of these diagnoses, they may also be genetically predisposed to abusing cocaine.

REINFORCEMENT. Learning and conditioning also play a unique role in the perpetuation of cocaine abuse. Each inhalation and injection of cocaine causes pleasurable feelings that reinforce the drug-taking procedure. In addition, the patient's environment also plays a role in cueing and reinforcing the experience in the patient's mind. The association between cocaine and environment is so strong that many people recovering from cocaine **addiction** report that being in an area where they used drugs brings back memories of the experience and makes them crave drugs. Specific areas of the **brain** are thought to be involved in cocaine craving, including the amygdala (a part of the brain that controls aggression and emotional reactivity), and the prefrontal cortex (a part of the brain that regulates anger, aggression, and the brain's assessment of fear, threats, and danger).

Symptoms

The following list is a summary of the acute (short-term) physical and psychological effects of cocaine on the body:

- blood vessels constrict
- elevated heart rate
- elevated blood pressure
- a feeling of intense happiness
- elevated energy level
- a state of increased alertness and sensory sensitivity
- elevated anxiety
- panic attacks
- elevated self-esteem
- diminished appetite
- spontaneous ejaculation and heightened sexual arousal
- psychosis (loss of contact with reality)

The following list is a summary of the chronic (long-term) physical and psychological effects of cocaine on the body:

- depressed mood
- irritability
- physical agitation
- decreased motivation
- difficulty sleeping
- hypervigilance
- elevated anxiety
- panic attacks
- hallucinations
- psychosis

Demographics

The patterns of cocaine abuse in the United States have changed much over the past thirty years. The patterns have also been changing in other parts of the world as well, including South America and Western Europe. In the United States, several studies have attempted to track drug abuse in many different populations. The studies include: the Monitoring the Future Study (MTF); the National Household Survey on Drug Abuse (NHSDA); the Drug Abuse Warning Network (DAWN), which gets reports from Emergency Rooms and medical examiners' offices on drug-related cases and deaths; and Arrestee Drug Abuse Monitoring (ADAM), which gets information on urine samples obtained from people who have been arrested.

In the annual MTF study, cocaine use among high school seniors had declined from 13.1% in 1985 to 3.1% in 1992—the lowest it had been since 1975 when the survey was first implemented. The rate of cocaine use began to rise again and peaked at 5.5% in 1997. The NHSDA found that the levels of cocaine use declined over the same time period. The decline in the rates has been thought to be due in part to education about the risks of cocaine abuse.

The incidence of new crack cocaine users has also decreased. There was a minimal decline in the numbers of excessive cocaine users between the years 1985 and 1997. The Epidemiologic Catchment Area (ECA) studies done in the early 1980s combined cocaine dependence with cocaine abuse and found that one-month to six-month prevalence rates for cocaine abuse and dependence were low or could not be measured. The lifetime rate of cocaine abuse was 0.2%.

A 1997 study from The National Institute on Drug Abuse indicates that among outpatients who abuse substances, 55% abuse cocaine.

Cocaine abuse affects both genders and many different populations across the United States. Males are one-

and-a-half to two times more likely to abuse cocaine than females. Cocaine began as a drug of the upper classes in the 1970s; now the socioeconomic status of cocaine users has shifted. Cocaine is more likely to be abused by the economically disadvantaged because it is easy for them to get, and it is inexpensive ($10 for a small bag of crack cocaine). These factors have led to increased violence (because people who are cocaine dependent often will become involved in illegal activity, such as drug dealing, in order to acquire funds for their habit) and higher rates of acquired immune deficiency (AIDS) among disadvantaged populations.

Diagnosis

If a mental health clinician suspects cocaine use, he or she may ask the patient specifically about swallowing, injecting, or smoking the substance. Urine and blood testing will also be conducted to determine the presence of the substance. Doctors may also talk to friends or relatives concerning the patient's drug use, especially for cases in which the physician suspects that the patient is not being entirely honest about substance use. The clinician may also investigate a patient's legal history for drug arrests that may give clues to periods of substance abuse to which the patient will not admit.

Differential diagnosis

Differential diagnosis is the process of distinguishing one condition from other, similar conditions. The cocaine abuse disorder is easily confused with other substance abuse disorders and various forms of mental illness.

The symptoms of cocaine intoxication, such as increased talkativeness, poor sleep, and the intense feelings of happiness are similar to the symptoms for **bipolar disorder**, so the urine toxification screening test may play a key role in the diagnosis. Patients with cocaine intoxication with hallucinations and delusions can be mistaken for schizophrenic patients instead, further emphasizing the importance of the urine and blood screens. As part of establishing the diagnosis, the physician must also rule out PCP (phencyclidine) intoxication and Cushing's disease (an endocrine disorder of excessive cortisol production). Withdrawal symptoms are similar to those of the patient with major depression. For this reason, the clinician may ask the patient about his or her mood during times of abstinence from drug use to discern if any true mood disorders are present. If cocaine use is causing depression, the depression should resolve within a couple of weeks of stopping drug use.

Laboratory testing

The breakdown products of cocaine remain in the urine. The length of time that they remain depends on the dose of cocaine, but most doses would not remain in the urine longer than a few days. Cocaine can also be found in other bodily fluids such as blood, saliva, sweat, and hair, and these provide better estimates as to recent cocaine use. The hair can hold evidence that a patient has been using drugs for weeks to months. **Positron emission tomography** (PET) and single-photon emission **computed tomography** (SPECT) are different kinds of **imaging studies**. Both kinds of scans look at the amount of blood that is flowing to the brain. When these images are taken of the brains of people who abuse cocaine, the resulting scans have revealed abnormalities in certain sections of the brain. The brains of people addicted to cocaine shrink, or atrophy.

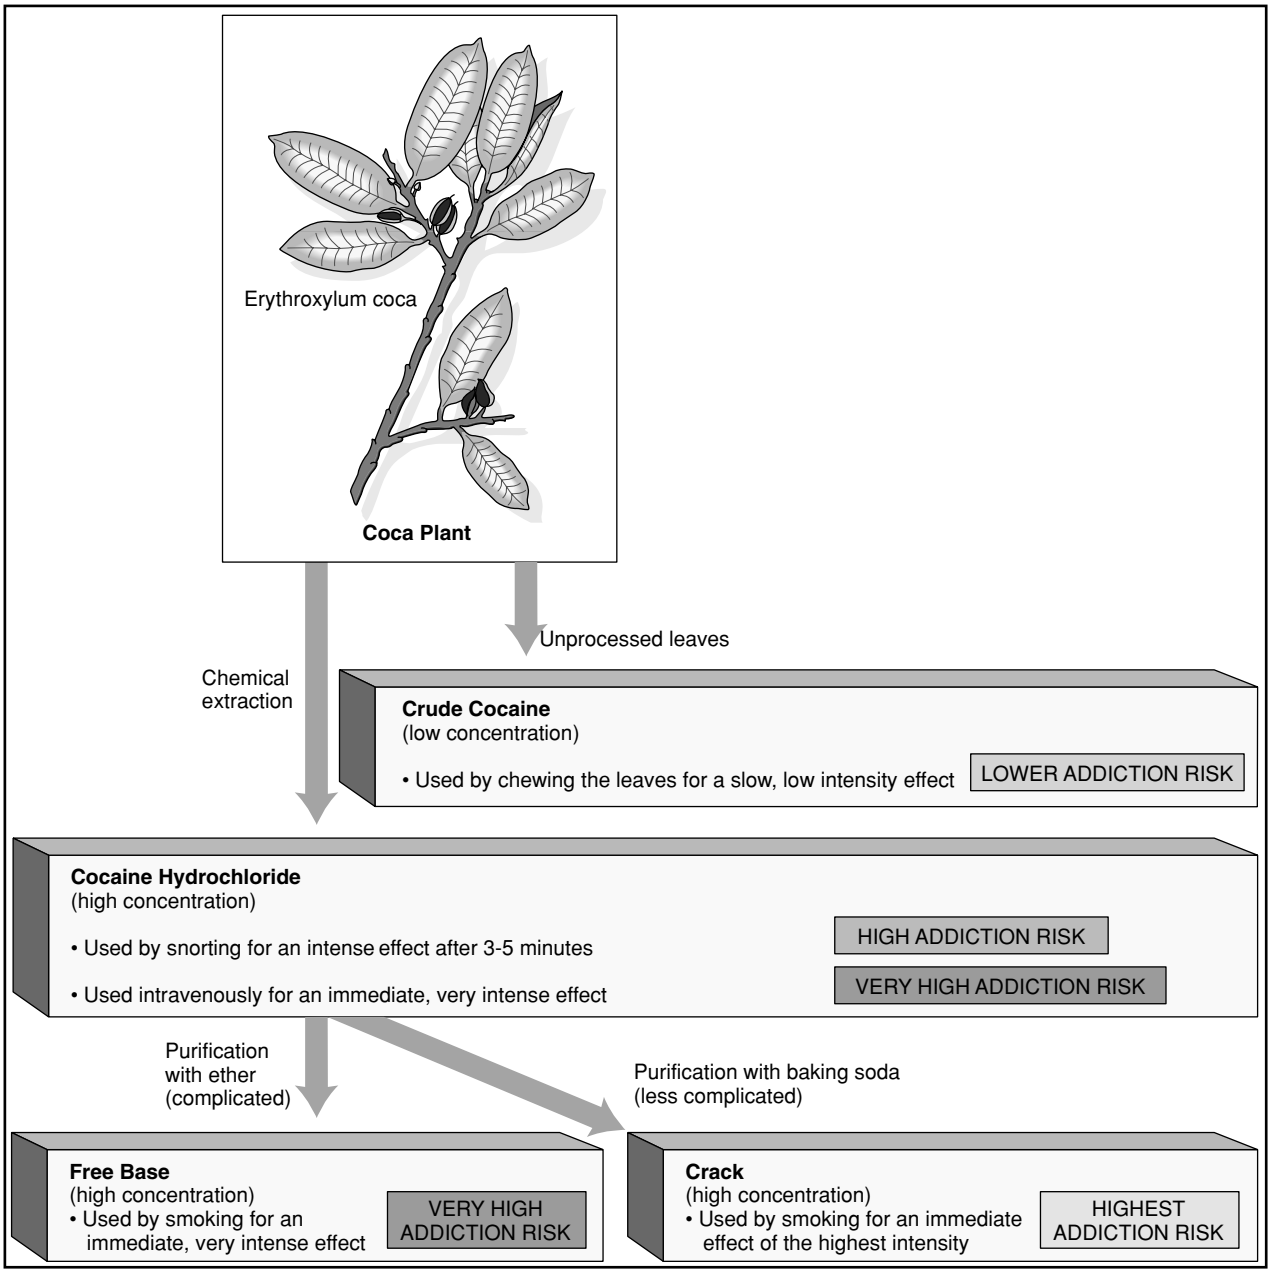
Neuropsychological assessment

Neuropsychological testing is also an important tool for examining the effects of toxic substances on brain functioning. Some physicians may use neuropsychological assessments to reveal patients' cognitive and physical impairment after cocaine use. Neuropsychological testing assesses brain functioning through structured and systematic behavioral observation. Neuropsychological tests are designed to examine a variety of cognitive abilities, including speed of information processing, attention, memory, and language. An example of a task that a physician might ask the patient to complete as part of a neuropsychological examination is to name as many words beginning with a particular letter as the patient can in one minute. Patients who abuse cocaine often have difficulty completing tasks, such as the one described, that require concentration and memory.

Treatments

Psychological and social interventions

TREATMENT SETTINGS. Not all patients who abuse cocaine need to resort to long-term treatment. Treatment length varies with the degree that a person is dependent on the substance. If the patient has other psychiatric conditions such as major depression or **schizophrenia** or has significant medical complications of cocaine abuse, then he or she is more likely to require higher-intensity treatment. Residential programs/therapeutic communities may be helpful, particularly in more severe cases. Patients typically spend six to 12 months in such programs, which may also include vocational training and other features. The availability of such treatment, as well



Various forms of cocaine and the addiction risks associated with them.

as medical insurance's ability to cover treatment, are all issues that affect the patient's access to treatment.

PSYCHOTHERAPY. A wide range of behavioral interventions have been successfully used to treat cocaine addiction. The approach used must be tailored to the specific needs of each individual patient, however.

Contingency management rewards drug abstinence (confirmed by urine testing) with points or vouchers which patients can exchange for such things as an evening out or membership in a gym. **Cognitive-behavioral therapy** helps users learn to recognize and avoid situations most likely to lead to cocaine use and to develop healthier ways to cope with stressful situations.

Supportive therapy helps patients to modify their behavior by preventing relapse by taking actions such as staying away from drug-using friends and from neighborhoods or situations where cocaine is abundant.

Self-help groups like Narcotics Anonymous (NA) or Cocaine Anonymous (CA) are helpful for many recovering substance abusers. CA is a twelve-step program for

cocaine abusers modeled after Alcoholics Anonymous (AA). **Support groups** and **group therapy** led by a therapist can be helpful because other addicts can share coping and relapse-prevention strategies. The group's support can help patients face devastating changes and life issues. Some experts recommend that patients be cocaine-free for at least two weeks before participating in a group, but other experts argue that a two-week waiting period is unnecessary and counterproductive. Group counseling sessions led by drug counselors who are in recovery themselves are also useful for some people overcoming their addictions. These group counseling sessions differ from group therapy in that the people in a counseling group are constantly changing.

The National Institute of Drug Abuse conducted a study comparing different forms of **psychotherapy**: patients who had both group drug counseling and individual drug counseling had improved outcomes. Patients who had cognitive-behavioral therapy stayed in treatment longer.

Medications

Many medications—greater than twenty—have been tested but none have been found to reduce the intensity of withdrawal. Dopamine agonists like **amantadine** and bromocriptine and tricyclic antidepressants such as **desipramine** have failed in studies to help treat symptoms of cocaine withdrawal or intoxication.

Alternative therapy

Alternative techniques, such as **acupuncture**, EEG **biofeedback**, and visualization, may be useful in treating addiction when combined with conventional treatment approaches.

Prognosis

Not all cocaine abusers become dependent on the drug. However, even someone who only uses occasionally can experience the harmful effects (interpersonal relationship conflicts, work or school difficulties, etc.) of using cocaine, and even occasional use is enough to addict. In the course of a person's battle with cocaine abuse, he or she may vary the forms of the drug that he or she uses. A person may use the inhaled form at one time and the injected form at another, for example.

Many studies of short-term outpatient treatment over a six-month to two-year period indicate that people addicted to cocaine have a better chance of recovering than people who are addicted to heroin. A study of veterans who participated in an inpatient or day hospital treatment program that lasted 28 days, revealed that about 60% of people who were abstinent at four months were able to maintain their abstinence at seven months.

Having a good social support network greatly improves the prognosis for recovery from cocaine abuse and dependence.

Prevention

Efforts to prevent cocaine abuse, as well as any substance abuse, begin with prevention programs that are based in schools, in the workplace, heath care clinics, criminal justice systems, and public housing. Programs such as Students Taught Awareness (STAR) are cost effective and have reduced the rates of substance abuse in the schools. These school-based programs also foster parental involvement and education about substance abuse issues. The juvenile justice system also implements drug prevention programs. Even many workplaces provide drug screening and treatment and counseling for those who test positive. Employers may also provide workshops on substance abuse prevention. The United States Department of Housing and Urban Development (HUD) also sponsors drug prevention programs.

Cognistat

Definition

The Cognistat is a standardized neurobehavioral screening test. It is a test that examines neurological (**brain** and central nervous system) health in relation to a person's behavior.

Purpose

As a screening test, the Cognistat may be administered to identify basic strengths and weaknesses so that further tests (if necessary) can be selected, and the data provided by the Cognistat can then be used as preliminary data against which scores from other tests given may be compared. Cognistat results have been used in a number of arenas, most notably in behavioral medicine. For example, Cognistat results may be useful to track cognitive decline (decreased thinking and reasoning abilities) in patients with organic brain disorders, to develop helpful strategies for cognitive problems associated with **schizophrenia**, and to help distinguish among terminally ill cancer patients those with depression and anxiety versus those with cognitive impairment.

KEY TERMS

Screening test—A test given as a preliminary tool, that helps to target a later, more thorough analysis.

Standardized test—A test that follows a regimented structure, and each individual's scores may be compared with those of groups of people. In the case of the Cognistat, test takers' scores can be compared to groups of young adults, middle-aged adults, the geriatric, and people who have undergone neurosurgery.

Precautions

The Cognistat is more sensitive than many similar tests, but considers a limited sample of behavior at a brief point in time. Thus, its results are not generalizable and should not be viewed as conclusive indicators of the areas being assessed. It is important that the examiner be properly trained in the use of the test. Test takers may be affected by test-related discomfort or performance anxiety. This may be particularly true when prior to testing, the examinee was not fully aware of his or her deficits, especially deficits that become more apparent as testing progresses. The test's reliability has not been fully documented. Further research and standardization data is needed.

Description

The Cognistat usually takes less than 45 minutes to take, and the test explores, quantifies, and describes performance in central areas of brain-behavior relations: level of consciousness, orientation, attention, language, constructional ability, memory, calculations and reasoning. The sub-areas of language are spontaneous speech, comprehension, repetition and naming. The sub-areas of reasoning are similarities and judgment. Exploration occurs through interactive behavioral tasks that rely on perception, cognitive processing, and motor skills. The test is more quickly administered to higher than lower functioning individuals by providing a difficult screening item at the beginning of each section. Only when a screening item is missed are the metric, or more remedial, items applied, usually from easiest to most difficult within that section.

The test begins with the examiner asking general questions of the test taker (name, address, age, etc.), and while these questions are being answered, the examiner is subjectively assessing the test taker's level of consciousness. Then, the examiner asks general questions to confirm the test taker's level of orientation, meaning that

the test taker is correctly oriented to place and time— he or she knows what day it is and where he or she is. To test the examinee's attention and memory, the test taker will be asked to repeat a series of digits and the first part of a verbal memory task will be given. (This task will be asked about again later in the test.)

The language section begins with a sample of spontaneous speech derived by asking for a description of a detailed line drawing. The language comprehension section requires responses to simple commands that involve manipulation of common objects placed before the examinee. In the language repetition subtest, the test taker is asked to repeat short phrases and simple sentences. In naming, the last of the language subtests, the screening item differs in form from the metric (easier) items. In the screening item, the examiner holds up an object and asks the test taker to name its four major parts, as the examiner points to them one after another. If the test taker fails, he or she is asked to name eight separate objects, one after another represented by line drawings.

In the next section, constructional ability, the screening item is a visual memory task wherein a stimulus sheet is presented for ten seconds, and the examinee is asked to draw the stimuli from memory. The test taker is then asked to assemble plastic tiles into designs, one after another, as each is shown on a card. Faster completion yields greater points. After the constructional items, the test taker is asked to recall the verbal memory items presented earlier. For items he or she cannot recall, the examiner provides prompts, or clues.

The calculations section is composed of simple verbal mathematics, and is followed by the reasoning section, which includes two subtests. The first consists of associative thinking items known as similarities. In similarities items, the examinee is asked to explain how two concepts are alike. Greater points are awarded if their concept is abstract rather than concrete. The final subtest on the Cognistat is the judgment subtest of the reasoning section. In the judgment subtest, the examinee is asked to answer questions that demonstrate practical judgment in solving basic problem scenarios. Scores for this subtest are weighted based on their appropriateness. There is only one fully appropriate response to each item.

The test booklet provides space for listing medications, and for noting comments about any physical deficits and the examinee's impression of his or her own performance.

Results

When test administration is complete, the examiner tallies the points earned in each section, and plots them on the cognitive status profile located on the front of the test booklet. On the profile, numerical scores are described to fall within the normal or impaired range. The impaired range is broken down into mild, moderate and severe. An individual's scores can also be compared to standardization group data, and their profile may be compared to five case study profiles presented in the test guide. The few items that do not allow for quantitative analysis —the sample of spontaneous speech, for example— are factored into the interpretation of results by the examiner. There is no mechanism for transforming raw scores into percentiles or standard scores, and the test is not designed to generate one main score.

Cognitive problem-solving skills training

Definition

Cognitive problem-solving skills training (CPSST) attempts to decrease a child's inappropriate or disruptive behaviors by teaching the child new skills for approaching situations that previously provoked negative behavior. Using both cognitive and behavioral techniques and focusing on the child more than on the parents or the family unit, CPSST helps the child gain the ability to self-manage thoughts and feelings and interact appropriately with others by developing new perspectives and solutions. The basis of the treatment is the underlying principle that children lacking constructive ways to address the environment have problematic behaviors; teaching these children ways to positively problem-solve and challenge dysfunctional thoughts improves functioning.

Purpose

The goal of CPSST is to reduce or terminate inappropriate, dysfunctional behaviors by expanding the *behavioral repertoire* (including ways of cognitive processing). The behavioral repertoire is the range of ways of behaving that an individual possesses. In children with **conduct disorder**, **intermittent explosive disorder**, **oppositional-defiant disorder**, antisocial behaviors, aggressive acting-out, or **attention-deficit/hyperactivity disorder** with disruptive behavior, the number of ways of interpreting reality and responding to the world are limited and involve negative responses. Although CPSST originally focused on children with problem behaviors or poor relationships with others, it has generalized to a variety of different disorders in children and adults (this treatment has the most research supporting its use in children).

Description

The therapist conducts individual CPSST sessions with the child, once a week for 45 minutes to an hour, typically for several months to a year. The cognitive portion of the treatment involves changing faulty or narrow views of daily situations, confronting irrational interpretations of others' actions, challenging unhelpful assumptions that typically underlie the individual's problem behaviors, and generating alternative solutions to problems. For example, meeting with a child who has received a school suspension for becoming physically enraged at a teacher, the therapist starts by exploring the situation with the child, asking what thoughts and feelings were experienced. The child might state, "My teacher hates me. I'm always getting sent to the principal and she yells at me all the time." The therapist helps the child see some faulty ways of thinking by asking what the child has seen or experienced in the classroom previous to this incident, thus exploring the supporting evidence for the "my teacher hates me" notion. Questions would be ones that could confirm or disconfirm the assumptions, or that identify the precipitants of the teacher disciplining the child. The therapist tries to help the child shift his or her perceptions so that, instead of seeing the student-teacher negative interactions as something external to the self, the child comes to see his or her part in the problem. This discussion also helps the child to discern opportunities to influence the outcome of the interactions. When the child makes a global, stable, and negative attribution about why the interactions with the teacher are negative—where the attitude of the teacher is the cause of the problems—the child loses the sense of having any efficacy and is liable to show poorer behavior. By changing the child's perceptions and examining different options for the child's-responses in that situation, however, the child can identify ways that changing his or her own behavior could improve the outcome.

KEY TERMS

Behavior modification—An approach to therapy based on the principles of operant conditioning. Behavior modification seeks to replace undesirable behaviors with preferable behaviors through the use of positive or negative reinforcement.

Cognitive-behavioral therapy—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Response-contingent learning—A principle that posits that the consequences of a behavior determine whether it will increase or decrease in frequency. Behaviors that bring about desired responses tend to decrease, while those that either remove the chance to obtain a desirable outcome, or those that cause some unpleasant or painful consequence, tend to decrease.

Social learning—Learning by observing others' responses and acquiring those responses through imitation of the role model(s).

The behavioral aspect of CPSST involves **modeling** of more positive behaviors; role-playing challenging situations; and rewarding improvement in behavior, providing corrective feedback on alternative (and more appropriate) ways of handling situations when undesirable behavior occurs. In each session, the child is coached on problem-solving techniques including brainstorming a number of possible solutions to difficulties, evaluating solutions, and planning the steps involving in gaining a desired goal (also called *means-end thinking*). For instance, if the child in the above example felt that the teacher's accusations were unfair, the therapist would help to come up with some options for the child to use in the event of a similar situation (such as visualizing a calming scene, using a mediator to work out the conflict, or avoiding the behaviors that precipitate a trip to the principal's office). The options generated would be discussed and evaluated as to how practical they are and how to implement them.

The child is given therapy homework of implementing these newer ways of thinking and behaving in specif-

ic types of problematic situations in school, with peers, or at home. The child might be asked to keep track of negative, externalizing thoughts by keeping a log of them for several days. The therapist would ask the child to conduct an experiment—try one of the new options and compare the results. Typically, the between-sessions work begins with the conditions that appear the easiest in which to successfully use the updated ways of thinking and behaving, gradually progressing to more complex or challenging circumstances. The child would get rewarded for trying the new techniques with praise, hugs, or earning points towards something desired.

Although the bulk of the sessions involve the individual child and the therapist, the parents are brought into the therapy for a portion of the work. The parents observe the therapist and the child as they practice the new skills and are educated on how to assist the child outside the sessions. Parents learn how to remind the child correctly to use the CPSST techniques for problem-solving in daily living and assist the child with the steps involved in applying these skills. Parents are also coached on how to promote the positive behaviors by rewarding their occurrence with praise, extra attention, points toward obtaining a reward desired by the child, stickers or other small indicators of positive behavior, additional privileges, or hugs (and other affectionate gestures). The scientific term for the rewarding of desired behavior is *positive reinforcement*, referring to consequences that cause the desired target behavior to increase.

In research studies of outcomes, CPSST has been found to be effective in changing children's behavior. Changes in behavior have been shown to persist long-term after completion of treatment. Success in altering undesirable behaviors is enhanced when CPSST is combined with **parent management training**. Parent management training is the in-depth education of parents or other primary caretakers in applying behavioral techniques such as positive **reinforcement** or time away from reinforcement opportunities in their parenting.

Risks

Inappropriate or inept application of cognitive-behavioral techniques such as those used in CPSST may intensify the problem. CPSST should be undertaken with a behavioral health professional (**psychologist**, **psychiatrist**, or clinical social worker) with experience in CPSST. Parents should seek therapists with good credentials, skills, and training.

Results

While individual results vary, problematic behaviors are reduced or eliminated in many children.

Cognitive remediation

Definition

Cognitive remediation is a teaching process that targets areas of neuropsychological functioning involved in learning and basic day-to-day functioning.

Purpose

The goals of cognitive remediation are to bolster specific cognitive capacities that are weak and also to teach compensatory strategies. Cognitive remediation is used primarily with two groups of people: those who have suffered from a traumatic **brain** injury (a **stroke**, tumor, or a head injury); and those who have learning disabilities. For people with brain injury, remediation typically targets the following neuropsychological func-

tions: attention and concentration; memory; planning; monitoring one's work or behavior; and making adjustments based on feedback. Remediation is also used to help children and adults cope with learning disabilities. Learning disabilities can interfere with progress in reading; in understanding and communicating through spoken language; in writing; in arithmetic; in understanding such nonverbal information as telling time or understanding visual information; and in comprehending social interactions and cues. Difficulties with concentration, problem-solving, organization, identifying errors, and using feedback effectively are also areas that can be treated with cognitive remediation.

KEY TERMS

Auditory—Pertaining to the sense of hearing.

Cognitive—Pertaining to the mental processes of memory, perception, judgment, and reasoning.

Compensatory—Counterbalancing or offsetting. A compensatory strategy is one that makes up for or balances a weakness in some area of functioning.

Modality—One of the primary forms of sensation, as vision, touch, or hearing.

Socialization—An ongoing process in which a person learns and internalizes the values and behavior patterns of his or her culture and social group.

Description

Individuals who have suffered a traumatic brain injury will work with a remediator using computer programs that target one area at a time, such as attention. The individual is then helped to generalize what is learned from the program to real life. This **intervention** is usually done at a hospital, although it is not limited to clinical settings. Remediation for this group of people is considered helpful but not curative. It is typically practiced by a neuropsychologist.

Remediation for individuals with learning disabilities aims to bolster a particular area of learning or adaptation, such as in academics or socialization. Although the intervention varies according to the disability and the individual's profile of strengths and weaknesses, the remediator will make use of the person's stronger capacities to bolster the weaker ones. For example, the person might need help with written language because he frequently omits words from his sentences. Once it has been determined that the person's oral language (both receptive and expressive) is adequate and that the motor aspect of writing is intact, the remediator has an idea of the person's strengths and weaknesses in the area of writing. In this case, the remediator makes use of the person's stronger auditory (hearing-related) skills to build up the capacity to translate spoken language into written (visual) language. Specifically, the remediator might read aloud a sentence written by the student (with omissions) and ask the student to identify the mistakes that he hears. The person identifies an omission that he hears and then is shown on paper the place where the word is missing. In this way, he can learn to identify errors visually that he can already identify through the auditory modality of listening. This particular exercise fosters visual awareness of errors, which is a symptom or outcome of the deeper problem of translating language from oral to visual form.

The process then continues with diminishing degrees of assistance. Specifically, after the student becomes more skillful in matching visual omissions with the auditory ones read by the remediator, the person himself begins to read the sentences aloud and identify the words that are missing from the sentences on the page. In the next step, he would begin to read his work silently with the same kind of scrutiny as in the previous exercise. In this manner, remediation fosters both learning and internalizing a cognitive capacity.

Cognitive remediation sessions for learning disabilities usually take place twice a week. This type of intervention is practiced by psychologists, neuropsychologists, special educators, and learning specialists. The depth and breadth of the intervention will vary according to the remediator's professional training and his or her particular area of expertise. Some professionals specialize in working with certain types of learning disabilities; some, like psychologists, may incorporate their understanding of emotional difficulties within their work as a cognitive remediator.

Preparation

Before remediation can begin, the person being treated must receive a neuropsychological or in-depth psychological evaluation in order to identify the underlying neuropsychological capacities (i.e., language, memory, attention, visual perception, visual spatial abilities, motor abilities) that are interfering with acquiring the skills that are needed. The evaluation is also intended to rule out emotional difficulties as the primary cause of learning problems. Children with learning disabilities frequently experience feelings of inadequacy and low self-esteem that need to be addressed. If psychological difficulties, however, are the main reason for a person's

academic struggles, he or she should be treated with **psychotherapy** rather than cognitive remediation.

Normal results

When remediation is targeting the problem area accurately, and the individual is actively engaging in the process, then progress should be evident in the skill area targeted; in the person's awareness of his or her area of difficulty; and his or her awareness of some techniques and strategies that are helpful.

Cognitive retraining

Definition

Cognitive retraining is a therapeutic strategy that seeks to improve or restore a person's skills in the areas of paying attention, remembering, organizing, reasoning and understanding, problem-solving, decision making, and higher level cognitive abilities. These skills are all interrelated. Cognitive retraining is one aspect of cognitive rehabilitation, a comprehensive approach to restoring such skills after **brain** injury or other disability.

Purpose

The purpose of cognitive retraining is the reduction of cognitive problems associated with brain injury, other disabilities or disorders, and/or aging. The overall purpose of the therapy is to decrease the everyday problems faced by individuals with cognitive difficulties, thereby improving the quality of their lives.

Precautions

The extent to which a person with a brain injury can recover from or compensate for cognitive problems related to the injury requires more information about the person and about their injury. Therapy must be tailored to each individual's needs and abilities. Some cognitive retraining techniques require higher levels of skill, and therefore would be more suitable for persons who have made some progress in their recovery. Moreover, a person's moods and emotions have an effect on their cognitive skills. Someone who is depressed, for example, may need **psychotherapy** and/or medication before he or she can engage in and benefit from cognitive retraining. Some persons with brain injuries may find it difficult to transfer a skill learned in one setting, such as a clinic, to another setting, such as their home. Although a specific individual may show some improvement on training tasks, his or her cognitive skills may not be considered improved or restored unless there is some evidence that the skills have been transferred to everyday settings and can be maintained over time.

Description

Professionals from a variety of fields, such as psychology, psychiatry, occupational therapy, and **speech-language pathology**, may be involved in cognitive retraining. The techniques of cognitive retraining are best known for their use with persons who have suffered a brain injury. Cognitive retraining has also been used to treat **dementia**, **schizophrenia**, attention-deficit disorder, learning disabilities, and cognitive changes associated with aging.

Cognitive retraining includes a considerable amount of repetitive practice that targets the skills of interest. In fact, repetition is essential for the newly retrained skills to become automatic. Regular feedback is another important element of cognitive retraining, as is the use of such rewards as money. Retraining usually begins with simpler skills and proceeds to more complicated skills. The therapist may address cognitive skills while the person is practicing real-life tasks, in an effort to improve their performance of these tasks. In fact, practicing skills in the ways and settings they will be used in real life is critical to the success of retraining efforts. The length of time for cognitive training varies according to the type and extent of the injury and the type of retraining skills used. For example, retraining memory may take months or years. In comparison, it may take only a few days or weeks to retrain someone to organize his or her home or workplace. The use of computers for cognitive retraining has become an increasingly common practice.

Types of cognitive retraining

- Attention and concentration retraining. This type of cognitive retraining aims to improve several abilities, including focusing attention; dividing attention; maintaining attention while reducing the effects of boredom and **fatigue**; and resisting distraction. Attention has been considered the foundation of other more complicated cognitive skills, and therefore an important skill for cognitive retraining. This area of cognitive retraining has been widely researched, and has been shown to improve patients' abilities in various tasks related to attention.
- Memory retraining. Memory retraining involves teaching the patient several strategies that can be used to recall certain types of information. For example, rhymes may be used as a memory aid. A series of numbers, such as a phone number with an area code, may be broken down into smaller groups. A person may be taught to go through each letter of the alphabet until he or she remembers someone's name. Both memory and organization problems are common and disabling after head injury.
- Organizational skills retraining. This approach is used when the person has difficulty keeping track of or finding items, doing tasks in a set order, and/or doing something in a timely manner. Strategies may include having one identified place for an item ("a place for everything and everything in its place"). In addition, the person can be taught to keep the items that are used most frequently closer to him or her (the front or the lower shelves of a cabinet, drawer, closet, or desk, for example). Items that are often used together (such as comb and brush, toothbrush and toothpaste) are placed beside each other. Items may be put into categories (Christmas decorations, Easter decorations, for example). These strategies help individuals function better in their home or work environment.
- Reasoning. Reasoning refers to the ability to connect and organize information in a logical, rational way. Reasoning retraining techniques include: listing the facts or reality of a situation; excluding irrelevant facts or details; putting the steps to solve a problem in a logical order; and avoiding irrational thinking, such as jumping to conclusions based on incomplete information, or focusing on the negative aspects of the situation and ignoring the positive. When the person can connect relevant information in a logical way, they are better able to understand or comprehend it.
- Problem solving. Problem-solving retraining aims to help people define a problem; come up with possible solutions to it; discuss the solution(s) with others and listen to their advice; review the various possible solutions from many perspectives; and evaluate whether the problem was solved after going through these steps. This sequence may be repeated several times until the problem is solved. This process is referred to as "SOLVE," from the first letter of the name of each step: Specify; Options; Listen; Vary; and Evaluate. The "SOLVE" technique is more appropriate for use with individuals at a higher level of functioning.
- Decision making. Decision-making retraining is used when a person must choose among a number of options. The goal of this retraining is to help him or her consider the decision thoroughly before taking any action. The considerations may range from such practical matters as money, people, rules and policies, to personality issues.
- Executive skills. Executive skills retraining refers to teaching individuals how to monitor themselves, control their thinking and actions, think in advance, set goals, manage time, act in socially acceptable ways, and transfer skills to new situations. These are higher-level cognitive skills. Charts and videotapes may be used to monitor behavior, and a variety of questions, tasks, and games may be used in retraining these skills.

KEY TERMS

Cognitive—Pertaining to the mental processes of memory, perception, judgment, and reasoning.

Executive skills—Higher-level cognitive skills that are used when a person makes and carries out plans, organizes and performs complex tasks, etc.

Preparation

Cognitive retraining usually takes place in a quiet room without distractions. It is also important for the person to feel relaxed and calm while they are being retrained in cognitive skills. Engaging in cognitive retraining is not recommended when someone is emotional distressed; for example, if they have recently lost a loved one. The therapist usually evaluates the person's level of cognitive skills and the extent of their cognitive problems before retraining begins. This evaluation provides a way to monitor improvement by comparing the patient's skill levels during and after retraining to his or her skill levels before retraining. Cognitive retraining requires patience and persistence from everyone involved.

Aftercare

The therapist will try to promote the transfer of skills learned using cognitive retraining techniques to the patient's everyday life settings and demands. Training may be continued until the patient's skills are improved, transferred to, and maintained in real world activities.

Risks

It is important for the therapist, patient, and the patient's friends or family members not to assume that improvement on training exercises and tests automatically leads to transfer of the skills to real-life settings.

Normal results

Cognitive retraining may be considered successful if performance on a behavior related to a particular cognitive skill has improved. It is ultimately successful if it helps the injured person improve his or her functioning and meet his or her needs in real-life situations and settings.

Cognitive-behavioral therapy

Definition

Cognitive therapy is a psychosocial (both psychological and social) therapy that assumes that faulty thought patterns (called cognitive patterns) cause maladaptive behavior and emotional responses. The treatment focuses on changing thoughts in order to solve psychological and personality problems. Behavior therapy is also a goal-oriented, therapeutic approach, and it treats emotional and behavioral disorders as maladaptive learned responses that can be replaced by healthier ones with appropriate training. Cognitive-behavioral therapy (CBT) integrates features of **behavior modification** into the traditional cognitive restructuring approach.

Purpose

Cognitive-behavioral therapy attempts to change clients' unhealthy behavior through cognitive restructuring (examining assumptions behind the thought patterns) and through the use of behavior therapy techniques.

Cognitive-behavioral therapy is a treatment option for a number of mental disorders, including depression, **dissociative identity disorder**, eating disorders, **generalized anxiety disorder**, **hypochondriasis**, **insomnia**, **obsessive-compulsive disorder**, and **panic disorder** without **agoraphobia**.

Precautions

Cognitive-behavioral therapy may not be appropriate for all patients. Patients with significant cognitive impairments (patients with traumatic **brain** injury or organic brain disease, for example) and individuals who are not willing to take an active role in the treatment process are not usually good candidates.

Description

Origins of the two approaches

Psychologist Aaron Beck developed cognitive therapy in the 1960s. The treatment is based on the principle that maladaptive behavior (ineffective, self-defeating behavior) is triggered by inappropriate or irrational thinking patterns, called automatic thoughts. Instead of reacting to the reality of a situation, an individual automatically reacts to his or her own distorted view of the situation. Cognitive therapy strives to change these thought patterns (also known as cognitive distortions), by examining the rationality and validity of the assumptions behind them. This process is termed cognitive restructuring.

Behavior therapy focuses on observable behavior and its modification in the present, in sharp contrast to the psychoanalytic method of Sigmund Freud (1856-1939), which focuses on unconscious mental processes and their roots in the past. Behavior therapy was developed during

the 1950s by researchers and therapists who were critical of the prevailing psychodynamic treatment methods. The therapy drew on a variety of theories and research, including the classical conditioning principles of the Russian physiologist Ivan Pavlov (1849-1936), the work of American B. F. Skinner (1904-1990), and the work of **psychiatrist** Joesph Wolpe (1915-1997). Pavlov became famous for experiments in which dogs were trained to salivate at the sound of a bell, and Skinner pioneered the concept of operant conditioning, in which behavior is modified by changing the response it elicits. Wolpe is probably best known for his work in the areas of desensitization and **assertiveness training**. By the 1970s, behavior therapy enjoyed widespread popularity as a treatment approach. Since the 1980s, many therapists have begun to use cognitive-behavioral therapy to change clients' unhealthy behavior by replacing negative or self-defeating thought patterns with more positive ones.

The combined approach

In cognitive-behavioral therapy, the therapist works with the patient to identify the thoughts that are causing distress, and employs behavioral therapy techniques to alter the resulting behavior. Patients may have certain fundamental core beliefs, known as schemas, that are flawed and are having a negative impact on the patient's behavior and functioning.

For example, a patient suffering from depression may develop a **social phobia** because he is convinced that he is uninteresting and impossible to love. A cognitive-behavioral therapist would test this assumption by asking the patient to name family and friends who care for him and enjoy his company. By showing the patient that others value him, the therapist exposes the irrationality of the patient's assumption and also provides a new model of thought for the patient to change his previous behavior pattern (i.e., I am an interesting and likeable person, therefore I should not have any problem making new social acquaintances). Additional behavioral techniques such as conditioning (the use of positive and/or negative reinforcements to encourage desired behavior) and **systematic desensitization** (gradual exposure to anxiety-producing situations in order to extinguish the fear response) may then be used to gradually reintroduce the patient to social situations.

Cognitive-behavioral therapy is usually administered in an outpatient setting (clinic or doctor's office) by a specially trained therapist. Therapy may be in either individual or group sessions. Therapists are psychologists (Ph.D., Psy.D., Ed.D., or M.A. degree), clinical **social workers** (M.S.W., D.S.W., or L.S.W. degree), counselors (M.A. or M.S. degree), or psychiatrists (M.D. trained in psychiatry).

Techniques

Therapists use several different techniques in the course of cognitive-behavioral therapy to help patients examine and change thoughts and behaviors. These include:

- *Validity testing.* The therapist asks the patient to defend his or her thoughts and beliefs. If the patient cannot produce objective evidence supporting his or her assumptions, the invalidity, or faulty nature, is exposed.
- *Cognitive rehearsal.* The patient is asked to imagine a difficult situation he or she has encountered in the past, and then works with the therapist to practice how to cope successfully with the problem. When the patient is confronted with a similar situation again, the rehearsed behavior will be drawn on to manage it.
- *Guided discovery.* The therapist asks the patient a series of questions designed to guide the patient towards the discovery of his or her cognitive distortions.
- *Writing in a journal.* Patients keep a detailed written diary of situations that arise in everyday life, the thoughts and emotions surrounding them, and the behaviors that accompany them. The therapist and patient then review the journal together to discover maladaptive thought patterns and how these thoughts impact behavior.
- *Homework.* In order to encourage self-discovery and reinforce insights made in therapy, the therapist may ask the patient to do homework assignments. These may include note-taking during the session, journaling, review of an audiotape of the patient session, or reading books or articles appropriate to the therapy. They may also be more behaviorally focused, applying a newly learned strategy or coping mechanism to a situation, and then recording the results for the next therapy session.
- *Modeling.* Role-playing exercises allow the therapist to act out appropriate reactions to different situations. The patient can then model this behavior.
- *Systematic positive reinforcement.* Human behavior is routinely motivated and rewarded by positive **reinforcement**, and a more specialized version of this phenomenon (systematic positive reinforcement) is used by behavior-oriented therapists. Rules are established that specify particular behaviors that are to be reinforced, and a reward system is set up. With children, this sometimes takes the form of tokens that may be accumulated and later exchanged for certain privileges. Just as providing reinforcement strengthens behaviors,

withholding it weakens them. Eradicating undesirable behavior by deliberately withholding reinforcement is another popular treatment method called extinction. For example, a child who habitually shouts to attract attention may be ignored unless he or she speaks in a conversational tone.

- *Aversive conditioning*. This technique employs the principles of classical conditioning to lessen the appeal of a behavior that is difficult to change because it is either very habitual or temporarily rewarding. The client is exposed to an unpleasant stimulus while engaged in or thinking about the behavior in question. Eventually the behavior itself becomes associated with unpleasant rather than pleasant feelings. One treatment method used with alcoholics is the administration of a nausea-inducing drug together with an alcoholic beverage to produce an aversion to the taste and smell of alcohol by having it become associated with nausea. In counterconditioning, a maladaptive response is weakened by the strengthening of a response that is incompatible with it. A well-known type of counterconditioning is **systematic desensitization**, which counteracts the anxiety connected with a particular behavior or situation by inducing a relaxed response to it instead. This method is often used in the treatment of people who are afraid of flying.

Preparation

Because cognitive-behavioral therapy is a collaborative effort between therapist and patient, a comfortable working relationship is critical to successful treatment. Individuals interested in CBT should schedule a consultation session with their prospective therapist before starting treatment. The consultation session is similar to an interview session, and it allows both patient and therapist to get to know one another. During the consultation, the therapist gathers information to make an initial assessment of the patient and to recommend both direction and goals for treatment. The patient has the opportunity to learn about the therapist's professional credentials, his/her approach to treatment, and other relevant issues.

In some managed-care settings, an intake interview is required before a patient can meet with a therapist. The intake interview is typically performed by a psychiatric nurse, counselor, or social worker, either face-to-face or over the phone. It is used to gather a brief background on treatment history and make a preliminary evaluation of the patient before assigning them to a therapist.

Results

Because cognitive-behavioral therapy is employed for such a broad spectrum of illnesses, and is often used in conjunction with medications and other treatment interventions, it is difficult to measure overall success rates for the therapy. However, several studies have indicated that CBT:

- may reduce the rate of rehospitalization and improve social and occupational functioning for **bipolar disorder** patients, when combined with pharmacotherapy (treatment with medication)
- is an effective treatment for patients with bulimia nervosa
- can help generalized anxiety patients manage their worry, when combined with relaxation exercises
- is helpful in treating hypochondriasis
- may be effective for treating depression, especially when combined with pharmacotherapy, and may also prevent depression in at-risk children
- is one of the first-line treatments for obsessive-compulsive disorder
- that focuses on education and provides some exposure and coping skills is effective for treating panic disorder without agoraphobia
- is effective for helping to treat insomnia, and its effects may be sustained longer than the effects of medications alone

Communication skills and disorders

Definition

Communication skills are the skills needed to use language (spoken, written, signed, or otherwise communicated) to interact with others, and communication disorders are problems related to the development of these skills.

Description

Language employs symbols—words, gestures, or spoken sounds—to represent objects and ideas. Communication of language begins with spoken sounds combined with gestures, relying on two different types of skills. Children first acquire the skills to receive communications, that is, the ability to listen and understand what they hear (supported by accompanying gestures). Next, they will begin experimenting with expressing themselves through speaking and gesturing. Speaking will begin as repetitive syllables, followed by words, phrases, and sentences. Later, children will acquire the skills of reading and writing—the written forms of communication. Although milestones are discussed for development of these skills, many children begin speaking significantly earlier or later than the milestone date. Parents should refrain from attaching too much significance to either deviation from the average. When a child's deviation from the average does cause the parents concern, they may contact a pediatrician or other professional for advice.

Spoken language problems are referred to by a number of labels, including language delay, language disability, or a specific type of language disability. In general, experts distinguish between those people who seem to be slow in developing spoken language (language delay) and those who seem to have difficulty achieving a milestone of spoken language (language disorders). Language disorders include **stuttering**; articulation disorders, such as substituting one sound for another (tandy for candy), omitting a sound (canny for candy), or distorting a sound (shlip for sip); and voice disorders, such as inappropriate pitch, volume, or quality. Causes can be related to hearing, nerve/muscle disorders, head injury, viral diseases, **mental retardation**, drug abuse, or cleft lip or palate.

The ***Diagnostic and Statistical Manual of Mental Disorders*** (also known as the *DSM-IV-TR*), published by the American Psychiatric Association, lists the following disorders as communication disorders:

- **Expressive language disorder:** Disorder characterized by impairment in expressive language development.
- **Mixed receptive-expressive language disorder**: Impairment in both receptive and expressive language development. The affected child has a more difficult time understanding and expressing language as compared to peers.
- **Phonological disorder**: Inability to use expected speech sounds appropriate for the child's age and dialect.
- Stuttering: Unexpected disturbances in the normal patterns and flow of speech.
- Communication disorder not otherwise specified: This may be diagnosed when a child has an irregularity in speech or a difficulty (in voice or pitch, etc.) but the child's symptoms do not exactly match any of the specific categories of impairment that the *DSM* recognizes.

Community mental health

Definition

Community mental health is a decentralized pattern of mental health, mental health care, or other services for people with mental illnesses. Community-based care is designed to supplement and decrease the need for more costly inpatient mental health care delivered in hospitals. Community mental health care may be more accessible and responsive to local needs because it is based in a variety of community settings rather than aggregating and isolating patients and patient care in central hospitals. Community mental health assessment, which has grown into a science called psychiatric epidemiology, is a field of research measuring rates of mental disorder upon which mental health care systems can be developed and evaluated.

KEY TERMS

Catchment—In mental health, a term that refers to a particular geographical area served by a particular mental health agency.

Psychiatric epidemiology—A field of research for establishing the incidence, distribution or prevalence, and control of mental disorders in a population, including the sum of the factors controlling the presence of mental disorders.

Community mental health centers

In the United States, a modern increase in community mental health care delivery began in the 1960s when President John F. Kennedy signed the 1963 Community Mental Health Centers (CMHC) Act (Public Law #88-164). Growing community mental health capacities were intended to complement and mirror trends toward fewer hospital stays and shorter visits for mental illness (see **Deinstitutionalization**). This restructuring of mental health service delivery has occurred in the context of evolving fiscal responsibilities, however. The goals and practices of community mental health have been complicated and revised by economic and political changes.

The National Institute of Mental Health (NIMH) initially developed a CMHC program in the 1960s. CMHCs were designed to provide comprehensive services for people with mental illness, locate these services closer to home, and provide an umbrella of integrated services for a catchment area of 125,000-250,000 people. CMHCs were designed to provide prevention, early treatment, and continuity of care in communities, promoting social integration of people with mental health needs.

Competing public interests

At the outset, CMHCs were providing outpatient care to people with less severe, episodic, or acute mental health problems. In the 1980s, more people with serious mental illness began using CMHCs, due in part to deinstitutionalization, and following the redirection and capping of federal funds for local mental health care. With growing awareness of the homeless mentally ill, state-funded CMHCs faced new challenges, and their work became fragmented according to catchment areas of responsibility, leaving some urban centers overburdened, while others maintained locally funded operations, limiting responsibility for their area only.

The growth of local community mental health centers was an example of competing governmental interests and authorities. Growing numbers of CMHCs were mandated federally and to be funded by local communities, bypassing state control. This growth in outpatient capacity was later used to complement decreases in inpatient hospital care, or deinstitutionalization, which reduced the costs of diminishing and state-funded mental hospitals.

Policies to improve public mental health care

Community mental health centers were the first of several programmatic attempts to improve mental health care in the latter part of the twentieth century. A second was when the federal government recommended Community Support Programs (CSPs) in 1977-78 in response to problems associated with deinstitutionalization. CSPs focused on providing direct care and rehabilitation for the chronically mentally ill. However, federal support for mental health care and CMHCs in particular was reduced in 1980-81, with the repeal of the Mental Health Systems Act and the federal budgeting actions that cut funding and provided it through block grants to states.

A third initiative has been to expand the national capacity for children's mental health care under the Child and Adolescent Service System Program (CASSP), beginning in the 1980s. Principles for this system of care included a continuum of services, including mental health. The expansion of mental health classification systems and the ***Diagnostic and Statistical Manual of Mental Disorders*** has helped identify and treat a growing number of children and youth. A fourth initiative was a joint effort by the Robert Wood Johnson Foundation and the department of Housing and Urban Development. Their Program on Chronic Mental Illness (PCMI) promoted the integration of regional mental health authorities in nine cities. Coordinated local mental health systems run by local mental health authorities remain an important goal of mental health policy.

Finally, many private and public health systems have moved towards managed mental health care, which has become also known as behavioral health care. This form of cost containment is a constellation of organizational reforms, financing systems, and regulatory techniques. **Managed care** expanded throughout health care in the 1990s, providing new challenges to mental health care policy. While federal health policy and medical assistance provide reimbursement for mental health care and for people with mental illness, the regulation of these systems has grown increasingly complex.

While the ideals of community mental health were supplemented with new ideals in the years following the CMHC Act, they were not forgotten. Thanks to the work of NIMH, Medicare and Medicaid legislation (1965), and Supplemental Security Income legislation (1972), com-

munities were able to provide mental health care for growing populations in need. National epidemiological studies in the 1980s and 1990s reinforced the large-scale need for mental health care, as CMHCs and subsequent organizational forms provided services to the nation.

Compliance

Definition

Compliance with appropriate, recommended, and prescribed mental health treatments simply means that a person is following a doctor's orders. Compliance is more likely when there is agreement and confidence regarding the medical **diagnosis** and prognosis. Compliance is complicated by uncertainty about the nature of an illness and/or the effects of certain treatments, particularly medications.

In everyday usage, the term compliance means deference and obedience, elevating the authority of medical expertise. Alternatively, adherence to medical advice refers to a somewhat more informed and equitable decision by a consumer to stick with appropriate medical treatment. In any case, a mental health treatment cannot be effective or even evaluated if a consumer does not follow a doctor's orders. A mental health treatment that is effective for one disorder may not be beneficial for other disorders, and diagnoses may evolve over time, complicating the issue of compliance.

Health providers and consumers

From a health provider's viewpoint, in order for effective medical treatments to have their desired effects, complying or conforming to treatments is absolutely necessary. The concept of medication management reflects this idea that the provider is responsible and in control, while the consumer is a docile body who is incapacitated by disease or condition. From the perspective of health consumers, adherence to medical treatment is enhanced when there is a good health care relationship and when consumers openly share their health beliefs and experience of illness with their provider.

Problems with compliance

In mental health care, uncertainty about compliance is a challenging source of variation in the effectiveness of treatments. Noncompliance can represent a significant risk and cost to the medical system. For providers, partial compliance or discontinuation of medications represents the difficulty of maintaining treatment successes over time. Problems with compliance are often attributed to the consumer, but may also reflect the appropriateness of a medication or treatment.

Compliance rates

Rates of compliance with mental health appointments are the greatest challenge (estimated in one hospital at 91%), while medication noncompliance is the second most challenging problem in the treatment of persons with mental illness. Mental health medication compliance can be determined by questioning patients, counting pills or prescriptions, and through drug monitoring with urine, blood, or other test measures. Overall, recent research estimates compliance to be 58%. Patients who report lower rates are often considered unreliable indicators of compliance, while physicians report higher rates. Compliance with antidepressant medications is higher on average (65%). Mental health medication compliance rates are only somewhat lower than medication compliance in other types of health care, which have been estimated at 76%.

Explaining variation in compliance

Research in psychiatry, psychology, and sociology provides many explanations for variations in compliance. In psychiatry, clinical problems such as drug or alcohol abuse are sometimes used to explain noncompliance. Patients may also discontinue taking medications because of unwanted side effects. Health beliefs and patient-provider relationships are also recognized. In psychology and sociology, health beliefs and behaviors (in context of family, work, etc.) may enhance or limit compliance. If an individual's family member supports medication compliance, and the individual believes in the medicine's benefits, compliance may be enhanced. If an individual discontinues a medicine because it makes him or her drowsy and affects work, compliance may be reduced. People who have limited access to or trust in doctors or medical science, and people whose faith precludes them from certain types of medical care, are less likely to comply with treatment recommendations.

To a large extent, patient compliance is a direct reflection of the quality of the doctor-patient relationship. When provider and consumer achieve a successful treatment alliance, and when the treatment is practical and beneficial for both the provider and the consumer, cooperation reduces concerns about treatment for both parties. When consumers are empowered and motivated to improve their health with the help of a doctor, compliance or adherence to treatment is higher. When there is distrust, disagreement, or misunderstanding involved, as when mental health status is uncertain or treatment side effects are unwelcome, compliance is lower. One British study found that patients with mental disorders were likely to prefer the form of treatment recommended by psychiatrists with whom they had good relationships, even if the treatment itself was painful. Some patients preferred **electroconvulsive therapy** (ECT) to tranquilizers for depression because they had built up trusting relationships with the doctors who used ECT, and perceived the doctors who recommended medications as bullying and condescending. Since noncompliant consumers are less likely to continue in care, they are also less likely to find helpful providers or successful treatments. Thus, noncompliance with treatment may become a self-fulfilling cycle.

Compliance is higher when treatments, including medications, help consumers feel better, when a family supports the treatment, and when taking medication prevents relapse of symptoms. However, as mentioned, people may be distressed by potential side effects of any medication, including those psychiatric medications that limit functioning. Limited functioning through drowsiness, also a problem of the older generation of antihistamines, is the best example. It is an effect of many medicines, particularly those for mental disorders. Other unwelcome side effects of various psychiatric medications include weight gain, involuntary movements such as muscle twitching, and impaired coordination. Consumers may feel embarrassed about taking medication, may have difficulty getting a prescription for medication, and may have financial problems paying for treatment or medication. In some cases, when a patient is non-compliant or perceived to be at odds with treatment recommendations, they may risk losing autonomy over medical decisions. When at risk to self or others, people who are medication noncompliant may be pressured or forced to take medication at the risk of being involuntarily hospitalized.

Multiple challenges in mental health care

Compliance rates reflect the proportion of individuals in treatment who have the highest possibility of successful treatment. Noncompliance rates reflect those individuals who have either discontinued or avoided treatment, and thus have lower probabilities of treatment success. Sometimes patients do not want to get rid of their symptoms (mania, for example), or patients may not consider their experiences (called symptoms) to be indicative of a disorder. In addition, successful mental health care is hampered by the fact that many people with mental health problems either do not use or lack access to mental health care.

The National Co-morbidity Survey shows that only 40% of individuals with serious mental illness receive any treatment in a given year, and 39% of this group receives minimally adequate care. This means that merely 15% of all people in need receive minimally adequate care. Therefore, compliance with treatment is part of a larger national challenge to provide quality mental health care and to use it well.

Compulsion

Definition

A compulsion is a repetitive, excessive, meaningless activity or mental exercise that a person performs in an attempt to avoid distress or worry.

Description

Compulsions are not voluntary activities and are not performed for pleasure. Instead, a person with a compulsion feels the need to engage in a particular behavior to relieve the **stress** and discomfort which would become overwhelming if the activity were not performed in a specific, repeated manner. Examples of compulsive motor activities are washing hands until raw, repeatedly checking the security of a locked door, and arranging and rearranging items in a set order. Some examples of compulsory mental acts are counting or silently repeating specific words. If a person troubled by compulsions is unable to perform such activities, stress and discomfort increase. The performance of the acts relieves distress but only temporarily.

Often, compulsions are not acts that could logically be expected to relieve or prevent the fears that inspire them. For example, a person might feel compelled to count numbers in a certain order to "undo" the perceived damage or threat that follows a thought or behavior. Or a person might check to make sure a door is locked every few minutes. Compulsions, in some cases, are attempts to undo obsessions and are usually not successful.

Computed tomography

Definition

Computed tomography scanning, also called CT scan, CAT scan, or computerized axial tomography, is a diagnostic tool that provides views of internal body structures using x rays. In the field of mental health, a CT scan may be used when a patient seeks medical help for symptoms that could possibly be caused by a **brain** tumor. These symptoms may include headaches, emotional abnormalities, or intellectual or memory problems. In these cases, a CT scan may be performed to "rule out" a tumor, so that other tests can be performed in order to establish an accurate **diagnosis**.

Purpose

CT scans are used to image bone, soft tissues, and air. Since the 1990s, CT equipment has become more affordable and available. CT scans have become the imaging exam of choice for the diagnoses of most solid tumors. Because the computerized image is sharp, focused, and three-dimensional, many structures can be better differentiated (visualized) when compared with standard x rays.

Common indications for CT scans include:

- Sinus studies. The CT scan can show details of sinusitis, bone fractures, and the presence of bony tumor involvement. Physicians may order a CT scan of the sinuses to provide an accurate map for surgery.

KEY TERMS

Aneurysm—A symptomless bulging of a weak arterial wall that can rupture, leading to stroke.

Cerebral ateriography—a procedure that allows a wire to be inserted in blood vessels in the brain which generates an image of diseases in these arteries.

Contrast (agent, medium)—A substance injected into the body that illuminates certain structures that would otherwise be hard to see on the radiograph (film).

Gantry—A name for the couch or table used in a CT scan. The patient lies on the gantry while it slides into the x-ray scanner.

Hematoma—An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

Metastasis—Secondary cancer, or cancer that has spread from one body organ or tissue to another.

Osteoporosis—A loss of bone minerals.

Radiologist—A medical doctor specially trained in radiology (x ray) interpretation and its use in the diagnosis of disease and injury.

Spiral CT—Also referred to as helical CT, this method allows for continuous 360-degree x-ray image capture.

Thoracic—Refers to the chest area. The thorax runs between the abdomen and neck and is encased in the ribs.

- Brain studies. Brain CT scans can detect hematomas (blood clotted mass), tumors, strokes, aneurysms (a blood vessel that ruptures), and degenerative or infected brain tissue. The introduction of CT scanning, especially spiral CT, has helped reduce the need for more invasive procedures such as cerebral angiography (inserting a wire through an artery to where it will reach brain vessels for visualization in real time).
- Body scans. CT scans of the chest, abdomen, spine, and extremities can detect the presence of tumors, enlarged lymph nodes, abnormal collection of fluid, and vertebral disc disease. These scans can also be helpful in evaluating the extent of bone breakdown in osteoporosis.
- Heart and aorta scans. CT scans can focus on the thoracic (chest) or abdominal aorta to locate aneurysms and other possible aortic diseases. A newer type of CT scan, called electron beam CT, can be used to detect calcium buildup in arteries. Because it is a new technology, it is not yet widely used and its indications are not yet well-defined.
- Chest scans. CT scans of the chest are useful in distinguishing tumors and in detailing accumulation of fluid in chest infections.

Precautions

Pregnant women or those who could possibly be pregnant should not have a CT scan, particularly a full body or abdominal scan, unless the diagnostic benefits outweigh the risks. If the exam is necessary for obstetric purposes, technologists are instructed not to repeat films if there are errors. Pregnant patients receiving a CT scan or any x ray exam away from the abdominal area may be protected by a lead apron; most radiation, known as scatter, travels through the body, however, and is not totally blocked by the apron.

Contrast agents are often used in CT exams, though some types of tumors are better seen without it. Patients should discuss the use of contrast agents with their doctor, and should be asked to sign a consent form prior to the administration of contrast. One of the common contrast agents, iodine, can cause allergic reactions. Patients who are known to be allergic to iodine or shellfish should inform the physician prior to the CT scan; a combination of medications can be given to such patients before the scan to prevent or minimize the reaction. Contrast agents may also put patients with diabetes at risk of kidney failure, particularly those taking the medication glucophage.

Description

Computed tomography, is a combination of focused x-ray beams and the computerized production of an image. Introduced in the early 1970s, this radiologic procedure has advanced rapidly and is now widely used, sometimes in the place of standard x rays.

CT equipment

A CT scan may be performed in a hospital or outpatient imaging center. Although the equipment looks large and intimidating, it is very sophisticated and fairly comfortable. The patient is asked to lie on a gantry, or narrow table, that slides into the center of the scanner. The scanner looks like a doughnut and is round in the middle, which allows the x-ray beam to rotate around the patient. The scanner section may also be tilted slightly to allow for certain cross-sectional angles.

CT procedure

The gantry moves very slightly as the precise adjustments for each sectional image are made. A technologist watches the procedure from a window and views the images on a computer screen. Generally, patients are alone during the procedure, though exceptions are sometimes made for pediatric patients. Communication is possible via an intercom system.

It is essential that the patient lie very still during the procedure to prevent motion blurring. In some studies, such as chest CTs, the patient will be asked to hold his or her breath during image capture.

Following the procedure, films of the images are usually printed for the radiologist and referring physician to review. A radiologist can also interpret CT exams on the computer screen. The procedure time will vary in length depending on the area being imaged. Average study times are from 30 to 60 minutes. Some patients may be concerned about claustrophobia (a feeling of being "closed in") but the width of the "doughnut" portion of the scanner is such that many patients can be reassured of openness. Doctors may consider giving sedatives to patients who have severe claustrophobia or difficulty lying still (such as small children).

The CT image

While traditional x-ray machines image organs in two dimensions, often resulting in organs in the front of the body being superimposed over those in the back, CT scans allow for a more three-dimensional effect. CT images can be likened to slices in a loaf of bread. Precise sections of the body can be located and imaged as cross-sectional views. The screen before the technologist shows a computer's analysis of each section detected by the x-ray beam. Thus, various densities of tissue can be easily distinguished.

Contrast agents

Contrast agents are often used in CT exams and in other radiology procedures to illuminate certain details of anatomy more clearly. Some contrasts are natural, such as air or water. A water-based contrast agent is sometimes administered for specific diagnostic purposes. Barium sulfate is commonly used in gastroenterology procedures. The patient may drink this contrast or receive it in an enema. Oral or rectal contrast is usually given when examining the abdomen or cells, but not when scanning the brain or chest. Iodine is the most widely used intravenous contrast agent and is given through an intravenous needle.

Patient lying on mobile table, entering a CT (computed tomography or CAT) scanner. *(Volker Steger/Science Photo Library, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

If contrast agents are used in the CT exam, these will be administered several minutes before the study begins. Patients undergoing abdominal CT may be asked to drink a contrast medium. Some patients may experience a salty taste, flushing of the face, warmth or slight nausea, or hives from an intravenous contrast injection. Technologists and radiologists have the equipment and training to help patients through these minor reactions and to handle more severe reactions. Severe reactions to contrast are rare, but do occur.

Newer types of CT scans

The spiral CT scan, also called a helical CT, is a newer version of CT. This type of scan is continuous in motion and allows for the continuous re-creation of images. For example, traditional CT allows the technologist to take slices at very small and precise intervals one after the other. Spiral CT allows for a continuous flow of images, without stopping the scanner to move to the next image slice. A major advantage of spiral CT is the ability to reconstruct images anywhere along the length of the study area. Because the procedure is faster, patients are required to lie still for shorter periods of time. The ability to image contrast more rapidly after it is injected, when it is at its highest level, is another advantage of spiral CT's high speed.

Electron beam CT scans are another newer type of CT technology that can be used to detect calcium buildup in arteries. These calcium deposits are potential risk factors for coronary artery disease. Electron beam CT scans take pictures much more quickly than conventional CTs, and are therefore better able to produce clear images of the

Computerized axial tomography (CAT) scan of a human brain with Parkinson's disease showing atrophy. *(GJLP/CNRI/Phototake. Reproduced by permission.) See color insert for color version of photo.*

heart as it pumps blood. Because it is a newer and expensive test, electron beam CT scanning is not widely used.

Some facilities will have spiral, electron, and conventional CT available. Although spiral is more advantageous for many applications, conventional CT is still a superior and precise method for imaging many tissues and structures. The physician will evaluate which type of CT works best for the specific exam purpose.

Preparation

If a contrast medium is administered, the patient may be asked to fast for about four to six hours prior to the procedure. Patients will usually be given a gown (like a typical hospital gown) to be worn during the procedure. All metal and jewelry should be removed to avoid artifacts on the film. Depending on the type of study, patients may also be required to remove dentures.

Aftercare

Generally, no aftercare is required following a CT scan. Immediately following the exam, the technologist will continue to watch the patient for possible adverse contrast reactions. Patients are instructed to advise the technologist of any symptoms, particularly respiratory difficulty. The site of contrast injection will be bandaged and may feel tender following the exam.

Risks

Radiation exposure from a CT scan is similar to, though higher than, that of a conventional x ray. Although this is a risk to pregnant women, the risk for other adults is minimal and should produce no effects. Severe contrast reactions are rare, but they are a risk of many CT procedures.

Normal results

Normal findings on a CT exam show bone, the most dense tissue, as white areas. Tissues and fat will show as various shades of gray, and fluids will be gray or black. Air will also look black. Intravenous, oral, and rectal contrast appear as white areas. The radiologist can determine if tissues and organs appear normal by the sensitivity of the gray shadows.

Abnormal results

Abnormal results may show different characteristics of tissues within organs. Accumulations of blood or other fluids where they do not belong may be detected. Radiologists can differentiate among types of tumors throughout the body by viewing details of their makeup.

Sinus studies

The increasing availability and lowered cost of CT scanning has led to its increased use in sinus studies, either as a replacement for a sinus x ray or as a follow-up to an abnormal sinus radiograph. The sensitivity of CT allows for the location of areas of sinus infection, particularly chronic infection. Sinus tumors will show as shades of gray indicating the difference in their density from that of normal tissues in the area.

Brain studies

The precise differences in density allowed by CT scan can clearly show tumors, strokes, or lesions in the brain area as altered densities. These lighter or darker areas on the image may indicate a tumor or hematoma within the brain and skull area. Different types of tumors can be identified by the presence of edema (fluid), by the tissue's density, or by studying blood vessel location and activity. The speed and convenience of CT often allows for detection of hemorrhage (bleeding) before symptoms even occur.

Body scans

The body CT scan can identify abnormal body structures and organs. A CT scan may indicate tumors or cysts, enlarged lymph nodes, abnormal collections of fluids, blood, fat, or cancer metastasis. Tumors resulting from metastasis (movement of the cancer from the primary site of cancer growth to a distant site) are different in makeup than primary (original) tumors.

Chest scans

In addition to those findings which may indicate aortic aneurysms (rupture of the largest artery in the body), chest CT studies can show other problems in the heart and lungs, and distinguish between an aortic aneurysm and a tumor adjacent to the aorta. CT will not only show differences between air, water, tissues and bone, but will also assign numerical values to the various densities. Coin-sized lesions in the lungs may be indicative of tuberculosis or tumors. CT will help distinguish among the two. Enlarged lymph nodes in the chest area may indicate Hodgkin's disease (a blood disorder).

Conduct disorder

Definition

Conduct disorder is a childhood behavior disorder characterized by aggressive and destructive activities that cause disruptions in the child's natural environments such as home, school, church, or the neighborhood. The overriding feature of conduct disorder is the repetitive and persistent pattern of behaviors that violate societal norms and the rights of other people. It is one of the most prevalent categories of mental health problems of children in the United States, with rates estimated at 9% for males and 2% for females.

Description

The specific behaviors used to produce a **diagnosis** of conduct disorder fall into four groups: aggressive conduct that causes or threatens physical harm to other people or animals, nonaggressive behavior that causes property loss or damage, deceitfulness or theft, and serious violations of rules. Two subtypes of conduct disorder can be delineated based on the age that symptoms first appear. Childhood-onset type is appropriate for children showing at least one of the behaviors in question before the age of 10. Adolescent onset type is defined by the absence of any conduct disorder criteria before the age of 10. Severity may be described as mild, moderate or severe, depending on the number of problems exhibited and their impact on other people.

Youngsters who show symptoms (most often aggression) before age 10 may also exhibit oppositional behavior and peer relationship problems. When they also show persistent conduct disorder and then develop adult **antisocial personality disorder**, they should be distinguished from individuals who had no symptoms of conduct disorder before age 10. The childhood type is more highly associated with heightened aggression, male gender, **oppositional defiant disorder**, and a family history of antisocial behavior.

The individual behaviors that can be observed when conduct disorder is diagnosed may be both common, problematic, and chronic. They tend to occur frequently and are distressingly consistent across time, settings, and families. Not surprisingly, these children function poorly in a variety of places. In fact, the behaviors clustered within the term "conduct disorder" account for a majority of clinical referrals, classroom detentions or other sanctions, being asked to stop participating in numerous activities, and can be extremely difficult (even impossible) for parents to manage.

The negative consequences of conduct disorder, particularly childhood onset, may include illicit drug use, dropping out of school, violent behavior, severe family conflict, and frequent delinquent acts. Such behaviors often result in the child's eventual placement out of the home, in special education and/or the juvenile justice system. There is evidence that the rates of disruptive behavior disorders may be as high as 50% in youth in public sectors of care such as juvenile justice, alcohol and drug

The overriding feature of conduct disorder is the repetitive and persistent pattern of behaviors that violate societal norms and the rights of other people. Youngsters with conduct disorder often exhibit aggressive behavior to other people (bullying, starting fights, etc.) or to animals. They may also damage others' property. *(Carolyn A. McKeone. Photo Researchers, Inc. Reproduced by permission.)*

services, schools for youths with serious emotional disturbances, child welfare, and mental health.

The financial costs of crime and correction for repeated juvenile offenses by youth with conduct disorder are extensive. The social costs include citizens' fear of such behavior, loss of a sense of safety, and disruptions in classrooms that interfere with other children's opportunity to learn. The costs to the child and his or her family are enormous in terms of the emotional and other resources needed to address the consequences of the constellation of symptoms that define conduct disorder.

Causes and symptoms

There is no known cause for conduct disorder. The frustrating behavior of youngsters with conduct disorder frequently leads to blaming, labeling, and other unproductive activities. Children who are "acting out" do not inspire sympathy or the benefit of the doubt. They are often ostracized by other children. Parents of such children are often blamed as poor disciplinarians or bad parents. As a result, parents of children with conduct disorder may be reluctant to engage with schools or other authorities. At the same time, there is a strong correlation between children diagnosed with conduct disorder and a significant level of family dysfunction, poor parenting practices, an overemphasis on coercion and hostile communication patterns, verbal and physical aggression and a history of maltreatment.

There is a suggestion of an, as yet, unidentified genetic component to what has generally been viewed as a behavioral disorder. One study with adopted children in the mid-1990s looked at the relationship between birth parents with antisocial personality disorder, and adverse adoptive home environments. When these two adverse conditions occurred, there was significantly increased aggressiveness and conduct disorder in the adopted children. That was not the case if there was no indication of antisocial personality disorder in the birth parents. This finding has important implications for prevention and **intervention** of conduct disorders and its associated conditions of substance abuse and aggressiveness.

Symptoms

The ***Diagnostic and Statistical Manual of Mental Disorders*** (also known as the *DSM-IV-TR*) indicates that for conduct disorder to be diagnosed, the patient has repeatedly violated rules, age-appropriate social norms and the rights of others for a period of at least twelve months. This is shown by three or more of the following behaviors, with at least one having taken place in the previous six months: aggression to people or animals, property destruction, lying or theft, and serious rule violations.

Aggression to people or animals includes:

- engaging in frequent bullying or threatening
- often starting fights
- using a weapon that could cause serious injury (gun, knife, club, broken glass)
- showing physical cruelty to people
- showing physical cruelty to animals
- engaging in theft with confrontation (armed robbery, extortion, mugging, purse snatching)
- forcing sex upon someone

Property destruction includes:

- deliberately setting fires to cause serious damage
- deliberately destroying the property of others by means other than fire setting

Lying or theft includes:

- breaking into building, car, or house belonging to someone else
- frequently lying or breaking promises for gain or to avoid obligations (called "conning")
- stealing valuables without confrontation (burglary, forgery, shop lifting)

Serious rule violations include:

- beginning before age 13, frequently staying out at night against parents' wishes

- running away from parents overnight twice or more or once if for an extended period
- engaging in frequent truancy beginning before the age of 13

Mild severity would mean there are few problems with conduct beyond those needed to make a diagnosis AND all of the problems cause little harm to other people. Moderate severity means the number and effect of the conduct problems is between the extremes of mild and severe. Severe is indicated if there are many more conduct symptoms than are needed to make the diagnosis (more than three in the previous twelve months or more than one in the previous six months), or, the behaviors cause other people considerable harm.

Diagnosis

Conduct disorder is generally diagnosed when somebody, often a child in school, comes to the attention of authorities (school, law enforcement, and others) most often because of behavior. The person might then be referred to a **psychiatrist** or **psychologist** for **assessment and diagnosis**. It is unlikely that any sort of specific test is given; rather, the individual would have to meet the criteria in the *DSM-IV-TR*. Usually there is a history of acting out in school, neighborhood, home, and other social settings. Court-ordered treatment would likely occur if the person comes to the attention of the police and if a crime is involved. A judge might order treatment as an alternative to jail, or before a sentence is served.

Treatments

Earlier treatments of youth with conduct disorder relied on legal processes to declare a child in need of supervision or treatment and thus able to be placed in residential settings established for this purpose. While residential placements may still be used, recent treatment models have relied less on such restrictive procedures. The increased visibility and sophistication of the consumer movement, comprised of families of children and youth with mental health disorders, is bringing pressure to bear on treatment providers to stop blaming families, stop removing children from their families for services, focus instead on strengths and assets in both the child and his or her family, and to use community-based interventions in several domains in which the child and family live.

Community-based interventions are sometimes called wrap-around services to describe the intention that they will be brought to the child's natural environment in a comprehensive and flexible way. The idea is to target a range of child, parent, family and social system factors associated with a child's behavioral problems. This approach has been successful in modifying antisocial behavior, rates of restrictive placement, and in reducing the cost of services.

Another treatment that has been used with some success is the *Child Cognitive Behavioral Treatment and Skills Training* which trains children with conduct disorder in anger-coping, peer coping, and problem-solving skills.

Parent Management Training and **family therapy** are also used to treat conduct disorder. Parents learn to apply behavioral principles effectively, how to play with their children, and how to teach and coach the child to use new skills.

Medication is sometimes used and may be effective in controlling aggression. Generally, a variety of treatment modes are used to address such a complex disorder. Severe antisocial behavior on the part of the child and adverse parenting practices may suggest that the family will stop treatment before it can be effective, or before meaningful change can result.

Prognosis

Early identification and appropriate and innovative treatment will improve the course of conduct disorder and possibly prevent a host of negative outcomes that are often a consequence of the behaviors associated with it. Unfortunately, the **stigma** of treatment and the undiagnosed problems of many parents are still significant enough that families whose children could benefit from treatment never find their way to a treatment setting. Instead their children come into contact with the juvenile and criminal justice system.

Prevention

Prognosis may best be improved by prevention of conduct disorder before it becomes so resistant to treatment. Research is being conducted on what early interventions hold the greatest promise. The research incorporates several components such as child tutoring, classroom intervention, peer training, social-cognitive skills training, parent training, and family problem-solving.

Other studies have included early parent or family interventions, school-based interventions and community interventions. Again, these include a variety of elements as suggested before, including parent training that includes education about normal child development, child problem-solving, and family communication skills training. Research is still needed to determine where and when to target specific preventive interventions.

KEY TERMS

Normed—Describes a process used in the developmental stages of a test instrument. The new test is first given to a cross-section of a population for which it is designed. The scores, placements, rankings, etc., of these persons then become the source for all future comparisons (norm group). When a new subject takes the test, his/her score, placement, ranking, etc., is determined based upon comparison with or deviation from the norm group.

Psychosomatic—Physical disorder originating in, or aggravated by, the psychic or emotional processes of the individual.

Conners' Rating Scales-Revised

Definition

Developed by C. Keith Conners, Ph.D., the Conners' Rating Scales-Revised (CRS-R) are paper and pencil screening questionnaires designed to be completed by parents and teachers to assist in evaluating children for **attention-deficit/hyperactivity disorder** (ADHD).

Purpose

The CSR-R is used as part of a comprehensive examination and are designed to be easily administered and scored. Both the long and short versions are tools to assist in determining whether children between the ages of three and 17 years might suffer from ADHD.

Precautions

Those who administer the CRS-R should have a good understanding of psychological testing and its limitations. Although the CRS-R can be readily administered and scored by a nonprofessional, the ultimate responsibility for interpretation lies with a seasoned professional. As with all psychological evaluation instruments, the CRS-R is not perfect. One runs the risk of obtaining false positives (incorrectly diagnosing the disorder) or false negatives (failing to identify the disorder). Therefore, the information obtained from completed forms should not be used in isolation. It should be one piece of a complex evaluation that includes a clinical interview with the child, other diagnostic measures such as a computerized continuous performance test, and patient self-report—for those old enough and with sufficient reading ability to do so.

Previous versions of the Conners' scales were criticized by those claiming disparity between results obtained in different ethnic groups. The most recent version should dispel this concern, since they were "normed" using data from more than 8,000 subjects crossing all cultural and ethnic boundaries. The technical

manual for CRS-R even contains separate normative information for specific ethnic groups. However, when age and sex are taken into account there were either no differences or insignificant differences. Statistically, a difference of two or three T-score points would be insignificant.

Description

The CRS-Rs are available in long and short versions for both parents and teachers. The long version for parents contains 80 items while the long version for teachers contains 59 items. The parents' short version contains 27 items and the teachers' short version has 28. The forms are multi-paged, and numbers circled on the front or back page are automatically transferred to a middle section for use by the clinician. The clinician transfers the circled scores into appropriate scales on the middle form and totals each scale at the bottom of the page. The parent version contains scales A through N. The teacher version is similar but lacks scale G (psychosomatic) contained on the parent version.

Results

After transferring the raw scores to the various scales and totaling them, the total of each scale (A–N) is transferred to another form designed to portray the results graphically. The clinician must be careful to transpose the raw scores to the correct age group column within each major scale. For example, column 1 is used for ages three to five, column 2 for ages six to eight, column 3 for ages nine to 11, etc. Each of these column scores can then be converted to a T-score. T-scores are standardized scores with a mean of 50 and a standard deviation of 10. These can be further converted to percentile scores as needed.

As a rule, T-scores above 60 are cause for concern and have interpretive value. Interpretable scores range from a low T-score of 61 (mildly atypical) to above 70 (markedly atypical). However, again, this information should not be used in isolation to make a **diagnosis**.

Conversion disorder

Definition

Conversion disorder is defined by ***Diagnostic and Statistical Manual of Mental Disorders***, 4th Edition, Text Revision, also known as the *DSM-IV-TR,* as a mental disorder whose central feature is the appearance of symptoms affecting the patient's senses or voluntary movements that suggest a neurological or general medical disease or condition. Somatoform disorders are marked by persistent physical symptoms that cannot be fully explained by a medical condition, substance abuse, or other mental disorder, and seem to stem from psychological issues or conflicts. The *DSM-IV-TR* classifies conversion disorder as one of the somatoform disorders, first classified as a group of mental disorders by the *DSM III* in 1980. Other terms that are sometimes used for conversion disorder include pseudoneurologic syndrome, hysterical **neurosis**, and psychogenic disorder.

Conversion disorder is a major reason for visits to primary care practitioners. One study of health care utilization estimates that 25–72% of office visits to primary care doctors involve psychological distress that takes the form of somatic (physical) symptoms. Another study estimates that at least 10% of all medical treatments and diagnostic services are ordered for patients with no evidence of organic disease. Conversion disorder carries a high economic price tag. Patients who convert their emotional problems into physical symptoms spend nine times as much for health care as people who do not somatosize; and 82% of adults with conversion disorder stop working because of their symptoms. The annual bill for conversion disorder in the United States comes to $20 billion, not counting absenteeism from work and disability payments.

Description

Conversion disorder has a complicated history that helps to explain the number of different names for it. Two eminent neurologists of the nineteenth century, Jean-Martin Charcot in Paris and Josef Breuer in Vienna were investigating what was then called hysteria, a disorder primarily affecting women (the term "hysteria" comes from the Greek word for uterus or womb). Women diagnosed with hysteria had frequent emotional outbursts and

KEY TERMS

Aphonia—Inability to speak caused by a functional disturbance of the voice box or vocal cords.

(la) Belle indifférence—A psychiatric symptom sometimes found in patients with conversion disorder, in which the patient shows a surprising lack of concern about the nature or implications of his/her physical symptom.

Conversion—In psychiatry, a process in which a repressed feeling, impulse, thought, or memory emerges in the form of a bodily symptom.

Diplopia—A disorder of vision in which a single object appears double. Diplopia is sometimes called double vision.

Dyskinesia—Difficulty in performing voluntary muscular movements.

Dystonia—A neurological disorder characterized by involuntary muscle spasms. The spasms can cause a painful twisting of the body and difficulty walking or moving.

Electroencephalogram—(EEG) A test that measures the electrical activity of the brain by means of electrodes placed on the scalp or on or in the brain itself.

Factitious disorder—A type of mental disturbance in which patients intentionally act physically or mentally ill without obvious benefits. It is distinguished from malingering by the absence of an obvious motive, and from conversion disorder by intentional production of symptoms.

Hysteria—In nineteenth-century psychiatric use, a neurotic disorder characterized by violent emotional outbursts and disturbances of the sensory and motor (movement-related) functions. The term "hysterical neurosis" is still used by some psychiatrists as a synonym for conversion disorder.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Myoclonus—An abrupt spasm or twitching in a muscle or group of muscles.

Narcotherapy—A form of psychotherapy that involves the administration of a drug that makes the patient drowsy.

Primary gain—In psychiatry, the principal psychological reason for the development of a patient's symptoms. In conversion disorder, the primary gain from the symptom is the reduction of anxiety and the exclusion of an inner conflict from conscious awareness.

Pseudoseizure—A fit that resembles an epileptic seizure but is not associated with abnormal electrical discharges in the patient's brain.

Psychogenic—Originating in the mind, or in a mental process or condition. The term "psychogenic" is sometimes used as a synonym for "conversion."

Ptosis—Drooping of the upper eyelid.

Secondary gain—A term that refers to other benefits that a patient obtains from a conversion symptom. For example, a patient's loss of function in an arm might require other family members to do the patient's share of household chores; or they might give the patient more attention and sympathy than he or she usually receives.

Shaman—In certain indigenous tribes or groups, a person who acts as an intermediary between the natural and supernatural worlds. Shamans are regarded as having the power or ability to cure illnesses.

Social modeling—A process of learning behavioral and emotional response patterns from observing one's parents or other adults. Some researchers think that social modeling plays a part in the development of conversion disorder in children.

Somatoform disorders—A group of psychiatric disorders in the *DSM-IV-TR* classification that are characterized by external physical symptoms or complaints that are related to psychological problems rather than organic illness. Conversion disorder is classified as a somatoform disorder.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

a variety of neurologic symptoms, including paralysis, fainting spells, convulsions, and temporary loss of sight or hearing. Pierre Janet (one of Charcot's students), and Breuer independently came to the same conclusion about the cause of hysteria—that it resulted from psychological trauma. Janet, in fact, coined the term "dissociation" to describe the altered state of consciousness experienced by many patients who were diagnosed with hysteria.

The next stage in the study of conversion disorder was research into the causes of "combat neurosis" in World War I (1914-1918) and World War II (1939-1945). Many of the symptoms observed in "shell-shocked" soldiers were identical to those of "hysterical" women. Two of the techniques still used in the treatment of conversion disorder—hypnosis and narcotherapy—were introduced as therapies for combat veterans. The various terms used by successive editions of the *DSM* and the *ICD* (the European equivalent of *DSM*) for conversion disorder reflect its association with hysteria and dissociation. The first edition of the *DSM* (1952) used the term "conversion reaction." *DSM-II* (1968) called the disorder "hysterical neurosis (conversion type)," *DSM-III* (1980), *DSM-III-R* (1987), and *DSM-IV* (1994) have all used the term "conversion disorder." ICD-10 refers to it as "dissociative (conversion) disorder."

DSM-IV-TR (2000) specifies six criteria for the **diagnosis** of conversion disorder. They are:

- The patient has one or more symptoms or deficits affecting the senses or voluntary movement that suggest a neurological or general medical disorder.
- The onset or worsening of the symptoms was preceded by conflicts or stressors in the patient's life.
- The symptom is not faked or produced intentionally.
- The symptom cannot be fully explained as the result of a general medical disorder, substance intake, or a behavior related to the patient's culture.
- The symptom is severe enough to interfere with the patient's schooling, employment, or social relationships, or is serious enough to require a medical evaluation.
- The symptom is not limited to pain or sexual dysfunction, does not occur only in the context of **somatization disorder**, and is not better accounted for by another mental disorder.

DSM-IV lists four subtypes of conversion disorder: conversion disorder with motor symptom or deficit; with sensory symptom or deficit; with **seizures** or convulsions; and with mixed presentation.

Although conversion disorder is most commonly found in individuals, it sometimes occurs in groups. One such instance occurred in 1997 in a group of three young men and six adolescent women of the Embera, an indigenous tribe in Colombia. The young people believed that they had been put under a spell or curse, and developed dissociative symptoms that were not helped by antipsychotic medications or traditional herbal remedies. They were cured when shamans from their ethnic group came to visit them. The episode was attributed to psychological **stress** resulting from rapid cultural change.

Another example of group conversion disorder occurred in Iran in 1992. Ten girls out of a classroom of 26 became unable to walk or move normally following tetanus inoculations. Although the local physicians were able to treat the girls successfully, public health programs to immunize people against tetanus suffered an immediate negative impact. One explanation of group conversion disorder is that an individual who is susceptible to the disorder is typically more affected by suggestion and easier to hypnotize than the average person.

Causes and symptoms

Causes

The immediate cause of conversion disorder is a stressful event or situation that leads the patient to develop bodily symptoms as symbolic expressions of a long-standing psychological conflict or problem. One **psychiatrist** has defined the symptoms as "a code that conceals the message from the sender as well as from the receiver.".

Two terms that are used in connection with the causes of conversion disorder are primary gain and secondary gain. Primary gain refers to the lessening of the anxiety and communication of the unconscious wish that the patient derives from the symptom(s). Secondary gain refers to the interference with daily tasks, removal from the uncomfortable situation, or increased attention from significant others that the patient obtains as a result of the symptom(s).

Physical, emotional, or sexual abuse can be a contributing cause of conversion disorder in both adults and children. In a study of 34 children who developed pseudoseizures, 32% had a history of depression or sexual abuse, and 44% had recently experienced a parental divorce, death, or violent quarrel. In the adult population, conversion disorder may be associated with mobbing, a term that originated among European psychiatrists and industrial psychologists to describe psychological abuse in the workplace. One American woman who quit her job because of mobbing was unable to walk for several months. Adult males sometimes develop conversion disorder during military basic training. Conversion disorder may also develop in adults as a long-delayed after-effect of childhood abuse. A team of surgeons reported on the case of a patient who went into a psychogenic coma following a throat operation. The surgeons found that she had been repeatedly raped as a child by her father, who stifled her cries by smothering her with a pillow.

Symptoms

In general, symptoms of conversion disorder are not under the patient's conscious control, and are fre-

quently mysterious and frightening to the patient. The symptoms usually have an acute onset, but sometimes worsen gradually.

The most frequent forms of conversion disorder in Western countries include:

- Pseudoparalysis. In pseudoparalysis, the patient loses the use of half of his/her body or of a single limb. The weakness does not follow anatomical patterns and is often inconsistent upon repeat examination.
- Pseudosensory syndromes. Patients with these syndromes often complain of numbness or lack of sensation in various parts of their bodies. The loss of sensation typically follows the patient's notion of their anatomy, rather than known characteristics of the human nervous system.
- Pseudoseizures. These are the most difficult symptoms of conversion disorder to distinguish from their organic equivalents. Between 5% and 35% of patients with pseudoseizures also have epilepsy. Electroencephalograms (EEGs) or measurement of serum prolactin levels, are useful in distinguishing pseudoseizures from epileptic seizures.
- Pseudocoma. Pseudocoma is also difficult to diagnose. Because true coma may indicate a life-threatening condition, patients must be given standard treatments for coma until the diagnosis can be established.
- Psychogenic **movement disorders**. These can mimic myoclonus, parkinsonism, dystonia, dyskinesia, and tremor. Doctors sometimes give patients with suspected psychogenic movement disorders a placebo medication to determine whether the movements are psychogenic or the result of an organic disorder.
- Pseudoblindness. Pseudoblindness is one of the most common forms of conversion disorder related to vision. Placing a mirror in front of the patient and tilting it from side to side can often be used to determine pseudoblindness, because humans tend to follow the reflection of their eyes.
- Pseudodiplopia. Pseudodiplopia, or seeing double, can usually be diagnosed by examining the patient's eyes.
- Pseudoptosis. Ptosis, or drooping of the upper eyelid, is a common symptom of myasthenia gravis and a few other disorders. Some people can cause their eyelids to droop voluntarily with practice. The diagnosis can be made on the basis of the eyebrow; in true ptosis, the eyebrows are lifted, whereas in pseudoptosis they are lowered.
- Hysterical aphonia. Aphonia refers to loss of the ability to produce sounds. In hysterical aphonia, the patient's cough and whisper are normal, and examination of the throat reveals normal movement of the vocal cords.

Psychiatrists working in various parts of the Middle East and Asia report that the symptoms of conversion disorder as listed by *DSM-IV* and ICD-10 do not fit well with the symptoms of the disorder most frequently encountered in their patient populations.

Demographics

The lifetime prevalence rates of conversion disorder in the general U.S. population are estimated to fall between 11 and 300 per 100,000 people. The differences in the estimates reflect differences in the method of diagnosis as well as some regional population differences. In terms of clinical populations, conversion disorder is diagnosed in 5%–14% of general hospital patients; 1%–3% of outpatient referrals to psychiatrists; and 5%–25% of psychiatric outpatients.

Among adults, women diagnosed with conversion disorder outnumber men by a 2:1 to 10:1 ratio; among children, however, the gender ratio is closer to 1:1. Less educated people and those of lower socioeconomic status are more likely to develop conversion disorder; race by itself does not appear to be a factor. There is, however, a major difference between the populations of developing and developed countries; in developing countries, the prevalence of conversion disorder may run as high as 31%.

Diagnosis

Conversion disorder is one of the few mental disorders that appears to be overdiagnosed, particularly in emergency departments. There are numerous instances of serious neurologic illness that were initially misdiagnosed as conversion disorder. Newer techniques of diagnostic imaging have helped to lower the rate of medical errors.

Diagnostic issues

Diagnosis of conversion disorder is complicated by its coexistence with physical illness in as many as 60% of patients. Alternatively explained, a diagnosis of conversion disorder does not exclude the possibility of a concurrent organic disease. The examining doctor will usually order a mental health evaluation when conversion disorder is suspected, as well as x rays, other **imaging studies** that may be useful, and appropriate laboratory tests. The doctor will also take a thorough patient history that will include the presence of recent stressors in the patient's life, as well as a history of abuse. Children and adolescents are usually asked about their school experiences; one question they are asked is whether a recent

change of school or an experience related to school may have intensified academic pressure.

In addition, there are a number of bedside tests that doctors can use to distinguish between symptoms of conversion disorder and symptoms caused by physical diseases. These may include the drop test, in which a "paralyzed" arm is dropped over the patient's face. In conversion disorder, the arm will not strike the face. Other tests include applying a mildly painful stimulus to a "weak" or "numb" part of the body. The patient's pulse rate will typically rise in cases of conversion disorder, and he or she will usually pull back the limb that is being touched.

Factors suggesting a diagnosis of conversion disorder

The doctor can also use a list of factors known to be associated with conversion disorder to assess the likelihood that a specific patient may have the disorder:

- Age. Conversion disorder is rarely seen in children younger than six years or adults over 35 years.
- Sex. The female to male ratio for the disorder ranges between 2:1 and 10:1. It is thought that higher rates of conversion disorder in women may reflect the greater vulnerability of females to abuse.
- Residence. People who live in rural areas are more likely to develop conversion disorder than those who live in cities.
- Level of education. Conversion disorder occurs less often among sophisticated or highly educated people.
- Family history. Children sometimes develop conversion disorder from observing their parents' reactions to stressors. This process is known as social **modeling**.
- A recent stressful change or event in the patient's life.

An additional feature suggesting conversion disorder is the presence of *la belle indifférence*. The French phrase refers to an attitude of relative unconcern on the patient's part about the symptoms or their implications. *La belle indifférence* is, however, much more common in adults with conversion disorder than in children or adolescents. Patients in these younger age groups are much more likely to react to their symptoms with fear or hopelessness.

Medical conditions that mimic conversion symptoms

It is important for the doctor to rule out serious medical disorders in patients who appear to have conversion symptoms. The following disorders must be considered in the differential diagnosis:

- multiple sclerosis (blindness resulting from optic neuritis)
- myasthenia gravis (muscle weakness)
- periodic paralysis (muscle weakness)
- myopathies (muscle weakness)
- polymyositis (muscle weakness)
- Guillain-Barré syndrome (motor and sensory symptoms)

Treatments

Patients diagnosed with conversion disorder frequently benefit from a team approach to treatment and from a combination of treatment modalities. A team approach is particularly beneficial if the patient has a history of abuse, or if he or she is being treated for a concurrent physical condition or illness.

Medications

While there are no drugs for the direct treatment of conversion disorder, medications are sometimes given to patients to treat the anxiety or depression that may be associated with conversion disorder.

Psychotherapy

Psychodynamic psychotherapy is sometimes used with children and adolescents to help them gain insight into their symptoms. Cognitive behavioral approaches have also been tried, with good results. **Family therapy** is often recommended for younger patients whose symptoms may be related to family dysfunction. **Group therapy** appears to be particularly useful in helping adolescents to learn social skills and coping strategies, and to decrease their dependency on their families.

Inpatient treatment

Hospitalization is sometimes recommended for children with conversion disorders who are not helped by outpatient treatment. Inpatient treatment also allows for a more complete assessment of possible coexisting organic disorders, and for the child to improve his or her level of functioning outside of an abusive or otherwise dysfunctional home environment.

Alternative and complementary therapies

Alternative and complementary therapies that have been shown to be helpful in the treatment of conversion disorder include hypnosis, relaxation techniques, visualization, and **biofeedback**.

Prognosis

The prognosis for recovery from conversion disorder is highly favorable. Patients who have clearly identifiable

stressors in their lives, acute onset of symptoms, and a short interval between symptom onset and treatment, have the best prognosis. Of patients hospitalized for the disorder, over half recover within two weeks. Between 20% and 25% will relapse within a year. The individual symptoms of conversion disorder are usually self-limited and do not lead to lasting disabilities; however, patients with hysterical aphonia, paralysis, or visual disturbances, have better prognoses for full recovery than those with tremor or pseudoseizures.

Prevention

The incidence of conversion disorder in adults is likely to continue to decline with rising levels of formal education and the spread of basic information about human psychology. Prevention of conversion disorder in children and adolescents depends on better strategies for preventing abuse.

Couples therapy

Definition

Couples therapy is a form of psychological therapy used to treat relationship distress for both individuals and couples.

Purpose

The purpose of couples therapy is to restore a better level of functioning in couples who experience relationship distress. The reasons for distress can include poor communication skills, incompatibility, or a broad spectrum of psychological disorders that include domestic violence, alcoholism, depression, anxiety, and **schizophrenia**. The focus of couples therapy is to identify the presence of dissatisfaction and distress in the relationship, and to devise and implement a treatment plan with objectives designed to improve or alleviate the presenting symptoms and restore the relationship to a better and healthier level of functioning. Couples therapy can assist persons who are having complaints of intimacy, sexual, and communication difficulties.

Precautions

Couples who seek treatment should consult for services from a mental health practitioner who specializes in this area.

Patients should be advised that honesty, providing all necessary information, cooperation, keeping appointments on time, and a sincere desire for change and improvement are all imperative to increase the chance of successful outcome. Additionally, a willingness to work "towards" and "with" the process of treatment is essential.

Description

Couples therapy sessions differ according to the chosen model, or philosophy behind the therapy. There are several models for treating couples with relationship difficulties. These commonly utilized strategies include psychoanalytic couples therapy, object relations couple therapy, ego analytical couples therapy, behavioral couples therapy, integrative behavioral couples therapy, and cognitive behavioral couples therapy.

Psychoanalytical couples therapy

Psychoanalytic therapy attempts to uncover unresolved childhood conflicts with parental figures and how these behaviors are part of the current relationship problems. The psychoanalytic approach tends to develop an understanding of interpersonal interactions (at present) in connection with early development. The success in development of early stages dictates the future behavior of interpersonal relationships. The essential core of this model deals with the process of separation and individuation (becoming a separate, distinct self) from mother-child interactions during childhood. A critical part of this model is introjection. The process of introjection includes introjects (infant processing versions) of the love object (mother). The developmental process of introjection forms the basis an unconscious representation of others (objects) and is vital for development of a separate and defined sense of self. The psychoanalytic approach analyzes marital relations and mate selection as originating from parent-child relationship during developmental stages of the child.

Object relations couple therapy

The object relations model creates an environment of neutrality and impartiality to understand the distortions and intrapsychic (internalized) conflicts that each partner contributes to the relationship in the form of dysfunctional behaviors. This model proposes that there is a complementary personality fit between couples that is unconscious and fulfills certain needs. This model supports the thought that a "mothering figure" is the central motivation for selection and attachment of a mate. Choosing a "mothering" figure induces further repression (non-development) of portions of personality that were not well-developed (referred to as "lost parts"). This repression causes relationship difficulties.

Ego analytic couples therapy

Ego analytical approaches utilize methods to foster the ability to communicate important feelings in the couple's relationship. This model proposes that dysfunction originates from the patient's incapabilities to recognize intolerance and invalidation of sensitivities and problems in a relationship. According to this model, there are two major categories of problems. The first category of problems relates to dysfunction brought into the relationship from early childhood trauma and experiences. The sec-

The focus of couples therapy is to identify the presence of dissatisfaction and distress in the relationship, and to devise and implement a treatment plan. The objectives of treatment are to improve or alleviate the symptoms and restore the relationship to a healthier level of functioning. *(Aaron Haupt. Photo Researchers, Inc. Reproduced by permission.)*

ond involves the patient's reaction to difficulties and a sense of unentitlement (a personal feeling that one does not deserve something). A patient's shame and guilt are major factors precipitating the thoughts of unentitlement.

Behavioral marital therapy

Behavioral marital therapists tend to improve relationships between a couple by increasing positive exchanges and decreasing the frequency of negative and punishing interactions. This model focuses on the influence that environment has in creating and maintaining relationship behavior. Behavior exchange between partners is flowing continuously and prior histories can affect relationship interactions. Behavior therapy in general is based on the idea that when certain behaviors are rewarded, they are reinforced. The amount of rewards (positive reinforcers) received in relation to the amount of aversive behavior is linked to an individual's sense of relationship dissatisfaction.

Integrative behavioral couples therapy

Integrative behaviorists help couples by improving behavior exchange, communication, and the couples' abilities for problem-solving skills. The integrative behavioral therapy approach examines functioning of the couple and is more flexible and individualized to specific problems in the relationship than behavior marital therapy. This approach examines problems and interactions that are repetitious (acts that are repeatedly done causing relationship problems).

Cognitive behavior marital therapy

The cognitive approach therapist educates and increases awareness concerning perceptions, assumptions, attributions or standards of interaction between the couple. The central theme for understanding marital discourse using cognitive behavioral therapy is based on the behavioral marital therapy model. A couple's emotional and behavioral dysfunction are related to inappropriate information processing (possibly "jumping to conclusions," for example) and negative cognitive appraisals. This models attempts to discover the negative types of thinking that drive negative behaviors that cause relationship distress.

Emotionally focused therapy

Emotionally focused therapy assists patients to acknowledge, assess, and express emotions that are related to distress. This model views emotion and cognition (thinking) as interdependent and that emotion is a primary "driver" of interpersonal expression. The primary theme of emotionally focused therapy is that couple distress stems from unexpressed and unacknowledged emotional needs. The dysfunction arises from negative interactions from emotions that have been withheld from disclosure from each partner.

Structural strategic marital therapy

Structural strategic therapists will challenge existing negative perceptions and present alternative possibilities and behaviors. These alternate behaviors encourage positive perceptions by role-playing. This model views relationship progression in developmental stages. According to this model, the couple's distress reflects difficulties in coping mechanisms related to life changes— either environmental or personal change. Despite relationship dissatisfaction, the couple will tend to resist change, maintaining status quo, and attempting baseline functioning to keep the system going.

Preparation

Couples should be informed that cooperation is vital for the process. Couples should have a desire to modify and/or change dysfunctional behaviors. Honesty and emotional openness is a necessary component for treatment. Results cannot be guaranteed. The psychotherapist would typically provide an extensive assessment process during the initial appointment. This couples assessment process usually includes in-depth information gathering concerning the presenting problem, and assessment of occupations, schooling, employment, childhood development, parental history, sub-

stance abuse, religion, relational, medical, legal, and past psychological history, in the form an interview. The psychotherapist can then devise the best course of treatment planning. Further psychological tests and measurements may be indicated initially or as the need arises during the treatment process.

Aftercare

Treatment usually takes several months or longer. Once the couple has developed adequate skills and has displayed an improved level of functioning that is satisfactory to both, then treatment can be terminated. An awareness of relapse prevention behaviors and relapsing behaviors is important. (Relapsing behaviors refer to the return to the behaviors that the couple is trying to change or eliminate.) Patients are encouraged to return to treatment if relapse symptoms appear. Follow-up visits and long-term psychological therapy can be arranged between parties if this is mutually decided as necessary and beneficial.

Risks

The major risk of couples therapy is lack of improvement or return to dysfunctional behaviors. These tend not to occur unless there is a breakdown in skills learned and developed during treatment, or a person is resistant to long-term change.

Normal results

A normal progression of couples therapy is relief from symptomatic behaviors that cause marital discourse, distress, and difficulties. The couple is restored to healthier interactions and behaviors are adjusted to produce a happier balance of mutually appropriate interactions. Patients who are sincere and reasonable with a willingness to change tend to produce better outcomes. Patients usually develop skills and increased awareness that promotes healthier relationship interactions.

Abnormal results

There are no known abnormal results from couples therapy. At worst, patients do not get better because they cannot break away from self-induced, self-defeating behaviors that precipitate marital dysfunction and distress. The problems are not worsened if treatment is provided by a trained mental health practitioner in this specialty.

Covert sensitization

Definition

Covert sensitization is a form of behavior therapy in which an undesirable behavior is paired with an unpleasant image in order to eliminate that behavior.

Purpose

As with other **behavior modification** therapies, covert sensitization is a treatment grounded in learning theory—one of the basic tenets being that all behavior is learned and that undesirable behaviors can be unlearned under the right circumstances. Covert sensitization is one of a group of behavior therapy procedures classified as covert conditioning, in which an aversive stimulus in the form of a nausea- or anxiety-producing image is paired with an undesirable behavior to change that behavior. It is best understood as a mixture of both the classical and the operant conditioning categories of learning. Based on research begun in the 1960s, psychologists Joseph Cautela and Albert Kearney published the 1986 classic *The Covert Conditioning Handbook*, which remains a definitive treatise on the subject.

The goal of covert sensitization is to directly eliminate the undesirable behavior itself, unlike insight-oriented psychotherapies that focus on uncovering unconscious motives in order to produce change. The behaviors tar-

KEY TERMS

Covert—Concealed, hidden, or disguised.

Operant—Conditioning in which the desired response is reinforced by an introduced stimulus.

Sensitization—To make sensitive or susceptible.

geted for modification are often referred to as "maladaptive approach behaviors," which includes behaviors such as alcohol abuse, drug abuse, and smoking, pathological gambling, overeating, sexual deviations, and sexually based nuisance behaviors such as obscene phone calling. The type of behavior to be changed and the characteristics of the aversive imagery to be used influence the treatment, which is usually administered in an outpatient setting either by itself or as a component of a multimodal program. Self-administered homework assignments are almost always part of the treatment package. Some therapists incorporate covert sensitization with hypnosis in the belief that outcome is enhanced.

Description

The patient being treated with covert sensitization can expect a fairly standard set of procedures. The therapist begins by assessing the problem behavior, and will most likely measure frequency, severity, and the environment in which it occurs. Depending upon the type of behavior to be changed, some therapists may also take treatment measures before, during, and after physiological arousal (such as heart rate) to better assess treatment impact. Although the therapeutic relationship is not the focus of treatment, the behavior therapist believes that good rapport will facilitate a more successful outcome and strives to establish positive but realistic expectations. Also, a positive relationship is necessary to establish patient confidence in the rationale for exposure to the discomfort of unpleasant images.

The therapist will explain the treatment rationale and protocol. Patient understanding and consent are important, since, by intention, he or she will be asked to experience images that arouse unpleasant and uncomfortable physical and psychological associations. The therapist and patient collaborate in creating a list of aversive images uniquely meaningful to the patient that will be applied in the treatment. Standard aversive images include vomiting, snakes, spiders, vermin, and embarrassing social consequences. An aversive image is then selected appropriate to the target problem behavior. Usually, the image with the most powerful aversive response is chosen. The patient is instructed on how to relax—an important precursor to generating intense imagery. The patient is then asked to relax and imagine approaching the situation where the undesirable behavior occurs (for example, purchasing donuts prior to overeating).

If the patient has a difficult time imagining the scene, the image may be presented verbally by the therapist. As the patient imagines getting closer to the situation (donut store), he or she is asked to clearly imagine an unpleasant consequence (such as vomiting) just before indulging in the undesirable behavior (purchasing donuts and overeating). The scene must be imagined with sufficient vividness so that a sense of physiological discomfort or high anxiety is actually experienced. Then the patient imagines leaving the situation and experiencing considerable relief. The patient learns to associate unpleasant sensations (nausea and vomiting) with the undesirable behavior, leading to decreased desire and avoidance of the situation in the future. An alternative behavior incompatible with the problem behavior may be recommended (eat fruit when hungry for a donut).

The patient is given the behavioral homework assignment to practice self-administering the treatment. The patient is told to alternate the aversive scenes with scenes of self-controlled restraint in which he or she rejects the undesirable behavior before indulging in it, thus avoiding the aversive stimulus. The procedure is practiced several times with the therapist in the office, and the patient practices the procedure ten to 20 times during each home session between office sessions. The patient is then asked to practice in the actual situation, imagining the aversive consequences and avoiding the situation. With much variation, and depending upon the nature of the behavior targeted for change, the patient may see the therapist anywhere from five to 20 sessions over a period of a few weeks to several months. The treatment goal is to eliminate the undesirable behavior altogether.

Aftercare

Patients completing covert sensitization treatment are likely to be asked by the therapist to return periodically over the following six to twelve months or longer, for booster sessions to prevent relapse.

Risks

Covert sensitization is comparatively risk-free. This is in contrast to the medical and ethical concerns raised by some other aversive procedures such as **aversion therapy**, in which potent chemical and pharmacological stimulants may be used as aversants.

Normal results

Depending upon the objectives established at the beginning of treatment, patients successfully completing covert sensitization might expect to stop the undesirable behavior. And, if they practice relapse prevention techniques, they can expect to maintain the improvement. Although this treatment may appear to be relatively simple, it has been found to be quite effective for treating many problem behaviors.

John Garrison, Ph.D.

KEY TERMS

Genogram—A family tree diagram that represents the names, birth order, sex, and relationships of the members of a family. Therapists use genograms to detect recurrent patterns in the family history and to help the members understand their problem(s).

Journaling—Involves writing out thoughts and feelings in an unstructured format. A "stream of consciousness" approach (writing whatever comes to mind) is suggested for greatest effectiveness.

Psychodrama—A specific form of role play that focuses on acting out "scripts" of unresolved issues within the family, or helping family members adopt new approaches and understanding of one another.

Role-playing—Involves adopting the role of other family members, oneself, or significant persons within the life of the individual and acting out various life situations in order to explore the relationships of those involved.

Creative therapies

Definition

Creative therapy refers to a group of techniques that are expressive and creative in nature. The aim of creative therapies is to help clients find a form of expression beyond words or traditional therapy, such as cognitive or **psychotherapy**. Therefore, the scope of creative therapy is as limitless as the imagination in finding appropriate modes of expression. The most commonly used and professionally supported approaches include art therapy, writing, sand play, clay, movement therapy, psychodrama, role play, and music therapy.

Purpose

Creative therapy includes techniques that can be used for self-expression and personal growth when the client is unable to participate in traditional "talk therapy," or when that approach has become ineffective. Appropriate clients include children, individuals who are unable to speak due to **stroke** or **dementia**, or people who are dealing with clinical issues that are hidden within the subconscious, beyond the reach of language. The latter often occurs when the focus is on trauma or **abuse** that may have occurred before the client was able to speak, or in families where there is a strict code against talking about feelings or "negative" things. Creative therapy is also effective when used to explore fears around medical issues, such as cancer or HIV.

Precautions

Caution is indicated when strong emotions become overwhelming, thus debilitating the client. Possible indications for caution include the presence of flashbacks, panic attacks, recently revealed trauma or abuse, and vivid and realistic nightmares. Other indications for caution include individual characteristics, such as a tendency toward overly emotional responses, difficulty managing change or surprises, and poor coping skills. Therapists should also take care with patients with **psychosis** or **borderline personality disorder**.

Description

Visually expressive forms of creative therapy include drawing, painting, and modeling with clay. The goal is to provide a medium for expression that bypasses

Writing in a journal can relieve stress and can be practiced on a regular basis by writing down whatever comes to mind, or it can be used for specific problem areas, such as focusing attention on goals or on unresolved feelings of grief or anger. *(Jeff Greenberg. Photo Researchers, Inc. Reproduced by permission.)*

words, thus helping the individual connect with emotions about various personal experiences. The scope of the drawings is limited only by the imagination of the individual and by the creativity of the therapists. This technique can often be continued by clients on their own after beginning the work in session.

Movement and music therapies are often used in conjunction with relaxation approaches. Movement therapy involves dance and the interpretation of feelings or thoughts into movement, and is often set to music. For teens in particular, music and movement are often healthy releases for **stress** and emotions. These therapies can also help people develop appropriate coping skills. Movement and music may be used in nursing homes, gym class, residential treatment centers, a therapist's office, or a home.

Journaling techniques have been studied extensively regarding their health benefits, both physical and emotional. Its application is broad and it can be used in various therapeutic approaches. Journaling can be used on a regular basis for stress relief by writing down whatever comes to mind, or it can be used for specific problem areas, such as focusing attention on goals or on unresolved feelings of **grief** or anger. In journaling, it seems to be more important to focus on emotional aspects, rather than using it to simply record daily events.

Other techniques include sand play, pet therapy, **play therapy**, and horticulture therapy. Sand play is a specialized form of play therapy in which sand is used to form designs or set up stories using play figures. Play therapy is an approach used with children, and is quite extensive in background theory and application. It is a psychological therapy in which the child plays in the therapist's presence. The therapist then uses a child's fantasies and the symbolic meanings of his or her play as a medium for understanding and communicating with the child. Pet therapy and horticulture therapy are often used in hospitals and residential treatment centers. Although these therapies are not expressive in the same way as other approaches, they offer a different experience for the individuals participating in them—helping people feel a sense of joy, connection, or accomplishment that may be missing from their lives.

Preparation

Little preparation is needed for the visually expressive forms. Drawing is often used in a first session with young children. When used with adults, drawing or painting is often helpful, especially at a time of impasse when "talk therapy" is not effective, or when focusing on more emotional aspects of the therapeutic work.

Role-playing requires the review of specific family roles to determine goals for the work. If the family work is focused on communication, each member may be asked to adopt the role of another family member to clarify their perceptions of current roles for themselves and the other family members. The purpose of adopting these roles is to gain insight and understanding about the other person's perspective in terms of their thoughts, feelings, and actions. Taking on the role of another helps to build empathy and provide a mechanism for personal growth and change.

A genogram or diagram of family members is sometimes helpful as a guide in identifying specific roles and directing the drama.

Aftercare

For most of the creative therapy techniques, aftercare will largely be maintained by the individual client, unless the individual is participating in a support group or ongoing therapy. One advantage of creative therapy is the ease of implementation. Little special equipment is needed, and many of the techniques easily lend themselves to use in the home. If an individual is participating in a support group or individual therapy following a **hospitalization**, the techniques can be maintained as part of those activities.

Self-portrait done by a girl while in treatment for anorexia nervosa. *(Susan Rosenberg, Science Photo Library/Photo Researchers, Inc. Reproduced by permission.)*

Risks

Risks occur when the client is exposed to intense emotional material or memories before the necessary preparatory work has been completed in therapy. Such negative reactions may include a psychotic break, or a need for hospitalization, although this is a rare occurrence.

A more likely risk is that of altering existing family relationships. Working through certain issues surrounding trauma or abuse may alter the participant's feelings or thoughts about significant people in his or her life. Conflicted feelings about these individuals may arise as recognition of certain patterns or behavior become apparent to the client. The increased awareness and insight may make it impossible for the client to continue some relationships. The resulting conflict may be uncomfortable for the client.

Normal results

Typical results include increased awareness, the release of suppressed emotions, a general lifting of depressive feelings, increased energy, and the resolution of internal conflict. Ongoing health benefits, such as lowered blood pressure, may result from decreased stress and improved coping skills. A greater sense of self-acceptance and decreased agitation are often experienced by clients.

Abnormal results

Unusual results include increasingly intense feelings of agitation and stress. For some individuals, the techniques may appear to have no benefits. It is recommended that these individuals seek clinical help.

Crisis housing

Definition

Crisis housing (or crisis residential services) are supervised short-term residential alternatives to **hospitalization** for adults with serious mental illnesses or children with serious emotional or behavioral disturbances.

Purpose

The course of most serious mental illness (such as **schizophrenia**, **bipolar disorder**, severe depression, and **borderline personality disorder**) is cyclical, typically characterized by periods of relative well-being, interrupted by periods of deterioration or relapse. When relapse occurs, the individual generally exhibits florid symptoms that require immediate psychiatric attention and treatment. More often than not, relapse is caused by the individual's failure to comply with a prescribed medication regimen (not taking medication regularly, not taking the amount or dose prescribed, or not taking it all). Relapse can also be triggered during periods of great **stress** or can even occur spontaneously, without any marked changes in lifestyle or medication regimen. When these crises recur, the goal of treatment is to stabilize the individual as soon as possible, since research suggests that these patients are also more likely to attempt **suicide**.

Description

Over the past 30 years, crisis housing programs have evolved as short-term, less costly, and less restrictive residential alternatives to hospitalization. Intended to divert individuals from emergency rooms, jails, and hospitals into community-based treatment settings, they offer intensive crisis support to individuals and their families. Services include **diagnosis**, assessment, and treatment (including medication stabilization); rehabilitation; and links to community-based services. These programs are intended to stabilize the individual as rapidly as possible—usually between eight and 60 days—so they can return to their home or residence in the community.

Some of the earliest crisis housing programs include Soteria House and La Posada, which began in northern California in the 1970s, and the START (short-term acute residential treatment) program that began in San Diego in 1980. While programs vary from location to location, most offer acute services 24 hours a day in a small non-institutional residential setting. Adequate structure and supervision is provided by an interdisciplinary team of professionals and other trained workers.

Beginning the day they arrive, residents help develop their own plans for recovery and continued care in the community. Patients receive state-of-the art psychopharmacological treatment and other cognitive-behavioral interventions. Residents are encouraged to play an active role in the operation of the household, including meal preparation. The home-like environment is helpful in lessening the **stigma** and sense of failure that often occurs when someone needs to return to an inpatient psychiatric unit.

Similarly, in the case of seriously emotionally disturbed children and adolescents, the goal of crisis housing is to avert visits to the emergency room or hospitalization by stabilizing the individual in as normal a setting as possible. Compared to these services for adults, there is typically greater emphasis placed on involving families and schools in planning for community-based care after discharge.

While the evidence base for crisis housing is comprised primarily of uncontrolled studies, evaluations of several of these programs suggest that they may provide high-quality treatment and care at a lower cost than hospitals. Crisis housing is not currently available in all communities, however.

Crisis intervention

Definition

Crisis intervention refers to the methods used to offer immediate, short-term help to individuals who experience an event that produces emotional, mental, physical, and behavioral distress or problems. A crisis can refer to any situation in which the individual perceives a sudden loss of his or her ability to use effective problem-solving and coping skills. A number of events or circumstances can be considered a crisis: life-threatening situations, such as natural disasters (such as an earthquake or tornado), sexual assault or other criminal victimization; medical illness; mental illness; thoughts of **suicide** or homicide; and loss or drastic changes in relationships (death of a loved one or divorce, for example).

KEY TERMS

Coping—In psychology, a term that refers to a person's patterns of response to stress.

Critical incident—Also known as a crisis event. An event that is stressful enough to overwhelm the coping skills of a person or group.

Stress—A physical and psychological response that results from being exposed to a demand or pressure.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

Purpose

Crisis intervention has several purposes. It aims to reduce the intensity of an individual's emotional, mental, physical and behavioral reactions to a crisis. Another purpose is to help individuals return to their level of functioning before the crisis. Functioning may be improved above and beyond this by developing new coping skills and eliminating ineffective ways of coping, such as withdrawal, isolation, and substance abuse. In this way, the individual is better equipped to cope with future difficulties. Through talking about what happened, and the feelings about what happened, while developing ways to cope and solve problems, crisis intervention aims to assist the individual in recovering from the crisis and to prevent serious long-term problems from developing. Research documents positive outcomes for crisis intervention, such as decreased distress and improved problem solving.

Description

Individuals are more open to receiving help during crises. A person may have experienced the crisis within the last 24 hours or within a few weeks before seeking help. Crisis intervention is conducted in a supportive manner. The length of time for crisis intervention may

Trained adults staff a 24-hour suicide hotline. *(Stock Boston, Inc. Reproduced by permission.)*

range from one session to several weeks, with the average being four weeks. Crisis intervention is not sufficient for individuals with long-standing problems. Session length may range from 20 minutes to two or more hours. Crisis intervention is appropriate for children, adolescents, and younger and older adults. It can take place in a range of settings, such as hospital emergency rooms, crisis centers, counseling centers, mental health clinics, schools, correctional facilities, and other social service agencies. Local and national telephone hotlines are available to address crises related to suicide, domestic violence, sexual assault, and other concerns. They are usually available 24 hours a day, seven days a week.

Responses to crisis

A typical crisis intervention progresses through several phases. It begins with an assessment of what happened during the crisis and the individual's responses to it. There are certain common patterns of response to most crises. An individual's reaction to a crisis can include emotional reactions (fear, anger, guilt, **grief**), mental reactions (difficulty concentrating, confusion, nightmares), physical reactions (headaches, dizziness, **fatigue**, stomach problems), and behavioral reactions (sleep and appetite problems, isolation, restlessness). Assessment of the individual's potential for suicide and/or homicide is also conducted. Also, information about the individual's strengths, coping skills, and social support networks is obtained.

Education

There is an educational component to crisis intervention. It is critical for the individual to be informed about various responses to crisis and informed that he or she is having normal reactions to an abnormal situation. The individual will also be told that the responses are temporary. Although there is not a specific time that a person can expect to recover from a crisis, an individual can help recovery by engaging in the coping and problem-solving skills described below.

Coping and problem solving

Other elements of crisis intervention include helping the individual understand the crisis and their response to it as well as becoming aware of and expressing feelings, such as anger and guilt. A major focus of crisis interven-

tion is exploring coping strategies. Strategies that the individual previously used but that have not been used to deal with the current crisis may be enhanced or bolstered. Also, new coping skills may be developed. Coping skills may include relaxation techniques and exercise to reduce body tension and **stress** as well as putting thoughts and feelings on paper through journal writing instead of keeping them inside. In addition, options for social support or spending time with people who provide a feeling of comfort and caring are addressed. Another central focus of crisis intervention is problem solving. This process involves thoroughly understanding the problem and the desired changes, considering alternatives for solving the problem, discussing the pros and cons of alternative solutions, selecting a solution and developing a plan to try it out, and evaluating the outcome. Cognitive therapy, which is based on the notion that thoughts can influence feelings and behavior, can be used in crisis intervention.

In the final phase of crisis intervention, the professional will review changes the individual made in order to point out that it is possible to cope with difficult life events. Continued use of the effective coping strategies that reduced distress will be encouraged. Also, assistance will be provided in making realistic plans for the future, particularly in terms of dealing with potential future crises. Signs that the individual's condition is getting worse or "red flags" will be discussed. Information will be provided about resources for additional help should the need arise. A telephone follow-up may be arranged at some agreed-upon time in the future.

Suicide intervention

Purpose

Suicidal behavior is the most frequent mental health emergency. The goal of crisis intervention in this case is to keep the individual alive so that a stable state can be reached and alternatives to suicide can be explored. In other words, the goal is to help the individual reduce distress and survive the crisis.

Assessment

Suicide intervention begins with an assessment of how likely it is that the individual will kill himself or herself in the immediate future. This assessment has various components. The professional will evaluate whether or not the individual has a plan for how the act would be committed, how deadly the method is (shooting, overdosing), if means are available (access to weapons), and if the plan is detailed and specific versus vague. The professional will also assess the individual's emotions, such as depression, hopelessness, hostility and anxiety. Past suicide attempts as well as completed suicides among family and friends will be assessed. The nature of any current crisis event or circumstance will be evaluated, such as loss of physical abilities because of illness or accident, unemployment, and loss of an important relationship.

Treatment plan

A written safekeeping contract may be obtained. This is a statement signed by the individual that he or she will not commit suicide, and agrees to various actions, such as notifying their clinician, family, friends, or emergency personnel, should thoughts of committing suicide again arise. This contract may also include coping strategies that the individual agrees to engage in to reduce distress. If the individual states that he or she is not able to do this, then it may be determined that medical assistance is required and voluntary or involuntary psychiatric **hospitalization** may be implemented. Most individuals with thoughts of suicide do not require hospitalization and respond well to outpatient treatment. Educating family and friends and seeking their support is an important aspect of suicide intervention. Individual therapy, **family therapy**, substance abuse treatment, and/or psychiatric medication may be recommended.

Critical incident stress debriefing and management

Definition

Critical incident stress debriefing (CISD) uses a structured, small group format to discuss a distressing crisis event. It is the best known and most widely used debriefing model. Critical incident stress management (CISM) refers to a system of interventions that includes CISD as well as other interventions, such as one-on-one crisis intervention, **support groups** for family and significant others, stress management education programs, and follow up programs. It was originally designed to be used with high-risk professional groups, such as emergency services, public safety, disaster response, and military personnel. It can be used with any population, including children. A trained personnel team conducts this intervention. The team usually includes professional support personnel, such as mental health professionals and clergy. In some settings, peer support personnel, such as emergency services workers, will be part of the debriefing team. It is recommended that a debriefing occur after the first 24 hours following a crisis event, but before 72 hours have passed since the incident.

Purpose

This process aims to prevent excessive emotional, mental, physical, and behavioral reactions and **post-traumatic stress disorder** (PTSD) from developing in response to a crisis. Its goal is to help individuals recover as quickly as possible from the stress associated with a crisis.

Phases of CISD

There are seven phases to a formal CISD.

1. Introductory remarks: team sets the tone and rules for the discussion, encourages participant cooperation.
2. Fact phase: participants describe what happened during the incident.
3. Thought phase: participants state the first or main thoughts while going through the incident.
4. Reaction phase: participants discuss the elements of the situation that were worst.
5. Symptom phase: participants describe the symptoms of distress experienced during or after the incident.
6. Teaching phase: team provides information and suggestions that can be used to reduce the impact of stress.
7. Re-entry phase: team answers participants' questions and makes summary comments.

Precautions

Some concern has been expressed in the research literature about the effectiveness of CISD. It is thought that as long as the provider(s) of CISD have been properly trained, the process should be helpful to individuals in distress. If untrained personnel conduct CISD, then it may result in harm to the participants. CISD is not **psychotherapy** or a substitute for it. It is not designed to solve all problems presented during the meeting. In some cases, a referral for follow-up assessment and/or treatment is recommended to individuals after a debriefing.

Medical crisis counseling

Medical crisis counseling is a brief intervention used to address psychological (anxiety, fear and depression) and social (family conflicts) problems related to chronic illness in the health care setting. It uses coping techniques and building social support to help patients manage the stress of being newly diagnosed with a chronic illness or suffering a worsening medical condition. It aims to help patients understand their reactions as normal responses to a stressful circumstance and to help them function better. Preliminary studies of medical crisis counseling indicate that one to four sessions may be needed. Research is also promising in terms of its effectiveness at decreasing patients' level of distress and improving their functioning.

Cyclothymic disorder

Definition

Cyclothymic disorder, also known as cyclothymia, is a relatively mild form of bipolar II disorder characterized by mood swings that may appear to be almost within the normal range of emotions. These mood swings range from mild depression, or dysthymia, to mania of low intensity, or hypomania.

Description

Cyclothymic disorder, a symptomatically mild form of bipolar II disorder, involves mood swings ranging from mild depression to mild mania. It is possible for cyclothymia to go undiagnosed, and for individuals with the disorder to be unaware that they have a treatable disease. Individuals with cyclothymia may experience episodes of low-level depression, known as dysthymia; periods of intense energy, creativity, and/or irritability, known as hypomania; or they may alternate between both mood states. Like other **bipolar disorders**, cyclothymia is a chronic illness characterized by mood swings that can occur as often as every day and last for several days, weeks, months, or as long as two years. Individuals with this disorder are never free of symptoms of either hypomania or mild depression for more than two months at a time.

The noted **psychiatrist** Emil Kraepelin first described the symptoms of cyclothymic disorder in the late nineteenth century. Kraepelin described four types of **personality disorders**: depressive (gloomy); manic (cheerful and uninhibited); irritable (emotionally unstable and explosive); and cyclothymic. He viewed the irritable personality as simultaneously depressive and manic, and the cyclothymic personality as alternating between depressive and manic states.

Persons with cyclothymic disorder differ in the relative proportion of depressive versus hypomanic episodes that they experience. Some individuals have more frequent depressive episodes, whereas others are more likely to feel hypomanic. Most individuals who seek help for the disorder alternate between feelings of mild depression and intense irritability. Those who feel energized and creative when they are hypomanic, and who find their emotional low periods tolerable, may never seek treatment.

Causes and symptoms

Causes

Controversy exists over whether cyclothymic disorder is truly a mood disorder in either biological or psychological terms, or whether it belongs in the class of disorders known as personality disorders. Despite this controversy, most of the evidence from biological and genetic research supports the placement of cyclothymia within the mood disorder category.

Genetic data provide strong support that cyclothymia is indeed a mood disorder. About 30% of all patients with cyclothymia have family histories of bipolar I disorder, which involves full-blown manic episodes alternating with periods of relative emotional stability. Full-blown depressive episodes are frequently, but not always, part of the picture in bipolar I disorder. Reviews of the family histories of bipolar I patients show a tendency toward illnesses that alternate across generations: bipolar I in one generation, followed by cyclothymia in the next, followed again by bipolar I in the third generation. The general prevalence of cyclothymia in families with bipolar I diagnoses is much higher than in families with other mental disorders or in the general population. It has been reported that about one-third of patients with cyclothymic disorder subsequently develop a major mood disorder.

Most psychodynamic theorists believe that the psychosocial origins of cyclothymia lie in early traumas and unmet needs dating back to the earliest stages of childhood development. Hypomania has been described as a deficiency of self-criticism and an absence of inhibitions. The patient is believed to use **denial** to avoid external problems and internal feelings of depression. Hypomania is also believed to be frequently triggered by profound interpersonal loss. The false feeling of euphoria (giddy or intense happiness) that arises in such instances serves as a protection against painful feelings of sadness, and even possibly anger against the lost loved one.

Symptoms

The symptoms of cyclothymic disorder are identical to those of bipolar I disorder except that they are usually less severe. It is possible, however, for the symptoms of cyclothymia to be as intense as those of bipolar I, but of shorter duration. About one-half of all patients with cyclothymic disorder have depression as their major symptom. These persons are most likely to seek help for their symptoms, especially during their depressed episodes. Other patients with cyclothymic disorder experience primarily hypomanic symptoms. They are less likely to seek help than those who suffer primarily from depression. Almost all patients with cyclothymic disorder have periods of mixed symptoms (both depression and hypomania together) during which time they are highly irritable.

KEY TERMS

Bipolar I disorder—A major mood disorder characterized by full-blown manic episodes, often interspersed with episodes of major depression.

Bipolar II disorder—Disorder with major depressive episodes and mild manic episodes known as hypomania.

Borderline personality disorder—A severe and usually life-long mental disorder characterized by violent mood swings and severe difficulties in sustaining interpersonal relationships.

Cyclothymia—An alternate name for cyclothymic disorder.

Cyclothymic disorder—A relatively mild mood disorder characterized by mood swings between mild depression to mild mania.

Denial—A psychological defense mechanism that reduces anxiety by excluding recognition of an addiction or similar problem from the conscious mind.

Dysthymia—Depression of low intensity.

Hypomania—A milder form of mania that is characteristic of bipolar II disorder.

Psychodynamic theorists—Therapists who believe that the origins of mental problems lie in a person's internal conflicts and complexes.

Psychosocial—A term that refers to the emotional and social aspects of psychological disorders.

Cyclothymic disorder may cause disruption in all areas of the person's life. Many individuals with this disorder are unable to succeed in their professional or personal lives as a result of their symptoms. A few who suffer primarily from hypomanic episodes are high achievers who work long hours and require little sleep. A person's ability to manage the symptoms of the disorder depends upon a number of personal, social, and cultural factors.

The lives of most people suffering from cyclothymic disorder are difficult. The cycles of the disorder tend to be much shorter than in bipolar I. In cyclothymic disorder, mood changes are irregular and abrupt, and can occur within hours. While there are occasional periods of normal mood, the unpredictability of the patient's feelings and behavior creates great **stress** for him or her and for those who must live or work with the patient. Patients often feel that their moods are out of control. During mixed periods, when they are highly irritable, they may become involved in unprovoked arguments with family, friends, and co-workers, causing stress to all around them.

It is common for cyclothymic disorder patients to abuse alcohol and/or other drugs as a means of self-medicating. It is estimated that about 5–10% of all patients with cyclothymic disorder suffer also from substance dependence.

Demographics

Patients with cyclothymic disorder are estimated to constitute from 3–10% of all psychiatric outpatients. They may be particularly well represented among those with complaints about marital and interpersonal difficulties. In the general population, the lifetime chance of developing cyclothymic disorder is about 1%. The actual percentage of the general population with cyclothymia is probably somewhat higher, however, as many patients may not be aware that they have a treatable disease.

Cyclothymic disorder frequently coexists with **borderline personality disorder**, which is a severe lifelong illness characterized by emotional instability and relationship problems. An estimated 10% of outpatients and 20% of inpatients with borderline personality disorder have a coexisting **diagnosis** of cyclothymic disorder. The female-to-male ratio in cyclothymic disorder is approximately 3:2. It is estimated that 50%–75% of all patients develop the disorder between the ages of 15 and 25.

Diagnosis

The diagnosis of cyclothymic disorder is usually made when a person with the disorder is sufficiently disturbed by the symptoms or their consequences to seek help. While there are no laboratory tests or **imaging studies** that can detect the disorder as of 2002, the doctor will usually give the patient a general physical examination to rule out general medical conditions that are often associated with depressed mood. The doctor will also take a detailed medical and psychiatric history. If the patient's history or other aspects of his or her behavior during the interview suggest the diagnosis of cyclothymic disorder, the doctor may follow up the interview with the patient by talking with friends or family members to confirm the diagnosis.

The manual used by mental health professionals to diagnose mental illnesses is called the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, text revision, also known as the *DSM-IV-TR*. This manual specifies six criteria that must be met for a diagnosis of cyclothymic disorder. These include:

- Numerous episodes of hypomania and depression that are not severe enough to be considered major depression. These episodes must have lasted for at least two years.
- During the same two-year period (one year for children and adolescents), the individual has not been free from either hypomania or mild depression for more than two months at a time.
- No major depression, mania, or mixed (both depression and mania together) condition has been present during the first two years of the disorder.
- The individual does not have a thought disorder such as **schizophrenia** or other psychotic condition.
- The symptoms are not due to the direct effects of substance use (such as a drug of abuse or a prescribed medication) or to a medical condition.
- The symptoms cause significant impairment in the patient's social, occupational, family, or other important areas of life functioning.

Treatments

Biological therapy

Medication is an important component of treatment for cyclothymic disorder. A class of drugs known as antimanic medications is usually the first line of treatment for these patients. Drugs such as lithium, **carbamazepine** (Tegretol), and sodium valproate (Depakene), have all been reported to be effective. While antidepressant medications might be prescribed, they should be used with caution, because these patients are highly susceptible to hypomanic or full-blown manic episodes induced by antidepressants. It is estimated that 40–50% of all patients with cyclothymic disorder who are treated with antidepressants experience such episodes.

Psychosocial therapy

Psychotherapy with individuals diagnosed with cyclothymic disorder is best directed toward increasing the patient's awareness of his or her condition and helping to develop effective coping strategies for mood swings. Often, considerable work is needed to improve the patient's relationships with family members and workplace colleagues because of damage done to these relationships during hypomanic episodes. Because cyclothymic disorder is a lifelong condition, psychotherapy is also a long-term commitment. Working with families of cyclothymic patients can help them adjust more effectively to the patients' mood swings as well.

Prognosis

While some patients later diagnosed with cyclothymic disorder were considered sensitive, hyperactive, or moody as children, the onset of cyclothymic disorder usually occurs gradually during the patient's late teens or early 20s. Often school performance becomes a problem along with difficulty establishing peer relationships. Approximately one-third of all patients with cyclothymic disorder develop a major mood disorder during their lifetime, usually bipolar II disorder.

Prevention

Cyclothymic disorder appears to have a strong genetic component. It is far more common among the first-degree biological relatives of persons with bipolar I disorder than among the general population. At this time, there are no known effective preventive measures that can reduce the risk of developing cyclothymic disorder. Genetic counseling, which assists a couple in understanding their risk of producing a child with the disorder, may be of some help.

Deinstitutionalization

Definition

Deinstitutionalization is a long-term trend wherein fewer people reside as patients in mental hospitals and fewer mental health treatments are delivered in public hospitals. This trend is directly due to the process of closing public hospitals and the ensuing transfers of patients to community-based mental health services in the late twentieth century. It represents the dissipation of patients over a wider variety of health care settings and geographic areas. Deinstitutionalization also illustrates evolution in the structure, practice, experiences, and purposes of mental health care in the United States.

History

Hospital care for mental health

In the United States in the nineteenth century, hospitals were built to house and care for people with chronic illness, and mental health care was a local responsibility. As with most chronic illness, **hospitalization** did not always provide a cure. Individual states assumed primary responsibilities for mental hospitals beginning in 1890. In the first part of the twentieth century, while mental health treatments had very limited efficacy, many patients received custodial care in state hospitals. Custodial care refers to care in which the patient is watched and protected, but a cure is not sought.

After the founding of the National Institutes of Mental Health (NIMH), new psychiatric medications were developed and introduced into state mental hospitals beginning in 1955. These new medicines brought new hope, and helped address some of the symptoms of mental disorders.

President John F. Kennedy's 1963 Community Mental Health Centers Act accelerated the trend toward deinstitutionalization with the establishment of a network of **community mental health** centers. In the 1960s, with the introduction of Medicare and Medicaid, the federal government assumed an increasing share of responsibility for the costs of mental health care. That trend continued into the 1970s with the implementation of the Supplemental Security Income program in 1974. State governments helped accelerate deinstitutionalization, especially of elderly people. In the 1960s and 1970s, state and national policies championed the need for comprehensive community mental health care, though this ideal was slowly and only partially realized.

Beginning in the 1980s, **managed care** systems began to review systematically the use of inpatient hospital care for mental health. Both public concerns and private health insurance policies generated financial incentives to admit fewer people to hospitals and discharge inpatients more rapidly, limit the length of patient stays, or to transfer responsibility to less costly forms of care.

Indicators and trends

Many statistical indicators show the amount of inpatient hospital care for persons with mental illness decreased during the latter half of the twentieth century, while the total volume of mental health care increased.

A patient care episode is a specific measure of the volume of care provided by an organization or system. It begins when a person visits a health care facility for treatment and ends when the person leaves the facility. In 1955, 77% of all patient care episodes in mental health organizations took place in 24-hour hospitals. By 1994, although the numbers of patient care episodes increased by more than 500%, only 26% of mental health treatment episodes were in these hospitals. The timing of this trend

KEY TERMS

Patient care episodes—A specific measure of the volume of care provided by an organization or system. It begins with a treatment visit to a health care facility (a hospital or residential treatment center, for example) and ends when a person leaves the facility, so it may vary by patient and visit. Over time, the volume of patient care episodes indicates the degree to which a population uses certain health care capacities. Other measures that may be used to measure volume of care include number of beds or bed-days, total number of patients served, and also more specific measures like patient-contact hours.

varied across different states and regions, but it was consistent across a variety of indicators.

The number of inpatient beds available to each group of 100,000 civilians decreased from over 200 beds in 1970 to less than 50 in 1992. The average number of patients in psychiatric hospitals decreased from over 2,000 in 1958 to about 500 in 1978. While adjusted per-capita spending on mental health rose from $16.53 in 1969 to $19.33 in 1994, the portion of funds spent on state and county mental hospitals fell from $9.11 to $4.56.

Transinstutionalization

Trends toward deinstitutionalization also reflect shifting demographics and boundaries of care. For example, decreases in inpatient mental health care can be complemented by increases in outpatient mental health care. Decreases in inpatient mental health care can also be paired with increases in other forms of care, such as social welfare, criminal justice, or nursing home care. Thus deinstitutionalization is part of a process sometimes called transinstutionalization, the transfer of institutional populations from hospitals to jails, nursing homes, and shelters.

Causes and consequences

Causes

Deinstitutionalization, originally and idealistically portrayed by advocates and consumers as a liberating, humane policy alternative to restrictive care, may also be interpreted as a series of health policy reforms that are associated with the gradual demise of mental health care dependent on large, state-supported hospitals. Deinstitutionalization is often attributed to decreased need for hospital care and to the advent of new psychiatric medicines.

Consequences

Ideally, deinstitutionalization represents more humane and liberal treatment of mental illness in community-based settings. Pragmatically, it represents a change in the scope of mental health care from longer, custodial inpatient care to shorter outpatient care.

The process of deinstitutionalization, combined with the scarcity of community-based care, is also associated with the visible problems of **homelessness**. Between 30-50% of homeless people in the United States are people with mental illness, and people with mental illness are disproportionate among the homeless.

Experience and adjustment

Deinstitutionalization also describes the adjustment process whereby people with illness are removed from the effects of life within institutions. Since people may become socialized to highly structured institutional environments, they often adapt their social behavior to institutional conditions. Therefore adjusting to life outside of an institution may be difficult.

Defined experientially, deinstitutionalization allows individuals to regain freedom and empower themselves through responsible choices and actions. With the assistance of **social workers** and through psychiatric rehabilitation, former inpatients can adjust to everyday life outside of institutional rules and expectations. This aspect of deinstitutionalization promotes hope and recovery, ongoing debates over the best structure and process of mental health service delivery notwithstanding.

Delirium

Definition

Delirium is a medical condition characterized by a vascillating general disorientation, which is accompanied by cognitive impairment, mood shift, self-awareness, and inability to attend (the inability to focus and maintain attention). The change occurs over a short period of time— hours to days— and the disturbance in consciousness fluctuates throughout the day.

Description

The word delirium comes from the Latin *delirare*. In its Latin form, the word means to become crazy or to rave. A phrase often used to describe delirium is "clouding of consciousness," meaning the person has a diminished awareness of their surroundings. While the delirium is active, the person tends to fade into and out of lucidity, meaning that he or she will sometimes appear to know what's going on, and at other times, may show disorientation to time, place, person, or situation. It appears that the longer the delirium goes untreated, the more progressive the disorientation becomes. It usually begins with disorientation to time, during which a patient will declare it to be morning, even though it may be late night. Later, the person may state that he or she is in a different place rather than at home or in a hospital bed. Still later, the patient may not recognize loved ones, close friends, or relatives, or may insist that a visitor is someone else altogether. Finally, the patient may not recognize the reason for his/her **hospitalization** and might accuse staff or others of some covert reason for his/her hospitalization (see example below). In fact, this waxing and waning of consciousness is often worse at the end of a day, a phenomenon known as "sundowning."

A delirious patient will have a difficult time with most mental operations. Due to the fact that the patient is unable to attend consistently to his environment, he/she can become disoriented. Nevertheless, disorientation and memory loss are not essential to the **diagnosis** of delirium; the inability to focus and maintain attention, however, is essential to rendering a correct diagnosis. Left unchecked, delirium tends to transition from inattention to increased levels of lethargy, leading to torpor, stupor, and coma. In its other form, delirious patients become agitated and almost hypervigilant, with their sleep-wake cycle dramatically altered, fluctuating between great guardedness and **hypersomnia** (excessive drowsiness) during the day and wakefulness during the night. Delirious patients can also experience **hallucinations** of the visual, auditory, or tactile type. In such cases, the patient will see things others cannot see, hear things others cannot hear, and/or feel things that others cannot, such as feeling as though his or her skin is crawling. In short, the extremes of delirium range from the appearance of simple confusion and **apathy** to the anxious, agitated, and hyperactive type, with some patients experiencing both ends of the spectrum during a single episode. It is imperative that a quick evaluation occur if delirium is suspected, because it can lead to death.

Causes and symptoms

Causes

While the symptoms of delirium are numerous and varied, the causes of delirium fall into four basic categories: metabolic, toxic, structural, and infectious. Stated another way, the bases of delirium may be medical, chemical, surgical, or neurological. Many metabolic disorders, such as hypothyroidism, hyperthyroidism, hypokalemia, anoxia, etc. can cause delirium. For example, hypothyroidism (the thyroid gland emits reduced levels of thyroid hormones) brings about a change in emotional responsiveness, which can appear similar to depressive symptoms and cause a state of delirium. Other metabolic sources of delirium involve the dysfunction of

KEY TERMS

Anoxia—Lack of oxygen.

Anticholinergic toxicity—A poisonous effect brought about by ingestion of medications or other toxins that block acetylcholine receptors. When these receptors are blocked, the person taking the medication may find that he or she gets overheated, has dry mouth, has blurry vision, and his or her body may retain urine.

Coma—Unconsciousness.

Hyperthyroidism—Condition resulting from the thyroid glands secreting excessive thyroid hormone, causing increased basal metabolic rate, and causing an increased need for food to meet the demand of the metabolic activity; generally, however, weight loss results.

Hypervigilant—Extreme attention and focus to both internal and external stimuli.

Hypokalemia—Abnormally low levels of potassium in the blood. Hypokalemia is a potential medical emergency, as it can lead to disturbances in of the heart rhythm.

Stupor—A trance-like state that causes a person to appear numb to their environment.

Subdural hematoma—Active bleeding or a blood clot inside the dura (leathery covering of the brain). This bleeding or clot causes swelling of the brain, and, untreated, the condition can cause death.

Torpor—Sluggishness or inactivity.

Tricyclic antidepressants—Antidepressant medications that have the common characteristic of a three-ring nucleus in their chemical structure. Imipramine and amitriptyline are examples of tricyclic antidepressants.

Vascular—Pertaining to the bloodstream (arteries, veins, and blood vessels).

the pituitary gland, pancreas, adrenal glands, and parathyroid glands. It should be noted that when a metabolic imbalance goes unattended, the **brain** may suffer irreparable damage.

One of the most frequent causes of delirium in the elderly is overmedication. The use of medications such as tricyclic antidepressants and antiparkinsonian medications can bring about an anticholinergic toxicity and subsequent delirium. In addition to the anticholinergic drugs, other drugs that can be the source of a delirium are:

- anticonvulsants, used to treat epilepsy
- antihypertensives, used to treat high blood pressure
- cardiac glycosides, such as Digoxin, used to treat heart failure
- cimetidine, used to reduce the production of stomach acid
- **disulfiram**, used in the treatment of alcoholism
- insulin, used to treat diabetes
- opiates, used to treat pain
- phencyclidine (PCP), used originally as an anesthetic, but later removed from the market, now only produced and used illicitly
- salicylates, basically found in aspirin
- steroids, sometimes used to prevent muscle wasting in bedridden or other immobile patients

Additionally, systemic poisoning by chemicals or compounds such as carbon monoxide, lead, mercury, or other industrial chemicals can be the source of delirium.

Just as the ingestion of certain drugs may cause delirium in some patients, the withdrawal of drugs can also cause it. Alcohol is the most widely used and most well known of these drugs whose withdrawal symptoms may include delirium. Delirium onset from the abstinence of alcohol in a chronic user can begin within three days of cessation of drinking. The term delirium tremens is used to describe this form of delirium. The resulting symptoms of this delirium are similar in nature to other delirious states, but may be preceded by clear-headed auditory hallucinations. In other words, the delirium has not begun, but the patient may experience auditory hallucinations. Delirium tremens follow and can have ominous consequences with as many as 15% dying.

Some of the structural causes of delirium include vascular blockage, subdural hematoma, and brain tumors. Any of these can damage the brain, through oxygen deprivation or direct insult, and cause delirium. Some patients become delirious following surgery. This can be due to any of several factors, such as: effects of anesthesia, infections, or a metabolic imbalance.

Infectious diseases can also cause delirium. Commonly diagnosed diseases such as urinary tract infections, pneumonia, or fever from a viral infection can induce delirium. Additionally, diseases of the liver, kidney, lungs, and cardiovascular system can cause delirium. Finally, an infection, specific to the brain, can cause delirium. Even a deficiency of thiamin (vitamin B1) can be a trigger for delirium.

Symptoms

Symptoms of delirium include a confused state of mind accompanied by poor attention, impaired recent memory, irritability, inappropriate behavior (such as the use of vulgar language, despite lack of a history of such behavior), and anxiety and fearfulness. In some cases, the person can appear to be psychotic, fostering illusions, **delusions**, hallucinations, and/or **paranoia**. In other cases, the patient may simply appear to be withdrawn and apathetic. In still other cases, the patient may become agitated and restless, unable to remain in bed, and feel a strong need to pace the floor.

A few examples of people affected by delirium follow:

- One gentleman, who had already been in the hospital for three days, when asked if he knew where he was, stated the correct city and hospital. He immediately followed this by saying, "but I started out in Dallas, Texas this morning." The hospital location was some 1,800 miles from Dallas, Texas, and as previously indicated, he had been in the same hospital for three days.
- In another case, an elderly gentleman was placed in a private room that had a wonderful large mural on one wall. The mural was that of a forest scene—no animals or people, only trees and sunlight. His chief complaint at various points during the day was that evil people were watching him from behind the trees in the forest scene.
- An elderly woman had to be subdued while attempting to flee from the hospital, because she was convinced that she had been brought there so surgeons could harvest her organs. Despite the lack of surgical scars or incisions, she insisted that she had been taken to the basement of the hospital the previous night and a surgeon had removed one of her kidneys.

Demographics

Delirium occurs most frequently in the elderly and the young, but can occur in anyone at any age. Of persons over 65 who are brought to the hospital for a general medical condition, roughly 10% show signs of delirium at admission. It is suspected that another 10%-15% may develop delirium while in the hospital. There appears to be no gender difference—delirium seems to affect males and females equally.

Diagnosis

Whether or not delirium is diagnosed in a patient depends on the type manifest. If the case is an elderly, postoperative patient who appears quiet and apathetic, the condition may go undiagnosed. However, if the patient presents with the agitated, uncooperative type of delirium, it will certainly be noticed. In any case, where there is sudden onset of a confused state accompanied by a behavioral change, delirium should be considered. This is not intended to imply that such a diagnosis will be made easily.

Frequent mental status examinations, at various times throughout the day, may be required to render a diagnosis of delirium. This is generally done using the **Mini-Mental State Examination** (MMSE). This abbreviated form of mental status examination begins by first assessing the patient's ability to attend. If the patient is inattentive or in a stuporous state, further examination of mental status cannot be done. However, assuming the patient is able to respond to questions asked, the examination can proceed. The Mini-Mental State Exam assesses the areas of orientation, registration, attention and concentration, recall, language, and spatial perception. Another recently evaluated and recommended tool for use in diagnosing delirium is the Delirium Rating Scale-Revised-98. This clinician-rated, 16-item scale allows for the assessment of 13 severity items and three diagnostic items. This test has been reported as more sensitive than the MMSE at detecting delirium.

At times, the untrained observer may mistake psychotic features of delirium for another primary mental illness such as **schizophrenia** or a **manic episode** such as that associated with **bipolar disorder**. However, it should be noted that there are major differences between these diagnoses and delirium. In people who have schizophrenia, their odd behavior, stereotyped motor activity, or abnormal speech persists in the absence of disorientation like that seen with delirium. The schizophrenic appears alert and although his/her delusions and/or hallucinations persist, he/she could be formally tested. In contrast, the delirious patient appears hapless and disoriented, between episodes of lucidity. The delirious patient may not be testable. A manic episode could be misconstrued for agitated delirium, but consistency of elevated mood would contrast sharply to the less consistent mood of the delirious patient. Once again, delirium should always be considered when there is a rapid onset and especially when there is waxing and waning of the ability to attend and the confusion state.

Since delirium can be superimposed into a pre-existing **dementia**, the most often posed question, when diagnosing delirium, is whether the person might have dementia instead. Both cause disturbances of memory, but a person with dementia does not reflect the disturbance of consciousness depicted by someone with delirium. Expert history taking is a must in differentiating dementia from delirium. Dementia is insidious in nature and thus progresses slowly, while delirium begins with a

sudden onset and acute symptoms. A person with dementia can appear clear-headed, but can harbor delusions not elicited during an interview. One does not see the typical fluctuation of consciousness in dementia that manifests itself in delirium. It has been stated that, as a general rule, delirium comes and goes, but dementia comes and stays. Delirium rarely lasts more than a month. Usually, by the end of that period, a patient with dementia has full-blown dementia or has died. As a final caution, the clinician must be prepared to rule out **factitious disorder** and **malingering** as possible causes for the delirium.

When a state of delirium is confirmed, the clinician is faced with the task of making the diagnosis in appropriate context to its cause. The delirium may be caused by a general medical condition. In such a case, the clinician must identify the source of the delirium within the diagnosis. For example, if the delirium is caused by liver dysfunction, wherein the liver is unable to clean the system of toxins, thereby allowing them to enter the system and so the brain, the diagnosis would be Delirium Due to Hepatic Encephalopathy. The delirium might also be caused by a substance such as alcohol. To render a diagnosis of Alcohol Intoxication Delirium, the cognitive symptoms should be more exaggerated than those found in intoxication syndrome. The delirium could also be caused by withdrawal from a substance. Continuing the alcohol theme, the diagnosis would be Alcohol Withdrawal Delirium (delirium tremens could be a feature of this diagnosis).

There may be instances in which delirium has multiple causes, such as when a patient has a head trauma and liver failure, or viral encephalitis and alcohol withdrawal. When delirium comes from multiple sources, a diagnosis of delirium precedes each medical condition that contributes. As an example, the multiple causes would be reflected as Delirium Due to Head Trauma and Delirium Due to Hepatic Encephalopathy. Finally, when delirium is the focus of clinical attention, but insufficient evidence exists to identify a specific causal factor, a diagnosis of Delirium Not Otherwise Specified is rendered. An example of this can occur in people who are exposed to sensory deprivation, such as might occur in Intensive Care Units or Cardiac Care Units where the patient is allowed no stimulation save that of the occasional member of the hospital staff.

In summary, delirium develops rapidly, has a fluctuating course involving waxing and waning lucidity, severely affects attention, must receive immediate medical attention, and is reversible in most cases.

Treatment

Treating delirium means treating the underlying illness that is its basis. This could include correcting any chemical disparities within the body, such as electrolyte imbalances, the treatment of an infection, reduction of a fever, or removal of a medication or toxin. A review of anticholinergic effects of medications administered to the patient should take place. It is suggested that sedatives and hypnotic-type medications not be used; however, despite the fact that they can sometimes contribute to delirium, in cases of agitated delirium, the use of these may be necessary. Medications that are often used to treat agitated delirium include **haloperidol**, **thioridazine** and **risperidone**. These can reduce the psychotic features and curb some of the volatility of the patient, but they are only treating symptoms of the delirium and not the source. Benzodiazepines (medications that slow the central nervous system to relax the patient) can also assist in controlling agitated patients, but since they can contribute to delirium, they should be used in the lowest therapeutic doses possible. The reduction and discontinuance of all psychotropic drugs should be the goal of treatment and occur as soon as possible to permit recovery and viable assessment of the patient.

Prognosis

If a quick diagnosis and treatment of delirium occurs, the condition is frequently reversible. However, if the condition goes unchecked or is treated too late, there is a high incidence of mortality or permanent brain damage associated with it. The underlying illness may respond quickly to a treatment regimen, but improvement in mental functioning may lag behind, especially in the elderly. Moreover, one study disclosed that one group of elderly survivors of delirium, at three years following hospital discharge, had a 33% higher rate of death than other patients. As a final note, delirium is a medical emergency, requiring prompt attention to avoid the potential for permanent brain damage or even death.

Delusional disorder

Definition

Delusional disorder is characterized by the presence of recurrent, persistent non-bizarre **delusions**.

Delusions are irrational beliefs, held with a high level of conviction, that are highly resistant to change even when the delusional person is exposed to forms of proof that contradict the belief. Non-bizarre delusions are considered to be plausible; that is, there is a possibility that what the person believes to be true could actually occur a small proportion of the time. Conversely, bizarre delusions focus on matters that would be impossible in reality. For example, a non-bizarre delusion might be the belief that one's activities are constantly under observation by federal law enforcement or intelligence agencies, which actually does occur for a small number of people. By contrast, a man who believes he is pregnant with German Shepherd puppies holds a belief that could never come to pass in reality. Also, for beliefs to be considered delusional, the content or themes of the beliefs must be uncommon in the person's culture or religion. Generally, in delusional disorder, these mistaken beliefs are organized into a consistent world-view that is logical other than being based on an improbable foundation.

In addition to giving evidence of a cluster of interrelated non-bizarre delusions, persons with delusional disorder experience **hallucinations** far less frequently than do individuals with **schizophrenia** or **schizoaffective disorder**.

Description

Unlike most other psychotic disorders, the person with delusional disorder typically does not appear obviously odd, strange or peculiar during periods of active illness. Yet the person might make unusual choices in day-to-day life because of the delusional beliefs. Expanding on the previous example, people who believe they are under government observation might seem typical in most ways but could refuse to have a telephone or use credit cards in order to make it harder for "those Federal agents" to monitor purchases and conversations. Most mental health professionals would concur that until the person with delusional disorder discusses the areas of life affected by the delusions, it would be difficult to distinguish the sufferer from members of the general public who are not psychiatrically disturbed. Another distinction of delusional disorder compared with other psychotic disorders is that hallucinations are either absent or occur infrequently.

The person with delusional disorder may or may not come to the attention of mental health providers. Typically, while delusional disorder sufferers may be distressed about the delusional "reality," they may not have the insight to see that anything is wrong with the way they are thinking or functioning. Regarding the earlier example, those suffering delusion might state that the only thing wrong or upsetting in their lives is that the government is spying, and if the surveillance would cease, so would the problems. Similarly, the people suffering the disorder attribute any obstacles or problems in functioning to the delusional reality, separating it from their internal control. Furthermore, whether unable to get a good job or maintain a romantic relationship, the difficulties would be blamed on "government interference" rather than on their own failures or omissions. Unless the form of the delusions causes illegal behavior, somehow affects an ability to work, or otherwise deal with daily activities, the delusional disorder sufferer may adapt well enough to navigate life without coming to clinical attention. When people with delusional disorder decide to seek mental health care, the motivation for getting treatment is usually to decrease the negative emotions of depression, fearfulness, rage, or constant worry caused

KEY TERMS

Hallucinations—False sensory perceptions. A person experiencing a hallucination may "hear" sounds or "see" people or objects that are not really present. Hallucinations can also affect the senses of smell, touch, and taste.

Psychosis or psychotic symptoms—Disruptions in perceiving reality, thinking logically, and speaking or behaving in normal fashion. Hallucinations, delusions, catatonic behavior and peculiar speech are all symptoms of psychosis. In *DSM-IV-TR*, psychosis is usually one feature of an over-arching disorder, not a disorder in itself (with the exception of the diagnosis *psychosis not otherwise specified.*

by living under the cloud of delusional beliefs, not to change the unusual thoughts themselves.

Forms of delusional disorder

An important aspect of delusional disorder is the identification of the form of delusion from which a person suffers. The most common form of delusional disorder is the persecutory or paranoid subtype, in which the patients are certain that others are striving to harm them.

In the erotomanic form of delusional disorder, the primary delusional belief is that some important person is secretly in love with the sufferer. The erotomanic type is more common in women than men. Erotomanic delusions may prompt stalking the love object and even violence against the beloved or those viewed as potential romantic rivals.

The grandiose subtype of delusional disorder involves the conviction of one's importance and uniqueness, and takes a variety of forms: believing that one has a distinguished role, has some remarkable connections with important persons, or enjoys some extraordinary powers or abilities.

In the somatic subtype, there is excessive concern and irrational ideas about bodily functioning, which may include worries regarding infestation with parasites or insects, imagined physical deformity, or a conviction that one is emitting a foul stench when there is no problematic odor.

The form of disorder most associated with violent behavior, usually between romantic partners, is the jealous subtype of delusional disorder. Patients are firmly convinced of the infidelity of a spouse or partner, despite contrary evidence and based on minimal data (like a messy bedspread or more cigarettes than usual in an ashtray, for instance). Delusional jealousy sufferers may gather scraps of conjectured "evidence," and may try to constrict their partners' activities or confine them to home. Delusional disorder cases involving aggression and injury toward others have been most associated with this subtype.

Delusion and other disorders

Even though the main characteristic of delusional disorder is a noticeable system of delusional beliefs, delusions may occur in the course of a large number of other psychiatric disorders. Delusions are often observed in persons with other psychotic disorders such as schizophrenia and schizoaffective disorder. In addition to occurring in the psychotic disorders, delusions also may be evident as part of a response to physical, medical conditions (such as **brain** injury or brain tumors), or reactions to ingestion of a drug.

Delusions also occur in the dementias, which are syndromes wherein psychiatric symptoms and memory loss result from deterioration of brain tissue. Because delusions can be shown as part of many illnesses, the **diagnosis** of delusional disorder is partially conducted by process of elimination. If the delusions are not accompanied by persistent, recurring hallucinations, then schizophrenia and schizoaffective disorder are not appropriate diagnoses. If the delusions are not accompanied by memory loss, then **dementia** is ruled out. If there is no physical illness or injury or other active biological cause (such as drug ingestion or drug withdrawal), then the delusions cannot be attributed to a general medical problem or drug-related causes. If delusions are the most obvious and pervasive symptom, without hallucinations, medical causation, drug influences or memory loss, then delusional disorder is the most appropriate categorization.

Because delusions occur in many different disorders, some clinician-researchers have argued that there is little usefulness in focusing on what diagnosis the person has been given. Those who ascribe to this view believe it is more important to focus on the symptom of delusional thinking, and find ways to have an effect on delusions, whether they occur in delusional disorder or schizophrenia or schizoaffective disorder. The majority of **psychotherapy** techniques used in delusional disorder come from symptom-focused (as opposed to diagnosis-focused) researcher-practitioners.

Causes and symptoms

Causes

Because clear identification of delusional disorder has traditionally been challenging, scientists have conducted far less research relating to the disorder than studies for schizophrenia or mood disorders. Still, some theories of causation have developed, which fall into several categories.

GENETIC OR BIOLOGICAL. Close relatives of persons with delusional disorder have increased rates of delusional disorder and paranoid personality traits. They do not have higher rates of schizophrenia, schizoaffective disorder or mood disorder compared to relatives of non-delusional persons. Increased incidence of these psychiatric disorders in individuals closely genetically related to persons with delusional disorder suggest that there is a genetic component to the disorder. Furthermore, a number of studies comparing activity of different regions of the brain in delusional and non-delusional research participants yielded data about differences in the functioning of the brains between members of the two groups. These differences in brain activity suggest that persons neurologically with delusions tend to react as if threatening conditions are consistently present. Non-delusional persons only show such patterns under certain kinds of conditions where the interpretation of being threatened is more accurate. With both brain activity evidence and family heritability evidence, a strong chance exists that there is a biological aspect to delusional disorder.

DYSFUNCTIONAL COGNITIVE PROCESSING. An elaborate term for thinking is "cognitive processing." Delusions may arise from distorted ways people have of explaining life to themselves. The most prominent cognitive problems involve the manner in which delusion sufferers develop conclusions both about other people, and about causation of unusual perceptions or negative events. Studies examining how people with delusions develop theories about reality show that the subjects have ideas which which they tend to reach an inference based on less information than most people use. This "jumping to conclusions" bias can lead to delusional interpretations of ordinary events. For example, developing flu-like symptoms coinciding with the week new neighbors move in might lead to the conclusion, "the new neighbors are poisoning me." The conclusion is drawn without considering alternative explanations—catching an illness from a relative with the flu, that a virus seems to be going around at work, or that the tuna salad from lunch at the deli may have been spoiled. Additional research shows that persons prone to delusions "read" people differently than non-delusional individuals do. Whether they do so more accurately or particularly poorly is a matter of controversy. Delusional persons develop interpretations about how others view them that are distorted. They tend to view life as a continuing series of threatening events. When these two aspects of thought co-occur, a tendency to develop delusions about others wishing to do them harm is likely.

MOTIVATED OR DEFENSIVE DELUSIONS. Some predisposed persons might suffer the onset of an ongoing delusional disorder when coping with life and maintaining high self-esteem becomes a significant challenge. In order to preserve a positive view of oneself, a person views others as the cause of personal difficulties that may occur. This can then become an ingrained pattern of thought.

Symptoms

The criteria that define delusional disorder are furnished in the ***Diagnostic and Statistical Manual of Mental Disorders*** Fourth Edition Text Revision, or *DSM-IV-TR*, published by the American Psychiatric Association. The criteria for delusional disorder are as follows:

- non-bizarre delusions which have been present for at least one month
- absence of obviously odd or bizarre behavior
- absence of hallucinations, or hallucinations that only occur infrequently in comparison to other psychotic disorders
- no memory loss, medical illness or drug or alcohol-related effects are associated with the development of delusions

Demographics

The base rate of delusional disorder in adults is unclear. The prevalence is estimated at 0.025-0.03%, lower than the rates for schizophrenia (1%). Delusional disorder may account for 1–2% of admissions to inpatient psychiatric hospitals. Age at onset ranges from 18–90 years, with a mean age of 40 years. More females than males (overall) suffer from delusional disorder, especially the late onset form that is observed in the elderly.

Diagnosis

Client interviews focused on obtaining information about the sufferer's life situation and past history aid in identification of delusional disorder. With the client's permission, the clinician obtains details from earlier medical records, and engages in thorough discussion with the client's immediate family—helpful measures in determining whether delusions are present. The clinician

may use a semi-structured interview called a mental status examination to assess the patient's concentration, memory, understanding the individual's situation and logical thinking. The mental status examination is intended to reveal peculiar thought processes in the patient. The Peters Delusion Inventory (PDI) is a psychological test that focuses on identifying and understanding delusional thinking; but its use is more common in research than in clinical practice.

Even using the *DSM-IV-TR* criteria listed above, classification of delusional disorder is relatively subjective. The criteria "non-bizarre" and "resistant to change" and "not culturally accepted" are all subject to very individual interpretations. They create variability in how professionals diagnose the illness. The utility of diagnosing the syndrome rather than focusing on successful treatment of delusion in any form of illness is debated in the medical community. Some researchers further contend that delusional disorder, currently classified as a psychotic disorder, is actually a variation of depression and might respond better to antidepressants or therapy more similar to that utilized for depression. Also, the meaning and implications of "culturally accepted" can create problems. The cultural relativity of "delusions,"—most evident where the beliefs shown are typical of the person's subculture or religion yet would be viewed as strange or delusional by the dominant culture—can force complex choices to be made in diagnosis and treatment. An example could be that of a Haitian immigrant to the United States who believed in voodoo. If that person became aggressive toward neighbors issuing curses or hexes, believing that death is imminent at the hands of those neighbors, a question arises. The belief is typical of the individual's subculture, so the issue is whether it should be diagnosed or treated. If it were to be treated, whether the remedy should come through Western medicine, or be conducted through voodoo shamanistic treatment is the problem to be solved.

Treatments

Delusional disorder treatment often involves *atypical* (also called *novel* or *newer-generation*) antipsychotic medications, which can be effective in some patients. **Risperidone** (Risperdal), **quetiapine** (Seroquel), and **olanzapine** (Zyprexa) are all examples of atypical or novel antipsychotic medications. If *agitation* occurs, a number of different antipsychotics can be used to conclude the outbreak of acute agitation. Agitation, a state of frantic activity experienced concurrently with anger or exaggerated fearfulness, increases the risk that the client will endanger self or others. To decrease anxiety and slow behavior in emergency situations where agitation is a factor, an injection of **haloperidol** (Haldol) is often given usually in combination with other medications (often **lorazepam**, also known as Ativan). Agitation in delusional disorder is a typical response to severe or harsh confrontation when dealing with the existence of the delusions. It can also be a result of blocking the individual from performing inappropriate actions the client views as urgent in light of the delusional reality. A novel antipsychotic is generally given orally on a daily basis for ongoing treatment meant for long-term effect on the symptoms. Response to antipsychotics in delusional disorder seems to follow the "rule of thirds," in which about one-third of patients respond somewhat positively, one-third show little change, and one-third worsen or are unable to comply.

Cognitive therapy has shown promise as an emerging treatment for delusions. The cognitive therapist tries to capitalize on any doubt the individual has about the delusions; then attempts to develop a joint effort with the sufferer to generate alternative explanations, assisting the client in checking the evidence. This examination proceeds in favor of the various explanations. Much of the work is done by use of empathy, asking hypothetical questions in a form of therapeutic Socratic dialogue—a process that follows a basic question and answer format, figuring out what is known and unknown before reaching a logical conclusion. Combining pharmacotherapy with cognitive therapy integrates both treating the possible underlying biological problems and decreasing the symptoms with psychotherapy.

Prognosis

Evidence collected to date indicates about 10% of cases will show some improvement of delusional symptoms though irrational beliefs may remain; 33–50% may show complete remission; and, in 30–40% of cases there will be persistent non-improving symptoms. The prognosis for clients with delusional disorder is largely related to the level of conviction regarding the delusions and the openness the person has for allowing information that contradicts the delusion.

Prevention

Little work has been done thus far regarding prevention of the disorder. Effective means of prevention have not been identified.

Delusions

Description

A delusion is a belief that is clearly false and that indicates an abnormality in the affected person's content of thought. The false belief is not accounted for by the person's cultural or religious background or his or her level of intelligence. The key feature of a delusion is the degree to which the person is convinced that the belief is true. A person with a delusion will hold firmly to the belief regardless of evidence to the contrary. Delusions can be difficult to distinguish from overvalued ideas, which are unreasonable ideas that a person holds, but the affected person has at least some level of doubt as to its truthfulness. A person with a delusion is absolutely convinced that the delusion is real.

KEY TERMS

Delusion—A false belief that is resistant to reason or contrary to actual fact.

Overvalued idea—An unreasonable, sustained belief that is held with less than delusional intensity (i.e., the person can acknowledge, to some degree, that the belief may be false). The belief is not accounted for by the individual's cultural or religious background.

Delusions are a symptom of either a medical, neurological, or mental disorder. Delusions may be present in any of the following mental disorders:

- psychotic disorders, or disorders in which the affected person has a diminished or distorted sense of reality and cannot distinguish the real from the unreal, including **schizophrenia**, **schizoaffective disorder**, **delusional disorder**, **schizophreniform disorder**, **shared psychotic disorder**, **brief psychotic disorder**, and substance-induced psychotic disorder
- **bipolar disorder**
- **major depressive disorder** with psychotic features
- **delirium**
- **dementia**

Overvalued ideas may be present in **anorexia nervosa**, **obsessive-compulsive disorder**, **body dysmorphic disorder**, or **hypochondriasis**.

Types

Delusions are categorized as either bizarre or non-bizarre and as either mood-congruent or mood-incongruent. A bizarre delusion is a delusion that is very strange and completely implausible for the person's culture; an example of a bizarre delusion would be that aliens have removed the affected person's **brain**. A non-bizarre delusion is one whose content is definitely mistaken, but is at least possible; an example may be that the affected person mistakenly believes that he or she is under constant police surveillance. A mood-congruent delusion is any delusion whose content is consistent with either a depressive or manic state; for example, a depressed person may believe that the world is ending, or a person in a manic state (a state in which the person feels compelled to take on new projects, has a lot of energy, and needs little sleep) believes that he or she has special talents or abilities, or is a famous person. A mood-incongruent delusion is any delusion whose content is not consistent with either a depressed or

manic state or is mood-neutral. An example is a depressed person who believes that thoughts are being inserted into his or her mind from some outside force, person, or group of people, and these thoughts are not recognized as the person's own thoughts (called "thought insertion").

In addition to these categories, delusions are often categorized according to theme. Although delusions can have any theme, certain themes are more common. Some of the more common delusion themes are:

- Delusion of control: This is a false belief that another person, group of people, or external force controls one's thoughts, feelings, impulses, or behavior. A person may describe, for instance, the experience that aliens actually make him or her move in certain ways and that the person affected has no control over the bodily movements. Thought broadcasting (the false belief that the affected person's thoughts are heard aloud), thought insertion, and thought withdrawal (the belief that an outside force, person, or group of people is removing or extracting a person's thoughts) are also examples of delusions of control.
- Nihilistic delusion: A delusion whose theme centers on the nonexistence of self or parts of self, others, or the world. A person with this type of delusion may have the false belief that the world is ending.
- Delusional jealousy (or delusion of infidelity): A person with this delusion falsely believes that his or her spouse or lover is having an affair. This delusion stems from pathological jealousy and the person often gathers "evidence" and confronts the spouse about the nonexistent affair.
- Delusion of guilt or sin (or delusion of self-accusation): This is a false feeling of remorse or guilt of delusional intensity. A person may, for example, believe that he or she has committed some horrible crime and should be punished severely. Another example is a person who is convinced that he or she is responsible for some disaster (such as fire, flood, or earthquake) with which there can be no possible connection.
- Delusion of mind being read: The false belief that other people can know one's thoughts. This is different from thought broadcasting in that the person does not believe that his or her thoughts are heard aloud.
- Delusion of reference: The person falsely believes that insignificant remarks, events, or objects in one's environment have personal meaning or significance. For instance, a person may believe that he or she is receiving special messages from the news anchorperson on television. Usually the meaning assigned to these events is negative, but the "messages" can also have a grandiose quality.
- Erotomania: A delusion in which one believes that another person, usually someone of higher status, is in love with him or her. It is common for individuals with this type of delusion to attempt to contact the other person (through phone calls, letters, gifts, and sometimes stalking).
- Grandiose delusion: An individual exaggerates his or her sense of self-importance and is convinced that he or she has special powers, talents, or abilities. Sometimes, the individual may actually believe that he or she is a famous person (for example, a rock star or Christ). More commonly, a person with this delusion believes he or she has accomplished some great achievement for which they have not received sufficient recognition.
- Persecutory delusions: These are the most common type of delusions and involve the theme of being followed, harassed, cheated, poisoned or drugged, conspired against, spied on, attacked, or obstructed in the pursuit of goals. Sometimes the delusion is isolated and fragmented (such as the false belief that co-workers are harassing), but sometimes are well-organized belief systems involving a complex set of delusions ("systematized delusions"). A person with a set of persecutory delusions may be believe, for example, that he or she is being followed by government organizations because the "persecuted" person has been falsely identified as a spy. These systems of beliefs can be so broad and complex that they can explain everything that happens to the person.
- Religious delusion: Any delusion with a religious or spiritual content. These may be combined with other delusions, such as grandiose delusions (the belief that the affected person was chosen by God, for example), delusions of control, or delusions of guilt. Beliefs that would be considered normal for an individual's religious or cultural background are not delusions.
- Somatic delusion: A delusion whose content pertains to bodily functioning, bodily sensations, or physical appearance. Usually the false belief is that the body is somehow diseased, abnormal, or changed. An example of a somatic delusion would be a person who believes that his or her body is infested with parasites.

Delusions of control, nihilistic delusions, and thought broadcasting, thought insertion, and thought withdrawal are usually considered bizarre delusions. Most persecutory, somatic, grandiose, and religious delusions, as well as most delusions of jealousy, delusions of mind being read, and delusions of guilt would be considered non-bizarre.

Dementia

Definition

Dementia is not a specific disorder or disease. It is a syndrome (group of symptoms) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with performing the tasks of daily life. Dementia can occur to anyone at any age from an injury or from oxygen deprivation, although it is most commonly associated with aging. It is the leading cause of institutionalization of older adults.

Description

The definition of dementia has become more inclusive over the past several decades. Whereas earlier descriptions of dementia emphasized memory loss, the last three editions of the professional's diagnostic handbook, ***Diagnostic and Statistical Manual of Mental Disorders*** (also known as the *DSM*) define dementia as an overall decline in intellectual function, including difficulties with language, simple calculations, planning and judgment, and motor (muscular movement) skills as well as loss of memory. Although dementia is not caused by aging itself— most researchers regard it as resulting from injuries, infections, **brain** diseases, tumors, or other disorders— it is quite common in older people. The prevalence of dementia increases rapidly with age; it doubles every five years after age 60. Dementia affects only 1% of people aged 60–64 but 30%–50% of those older than 85. About four to five million persons in the United States are affected by dementia as of 2002. Surveys indicate that dementia is the condition most feared by older adults in the United States.

Causes and symptoms

Causes

Dementia can be caused by nearly forty different diseases and conditions, ranging from dietary deficiencies and metabolic disorders to head injuries and inherited diseases. The possible causes of dementia can be categorized as follows:

- Primary dementia. These dementias are characterized by damage to or wasting away of the brain tissue itself. They include **Alzheimer's disease** (AD), frontal lobe dementia (FLD), and Pick's disease. FLD is dementia caused by a disorder (usually genetic) that affects the front portion of the brain, and Pick's disease is a rare type of primary dementia that is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.
- Multi-infarct dementia (MID). Sometimes called **vascular dementia**, this type is caused by blood clots in the small blood vessels of the brain. When the clots cut off the blood supply to the brain tissue, the brain cells are damaged and may die. (An infarct is an area of dead tissue caused by obstruction of the circulation.)
- Lewy body dementia. Lewy bodies are areas of injury found on damaged nerve cells in certain parts of the brain. They are associated with Alzheimer's and Parkinson's disease, but researchers do not yet know whether dementia with Lewy bodies is a distinct type of dementia or a variation of Alzheimer's or Parkinson's disease.
- Dementia related to alcoholism or exposure to heavy metals (arsenic, antimony, bismuth).
- Dementia related to infectious diseases. These infections may be caused by viruses (HIV, viral encephalitis); spirochetes (Lyme disease, syphilis); or prions (Creutzfeldt-Jakob disease). Spirochetes are certain kinds of bacteria, and prions are protein particles that lack nucleic acid.
- Dementia related to abnormalities in the structure of the brain. These may include a buildup of spinal fluid in the brain (hydrocephalus); tumors; or blood collecting beneath the membrane that covers the brain (subdural hematoma).

Dementia may also be associated with depression, low levels of thyroid hormone, or niacin or vitamin B_{12} deficiency. Dementia related to these conditions is often reversible.

Genetic factors in dementia

Genetic factors play a role in several types of dementia, but the importance of these factors in the

KEY TERMS

Age-associated memory impairment (AAMI)—A condition in which an older person suffers some memory loss and takes longer to learn new information. AAMI is distinguished from dementia in that it is not progressive and does not represent a serious decline from the person's previous level of functioning. Benign senescent forgetfulness is another term for AAMI.

Agnosia—Loss of the ability to recognize familiar people, places, and objects.

Amyloid—A waxy translucent substance composed mostly of protein, that forms plaques (abnormal deposits) in the brain during the progression of Alzheimer's disease.

Aphasia—Loss of previously acquired ability to understand or use written or spoken language, due to brain damage or deterioration.

Apraxia—Inability to perform purposeful movements that is not caused by paralysis or loss of feeling.

Creutzfeldt-Jakob disease—A degenerative disease of the central nervous system caused by a prion, or "slow virus."

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from dementia by its relatively sudden onset and variation in the severity of the symptoms.

Diagnostic and Statistical Manual of Mental Disorders—A handbook for mental health professionals that includes lists of symptoms that indicate diagnoses of mental disorders.

Frontal lobe dementia—Dementia caused by a disorder, usually genetic, that affects the front portion of the brain.

Hematoma—An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

Huntington's disease—A hereditary disorder that appears in middle age and is characterized by gradual brain deterioration, progressive dementia, and loss of voluntary movement. It is sometimes called Huntington's chorea.

Hydrocephalus—The accumulation of cerebrospinal fluid (CSF) in the ventricles of the brain.

Lewy bodies—Areas of injury found on damaged nerve cells in certain parts of the brain associated with dementia.

Multi-infarct dementia—Dementia caused by damage to brain tissue resulting from a series of blood clots or clogs in the blood vessels. It is also called vascular dementia.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness. It may be related in some way to Lewy body dementia.

Pick's disease—A rare type of primary dementia that affects the frontal lobes of the brain. It is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.

Prion—A protein particle that lacks nucleic acid.

Pseudodementia—A term for a depression with symptoms resembling those of dementia. The term "dementia of depression" is now preferred.

development of the dementia varies considerably. Alzheimer's disease (AD) is known, for example, to have an autosomal (non-sex-related) dominant pattern in most early-onset cases as well as in some late-onset cases, and to show different degrees of penetrance (frequency of expression) in late-life cases. Moreover, researchers have not yet discovered how the genes associated with dementia interact with other risk factors to produce or trigger the dementia. One non-genetic risk factor presently being investigated is toxic substances in the environment.

EARLY-ONSET ALZHEIMER'S DISEASE. In early-onset AD, which accounts for 2%–7% of cases of AD, the symptoms develop before age 60. It is usually caused by an inherited genetic mutation. Early-onset AD is also associated with Down syndrome, in that persons with trisomy 21 (three forms of human chromosome 21 instead of a pair) often develop early-onset AD.

LATE-ONSET ALZHEIMER'S DISEASE. Recent research indicates that late-onset Alzheimer's disease is a polygenic disorder; that is, its development is influenced by more than one gene. It has been known since 1993 that a

specific form of a gene (the APOE gene) on human chromosome 19 is a genetic risk factor for late-onset AD. In 1998 researchers at the University of Pittsburgh reported on another gene that controls the production of bleomycin hydrolase (BH) as a second genetic risk factor that acts independently of the APOE gene. In December 2000, three separate research studies reported that a gene on chromosome 10 that may affect the processing of a protein (called amyloid-beta protein) is also involved in the development of late-onset AD. When this protein is not properly broken down, a starchy substance builds up in the brains of people with AD to form the plaques that are characteristic of the disease.

MULTI-INFARCT DEMENTIA (MID). While the chief risk factors for MID are high blood pressure, advanced age, and male sex, there is an inherited form of MID called CADASIL, which stands for cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. CADASIL can cause psychiatric disturbances and severe headaches as well as dementia.

FRONTAL LOBE DEMENTIAS. Researchers think that between 25% and 50% of cases of frontal lobe dementia involve genetic factors. Pick's dementia appears to have a much smaller genetic component than FLD. It is not yet known what other risk factors combine with inherited traits to influence the development of frontal lobe dementias.

FAMILIAL BRITISH DEMENTIA (FBD). FBD is a rare autosomal dominant disorder that was first reported in the 1940s in a large British family extending over nine generations. FBD resembles Alzheimer's in that the patient develops a progressive dementia related to amyloid deposits in the brain. In 1999, a mutated gene that produces the amyloid responsible for FBD was discovered on human chromosome 13. Studies of this mutation may yield further clues to the development of Alzheimer's disease as well as FBD itself.

CREUTZFELDT-JAKOB DISEASE. Although Creutzfeldt-Jakob disease is caused by a prion, researchers think that 5%–15% of cases may have a genetic component.

Symptoms

The fourth edition, text revised version of the *DSM* was published in 2000, and is known as *DSM-IV-TR*. *DSM-IV-TR* identifies certain symptoms as criteria that must be met for a patient to be diagnosed with dementia. One criterion is significant weakening of the patient's memory with regard to learning new information as well as recalling previously learned information. In addition, the patient must be found to have one or more of the following disturbances:

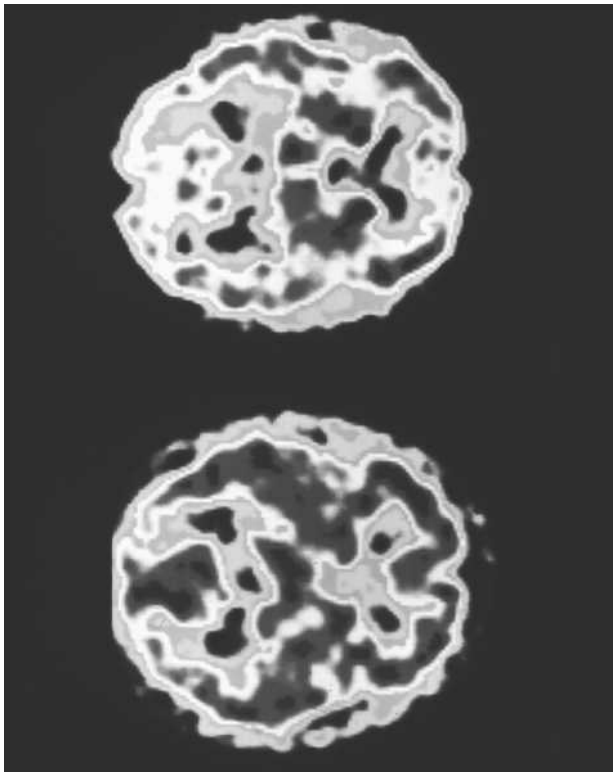
- Aphasia. Aphasia refers to loss of language function. A person with dementia may use vague words like "it" or "thing" often because he or she can't recall the exact name of an object; the affected person may echo what other people say, or repeat a word or phrase over and over. People in the later stages of dementia may stop speaking at all.
- Apraxia. Apraxia refers to loss of the ability to perform intentional movements even though the person is not paralyzed, has not lost the sense of touch, and knows what he or she is trying to do. For example, a patient with apraxia may stop brushing their teeth, or have trouble tying their shoelaces.
- Agnosia. Agnosia refers to loss of the ability to recognize objects even though the person's sight and sense of touch are normal. People with severe agnosia may fail to recognize family members or even their own face reflected in a mirror.
- Problems with abstract thinking and complex behavior. This criterion refers to the loss of the ability to make plans, carry out the steps of a task in the proper order, make appropriate decisions, evaluate situations, show good judgment, etc. For example, a patient might light a stove burner under a saucepan before putting food or water in the pan, or be unable to record checks and balance their checkbook.

DSM-IV-TR also specifies that these disturbances must be severe enough to cause problems in the person's daily life, and that they must represent a decline from a previously higher level of functioning.

In addition to the changes in cognitive functioning, the symptoms of dementia may also include personality changes and emotional instability. Patients with dementia sometimes become mildly paranoid because their loss of short-term memory leads them to think that mislaid items have been stolen. About 25% of patients with dementia develop a significant degree of **paranoia**, that is, generalized suspiciousness or specific **delusions** of persecution. Mood swings, anxiety, and irritability or anger are also frequent occurrences, particularly when patients with dementia are in situations that force them to recognize the extent of their impairment.

The following sections describe the signs and symptoms that are used to differentiate among the various types of dementia during a diagnostic evaluation.

ALZHEIMER'S DISEASE. Dementia related to AD often progresses slowly; it may be accompanied by irritability, wide mood swings, and personality changes in the early stage. Many patients, however, retain their normal degree of sociability in the early stages of Alzheimer's. In second-stage AD, the patient typically gets lost easily, is



Colored positron emission tomography scan of an AIDS patient with dementia. *(Photo Researchers, Inc. Reproduced by permission.) See color insert for color version of photo.*

completely disoriented with regard to time and space, and may become angry, uncooperative, or aggressive. Patients in second-stage AD are at high risk for falls and other accidents. In final-stage AD, the patient is completely bedridden, has lost control over bowel and bladder functions, and may be unable to swallow or eat. The risk of **seizures** increases as the patient progresses from early to end-stage Alzheimer's. Death usually results from an infection or from malnutrition.

MULTI-INFARCT DEMENTIA. In MID, the symptoms are more likely to occur after age 70. In the early stages, the patient retains his or her personality more fully than a patient with AD. Another distinctive feature of this type of dementia is that it often progresses in a stepwise fashion; that is, the patient shows rapid changes in functioning, then remains at a plateau for a while rather than showing a continuous decline. The symptoms of MID may also have a "patchy" quality; that is, some of the patient's mental functions may be severely affected while others are relatively undamaged. Other symptoms of MID include exaggerated reflexes, an abnormal gait (manner of walking), loss of bladder or bowel control, and inappropriate laughing or crying.

DEMENTIA WITH LEWY BODIES. This type of dementia may combine some features of AD, such as severe memory loss and confusion, with certain symptoms associated with Parkinson's disease, including stiff muscles, a shuffling gait, and trembling or shaking of the hands. Visual **hallucinations** may be one of the first symptoms of dementia with Lewy bodies.

FRONTAL LOBE DEMENTIAS. The frontal lobe dementias are gradual in onset. Pick's dementia is most likely to develop in persons between 40 and 60, while FLD typically begins before the age of 65. The first symptoms of the frontal lobe dementias often include socially inappropriate behavior (rude remarks, sexual acting-out, disregard of personal hygiene, etc.). Patients are also often obsessed with eating and may put non-food items in their mouths as well as making frequent sucking or smacking noises. In the later stages of frontal lobe dementia or Pick's disease, the patient may develop muscle weakness, twitching, and delusions or hallucinations.

CREUTZFELDT-JAKOB DISEASE. The dementia associated with Creutzfeldt-Jakob disease occurs most often in persons between 40 and 60. It is typically preceded by a period of several weeks in which the patient complains of unusual **fatigue**, anxiety, loss of appetite, or difficulty concentrating. This type of dementia also usually progresses much more rapidly than other dementias, frequently over a span of a few months.

Demographics

The demographic distribution of dementia varies somewhat according to its cause. Moreover, recent research indicates that dementia in many patients has overlapping causes, so that it is not always easy to assess the true rates of occurrence of the different types. For example, AD and MID are found together in about 15%–20% of cases.

Alzheimer's disease

AD is by far the most common cause of dementia in the elderly, accounting for 60%–80% of cases. It is estimated that four million adults in the United States suffer from AD. The disease strikes women more often than men, but researchers don't know yet whether the sex ratio simply reflects the fact that women in developed countries tend to live longer than men, or whether female sex is itself a risk factor for AD. One well-known long-term study of Alzheimer's in women is the Nun Study, begun in 1986 and presently conducted at the University of Kentucky.

Multi-infarct dementia

MID is responsible for between 15% and 20% of cases of dementia (not counting cases in which it coexists with AD). Unlike AD, MID is more common in men than in women. Diabetes, high blood pressure, a history of smoking, and heart disease are all risk factors for MID. Researchers in Sweden have suggested that MID is underdiagnosed, and may coexist with other dementias more frequently than is presently recognized.

Dementia with Lewy bodies

Dementia with Lewy bodies is now thought to be the second most common form of dementia after Alzheimer's disease. But because researchers don't completely understand the relationship between Lewy bodies, AD, and Parkinson's disease, the demographic distribution of this type of dementia is also unclear.

Other dementias

FLD, Pick's disease, Huntington's disease, Parkinson's disease, HIV infection, alcoholism, head trauma, etc. account for about 10% of all cases of dementia. In FLD and Pick's dementia, women appear to be affected slightly more often than men.

Diagnosis

In some cases, a patient's primary physician may be able to diagnose the dementia; in many instances, however, the patient will be referred to a neurologist or a gerontologist (specialist in medical care of the elderly). Distinguishing one disorder from other similar disorders is a process called differential **diagnosis**. The differential diagnosis of dementia is complicated because of the number of possible causes; because more than one cause may be present at the same time; and because dementia can coexist with such other conditions as depression and **delirium**. Delirium is a temporary disturbance of consciousness marked by confusion, restlessness, inability to focus one's attention, hallucinations, or delusions. In elderly people, delirium is frequently a side effect of surgery, medications, infectious illnesses, or dehydration. Delirium can be distinguished from dementia by the fact that delirium usually comes on fairly suddenly (in a few hours or days) and may vary in severity— it is often worse at night. Dementia develops much more slowly, over a period of months or years, and the patient's symptoms are relatively stable. It is possible for a person to have delirium and dementia at the same time.

Another significant diagnostic distinction in elderly patients is the distinction between dementia and age-associated memory impairment (AAMI), which is sometimes called benign senescent forgetfulness. Older people with AAMI have a mild degree of memory loss; they do not learn new information as quickly as younger people, and they may take longer to recall a certain fact or to balance their checkbook. But they do not suffer the degree of memory impairment that characterizes dementia, and they do not get progressively worse.

Clinical interview

The doctor will begin by taking a full history, including the patient's occupation and educational level as well as medical history. The occupational and educational history allows the examiner to make a more accurate assessment of the extent of the patient's memory loss and other evidence of intellectual decline. In some cases, the occupational history may indicate exposure to heavy metals or other toxins. A complete medical history allows the doctor to assess such possibilities as delirium, depression, alcohol-related dementia, dementia related to head injury, or dementia caused by infection. It is particularly important for the doctor to have a list of all the patient's medications, including over-the-counter and alternative herbal preparations, because of the possibility that the patient's symptoms are related to side effects of these substances.

Whenever possible, the examiner will consult the patient's family members or close friends as part of the history-taking process. In many cases, friends and relatives can provide more detailed information about the patient's memory problems and loss of function.

Mental status examination

A mental status examination (MSE) evaluates the patient's ability to communicate, follow instructions, recall information, perform simple tasks involving movement and coordination, as well as his or her emotional state and general sense of space and time. The MSE includes the doctor's informal evaluation of the patient's appearance, vocal tone, facial expressions, posture, and gait as well as formal questions or instructions. A common form that has been used since 1975 is the so-called Folstein Mini-Mental Status Examination, or MMSE. Questions that are relevant to diagnosing dementia include asking the patient to count backward from 100 by 7s, to make change, to name the current President of the United States, to repeat a short phrase after the examiner (such as, "no ifs, ands, or buts"); to draw a clock face or geometric figure, and to follow a set of instructions involving movement (such as, "Show me how to throw a ball" or "Fold this piece of paper and place it under the lamp on the bookshelf.") The examiner may test the patient's abstract reasoning ability by asking him or her

to explain a familiar proverb ("People who live in glass houses shouldn't throw stones," for example) or test the patient's judgment by asking about a problem with a common-sense solution, such as what one does when a prescription runs out.

Neurological examination

A neurological examination includes an evaluation of the patient's cranial nerves and reflexes. The cranial nerves govern the ability to speak as well as sight, hearing, taste, and smell. The patient will be asked to stick out the tongue, follow the examiner's finger with the eyes, raise the eyebrows, etc. The patient is also asked to perform certain actions (such as touching the nose with the eyes closed) that test coordination and spatial orientation. The doctor will usually touch or tap certain areas of the body, such as the knee or the sole of the foot, to test the patient's reflexes. Failure to respond to the touch or tap may indicate damage to certain parts of the brain.

Laboratory tests

Blood and urine samples may be collected in order to rule out such conditions as thyroid deficiency, niacin or vitamin B_{12} deficiency, heavy metal poisoning, liver disease, HIV infection, syphilis, anemia, medication reactions, or kidney failure. A lumbar puncture (spinal tap) may be done to rule out neurosyphilis.

Diagnostic imaging

The patient may be given a **computed tomography** (CT) scan or **magnetic resonance imaging** (MRI) to detect evidence of strokes, disintegration of the brain tissue in certain areas, blood clots or tumors, a buildup of spinal fluid, or bleeding into the brain tissue. Positron-emission tomography (PET) or single-emission computed tomography (SPECT) imaging is not used routinely to diagnose dementia, but may be used to rule out Alzheimer's disease or frontal lobe degeneration if a patient's CT scan or MRI is unrevealing.

Treatments

Reversible and responsive dementias

Some types of dementia are reversible, and a few types respond to specific treatments related to their causes. Dementia related to dietary deficiencies or metabolic disorders is treated with the appropriate vitamins or thyroid medication. Dementia related to HIV infection often responds well to zidovudine (Retrovir), a drug given to prevent the AIDS virus from replicating. Multi-infarct dementia is usually treated by controlling the patient's blood pressure and/or diabetes; while treatments for these disorders cannot undo damage already caused to brain tissue, they can slow the progress of the dementia. Patients with alcohol-related dementia often improve over the long term if they are able to stop drinking. Dementias related to head injuries, hydrocephalus, and tumors are treated by surgery.

It is important to evaluate and treat elderly patients for depression, because the symptoms of depression in older people often mimic dementia. This condition is sometimes called pseudodementia. In addition, patients who suffer from both depression and dementia often show some improvement in intellectual functioning when the depression is treated. The medications most often used for depression related to dementia are the selective serotonin reuptake inhibitors (SSRIs) **paroxetine** and **sertraline**. The mental status examination should be repeated after six–12 weeks of antidepressant medication.

Irreversible dementias

As of 2001, there are no medications or surgical techniques that can cure Alzheimer's disease, the frontal lobe dementias, MID, or dementia with Lewy bodies. There are also no "magic bullets" that can slow or stop the progression of these dementias. There is, however, one medication, Aricept, that is being used to halt the progression of Alzheimer's disease. In addition, another medication called **galantamine** (Reminyl) is also being used to treat the symptoms of Alzheimer's disease. Patients may be given medications to ease the depression, anxiety, sleep disturbances, and other behavioral symptoms that accompany dementia, but most physicians prescribe relatively mild dosages in order to minimize the troublesome side effects of these drugs. Dementia with Lewy bodies appears to respond better to treatment with the newer antipsychotic medications than to treatment with such older drugs as **haloperidol** (Haldol).

Patients in the early stages of dementia can often remain at home with some help from family members or other caregivers, especially if the house or apartment can be fitted with safety features (handrails, good lighting, locks for cabinets containing potentially dangerous products, nonslip treads on stairs, etc.). Patients in the later stages of dementia, however, usually require skilled care in a nursing home or hospital.

Prognosis

The prognosis for reversible dementia related to nutritional or thyroid problems is usually good once the cause has been identified and treated. The prognoses for dementias related to alcoholism or HIV infection depend on the patient's age and the severity of the underlying disorder.

The prognosis for the irreversible dementias is gradual deterioration of the patient's functioning ending in death. The length of time varies somewhat. Patients with Alzheimer's disease may live from two–20 years with the disease, with an average of seven years. Patients with frontal lobe dementia or Pick's disease live on average between five and 10 years after diagnosis. The course of Creutzfeldt-Jakob disease is much more rapid, with patients living between five and 12 months after diagnosis.

Prevention

The reversible dementias related to thyroid and nutritional disorders can be prevented in many cases by regular physical checkups and proper attention to diet. Dementias related to toxic substances in the workplace may be prevented by careful monitoring of the work environment and by substituting less hazardous materials or substances in manufacturing processes. Dementias caused by infectious diseases are theoretically preventable by avoiding exposure to the prion, spirochete, or other disease agent. Multi-infarct dementia may be preventable in some patients by attention to diet and monitoring of blood pressure. Dementias caused by abnormalities in the structure of the brain are not preventable as of 2002.

With regard to genetic factors, tests are now available for the APOE gene implicated in late-onset Alzheimer's, but these tests are used primarily in research instead of clinical practice. One reason is that the test results are not conclusive; about 20% of people who eventually develop AD do not carry this gene. Another important reason is the ethical implications of testing for a disease that presently has no cure. These considerations may change, however, if researchers discover better treatments for primary dementia, more effective preventive methods, or more reliable genetic markers.

Denial

Definition

Denial is the refusal to acknowledge the existence or severity of unpleasant external realities or internal thoughts and feelings.

Theory of denial

In psychology, denial is a concept originating with the psychodynamic theories of Sigmund Freud.

KEY TERMS

Antisocial behavior—Behavior characterized by high levels of anger, aggression, manipulation, or violence.

Cognitive-behavioral therapies—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Defense mechanisms—Indirect strategies used to reduce anxiety rather than directly facing the issues causing the anxiety.

Dependent personality disorder—Personality disorder characterized by a constant, unhealthy need to be liked and appreciated by others at all costs.

Ego—In Freudian psychology, the conscious, rational part of the mind that experiences and reacts to the outside world.

Humanistic and existential therapies—Therapies that focus on achieving one's full potential, guided by subjective experience.

Id—A construct in Freudian psychodynamic theory that represents the irrational, self-centered aspects of human thought.

Motivational enhancement therapy—Therapy that focuses on increasing motivation for change by empathically comparing and contrasting the consequences and benefits of changing or not changing.

Narcissistic personality disorder—Personality characterized by continually exaggerating one's own positive qualities and refusing to recognize personal defects or flaws.

Psychoanalytic therapy—Therapy based on the psychodynamic theory of Sigmund Freud.

Psychodynamic—Referring to the motivational forces, unconscious as well as conscious, that form human attitudes and behavior.

Superego—According to Freud, the part of the mind that represents traditional parental and societal values. The superego is the source of guilt feelings.

According to Freud, three mental dynamics, or motivating forces, influence human behavior: the id, ego, and superego. The id consists of basic survival instincts and what Freud believed to be the two dominant human drives: sex and aggression. If the id were the only influence on behavior, humans would exclusively seek to increase pleasure, decrease pain, and achieve immediate gratification of desires. The ego consists of logical and rational thinking. It enables humans to analyze the realistic risks and benefits of a situation, to tolerate some pain for future profit, and to consider alternatives to the impulse-driven behavior of the id. The superego consists of moralistic standards and forms the basis of the conscience. Although the superego is essential to a sense of right and wrong, it can also include extreme, unrealistic ideas about what one should and should not do.

These three forces all have different goals (id, pleasure; ego, reality; superego, morality) and continually strive for dominance, resulting in internal conflict. This conflict produces anxiety. The ego, which functions as a mediator between the two extremes of the id and the superego, attempts to reduce this anxiety by using defense mechanisms. Defense mechanisms are indirect ways of dealing or coping with anxiety, such as explaining problems away or blaming others for problems. Denial is one of many defense mechanisms. It entails ignoring or refusing to believe an unpleasant reality. Defense mechanisms protect one's psychological well-being in traumatic situations, or in any situation that produces anxiety or conflict. However, they do not resolve the anxiety-producing situation and, if overused, can lead to psychological disorders. Although Freud's model of the id, ego, and superego is not emphasized by most psychologists today, defense mechanisms are still regarded as potentially maladaptive behavioral patterns that may lead to psychological disorders.

Examples of denial

Death is a common occasion for denial. When someone learns of the sudden, unexpected death of a loved one, at first he or she may not be able to accept the reality of this loss. The initial denial protects that person from the emotional shock and intense **grief** that often accompanies news of death. Chronic or terminal illnesses also encourage denial. People with such illnesses may think, "It's not so bad; I'll get over it," and refuse to make any lifestyle changes.

Denial can also apply to internal thoughts and feelings. For instance, some children are taught that anger is wrong in any situation. As adults, if these individuals experience feelings of anger, they are likely to deny their feelings to others. Cultural standards and expectations can encourage denial of subjective experience. Men who belong to cultures with extreme notions of masculinity may view fear as a sign of weakness and deny internal feelings of fear. The Chinese culture is thought to discourage the acknowledgment of mental illness, resulting

in individuals denying their psychological symptoms and often developing physical symptoms instead.

Certain **personality disorders** tend to be characterized by denial more than others. For example, those with **narcissistic personality disorder** deny information that suggests they are not perfect. Antisocial behavior is characterized by denial of the harm done to others (such as with sexual offenders or substance abusers).

Denial can also be exhibited on a large scale—among groups, cultures, or even nations. Lucy Bregman gives an example of national denial of imminent mortality in the 1950s: school children participated in drills in which they hid under desks in preparation for atomic attacks. Another example of large-scale denial is the recent assertion by some that the World War II Holocaust never occurred.

Treatment of denial

Denial is treated differently in different types of therapy. In psychoanalytic therapy, denial is regarded as an obstacle to progress that must eventually be confronted and interpreted. Timing is important, however. Psychoanalytic therapists wait until clients appear emotionally ready or have some degree of insight into their problems before confronting them. In the humanistic and existential therapies, denial is considered the framework by which clients understand their world. Not directly confronting denial, therapists assist clients in exploring their world view and considering alternative ways of being. In cognitive-behavioral therapies, denial is not regarded as an important phenomenon. Rather, denial would suggest that an individual has not learned the appropriate behaviors to cope with a stressful situation. Therapists assist individuals in examining their current thoughts and behaviors and devising strategic ways to make changes.

Traditional treatment programs for substance abuse and other addictions view denial as a central theme. Such programs teach that in order to overcome **addiction**, one must admit to being an alcoholic or addict. Those who are unable to accept such labels are informed they are in denial. Even when the labels are accepted, individuals are still considered to be in denial if they do not acknowledge the severity of their addictions. From this perspective, progress cannot be made until individuals recognize the extent of their denial and work toward acceptance. However, there is much controversy in the field of addictions regarding the role of denial and how it should be addressed. Traditional programs **stress** direct confrontation. Other professionals do not insist on the acceptance of labels. They believe that denial should be worked through more subtly, empathically focusing on the personal reasons surrounding denial and seeking to strengthen the desire to change. This subtle form of addressing denial is known as motivational enhancement therapy, and can be used with other types of disorders as well.

Dependent personality disorder

Definition

Dependent personality disorder is characterized by an excessive need to be taken care of or depend upon others. Persons with this disorder are typically submissive and display clinging behavior toward those from whom they fear being separated.

Dependent personality disorder is one of several **personality disorders** listed in the newest edition of the stan-

KEY TERMS

Millon Clinical Multiaxial Inventory (MCMI-II)—A self-report instrument designed to help the clinician assess DSM-IV-related personality disorders and clinical syndromes. It provides insight into 14 personality disorders and 10 clinical syndromes.

Minnesota Multiphasic Personality Inventory (MMPI-2)—A comprehensive assessment tool widely used to diagnose personality disorders.

Rorschach Psychodiagnostic Test—This series of 10 "ink blot" images allows the patient to project their interpretations which can be used to diagnose particular disorders.

Thematic Apperception Test (TAT)—A projective test using stories and descriptions of pictures to reveal some of the dominant drives, emotions, sentiments, conflicts, and complexes of a personality.

dard reference guide: ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR*.

Description

Persons with dependent personality disorder are docile, passive, and nonassertive. They exert a great deal of energy to please others, are self-sacrificing, and constantly attempt to elicit the approval of others. They are reluctant to express disagreement with others, and are often willing to go to abnormal lengths to win the approval of those on whom they rely. They are easily influenced and can be taken advantage of easily. This **compliance** and reliance upon others leads to a subtle message that someone should assume responsibility for significant areas of the patient's life. This is often displayed as helplessness, even for completion of seemingly simple tasks.

Patients with dependent personality disorder have a low level of confidence in their own intelligence and abilities. They often have difficulty making decisions and undertaking projects on their own. They are prone to be pessimistic, self-doubting, and belittle their own accomplishments. They shy away from responsibility in occupational settings.

Affected individuals are uneasy being alone and are preoccupied with the fear of being abandoned or rejected by others. Their moods are characterized by frequent bouts of anxiety or fearfulness; generally, their demeanor is sad. Their style of thinking is naïve, uncritical, and lacks discretion.

Causes and symptoms

Causes

It is commonly thought that the development of dependence in these individuals is a result of overinvolvement and intrusive behavior by their primary caretakers. Caretakers may foster dependence in the child to meet their own dependency needs, and may reward extreme loyalty but reject attempts the child makes towards independence. Families of those with dependent personality disorder are often do not express their emotions and are controlling; they demonstrate poorly defined relational roles within the family unit.

Individuals with dependent personality disorder often have been socially humiliated by others in their developmental years. They may carry significant doubts about their abilities to perform tasks, take on new responsibilities, and generally function independently of others. This reinforces their suspicions that they are incapable of living autonomously. In response to these feelings, they portray a helplessness that elicits caregiving behavior from some people in their lives.

Symptoms

DSM-IV-TR specifies eight diagnostic criteria for dependent personality disorder. Individuals with this disorder:

- Have difficulty making common decisions. These individuals typically need an excessive amount of advice and reassurance before they can make even simple decisions, such as the clothing to wear on a given day.
- Need others to assume responsibility for them. Because they view themselves as incapable of being autonomous, they withdraw from adult responsibilities by acting passive and helpless. They allow others to take the initiative for many areas of their life. Adults with this disorder typically depend on a parent or spouse to make major decisions for them, such as where to work, to live, or with whom to be friends.
- Have difficulty expressing disagreement with others. Disagreeing with others is often viewed as too risky. It might sever the support or approval of those they upon whom they depend. They are often overly agreeable, as they fear alienating other people.
- Have difficulty initiating or doing things on their own. They lack self-confidence and believe they need help to begin or sustain tasks. They often present themselves as

inept and unable to understand or accomplish the task at hand.

- Go to excessive lengths to obtain support or nurturing from others. They may even volunteer to do unpleasant tasks if they believe that doing so will evoke a positive response from others. They may subject themselves to great personal sacrifice or tolerate physical, verbal, or sexual **abuse** in their quest to get what they believe they need from others.
- Feel helpless when alone. Because they feel incapable of caring for themselves, they experience significant anxiety when alone. To avoid being alone, they may be with people in whom they have little interest.
- Quickly seek a new relationship when a previous one ends. When a marriage, dating, or other close relationship ends, there is typically an urgency to find a new relationship that will provide the support of the former relationship.
- Are preoccupied with fears of being left to take care of themselves. Their greatest fear is to be left alone and to be responsible for themselves. Even as adults, their dependence upon others may appear childlike.

Demographics

Dependent personality disorder should rarely, if ever, be diagnosed in children or adolescents because of their dependence on others because of their age and developmental limitations.

Diagnosis

Age and cultural factors should be considered in diagnosing dependent personality disorder. Certain cultural norms suggest a submissive, polite, or dependent posture in relating to the opposite sex, or authority figures. Dependent personality disorder should only be diagnosed when it meets the above criteria and is clearly outside one's cultural norms.

The **diagnosis** of dependent personality disorder is based on a clinical interview to assess symptomatic behavior. Other assessment tools helpful in confirming the diagnosis of dependent personality disorder include:

- **Minnesota Multiphasic Personality Inventory** (MMPI-2)
- Millon Clinical Multi-axial Inventory (MCMI-II)
- Rorschach Psychodiagnostic Test
- **Thematic Appreception Test** (TAT)

For a person to be diagnosed with dependent personality disorder, at least five of the eight symptoms described above must be the present, and these symptoms must begin by early adulthood and be evident in a variety of contexts.

The diagnosis of dependent personality disorder must be distinguished from **borderline personality disorder**, as there are common characteristics. Borderline personality disorder is characterized by fear of abandonment, as well, but with feelings of emptiness and rage. In contrast, the dependent personality responds to this fear of abandonment with submissiveness, and searches for a replacement relationship to maintain dependency.

Likewise, persons with histrionic personality disorder have a strong need for reassurance and approval, and may appear childlike in their clinging behavior. Histrionics are characterized by a gregarious demeanor and make active demands for attention, whereas dependents respond with docile and self-deprecating behavior.

The **avoidant personality disorder** can also be confused with dependent personality disorder. Both are characterized by feelings of inadequacy, an oversensitivity to criticism, and a frequent need for assurance. However, patients with avoidant personality disorder typically have such an intense fear of rejection that they will instinctively withdraw until they are certain of acceptance. People with dependent personality disorder, in contrast, actually seek out contact with others because they need the approval of others.

Treatments

The general goal of treatment of dependent personality disorder is to increase the individual's sense of autonomy and ability to function independently.

Psychodynamically oriented therapies

A long-term approach to psychodynamic treatment can be successful, but may lead to heightened dependencies and difficult separation in the therapeutic relationship over time. The preferred approach is a time-limited treatment plan consisting of a predetermined number of sessions. This has been proved to facilitate the exploration process of dependency issues more effectively than long-term therapy in most patients.

Cognitive-behavioral therapy

Cognitive-behavioral approaches attempt to increase the affected person's ability to act independently of others, improve their self-esteem, and enhance the quality of their interpersonal relationships. Often, patients will play an active role in setting goals. Methods often used in **cognitive-behavioral therapy** (CBT) include assertiveness and **social skills training** to help reduce reliance on others, including the therapist.

Interpersonal therapy

Treatment using an interpersonal approach can be useful because the individual is usually receptive to treatment and seeks help with interpersonal relationships. The therapist would help the patient explore their long-standing patterns of interacting with others, and understand how these have contributed to dependency issues. The goal is to show the patient the high price they pay for this dependency, and to help them develop healthier alternatives. **Assertiveness training** and learning to identify feelings is often used to improve interpersonal behavior.

Group therapy

When a person is highly motivated to see growth, a more interactive therapeutic group can be successful in helping him/her to explore passive-dependent behavior. If the individual is socially reluctant or impaired in his/her assertiveness, decision-making, or negotiation, a supportive decision-making group would be more appropriate. Time-limited assertiveness-training groups with clearly defined goals have been proven to be effective.

Family and marital therapy

Individuals with dependent personality disorder are usually brought to therapy by their parents. They are often young adults who are struggling with neurotic or psychotic symptoms. The goal of **family therapy** is often to untangle the enmeshed family relationships, which usually elicits considerable resistance by most family members unless all are in therapy.

Marital therapy can be productive in helping couples reduce the anxiety of both partners who seek and meet dependency needs that arise in the relationship.

Medications

Individuals with dependent personality disorder can experience anxiety and depressive disorders as well. In these cases, it may occasionally prove useful to use antidepressants or anti-anxiety agents. Unless the anxiety or depression is considered worthy of a primary diagnosis, medications are generally not recommended for treatment of the dependency issues or the anxiety or depressive responses. Persons with dependent personality disorder may become overly dependent on any medication used.

Prognosis

The general prognosis for individuals with dependent personality disorder is good. Most people with this disorder have had a supportive relationship with at least one parent. This enables them to engage in treatment to varying degrees and to explore the source of their dependent behavior. If persons who enter treatment can learn to become more autonomous, improved functioning can be expected.

Prevention

Since dependent personality disorder originates in the patient's family, the only known preventive measure is a nurturing, emotionally stimulating, and expressive caregiving environment.

Depersonalization

Definition

Depersonalization is a mental state in which a person feels detached or disconnected from his or her personal identity or self. This may include the sense that one is "outside" oneself, or is observing one's own actions, thoughts or body.

Description

A person experiencing depersonalization may feel so detached that he or she feels more like a robot than a human being. However, the person always is aware that this is just a feeling; there is no delusion that one is a lifeless robot or that one has no personal identity. The sense of detachment that characterizes the state may result in mood shifts, difficulty thinking, and loss of some sensations— a state that can be described as numbness or sensory anesthesia. Twice as many women as men are treated for depersonalization, which can last from a few seconds to years. Episodes may increase after traumatic events such as exposure to combat, accidents or other forms of violence or **stress**. Treatment is difficult and the state is often chronic, although it may occur during discrete periods or increase and decrease in intensity over time. Individuals with depersonalization often feel that events and the environment are unreal or strange, a state called derealization.

See also Acute stress disorder; Dissociation and dissociative disorders; Post-traumatic stress disorder; Schizophrenia

Dean A. Haycock, Ph.D.

Depersonalization disorder

Definition

Depersonalization is a state in which the individual ceases to perceive the reality of the self or the environment. The patient feels that his or her body is unreal, is changing, or is dissolving; or that he or she is outside of the body.

Depersonalization disorder is classified by the ***Diagnostic and Statistical Manual of Mental Disorders***, 4th Edition, text Revision, also known as the *DSM-IV-TR* as one of the dissociative disorders. These are mental disorders in which the normally well-integrated functions of memory, identity, perception, and consciousness are separated (dissociated). The dissociative disorders are usually associated with trauma in the recent or distant past, or with an intense internal conflict that forces the mind to separate incompatible or unacceptable knowledge, information, or feelings. In depersonalization disorder, the patient's self-perception is disrupted. Patients feel as if they are external observers of their own lives, or that they are detached from their own bodies. Depersonalization disorder is sometimes called "depersonalization neurosis."

Depersonalization as a symptom may occur in **panic disorder**, **borderline personality disorder**, **post-traumatic stress disorder** (PTSD), **acute stress disorder**, or another dissociative disorder. The patient is not given the **diagnosis** of depersonalization disorder if the episodes of depersonalization occur only during panic attacks or following a traumatic stressor.

The symptom of depersonalization can also occur in normal individuals under such circumstances as sleep deprivation, the use of certain anesthetics, experimental conditions in a laboratory (experiments involving weightlessness, for example), and emotionally stressful situations (such as taking an important academic examination or being in a traffic accident). One such example involves some of the rescue personnel from the September 11, 2001 terrorist attacks on the World Trade Center and the Pentagon. These individuals experienced episodes of depersonalization after a day and a half without sleep. A more commonplace example is the use of nitrous oxide, or "laughing gas" as an anesthetic during oral surgery. Many dental patients report a sense of unreality or feeling of being outside their bodies during nitrous oxide administration.

To further complicate the matter, depersonalization may be experienced in different ways by different individuals. Common descriptions include a feeling of being outside one's body; "floating on the ceiling looking down at myself" feeling as if one's body is dissolving or changing; feeling as if one is a machine or robot; "unreal" feeling that one is in a dream or that one"is on automatic pilot." Most patients report a sense of emotional detachment or uninvolvement, or a sense of emotional numbing. Depersonalization differs from "derealization," which is a dissociative symptom in which people perceive the external world as unreal, dreamlike, or changing. The various ways that people experience depersonalization are related to their bodies or their sense of self.

Depersonalization is a common experience in the general adult population. However, when a patient's symptoms of depersonalization are severe enough to cause significant emotional distress, or interfere with normal functioning, the criteria of the *DSM-IV-TR* for "depersonalization disorder" are met.

Description

A person suffering from depersonalization disorder experiences subjective symptoms of unreality that make him or her uneasy and anxious. "Subjective" is a word

KEY TERMS

Abuse—Physical, emotional, or sexual harm.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving; or that he or she is outside the body.

Depersonalization neurosis—Another name for depersonalization disorder.

Derealization—A dissociative symptom in which the external environment is perceived as unreal or dreamlike.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Dissociative disorders—A group of disorders marked by the separation (dissociation) of perception, memory, personal identity, and consciousness. Depersonalization disorder is one of five dissociative disorders defined by *DSM-IV-TR*.

Hypothalamic-pituitary-adrenal (HPA) system—A part of the brain involved in the human stress response. The HPA system releases cortisol, the primary human stress hormone, and neurotransmitters that activate other brain structures associated with the "fight-or-flight" reaction. The HPA system appears to function in abnormal ways in patients diagnosed with depersonalization disorder. It is sometimes called the HPA axis.

Reality testing—A phrase that refers to a person's ability to distinguish between subjective feelings and objective reality. A person who knows that their body is real even though they may be experiencing it as unreal, for example, is said to have intact reality testing. Intact reality testing is a *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision (also known as the *DSM-IV-TR*) criterion for depersonalization disorder.

Selective serotonin reuptake inhibitor—Commonly prescribed drugs for treating depression. SSRIs affect the chemicals that nerves in the brain use to send messages to one another. These chemical messengers (neurotransmitters) are released by one nerve cell and taken up by others. Neurotransmitters not taken up by other nerve cells are taken up by the same cells that released them. This process is termed "reuptake." SSRIs work by inhibiting the reuptake of serotonin, an action which allows more serotonin to be taken up by other nerve cells.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Stress—A physical and psychological response that results from being exposed to a demand or pressure.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

Subjective—Referring to a person's unique internal thoughts and feelings, as distinct from the objects of those thoughts and feelings in the eternal world.

Tricyclic antidepressants (TCAs)—Antidepressant medications that have the common characteristic of a three-ring nucleus in their chemical structure. Imipramine and amitriptyline are examples of tricyclic antidepressants.

that refers to the thoughts and perceptions inside an individual's mind, as distinct from the objects of those thoughts and perceptions outside the mind. Because depersonalization is a subjective experience, many people who have chronic or recurrent episodes of depersonalization are afraid others will not understand if they try to describe what they are feeling, or will think they are "crazy." As a result, depersonalization disorder may be underdiagnosed because the symptom of depersonalization is underreported.

Causes and symptoms

Causes

Depersonalization disorder, like the dissociative disorders in general, has been regarded as the result of severe **abuse** in childhood. This can be of a physical, emotional, and/or sexual nature.

Findings in 2002 indicate that emotional abuse in particular is a strong predictor of depersonalization disorder in adult life, as well as of depersonalization as a

symptom in other mental disorders. Analysis of one study of 49 patients diagnosed with depersonalization disorder indicated much higher scores than the control subjects for the total amount of emotional abuse endured and for the maximum severity of this type of abuse. The researchers concluded that emotional abuse has been relatively neglected by psychiatrists compared to other forms of childhood trauma.

It is thought that abuse in childhood or trauma in adult life may account for the distinctive cognitive (knowledge-related) profile of patients with depersonalization disorder. These patients have significant difficulties focusing their attention, with spatial reasoning, and with short-term visual and verbal memory. However, they have intact reality testing. (Reality testing refers to a person's ability to distinguish between their internal experiences and the objective reality of persons and objects in the outside world.) Otherwise stated, a patient with depersonalization disorder may experience his/her body as unreal, but knows that "feelings aren't facts." The *DSM-IV-TR* specifies intact reality testing as a diagnostic criterion for depersonalization disorder.

The causes of depersonalization disorder are not completely understood. Recent advances in **brain** imaging and other forms of neurological testing, however, have confirmed that depersonalization disorder is a distinct diagnostic entity and should not be considered a subtype of PTSD.

No specific genes have been associated with susceptibility to depersonalization disorder as of early 2002. It is possible that a genetic factor will be identified in the future.

NEUROBIOLOGICAL. In the past few years, several features of depersonalization disorder have been traced to differences in brain functioning. A group of British researchers found that the emotional detachment that characterizes depersonalization is associated with a lower level of nerve cell responses in regions of the brain that are responsible for emotional feeling; an increased level of nerve cell responses was found in regions of the brain related to emotional regulation.

A group of American researchers concluded that patients with depersonalization disorder had different patterns of response to tests of the hypothalamic-pituitary-adrenal axis (HPA, the part of the brain involved in the "fight-or-flight" reaction to **stress**) than did patients with PTSD. Other tests by the same research team showed that patients with depersonalization disorder can be clearly distinguished from patients with major depression by tests of the functioning of the HPA axis.

Other neurobiological studies involving **positron emission tomography** (PET) measurements of glucose (sugar) metabolism in different areas of the brain found that patients with depersonalization disorder appear to have abnormal functioning of the sensory cortex. The sensory cortex is the part of the brain that governs the senses of sight, hearing, and perceptions of the location of one's body in space. These studies indicate that depersonalization is a symptom that involves differences in sensory perception and subjective experiences.

HISTORICAL. Depersonalization disorder may be a reflection of changes in people's sense of self or personal identity within Western cultures since the eighteenth century. Historians of psychiatry have noted that whereas some mental disorders, such as depression, have been reported since the beginnings of Western medicine, no instances of the dissociative disorders were recorded before the 1780s. It seems that changes in social institutions and the structure of the family since the mid-eighteenth century may have produced a psychological structure in Westerners that makes individuals increasingly vulnerable to self disorders—as they are now called. Experiences of the unreality of one's body or one's self, such as those that characterize depersonalization disorder, presuppose a certain notion of how the self is presumed to feel. The emphasis on individualism and detachment from one's family is a mark of adult maturity in contemporary Western societies that appears to be a contributing factor to the frequency of dissociative symptoms and disorders.

Symptoms

The symptoms of depersonalization disorder have been described earlier. Although *DSM-IV-TR* does not specify a list of primary symptoms of depersonalization, British clinicians generally consider the triad of emotional numbing, changes in visual perception, and altered experience of one's body to be important core symptoms of depersonalization disorder.

DSM-IV-TR notes that patients with depersonalization disorder frequently score high on measurements of hypnotizability.

Demographics

The lifetime prevalence of depersonalization disorder in the general population is unknown, possibly because many people are made anxious by episodes of depersonalization and afraid to discuss them with a primary care physician. One survey done by the National Institutes of Mental Health (NIMH) indicates that about half of the adults in the U.S. have had one or two brief episodes of depersonalization in their lifetimes, usually

resulting from severe stress. About a third of people exposed to life-threatening dangers develop brief periods of depersonalization, as do 40% of psychiatric inpatients.

Depersonalization disorder is diagnosed about twice as often in women as in men. It is not known, however, whether this sex ratio indicates that women are at greater risk for the disorder or if they are more likely to seek help for its symptoms, or both. Little information is available about the incidence of the disorder in different racial or ethnic groups.

Diagnosis

The diagnosis of depersonalization disorder is usually a diagnosis of exclusion. The doctor will take a detailed medical history, give the patient a physical examination, and order blood and urine tests in order to rule out depersonalization resulting from epilepsy, substance abuse, medication side effects, or recent periods of sleep deprivation.

There are several standard diagnostic questionnaires that may be given to evaluate the presence of a dissociative disorder. The Dissociative Experiences Scale, or DES, is a frequently administered self-report screener for dissociation. The Structured Clinical Interview for DSM-IV Dissociative Disorders, or SCID-D, can be used to make the diagnosis of depersonalization disorder distinct from the other dissociative disorders defined by *DSM-IV*. The SCID-D is a semi-structured interview, which means that the examiner's questions are open-ended and allow the patient to describe experiences of depersonalization in some detail—distinct from simple "yes" or "no" answers.

In addition to these instruments, a six-item Depersonalization Severity Scale, or DSS, has been developed to discriminate between depersonalization disorder and other dissociative or post-traumatic disorders, and to measure the effects of treatment in patients.

Treatments

Depersonalization disorder sometimes resolves on its own without treatment. Specialized treatment is recommended only if the symptoms are persistent, recurrent, or upsetting to the patient. Insight-oriented **psychodynamic psychotherapy**, **cognitive-behavioral therapy**, and hypnosis have been demonstrated to be effective with some patients. There is, however, no single form of **psychotherapy** that is effective in treating all patients diagnosed with depersonalization disorder.

Medications that have been helpful to patients with depersonalization disorder include the benzodiazepine tranquilizers, such as **lorazepam** (Ativan), **clorazepate** (Tranxene), and **alprazolam** (Xanax), and the tricyclic antidepressants, such as **amitriptyline** (Elavil), **doxepin** (Sinequan), and **desipramine** (Norpramin). As of 1999, newer, promising medications called selective serotonin reuptake inhibitors (SSRIs) became available. Some SSRIs include **fluoxetine** (Prozac), **sertraline** (Zoloft), and **paroxetine** (Paxil). SSRIs act on brain chemicals that nerve cells use to send messages to each another. These chemical messengers (**neurotransmitters**) are released by one nerve cell and taken up by others. Those that are not taken up by other cells are taken up by the ones that released them. This is called "reuptake." SSRIs work by preventing the reuptake of serotonin—an action which allows more serotonin to be taken up by nerve cells.

Unfortunately, there have been very few well-designed studies comparing different medications for depersonalization disorder. Because depersonalization disorder is frequently associated with trauma, effective treatment must include other stress-related symptoms, as well.

Relaxation techniques have been reported to be a beneficial adjunctive treatment for persons diagnosed with depersonalization disorder, particularly for those who are worried about their sanity.

Prognosis

The prognosis for recovery from depersonalization disorder is good. Most patients recover completely, particularly those who developed the disorder in connection with traumas that can be explored and resolved in treatment. A few patients develop a chronic form of the disorder; this is characterized by periodic episodes of depersonalization in connection with stressful events in their lives.

Prevention

Some clinicians think that depersonalization disorder has an undetected onset in childhood, even though most patients first appear for treatment as adolescents or young adults. Preventive strategies could include the development of screening techniques for identifying children at risk, as well as further research into the effects of emotional abuse on children.

It is also hopeful that further neurobiological research will lead to the development of medications or other treatment modalities for preventing, as well as treating, depersonalization.

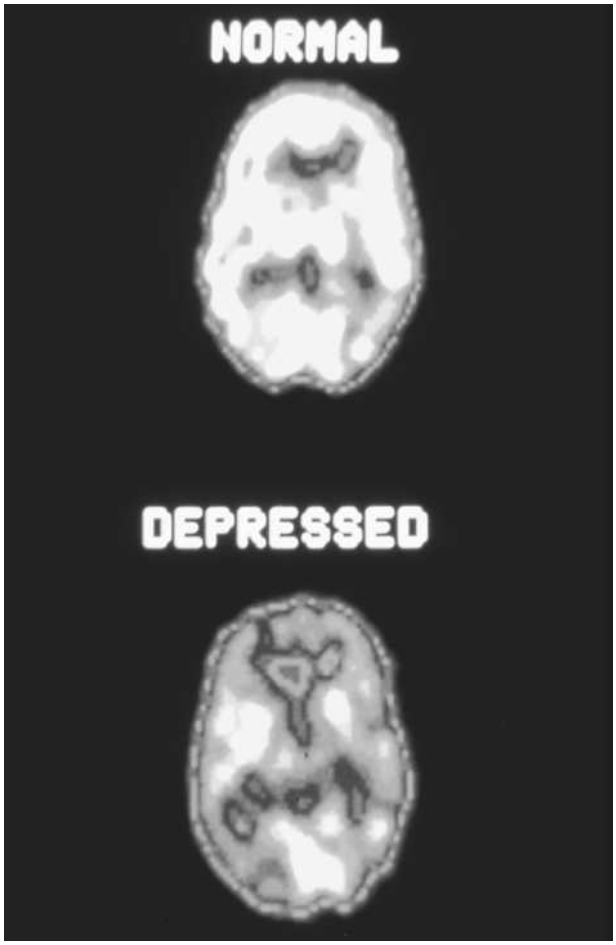
Depression and depressive disorders

Definition

Depression or depressive disorders (unipolar depression) are mental illnesses characterized by a profound and persistent feeling of sadness or despair and/or a loss of interest in things that were once pleasurable. Disturbance in sleep, appetite, and mental processes are a common accompaniment.

Description

Everyone experiences feelings of unhappiness and sadness occasionally. But when these depressed feelings start to dominate everyday life and cause physical and mental deterioration, they become what are known as depressive disorders. Each year in the United States, depressive disorders affect an estimated 17 million people at an approximate annual direct and indirect cost of $53 billion. One in four women is likely to experience an episode of severe depression in her lifetime, with a



Two false-colored positron emission tomography (PET) scans of human brains. At the top is the brain of a healthy person, and below that is the brain of a depressed person. *(NIH/Science Source, National Audubon Society Collection/ Photo Researchers, Inc. Reproduced by permission.) See color insert for color version.*

10–20% lifetime prevalence, compared to 5–10% for men. The average age a first depressive episode occurs is in the mid-20s, although the disorder strikes all age groups indiscriminately, from children to the elderly.

There are two main categories of depressive disorders: **major depressive disorder** and **dysthymic disorder**. Major depressive disorder is a moderate to severe episode of depression lasting two or more weeks. Individuals experiencing this major depressive episode may have trouble sleeping, lose interest in activities they once took pleasure in, experience a change in weight, have difficulty concentrating, feel worthless and hopeless, or have a preoccupation with death or **suicide**. In children, the major depression may appear as irritability.

While major depressive episodes may be acute (intense but short-lived), dysthymic disorder is an ongoing, chronic depression that lasts two or more years (one or more years in children) and has an average duration of 16 years. The mild to moderate depression of dysthymic disorder may rise and fall in intensity, and those afflicted with the disorder may experience some periods of normal, non-depressed mood of up to two months in length. Its onset is gradual, and dysthymic patients may not be able to pinpoint exactly when they started feeling depressed. Individuals with dysthymic disorder may experience a change in sleeping and eating patterns, low self-esteem, **fatigue**, trouble concentrating, and feelings of hopelessness.

Depression can also occur in **bipolar disorder**, a mood disorder that causes radical emotional changes and mood swings, from manic highs to depressive lows. The majority of bipolar individuals experience alternating episodes of mania and depression.

Some theories about the causes of depression

The causes behind depression are complex and not yet fully understood. While an imbalance of certain neurotransmitters—the chemicals in the **brain** that transmit messages between nerve cells— are thought to be key to depression, external factors such as upbringing (more so in dysthymia than major depression) may be as important. For example, it is speculated that, if an individual is abused and neglected throughout childhood and adolescence, a pattern of low self-esteem and negative thinking may emerge. From that, a lifelong pattern of depression may follow.

Depression is also associated with an imbalance of cortisol, the main hormone secreted by the adrenal glands. Other physiological factors sometimes associated with depression include viral infections, low thyroid hormone levels, and biological rhythms, including women's menstrual cycles—depression is a prominent symptom of premenstrual syndrome (PMS).

Heredity seems to play a role in the development of depressive disorders. Individuals with major depression in their immediate family are up to three times more likely to have the disorder themselves. It would seem that biological and genetic factors may make certain individuals pre-disposed or prone to depressive disorders, but environmental circumstances may often trigger the disorder.

External stressors and significant life changes, such as chronic medical problems, death of a loved one, divorce or estrangement, miscarriage, or loss of a job, can also result in a form of depression known as **adjustment disorder**. Although periods of adjustment disorder usually resolve themselves, occasionally they may evolve into a major depressive disorder.

ANTIDEPRESSANT DRUGS	
Brand Name (Generic Name)	***Possible Common Side Effects Include:***
Desyrel (trazodone hydrochloride)	Allergic skin reactions, blurred vision, decreased appetite, fluid retention, headache
Effexor (venlafaxine hydrochloride)	Diarrhea, dizziness, gas, headache, insommia, rash, vomiting
Elavil (amitriptyline hydrochloride)	Constipation, dizziness, high blood pressure, fever, nausea, rash, weight gain or loss
Nardil (phenelzine sulfate)	Dry mouth, fatigue, headache, muscle spasms, tremors
Norpramin (desipramine hydrochloride)	Blurred vision, cramps, hallucinations, hair loss, vomiting
Pamelor (nortriptyline hydrochloride)	Diarrhea, fatigue, headache, decreased coordination
Paxil (paroxetine hydrochloride)	Cold symptoms, drowsiness, nervousness, stomach pain
Prozac (fluoxetine hydrochloride)	Bronchitis, drowsiness, fatigue, nausea, tremors
Sinequan (doxepin hydrochloride)	Bruising, constipation, fluid retention, itching, increased heartbeat
Surmontil (trimipramine maleate)	Disorientation, flushing, headache, nausea, vomiting
Tofranil (imipramine hydrochloride)	Bleeding sores, fever, hives, decreased coordination
Travil	Asthma, diarrhea, dizziness, fatigue, seizures
Wellbutrin (bupropion hydrochloride)	Agitation, dry mouth, headache, nausea, rash
Zoloft (sertraline)	Diarrhea, fainting, gas, headache, nervousness

Some of the antidepressant medications that may be prescribed and some of their potential side effects. *(Stanley Publishing.)*

Desensitization *see* **Systematic desensitization**

Desipramine

Definition

Desipramine is an antidepressant drug used to elevate mood and promote recovery of a normal range of emotions in patients with depressive disorders. In addition, desipramine has uses in a number of other psychiatric and medical conditions. In the United States, the drug is also known by its brand name, Norpramin.

Purpose

Desipramine is known principally as an antidepressant drug used to promote recovery of depressed patients. It also has therapeutic uses in **panic disorder**, pain management, **attention-deficit/hyperactivity disorder** (ADHD), sleep attacks (**narcolepsy** and cataplexy), **binge eating** (bulimia), and in cocaine craving in the treatment of **addiction**.

Description

Desipramine is one of the tricyclic antidepressants, so-called because of the three-ring chemical structure common to these drugs. Until the late 1980s, desipramine and other tricyclic antidepressants, such as **imipramine**, formed the mainstay of the pharmacological treatment of depressive disorders.

KEY TERMS

Autonomic—The part of the nervous system that governs the heart, involuntary muscles, and glands.

Cataplexy—A symptom of narcolepsy marked by a sudden episode of muscle weakness triggered by strong emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to minutes.

Epilepsy—A neurological disorder characterized by the onset of seizures. Seizures are caused by a disturbance in the electrical activity in the brain and can cause loss of consciousness, muscle spasms, rhythmic movements, abnormal sensory experiences, or altered mental states.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

The therapeutic action of antidepressants is not completely understood. It is known that these drugs boost the levels of certain messenger chemicals, called **neurotransmitters**, which are involved in transmitting signals between nerve cells in the **brain**. This action may help to restore normal emotional feelings by counteracting abnormalities of nerve signal transmission that occur in depressive disorders.

Desipramine is one of a large number of tricyclic antidepressant compounds. Each was developed for somewhat differing pharmacological effects and side-effect profiles. The effects of desipramine are very similar to those of other tricyclics, although some individual patients may find one drug of this group more effective or more tolerable than another. It is available as Norpramin in 10-, 25-, 50-, 75-, 100-, and 150-mg tablets, although generic manufacturers may supply a somewhat different set of dosages.

Recommended dosage

For adults, desipramine is usually administered in dosages of 100–200 mg per day. Doses ranging from 75 mg to 300 mg per day are sometimes prescribed. The initial daily dose is usually low to avoid side effects, and it is usually increased, as necessary, until a therapeutic effect is achieved. Desipramine may be administered in divided doses or a single daily dose.

Geriatric patients, children, and adolescents are more sensitive to the side effects and toxicities of tricyclic antidepressants than other people. For geriatric patients, the dose may range from 25 to 100 mg per day. For children six to 12 years old, the recommended dose ranges from 10 to 30 mg per day in divided doses. For adolescents, daily dosages range from 25 to 50 mg but may be increased up to 100 mg, if needed.

Precautions

Desipramine and other tricyclic antidepressants may cause drowsiness. Activities requiring alertness, such as driving, may be impaired. Dizziness or lightheadedness may occur on arising due to sudden decreases in blood pressure. Fainting may occur. Some patients may experience difficulty urinating, especially men with prostate enlargement. Glaucoma may be aggravated. Sensitivity to ultraviolet light may be increased, and sunburns may occur more easily. Sweating may be reduced, causing sensitivity to heat and hot weather. Among patients with epilepsy, **seizures** may become more frequent.

Tricyclic antidepressants, including desipramine, should be used with caution in patients with heart disease because of the possibility of adverse effects on heart rhythm. Adverse effects on the heart occur frequently when tricyclics are taken in overdose. Only small quantities of these drugs should be given to patients who may be suicidal.

Tricyclic antidepressants may cause dry mouth due to decreased saliva, possibly contributing to the development of tooth decay, gum disease, and mouth infections. Patients should avoid sweets, sugary beverages, and chewing gum containing sugar.

It has not been determined whether desipramine is safe to take during pregnancy, and the patient's need for this medicine should be balanced against the possibility of harm to the fetus. Tricyclic antidepressants may be secreted in breast milk and may cause sedation and depressed breathing in a nursing infant.

Side effects

Desipramine may cause many side effects. Initially, the side effects of tricyclic drugs may be more pronounced, but sensitivity may decrease with continued treatment. The following more common side effects are grouped by the body system affected:

- Cardiovascular: decreases of blood pressure on rising from a sitting or lying position, which may cause dizziness or fainting; increases of blood pressure, rapid heart rate, pounding heart, altered heart rhythm.
- Nervous system: sedation, confusion, nervousness, restlessness, sleep difficulties, numbness, tingling sensations, tremors, increased seizure tendency.
- Autonomic: blurred vision, dry mouth, decreased sweating, difficulty urinating, constipation.
- Skin: rashes, sensitivity to sunlight.
- Body as a whole: weight gain.

Less commonly, tricyclic drugs may cause adverse effects on almost any organ or system of the body, particularly the blood, hormones, kidney, and liver. Patients should consult their physicians if symptoms develop or bodily changes occur.

Interactions

Tricyclic antidepressants, such as desipramine, may interact with many other drugs. Patients should inform their physicians about all other drugs they are taking. Tricyclic drugs may intensify the effects of drugs causing sedation, including alcohol, **barbiturates**, narcotic pain medications, minor tranquilizers, and antihistamines. Tricyclics may cause excessive reductions of blood pressure in patients taking blood pressure medicine, especially on arising or standing up. Conversely, these drugs may interfere with the pressure-reducing effects of certain other blood pressure medicines. Tricyclics may interact with thyroid medications to produce heart rhythm abnormalities. Also, they may increase seizure tendency in patients with epilepsy, requiring adjustment of anti-epileptic medication. Concurrent use of tricyclic antidepressants with other antidepressants or other psychiatric medicines may result in intensification of certain side effects.

Certain drugs may interfere with the elimination of tricyclic antidepressants from the body causing higher blood levels and increased side effects. This effect may occur with cimetidine (Tagamet), other antidepressants, **methylphenidate** (Ritalin, Concerta), and some antipsychotic medications.

Detoxification

Definition

Detoxification is a process in which the body is allowed to free itself of a drug. During this period, the symptoms of withdrawal are also treated. Detoxification is the primary step in any drug treatment program, and is used as the initial phase in treating alcohol, heroin, inhalant, sedative, and hypnotic addictions.

Purpose

The goal of detoxification is to clear the toxins out of the body so that the body can adjust and heal itself after being dependent on a substance. In order for the recovering person to stay abstinent on a long-term basis, detoxification needs to lead into long-term community residential program treatment or outpatient drug treatment lasting three to six months.

Precautions

When individuals are physically dependent on a substance, they experience withdrawal symptoms when they abstain from the drug. Withdrawal symptoms vary with each drug of abuse, but can be severe, and even dangerous. Patients who want to overcome their dependence need help managing the withdrawal symptoms. The patient's medical team strives to get the patient off a substance on which he or she is physically dependent, while treating the withdrawal symptoms.

KEY TERMS

Agonist—A chemical that reproduces the mechanism of action of a neurotransmitter.

Antagonist—A substance whose actions counteract the effects of or work in the opposite way from another chemical or drug.

Buprenorphine—A medication that blocks some of the withdrawal effects during heroin detoxification.

Detoxification—A process in which the body is allowed to free itself of a drug while the symptoms of withdrawal are treated. It is the primary step in any treatment program for drug or alcohol abuse.

Disulfiram—A medication that helps reinforce abstinence in people who are recovering from alcohol abuse. If a person taking disulfiram drinks even a small amount of alcohol, he or she experiences facial flushing, headache, nausea and vomiting.

Lofexidine—A medication approved for use in England to aid the opioid detoxification process.

Methadone—A drug often prescribed legally as a replacement for heroin. It induces a slight high but blocks heroin from producing a more powerful euphoric effect. It may be used in heroin detoxification to ease the process, or it may be used daily after detoxification as maintenance therapy. Methadone maintenance therapy is controversial.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

Pregnant women cannot be detoxified from opiates (also called narcotics, including morphine, heroin, and similar drugs) because strict detoxification can increase the risk of spontaneous abortion or premature birth. These women are treated with **methadone** as an alternative. (Methadone acts as a replacement for the heroin in the woman's body, but the methadone does not provide the "high" that the heroin provides. In addition, methadone is safer for the fetus than heroin.)

In order to be an effective first step of treatment, detoxification must be an individualized process because patients have varying needs.

Description

The body, when allowed to be free from drugs, detoxifies itself through its normal metabolic processes. The withdrawal symptoms are treated during this process so that the patient will be comfortable while the body detoxifies itself.

The process of substance addiction

Before discussing detoxification, it may be useful to understand how the body becomes addicted and why withdrawal symptoms are experienced. In physical **addiction** or dependence, as a person uses a substance or chemical over a long period of time, his or her body chemistry changes. Once a substance enters the body through drinking, smoking, injecting or inhaling, it travels through the bloodstream to the **brain**. The brain has a complex reward system built in— when people engage in activities that are important for survival (such as eating), special nerve cells in the brain release chemicals (**neurotransmitters**, including dopamine) that induce feelings of pleasure. Because of this reward system in the brain, humans are programmed to want to repeat actions that elicit those pleasant sensations. In other words, feelings of pleasure reinforce certain activities or behaviors. Addictive substances interfere with this reward system. Some drugs mimic the effects of a natural chemical, some block the communication between nerve cells, and some substances trigger a larger-than-normal release of neurotransmitters like dopamine. The result of this interference is that dependent drug users physically need the drug to feel pleasure. As they become more dependent, their bodies becomes less responsive to the substance, and need more of it to get the desired response—a phenomenon called tolerance. Also as a result of the interference with the brain's system, when the dependent user does not have the drug in his or her system, feelings of depression or unpleasant withdrawal symptoms may be experienced. These consequences also reinforce the substance use— people dependent on substances resort to using more drugs to avoid the depression or the withdrawal symptoms.

Withdrawal symptoms

The symptoms and severity of these symptoms vary from one substance to another.

ALCOHOL. After a person who has used alcohol heavily for a long time stops drinking, he or she may experience increased heart rate, shaking, difficulty sleeping, nausea, restlessness, anxiety, and even **seizures**. The affected person may also experience **hallucinations** (seeing, hearing, or feeling something that isn't really present). In some cases, delirium tremens (DTs) may occur as part of the withdrawal. Delirium tremens is a violent **delirium** (fading in and out of consciousness) with tremors, increased motor activity, visual hallucina-

tions, disorientation, confusion, and fever that happens 48-96 hours after the alcohol-dependent person has had his or her last drink. These symptoms can last anywhere from three to 10 days. This state is a medical emergency because it could be fatal.

HEROIN AND OTHER OPIATES. Heroin is part of a family of drugs called opiates or opioids, which are made up of drugs that come from the seeds of the Asian poppy (heroin, opium and morphine, for example) and also manufactured drugs that act like the natural drugs (meperidine or Demerol). Symptoms of opiate withdrawal include restlessness, **insomnia**, anxiety, irritability, loss of appetite, diarrhea, abdominal cramps, nausea, sweating, chills, and runny eyes and nose.

SEDATIVES AND HYPNOTICS. Sedatives and hypnotics are drug families that are often considered in one group called the sedative-hypnotics. These drugs depress or slow down the body's functions, and can be used to calm anxiety or to induce sleep. When taken in high doses or when abused, these drugs can cause unconsciousness or death. These drugs include **barbiturates** and benzodiazepines. Some barbiturates are amobarbital (Amytal), pentobarbital (Nembutal), and secobarbital (Seconal). Some benzodiazepines include **diazepam** (Valium), **chlordiazepoxide** (Librium), and **lorazepam** (Ativan). When a person dependent on these drugs stops taking them suddenly, he or she might experience restlessness, muscle cramps, anxiety, insomnia, irritability, paranoid behavior, and even seizures or death.

Alcohol detoxification

Patients being detoxified from alcohol can safely be treated with rest, nutrition, vitamins, and thiamin (a B vitamin whose absorption is affected by alcohol abuse). Detoxification can be completed in an inpatient setting, or patients may participate in intensive outpatient (day hospital) treatment. People with mild or moderate withdrawal symptoms undergo detoxification over a five-day period and receive a benzodiazepine or phenobarbital to help ease the withdrawal symptoms. Delirium tremens can be treated with very high-dose benzodiazepines (such as chlordiazepoxide or diazepam) or with antipsychotic medications such as Haldol (**haloperidol**). The patient usually receives medication at doses high enough to give 60 mg or more of the medication over a 24- to 36-hour period, and the doses of these medications are gradually decreased by 20% each day. Patients who have liver disease, **dementia**, or patients who are over the age of 65 or with significant medical problems may receive lorazepam for the withdrawal symptoms.

Heroin detoxification

Patients with heroin dependence may receive help with their detoxification in one of two forms. Opioid agonists are drugs that act like heroin in the patient's body but do not provide the same "high," and are given in gradually decreasing doses. Because these medications "act" like heroin, the person does not experience withdrawal symptoms. Some examples of this kind of medication are methadone and levo-alpha-acetylmethadol (LAAM); buprenorphine is a partial opioid agonist, which means that it acts like heroin or methadone, but it limits the effects of opioids so that higher doses produce no greater effects. The second form of help for patients undergoing heroin detoxification is the use of a drug, such as **clonidine** (Catapres), that blocks some of the withdrawal symptoms. There is also a new method of heroin detoxification called ultra-rapid opioid detoxification under anesthesia/sedation, and there is an experimental method using a medication called lofexidine.

METHADONE SUBSTITUTION. Methadone substitution can occur in outpatient or inpatient settings, and is a method of detoxification that involves helping patients off substances such as heroin by substituting these substances with methadone to ease the withdrawal symptoms, and gradually decreasing the dose until no methadone is needed for the symptoms. Patients may begin with a dose of methadone that is between 20 mg and 40 mg per day. The initial dose may be adjusted so that the most beneficial dose can be discovered, based on the patient's withdrawal symptoms. The dose is then gradually decreased over the next several days. The decrease in methadone dosage is called tapering. If the detoxification is being completed in an inpatient setting, the methadone dose can be tapered more quickly, because medical staff can closely monitor patients for withdrawal, and detoxification can be achieved in about five to 10 days. However, in the case of outpatient detoxification, the taper has to be done much more slowly to assure that the patient does not have an adverse reaction or relapse (use the drug of abuse again) to treat their withdrawal symptoms. The dose may be decreased about 10% per week initially until a dose of 20 mg is reached. Then the dose can be decreased by 3% per week for the rest of the time that the patient needs to be detoxified. Patients are usually comfortable with the slow decrease of the medication until the dose gets below 20 mg/day. At that point, patients tend to become fearful of being off opioids and having symptoms of withdrawal.

Clonidine is used much more frequently than methadone in detoxification. Methadone is used frequently as long-term maintenance treatment for heroin addiction.

A doctor implants a naltrexone pellet into a patient's stomach. The patient had undergone rapid opiate detoxification months before this procedure. The naltrexone blocks the euphoria-producing effects of heroin, discouraging recovering addicts to relapse and abuse the drug from which they are recovering. *(AP Photo/ Charles Rex Arbogast. Photo reproduced with permission.)*

BUPRENORPHINE. Buprenorphine is another medication that is used during opioid detoxification. Because it also acts like heroin in the body, the patient does not experience the withdrawal symptoms as the heroin is being eliminated from the body. It is given as an intramuscular injection or intravenously. It begins to work within 15 minutes and its effects last six hours. A patient receiving buprenorphine receives this medication for at least three days, and then the medication is either gradually withdrawn or discontinued abruptly.

CLONIDINE. Clonidine is a medication that decreases many of the symptoms of opioid withdrawal. Patients may require nonsteroidal anti-inflammatory drugs (NSAIDS, such as ibuprofen) for the treatment of muscle aches. Clonidine's major side effects include sedation and hypotension (low blood pressure). Patients undergoing detoxification using clonidine will have their blood pressure and pulse checked regularly. The starting dose of clonidine is 0.1–0.3 mg every four to six hours— the maximum amount that can be given in one day is 1 mg. During days two through four of the detoxification, the dose of clonidine is adjusted to control the withdrawal symptoms. Again, however, the dose cannot exceed the maximum dose. On the fifth day of detoxification, the dose starts to get slowly tapered.

The clonidine patch is a transdermal patch, meaning that the drug is delivered through the skin and causes the patient to be exposed to a constant amount of the drug over a seven-day period. It also allows the person to experience a more comfortable heroin detoxification. It comes in three doses: 0.1-mg, 0.2-mg, and 0.3-mg. Patients who will use the clonidine patch need to have both the patch on and take oral clonidine during the first two days of the detoxification, because it takes the patch two days to reach a steady state and be effective. The patient takes 0.2 mg of oral clonidine three times a day, and the weight of the patient determines the dose of the patch. On day two, the amount of clonidine that the patient takes by mouth is reduced by half and then it is completely stopped after day three. After seven days, the patch is removed and replaced with a patch that is half the amount of the original dose. The patch is continued for as long as the patient continues to have symptoms of withdrawal. Blood pressure is monitored for the patient

using the patch, as well. The detoxification process in general takes about seven days using clonidine.

CLONIDINE-NALTREXONE ULTRA-RAPID DETOXIFICATION. Clonidine-naltrexone ultra-rapid detoxification is a faster means of detoxification than using clonidine alone. The higher the dose of **naltrexone** that the person receives, the faster he or she can be detoxified. Very close monitoring for withdrawal symptoms is necessary, however, particularly during the first eight hours of the detoxification process. (Naltrexone accelerates the withdrawal.) On the first day of the detoxification process, the patient is premedicated with **oxazepam** and clonidine. A couple hours later, the patient receives naltrexone. Throughout the rest of the first day, the patient receives oxazepam and clonidine every four to six hours. On the second and third days, the patient receives a larger dose of naltrexone, and continues to receive oxazepam and clonidine throughout the day. After day three, the naltrexone is no longer given, and the patient continues to take the clonidine and oxazepam for two to three more days. Additional medications to help with muscle cramping and nausea may be necessary. In an inpatient setting, the naltrexone can be increased so that the patient can complete detoxification in two to three days.

LOFEXIDINE. Lofexidine is approved for use in England for opioid detoxification. It appears to cause less sedation and fewer cases of low blood pressure than clonidine. In the United States, the National Institute of Drug Abuse (NIDA) is conducting studies on this drug.

ULTRA-RAPID OPIOID DETOXIFICATION UNDER ANESTHESIA/SEDATION. In this new procedure, anesthesia is induced and the patient receives a tracheal tube— a tube in the throat— and a tube in the nose (a nasogastric tube). The patient is given intravenous naloxone or naltrexone through the nasogastric tube. The procedure takes only eight hours and the patient can leave the hospital in one or two days. The patient's withdrawal symptoms are treated with a variety of medications including clonidine, antidiarrheal medications, and benzodiazepines.

Mixed substance abuse

Mixed substance abuse (also called polysubstance abuse) occurs when individuals abuse more than one substance. Many doctors prefer to use phenobarbital to detoxify patients with polysubstance abuse problems. Patients receiving phenobarbital may receive a test dose, and then based on his or her tolerance and symptoms, the dose will be adjusted. Patients cannot receive more than 600 mg of phenobarbital a day. After two to three days, once the patient is doing well, the dose can be reduced by 30-60 mg. Whether detoxification for polysubstance abusers will be completed on an inpatient or outpatient status depends on the drugs the patient abuses.

Benzodiazepines

These medications are often used to help patients during detoxification, but these substances themselves can be abused and addictive. Patients who have taken a prescribed benzodiazepine for two weeks, even in a therapeutic dose, need to be safely detoxified with a slow taper. The amount of drug the person takes is dropped by 10-25% every week if the patient has minimal withdrawal symptoms. If the patient has taken very high doses for long periods of time, he or she is at increased risk for addiction. If the person has been taking a benzodiazepine medication for years, it can take months before he or she can get off the drug. Anticonvulsant medications like **carbamazepine** (Tegretol) and **divalproex sodium** (Depakote) can be used to make the detoxification process faster and more comfortable for the patient.

Preparation

The first step in any detoxification, regardless of the substance, is a physical exam and history taken by a physician. This information-gathering and examination will help the treatment team assess the patient's overall health. In general, the healthier the patient is, the better the chances are that the patient will experience a detoxification without serious or life-threatening complications. Patients also need to give urine and blood samples to test for drugs and alcohol.

Aftercare

After the patient has completed detoxification, he or she needs further treatment either at an outpatient, inpatient, residential, or day hospital program in order to remain drug-free for the long term. Patients are treated by trained health care professionals, and some patients are also counseled by people who are recovering from addiction themselves. Many patients also benefit from 12-step programs or **self-help groups**, such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA).

Most opioid users are treated with ambulatory or outpatient detoxification or residential treatment followed by outpatient counseling. Some people who have abused opioids and have undergone detoxification and counseling are able to remain drug-free. Many, however, relapse, even after receiving **psychotherapy**. People recovering from opioid addiction can receive methadone or LAAM as maintenance therapy to prevent relapse. Similar to the aid these medications can give patients during detoxification, when taken daily as a therapy, they

continue to "act" as heroin, keeping the withdrawal symptoms from appearing. Methadone maintenance therapy can be provided through either residential or therapeutic communities and outpatient drug-free programs. Methadone maintenance treatment therapy is controversial, however, because it does not cure the person's addiction— it replaces it with another substance. Proponents of methadone maintenance therapy argue that people receiving methadone are able to function much better in society than people addicted to heroin. Because their drug-seeking behavior is reduced, these patients are able to become productive at work and their interpersonal relations improve.

People recovering from alcoholism can also benefit from counseling and support after detoxification, and a maintenance therapy is available to them, as well. **Disulfiram** (Antabuse) is a medication that interferes with the body's breakdown and processing of alcohol. When alcohol is consumed while a patient is taking disulfiram, the medication makes the effects of the alcohol much worse than the patient would normally experience—facial flushing, headache, nausea and vomiting occurs, even if alcohol is consumed in a small amount. In order for disulfiram to be effective, the patient must want this kind of **reinforcement** to maintain abstinence and must be committed to it. Patients also must note that any form of alcohol can trigger the undesired effects, including cooking wine or mouthwash with alcohol.

Risks

When benzodiazepines are the drug to which a person is addicted, they have to be discontinued and cannot be given on an outpatient basis because of their potential for abuse. For all patients undergoing detoxification, benzodiazepine use must be monitored carefully because of the potential for new addiction. Elderly patients undergoing detoxification and receiving benzodiazepines must be monitored closely because they are more sensitive to the sedating effects of these drugs, and are also more prone to falls while receiving these drugs. If benzodiazepines are not discontinued gradually, patients can have withdrawal symptoms such as irritability, poor sleep, agitation and seizures. Ultra-rapid opioid detoxification under anesthesia/sedation remains a new and serious procedure. Patients have died receiving this procedure, and this procedure is still being researched.

It should also be noted that many of the substances used in detoxification can themselves cause addictions. An example of this risk has already been given with benzodiazepines—these medications ease withdrawal symptoms during detoxification, but patients can get addicted to these medications, as well.

Normal results

Normal results for a well-managed detoxification would include freedom from the drug of addiction and ability to enter long-term treatment.

Success rates vary among people recovering from substance abuse. As might be expected, patients who successfully complete a full treatment program after detoxification (that includes counseling, psychotherapy, **family therapy**, and/or **group therapy** or some combination of those therapy types) achieve higher rates of success at remaining drug-free. Patients who were addicted for shorter periods of time and patients who spend longer periods in treatment are generally more successful at remaining abstinent from drugs over the long term.

Studies indicate that people who abuse alcohol and who want to stop have a higher chance of success if they undergo inpatient detoxification versus outpatient detoxification.

Abnormal results

One abnormal result that may occur is that patients who received nasogastric or tracheal tubes for opioid detoxification under anesthesia may experience adverse effects or complications. These patients are at risk for: trauma to their lips, vocal cords, larynx, teeth; nose bleeds; high blood pressure; elevated heart rate; irregular heartbeat; and vomiting, which can lead to aspiration pneumonia.

An additional abnormal result would be a new addiction as a consequence of the detoxification.

After the detoxification is completed, patients may relapse. Support is critical for patients to continue long-term therapy and successfully overcome addiction.

Developmental coordination disorder

Definition

Developmental coordination disorder is diagnosed when children do not develop normal motor coordination (coordination of movements involving the voluntary muscles).

Description

Developmental coordination disorder has been known by many other names, some of which are still used today. It has been called clumsy child syndrome, clumsiness, developmental disorder of motor function, and congenital maladroitness. Developmental coordination disorder is usually first recognized when a child fails to reach such normal developmental milestones as walking or beginning to dress him- or herself.

KEY TERMS

Maladroitness—Another word for awkwardness or clumsiness.

Motor skills—Skills pertaining to or involving muscular movement.

Children with developmental coordination disorder often have difficulty performing tasks that involve both large and small muscles, including forming letters when they write, throwing or catching balls, and buttoning buttons. Children who have developmental coordination disorder have often developed normally in all other ways. The disorder can, however, lead to social or academic problems for children. Because of their underdeveloped coordination, they may choose not to participate in activities on the playground. This avoidance can lead to conflicts with or rejection by their peers. Also, children who have problems forming letters when they write by hand, or drawing pictures, may become discouraged and give up academic or artistic pursuits even though they have normal intelligence.

Causes and symptoms

The symptoms of developmental coordination disorder vary greatly from child to child. The general characteristic is that the child has abnormal development of one or more types of motor skills when the child's age and intelligence quotient (IQ) are taken into account. In some children these coordination deficiencies manifest as an inability to tie shoes or catch a ball, while in other children they appear as an inability to draw objects or properly form printed letters.

Some investigators believe that there are different subtypes of developmental coordination disorder. While there is disagreement over how to define these different subtypes, they can provide a useful framework for the categorization of symptoms. There are six general groups of symptoms. These include:

- general unsteadiness and slight shaking
- an at-rest muscle tone that is below normal
- muscle tone that is consistently above normal
- inability to move smoothly because of problems putting together the subunits of the whole movement
- inability to produce written symbols

Children with developmental coordination disorder have difficulty performing tasks that require motor skills or eye-hand coordination, such as catching a ball. *(Anthony Nex. CORBIS. Photo reproduced by permission.)*

- visual perception problems related to development of the eye muscles

Children can have one or more of these types of motor difficulties.

Developmental coordination disorder usually becomes apparent when children fail to meet normal developmental milestones. Some children with developmental coordination disorder do not learn large motor skills such as walking, running, and climbing until a much later point in time than their peers. Others have problems with such small muscle skills as learning to fasten buttons, close or open zippers, or tie shoes. Some children have problems learning how to handle silverware properly. In others, the disorder does not appear until they are expected to learn how to write in school. Some children just look clumsy and often walk into objects or drop things.

There are no known causes of developmental coordination disorder. There are, however, various theories about its possible causes. Some theories attribute the disorder to biological causes. Some of the possible biological causes include such prenatal complications as fetal malnutrition. Low birth weight or prematurity are thought to be possible causes, but there is no hard evidence supporting these claims.

Demographics

It is estimated that as many as 6% of children between the ages of five and 11 have developmental coordination disorder. Males and females are thought to be equally likely to have this disorder, although males may be more likely to be diagnosed. Developmental coordination disorder and speech-language disorders seem to be closely linked, although it is not clear why this is the case. Children with one disorder are more likely to have the other also.

Diagnosis

The **diagnosis** of developmental coordination disorder is most commonly made when a child's parents or teachers notice that he or she is lagging behind peers in learning motor skills, is having learning problems in school, or is suffering frequent injuries from falls and other accidents resulting from clumsiness. In most cases, the child's pediatrician will perform a physical examination in order to rule out problems with eyesight or hearing that interfere with muscular coordination, and to rule out disorders of the nervous system. In addition to a medical examination, a learning specialist or child **psychiatrist** may be consulted to rule out other types of learning disabilities.

The types of motor impairment that lead to a diagnosis of developmental coordination disorder are somewhat vague, as the disorder has different symptoms in different children. There are many ways in which this kind of motor coordination problem can manifest itself, all of which may serve as criteria for a diagnosis of developmental coordination disorder. The core of the diagnosis rests on the child's being abnormally clumsy. To make this determination, the child's motor coordination must be compared to that of other children of a similar age and intelligence level.

The difference between a child who has developmental coordination disorder and one who is simply clumsy and awkward can be hard to determine. For a child to be diagnosed with developmental coordination disorder there must be significant negative consequences for the child's clumsiness. The negative effects may be seen in the child's performance in school, activities at play, or other activities that are necessary on a day-to-day basis. Also, for developmental coordination disorder to be diagnosed, the child's problems with motor coordination cannot result from such general medical conditions as muscular dystrophy, and cannot result directly from

mental retardation. Some criteria require that the child have an IQ of at least 70 to be diagnosed with developmental coordination disorder.

Treatments

No treatments are known to work for all cases of developmental coordination disorder. Experts recommend that a specialized course of treatment, possibly involving work with an occupational therapist, be drawn up to address the needs of each child. Many children can be effectively helped in special education settings to work more intensively on such academic problems as letter formation. For other children, physical education classes designed to improve general motor coordination, with emphasis on skills the child can use in playing with peers, can be very successful. Any kind of physical training that allows the child to safely practice motor skills and motor control may be helpful.

It is important for children who have developmental coordination disorder to receive individualized therapy, because for many children the secondary problems that result from extreme clumsiness can be very distressing. Children who have developmental coordination disorder often have problems playing with their peers because of an inability to perform the physical movements involved in many games and sports. Unpopularity with peers or exclusion from their activities can lead to low self-esteem and poor self-image. Children may go to great lengths to avoid physical education classes and similar situations in which their motor coordination deficiencies might be noticeable. Treatments that focus on skills that are useful on the playground or in the gymnasium can help to alleviate or prevent these problems.

Children with developmental coordination disorder also frequently have problems writing letters and doing sums, or performing other motor activities required in the classroom— including coloring pictures, tracing designs, or making figures from modeling clay. These children may become frustrated by their inability to master tasks that their classmates find easy, and therefore may stop trying or become disruptive. Individualized programs designed to help children master writing or skills related to arts and crafts may help them regain confidence and interest in classroom activities.

Prognosis

For many people, developmental coordination disorder lasts into adulthood. Through specialized attention and teaching techniques it is possible over time for many children to develop the motor skills that they lack. Some children, however, never fully develop the skills they need. Although many children improve their motor skills significantly, in most cases their motor skills will never match those of their peers at any given age.

Prevention

There is no known way to prevent developmental coordination disorder, although a healthy diet throughout pregnancy and regular prenatal care may help, as they help to prevent many childhood problems.

Diagnosis

Definition

Diagnosis can be defined as the identification and labeling of a disease based on its signs and symptoms. Mental health clinicians (psychiatrists, psychologists, and psychiatric nurse practitioners) diagnose mental disorders using the criteria listed in the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM,* published by the American Psychiatric Association.

Description

According to the *DSM,* fourth edition, text revised (the *DSM-IV-TR*), the term *mental disorder* is unfortunate because it implies that a mental disorder is separate from a physical illness, when actually, according to the American Psychiatric Association (APA), researchers and scientists now know that that distinction is not a clear one to make. The APA argues that "there is much 'physical' in 'mental disorders' and much 'mental' in 'physical disorders,'" and continues to use the term "mental disorders" because a better term has not yet been found. The APA defines a mental disorder as "a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress or disability or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom." Many people fear that when a mental disorder is classified, *people* are actually classified, and the *DSM-IV-TR* strives to contradict this notion. The American Psychiatric Association believes their manual to be strictly a manual classifying mental disorders themselves, and does not advocate the use of the diagnoses to discriminate.

The manual lists various criteria for each mental disorder included in the book. When an individual seeks the help of a mental health clinician, the clinician interviews the client (along with family members when appropriate), gathers a medical history, and may administer psychological evaluations (various checklists or tests that the patient may complete) in order to establish a diagnosis. Once the clinician has gathered the necessary information, a diagnosis based on the symptoms may be assigned from the *DSM.*

One of the main purposes of diagnosis is to guide treatment planning. If doctors know that a particular disorder has shown to be treated effectively with a drug or with a specific therapy, then the best practice can be applied to a new case of that disorder. The diagnosis also helps to establish a prognosis for the patient and his or her family, and it helps to enable communication among the professionals (including insurers) involved in a patient's care. Additionally, a formal diagnosis as recognized by the *DSM* may be necessary in order for insurers to pay for medical services. The act of labeling a mental disorder may have unintended effects for the person with the disorder, however. Although the *DSM* states that its diagnoses do not label people, in reality, many people who have received diagnoses of mental disorders may feel affected by the label their disorder has been given. People diagnosed with mental disorders may feel stigmatized, and that others' perceptions of them—as well as their self-perceptions— have changed as a result of their diagnosis.

Allen, John J. B. "DSM-IV." In *Encyclopedia of Mental Health,* edited by Howard S. Friedman. San Diego, CA: Academic Press, 1998.

American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders.* Fourth edition, text revised. Washington DC: American Psychiatric Association, 2000.

Diagnostic and Statistical Manual of Mental Disorders

Nature and purposes

The *Diagnostic and Statistical Manual of Mental Disorders* is a reference work consulted by psychiatrists, psychologists, physicians in clinical practice, **social workers**, medical and nursing students, pastoral counselors, and other professionals in health care and social service fields. The book's title is often shortened to *DSM*, or an abbreviation that also indicates edition, such as *DSM-IV-TR,* which indicates fourth edition, text revision of the manual, published in 2000. The *DSM-IV-TR* provides a classification of mental disorders, criteria sets to guide the process of differential **diagnosis**, and numerical codes for each disorder to facilitate medical record-keeping. The stated purpose of the *DSM* is threefold: to provide "a helpful guide to clinical practice"; "to facilitate research and improve communication among clinicians and researchers"; and to serve as "an educational tool for teaching psychopathology."

The multi-axial system

The third edition of *DSM*, or *DSM-III*, which was published in 1980, introduced a system of five axes or dimensions for assessing all aspects of a patient's mental and emotional health. The multi-axial system is designed to provide a more comprehensive picture of complex or concurrent mental disorders. According to the *DSM-IV-TR,* the system is also intended to "promote the application of the biopsychosocial model in clinical, educational and research settings." The reference to the *biopsychosocial model* is significant, because it indicates that the *DSM-IV-TR* does not reflect the view of any specific "school" or tradition within psychiatry regarding the cause or origin (also known as "etiology") of mental disorders. In other words, the *DSM-IV-TR* is atheoretical in its approach to diagnosis and classification— the axes and categories do not represent any overarching theory about the sources or fundamental nature of mental disorders.

The biopsychosocial approach was originally proposed by a **psychiatrist** named George Engel in 1977 as a way around the disputes between psychoanalytically and biologically oriented psychiatrists that were splitting the field in the 1970s. The introduction to *DSM-IV-TR* is quite explicit about the manual's intention to be "applicable in a wide variety of contexts" and "used by clinicians and researchers of many different orientations (e.g., biological, psychodynamic, cognitive, behavioral, interpersonal, family/systems)."

The atheoretical stance of *DSM-IV-TR* is also significant in that it underlies the manual's approach to the legal implications of mental illness. *DSM* notes the existence of an "imperfect fit between questions of ultimate concern to the law and the information contained in a clinical diagnosis." What is meant here is that the *DSM-IV-TR* diagnostic categories do not meet forensic standards for defining a "mental defect," "mental disability," or similar terms. Because *DSM-IV-TR* states that "inclusion of a disorder in the classification ... does not require that there be knowledge about its etiology," it advises legal professionals against basing decisions about a person's criminal responsibility, competence, or degree of behavioral control on *DSM* diagnostic categories.

The five diagnostic axes specified by *DSM-IV-TR* are:

- Axis I: Clinical disorders, including anxiety disorders, mood disorders, **schizophrenia** and other psychotic disorders.
- Axis II: **Personality disorders** and **mental retardation**. This axis includes notations about problematic aspects of the patient's personality that fall short of the criteria for a personality disorder.
- Axis III: General medical conditions. These include diseases or disorders that may be related physiologically to the mental disorder; that are sufficiently severe to affect the patient's mood or functioning; or that influence the choice of medications for treating the mental disorder.
- Axis IV: Psychosocial and environmental problems. These include conditions or situations that influence the diagnosis, treatment, or prognosis of the patient's mental disorder. *DSM-IV-TR* lists the following categories of problems: family problems; social environment problems; educational problems; occupational problems; housing problems; economic problems; problems with access to health care; problems with the legal system; and other problems (war, disasters, etc.).

KEY TERMS

Atheoretical—Unrelated to any specific theoretical approach or conceptual framework. The classification system of *DSM-IV-TR* is atheoretical.

Differential diagnosis—The process of distinguishing one disorder from other, similar disorders.

Empirical—Verified by actual experience or by scientific experimentation.

Etiology—The cause or origin of a disease or disorder. The word is also used to refer to the study of the causes of disease.

Forensic—Pertaining to courtroom procedure or evidence used in courts of law.

Holistic—An approach to health care that emphasizes the totality of an individual's well-being, spiritual and psychological as well as physical; and that situates a disease or disorder within that totality.

Implicit—Implied or suggested without being clearly stated. Some critics of *DSM-IV-TR* maintain that its contributors based the criteria sets for certain disorders on an implicit notion of a mentally healthy human being.

Medical model—The basic conceptual framework in the West since the nineteenth century for understanding, researching, and classifying mental disorders.

Nosology—The branch of medicine that deals with the systematic classification of diseases and disorders.

- Axis V: Global assessment of functioning. Rating the patient's general level of functioning is intended to help the doctor draw up a treatment plan and evaluate treatment progress. The primary scale for Axis V is the Global Assessment of Functioning (GAF) Scale, which measures level of functioning on a scale of 1–100. *DSM-IV-TR* includes three specialized global scales in its appendices: the Social and Occupational Functioning Assessment Scale (SOFAS); the Defensive Functioning Scale; and the Global Assessment of Relational Functioning (GARF) Scale. The GARF is a measurement of the maturity and stability of the relationships within a family or between a couple.

Diagnostic categories

The Axis I clinical disorders are divided among 15 categories: disorders usually first diagnosed in infancy, childhood, or adolescence; **delirium**, **dementia**, amnestic, and other cognitive disorders; medical disorders due to a general medical condition; substance-related disorders; schizophrenia and other psychotic disorders; mood disorders; anxiety disorders; somatoform disorders; factitious disorders; dissociative disorders; sexual and gender identity disorders; eating disorders; **sleep disorders**; impulse control disorders not elsewhere classified; and adjustment disorders.

The diagnostic categories of *DSM-IV-TR* are essentially symptom-based, or, as the manual puts it, based "on criteria sets with defining features." Another term that is sometimes used to describe this method of classification is *phenomenological*. A phenomenological approach to classification is one that emphasizes externally observable phenomena rather than their underlying nature or origin.

Another important characteristic of *DSM-IV-TR's* classification system is its dependence on the *medical model* of mental disorders. Such terms as "psychopathology," "mental illness," "differential diagnosis," and "prognosis" are all borrowed from medical practice. One should note, however, that the medical model is not the only possible conceptual framework for understanding mental disorders. Historians of Western science have observed that the medical model for psychiatric problems was preceded by what they term the supernatural model (mental disorders understood as acts of God or the result of demon possession), which dominated the field until the late seventeenth century. The supernatural model was followed by the moral model, which was based on the values of the Enlightenment and regarded mental disorders as bad behaviors deliberately chosen by perverse or ignorant individuals.

The medical model as it came to dominate psychiatry can be traced back to the work of Emil Kraepelin, an eminent German psychiatrist whose *Handbuch der Psychiatrie* was the first basic textbook in the field and introduced the first nosology, or systematic classification, of mental disorders. By the early 1890s Kraepelin's handbook was used in medical schools across Europe. He updated and revised it periodically to accommodate new findings, including a disease that he named after one of his clinical assistants, Alois Alzheimer. The classification in the 1907 edition of Kraepelin's handbook includes 15 categories, most of which are still used nearly a century later. Kraepelin is also important in the history of diagnostic classification because he represented a biologically based view of mental disorders in opposition to the psychoanalytical approach of Sigmund Freud. Kraepelin thought that mental disorders could ultimately be traced to organic diseases of the **brain** rather than disordered emotions or psychological processes. This controversy between the two perspectives dominated psychiatric research and practice until well after the Second World War.

Background of *DSM*

The American *Diagnostic and Statistical Manual of Mental Disorders* goes back to the 1840s, when the United States Bureau of the Census attempted for the first time to count the numbers of patients confined in mental hospitals. Isaac Ray, superintendent of the Butler Hospital in Rhode Island, presented a paper at the 1849 meeting of the Association of Medical Superintendents of American Institutions for the Insane (the forerunner of the present American Psychiatric Association) in which he called for a uniform system of naming, classifying and recording cases of mental illness. The same plea was made in 1913 by Dr. James May of New York to the same organization, which by then had renamed itself the American Medico-Psychological Association. In 1933, the New York Academy of Medicine and the Medico-Psychological Association compiled the first edition of the *Statistical Manual for Mental Diseases*, which was also adopted by the American Neurological Association. The *Statistical Manual* went through several editions between 1933 and 1952, when the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* appeared. The task of compiling mental hospital statistics was turned over to the newly formed National Institute of Mental Health in 1949.

DSM-I and DSM-II

DSM-I, which appeared in 1952, maintained the coding system of earlier American manuals. Many of the disorders in this edition were termed "reactions," a term borrowed from a German psychiatrist named Adolf Meyer. Meyer viewed mental disorders as reactions of an

individual's personality to a combination of psychological, social, and biological factors. *DSM-I* also incorporated the nomenclature for disorders developed by the United States Army and modified by the Veterans Administration to treat the postwar mental health problems of service personnel and veterans. The VA classification system grouped mental problems into three large categories: psychophysiological, personality, and acute disorders.

DSM-II, which was published in 1968, represented the first attempt to coordinate the American *Diagnostic and Statistical Manual of Mental Disorders* with the World Health Organization's (WHO) *International Classification of Diseases*, or *ICD*. *DSM-II* appeared before the ninth edition of the *ICD*, or *ICD-9,* which was published in 1975. *DSM-II* continued *DSM-I's* psychoanalytical approach to the etiology of the nonorganic mental disorders and personality disorders.

DSM-III, DSM-III-R and DSM-IV

DSM-III, which was published in 1980 after six years of preparatory work, represented a major break with the first two editions of *DSM. DSM-III* introduced the present descriptive symptom-based or phenomenological approach to mental disorders, added lists of explicit diagnostic criteria, removed references to the etiology of disorders, did away with the term "neurosis," and established the present multi-axial system of symptom evaluation. This sweeping change originated in an effort begun in the early 1970s by a group of psychiatrists at the medical school of Washington University in St. Louis to improve the state of research in American psychiatry. The St. Louis group began by drawing up a list of "research diagnostic criteria" for schizophrenia, a disorder that can manifest itself in a variety of ways. The group was concerned primarily with the identification of markers for schizophrenia that would allow the disease to be studied at other research sites without errors introduced by using different types of patients in different centers. What happened with *DSM-III, DSM-III-R,* and *DSM-IV,* however, was that a tool for scholarly investigation of a few mental disorders was transformed into a diagnostic method applied to all mental disorders without further distinction. The leaders of this transformation were biological psychiatrists who wanted to empty the diagnostic manual of terms and theories associated with hypothetical or explanatory concepts. The transition from an explanatory approach to mental disorders to a descriptive or phenomenological one in the period between *DSM-II* and *DSM-III* is sometimes called the "neo-Kraepelinian revolution" in the secondary literature. Another term that has been applied to the orientation represented in *DSM-III* and its successors is *empirical*, which denotes reliance on experience or experiment alone, without recourse to theories or hypotheses. The word occurs repeatedly in the description of "The DSM-IV Revision Process" in the Introduction to *DSM-IV-TR.*

DSM-IV built upon the research generated by the empirical orientation of *DSM-III.* By the early 1990s, most psychiatric diagnoses had an accumulated body of published studies or data sets. Publications up through 1992 were reviewed for *DSM-IV,* which was published in 1994. Conflicting reports or lack of evidence were handled by data reanalyses and field trials. The National Institute of Mental Health sponsored 12 *DSM-IV* field trials together with the National Institute on Drug Abuse (NIDA) and the National Institute on Alcohol Abuse and Alcoholism (NIAAA). The field trials compared the diagnostic criteria sets of *DSM-III, DSM-III-R, ICD-10* (which had been published in 1992), and the proposed criteria sets for *DSM-IV.* The field trials recruited subjects from a variety of ethnic and cultural backgrounds, in keeping with a new concern for cross-cultural applicability of diagnostic standards. In addition to its inclusion of culture-specific syndromes and disorders, *DSM-IV* represented much closer cooperation and coordination with the experts from WHO who had worked on *ICD-10.* A modification of *ICD-10* for clinical practitioners, the *ICD-10-CM,* is scheduled to be introduced in the United States in 2004.

Textual revisions in DSM-IV-TR

DSM-IV-TR does not represent either a fundamental change in the basic classification structure of *DSM-IV* or the addition of new diagnostic entities. The textual revisions that were made to the 1994 edition of *DSM-IV* fall under the following categories:

- correction of factual errors in the text of *DSM-IV*
- review of currency of information in *DSM-IV*
- changes reflecting research published after 1992, which was the last year included in the literature review prior to the publication of *DSM-IV*
- improvements to enhance the educational value of *DSM-IV*
- updating of *ICD* diagnostic codes, some of which were changed in 1996

Critiques of *DSM-IV* and *DSM-IV-TR*

A number of criticisms of *DSM-IV* have arisen since its publication in 1994. They include the following observations and complaints:

- The medical model underlying the empirical orientation of *DSM-IV* reduces human beings to one-dimen-

sional sources of data; it does not encourage practitioners to treat the whole person.

- The medical model perpetuates the social **stigma** attached to mental disorders.
- The symptom-based criteria sets of *DSM-IV* have led to an endless multiplication of mental conditions and disorders. The unwieldy size of *DSM-IV* is a common complaint of doctors in clinical practice— a volume that was only 119 pages long in its second (1968) edition has swelled to 886 pages in less than thirty years.
- The symptom-based approach has also made it easier to politicize the process of defining new disorders for inclusion in *DSM* or dropping older ones. The inclusion of **post-traumatic stress disorder** (PTSD) and the deletion of homosexuality as a disorder are often cited as examples of this concern for political correctness.
- The criteria sets of *DSM-IV* incorporate implicit (implied but not expressly stated) notions of human psychological well-being that do not allow for ordinary diversity among people. Some of the diagnostic categories of *DSM-IV* come close to defining various temperamental and personality differences as mental disorders.
- The *DSM-IV* criteria do not distinguish adequately between poor adaptation to ordinary problems of living and true psychopathology. One byproduct of this inadequacy is the suspiciously high rates of prevalence reported for some mental disorders. One observer remarked that "... it is doubtful that 28% or 29% of the population would be judged [by **managed care** plans] to need mental health treatment in a year."
- The 16 major diagnostic classes defined by *DSM-IV* hinder efforts to recognize disorders that run across classes. For example, PTSD has more in common with respect to etiology and treatment with the dissociative disorders than it does with the anxiety disorders with which it is presently grouped. Another example is **body dysmorphic disorder**, which resembles the obsessive-compulsive disorders more than it does the somatoform disorders.
- The current classification is deficient in acknowledging disorders of uncontrolled anger, hostility, and aggression. Even though inappropriate expressions of anger and aggression lie at the roots of major social problems, only one *DSM-IV* disorder (**intermittent explosive disorder**) is explicitly concerned with them. In contrast, entire classes of disorders are devoted to depression and anxiety.
- The emphasis of *DSM-IV* on biological psychiatry has contributed to the widespread popular notion that most problems of human life can be solved by taking pills.

Alternative nosologies

A number of different nosologies or schemes of classification have been proposed to replace the current descriptive model of mental disorders. Three of them will be briefly described.

The dimensional model

Dimensional alternatives to *DSM-IV* would replace the categorical classification now in use with a recognition that mental disorders lie on a continuum with mildly disturbed and normal behavior, rather than being qualitatively distinct. For example, the personality disorders of Axis II are increasingly regarded as extreme variants of common personality characteristics. In the dimensional model, a patient would be identified in terms of his or her position on a specific dimension of cognitive or affective capacity rather than placed in a categorical "box."

The holistic model

The holistic approach to mental disorders places equal emphasis on social and spiritual as well as pharmacological treatments. A biochemist who was diagnosed with schizophrenia and eventually recovered compared the reductionism of the biological model of his disorder with the empowering qualities of holistic approaches. He stressed the healing potential in treating patients as whole persons rather than as isolated collections of nervous tissue with chemical imbalances: "The major task in recovering from mental illness is to regain social roles and identities. This entails focusing on the individual and building a sense of responsibility and self-determination."

The essential or perspectival model

The third and most complex alternative model is associated with the medical school of Johns Hopkins University, where it is taught as part of the medical curriculum. This model identifies four broad "essences" or perspectives that can be used to identify the distinctive characteristics of mental disorders, which are often obscured by the present categorical classifications.

The four perspectives are:

- Disease. This perspective works with categories and accounts for physical diseases or damage to the brain that produces psychiatric symptoms. It accounts for such disorders as **Alzheimer's disease** or schizophrenia.
- Dimensions. This perspective addresses disorders that arise from the combination of a cognitive or emotional weakness in the patient's constitution and a life experience that challenges their vulnerability.

- Behaviors. This perspective is concerned with disorders associated with something that the patient is doing (alcoholism, drug **addiction**, eating disorders, etc.) that has become a dysfunctional way of life.
- Life story. This perspective focuses on disorders related to what the patient has encountered in life, such as events that have injured his or her hopes and aspirations.

In the Johns Hopkins model, each perspective has its own approach to treatment: the disease perspective seeks to cure or prevent disorders rooted in biological disease processes; the dimensional perspective attempts to strengthen constitutional weaknesses; the behavioral perspective seeks to interrupt the problematic behaviors and assist patients in overcoming their appeal; and the life story perspective offers help in "rescripting" a person's life narrative, usually through cognitive behavioral treatment.

Diazepam

Definition

Diazepam is a mild tranquilizer in the class of drugs known as benzodiazepines. It is most commonly sold in the United States under the brand name Valium. The generic form of this drug is also available.

Purpose

Diazepam is used on a short-term basis to treat patients with mild to moderate anxiety. It is also used to treat some types of **seizures** (epilepsy), muscle spasms, nervous tension, and symptoms relating to alcohol withdrawal.

Description

Diazepam is one of many chemically-related tranquilizers in the class of drugs called benzodiazepines. Benzodiazepines are sedative-hypnotic drugs that help to relieve nervousness, tension, and other anxiety symptoms by slowing the central nervous system. To do this, they block the effects of a specific chemical involved in the transmission of nerve impulses in the **brain**, decreasing the excitement level of the nerve cells. All benzodiazepines, including diazepam, cause sedation, drowsiness, and reduced mental and physical alertness.

Recommended dosage

The typical dose of diazepam used to treat anxiety or seizures in healthy adults ranges from a total of 6 milligrams (mg) to 40 mg per day given in three or four doses. Elderly people (over age 60) are usually given lower doses in the range of 4–10 mg per day to treat anx-

KEY TERMS

Albumin—A simple protein that is widely distributed in human blood.

Anxiety—A feeling of apprehension and fear characterized by physical symptoms (heart palpitations, sweating, and feelings of stress, for example).

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Tranquilizer—A medication that induces a feeling of calm and relaxation.

iety or nervous tension. For acute treatment of seizures, a higher dose of diazepam is given intravenously (directly into the vein) only in a controlled medical setting such as a hospital or emergency room. For alcohol withdrawal, the typical dose is a total of 30–40 mg per day given in three or four doses.

The typical dose for a child over age six months with anxiety or seizures is a total of 3–10 mg per divided into several doses. In general, children receive lower doses of diazepam even when they have a body weight equivalent to a small adult. Diazepam is usually taken as a pill, but an injectable form is sometimes used when a serious seizure is in progress or when muscle spasms are severe. There is also a liquid oral form of the drug available.

Precautions

The elderly, children, and those with significant health problems need to be carefully evaluated before receiving diazepam. Children under the age of six months should not take diazepam. In addition, people with a history of liver disease, kidney disease, or those with low levels of a protein in the blood called albumin need to be carefully assessed before starting this drug.

People taking diazepam should not drive, operate dangerous machinery, or engage in hazardous activities that require mental alertness, because diazepam can cause drowsiness. Alcohol and any drugs that treat mental illness should not be used when taking this medication. People who have previously had an allergic reaction to any dosage level of diazepam or any other benzodiazepine drug should not take diazepam. People with acute narrow-angle glaucoma should not take diazepam.

The prescribing physician should be consulted regularly if diazepam is taken consistently for more than two weeks. Diazepam and other drugs in this class can be habit-forming. Diazepam can become a drug of abuse and should be used with caution in patients with history of substance abuse. People taking diazepam should not stop taking the drug abruptly. This can lead to withdrawal effects such as shaking, stomach cramps, nervousness, and irritability.

Side effects

Anxiety, irregular heartbeat, forgetfulness, mental depression, and confusion are side effects that could require prompt medical attention. However, these side effects are not common when taking diazepam. Even less common, but serious events, are behavior changes, low blood pressure, muscle weakness, and the yellowing of the eyes or skin (jaundice). More common, but less serious side effects, include drowsiness, clumsiness, slurred speech, and dizziness. Rare among these less serious side effects are stomach cramps, headache, muscle spasm, nausea, vomiting, and dry mouth.

Once a person stops taking diazepam, the following side effects could occur from withdrawal: sleeping difficulties, nervousness, and irritability. Less common side effects from withdrawal include confusion, abdominal cramps, mental depression, sensitivity to light, nausea, shaking, and increased sweating. Rarely seen side effects include seizures, **hallucinations**, and feelings of distrust in the patient.

Interactions

Diazepam interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all their health care providers, including dentists, that they are taking diazepam. Diazepam can add to the depressive effects of other central nervous system depressant drugs (for example, alcohol, other tranquilizers, or sleeping pills) when taken together. In severe cases, this can result in death.

Several drugs reduce the ability of diazepam to be broken down and cleared from the body. This results in higher levels of the drug in the blood and increases the probability that side effects will occur. These drugs include several antibiotics, such as erythromycin, anti-

stomach acid drugs, such as cimetidine (Tagamet), and antifungal drugs, such as fluconazole. Alcohol should not be used when taking diazepam and other benzodiazepine drugs. Other drugs that are used to treat mental disorders should not be combined with diazepam unless the patient is under the careful supervision and monitoring of a doctor.

Diets

Definition

Special diets are designed to help individuals make changes in their usual eating habits or food selection. Some special diets involve changes in the overall diet, such as diets for people needing to gain or lose weight or eat more healthfully. Other special diets are designed to help a person limit or avoid certain foods or dietary components that could interfere with the activity of a medication. Still other special diets are designed to counter nutritional effects of certain medications.

Purpose

Special diets are used in the treatment of persons with certain mental disorders to:

- identify and correct disordered eating patterns
- prevent or correct nutritional deficiencies or excesses
- prevent interactions between foods or nutrients and medications

Special types of diets or changes in eating habits have been suggested for persons with certain mental disorders. In some disorders, such as eating disorders or substance abuse, dietary changes are an integral part of therapy. In other disorders, such as **attention-deficit/hyperactivity disorder**, various proposed diets have questionable therapeutic value.

Many medications for mental disorders can affect a person's appetite or nutrition-related functions such as saliva production, ability to swallow, bowel function, and activity level. Changes in diet or food choices may be required to help prevent negative effects of medications.

Finally, interactions can occur between some medications used to treat persons with mental disorders and certain foods or nutritional components of the diet. For example, grapefruit and apple juice can interact with some specific psychotropic drugs (medications taken for psychiatric conditions) and should be avoided by individuals taking those medicines. Tyramine, a natural substance found in aged or fermented foods, can interfere with the functioning of monoamine oxidase inhibitors and must be restricted in individuals using these types of medications. A person's pre-existing medical condition and nutritional needs should be taken into account when designing any special diet.

Special diets for specific disorders

Eating disorders

The two main types of eating disorders are **anorexia nervosa** and **bulimia nervosa**. Individuals with anorexia nervosa starve themselves, while individuals with bulimia nervosa usually have a normal or slightly above normal body weight but engage in **binge eating** followed by purging with laxatives, vomiting, or exercise.

Special diets for individuals with eating disorders focus on restoration of a normal body weight and control of bingeing and purging. These diets are usually carried out under the supervision of a multidisciplinary team, including a physician, **psychologist**, and dietitian.

The overall dietary goal for individuals with anorexia nervosa is to restore a healthy body weight. An initial goal might be to stop weight loss and improve food choices. Energy intake is then increased gradually until normal weight is restored. Because individuals with anorexia nervosa have an intense fear of gaining weight and becoming fat, quantities of foods eaten are increased very slowly so that the patient will continue treatments and therapy.

The overall dietary goal for individuals with bulimia nervosa is to gain control over eating behavior and to achieve a healthy body weight. An initial goal is to stabilize weight and eating patterns to help the individual gain control over the binge-purge cycle. Meals and snacks are eaten at regular intervals to lessen the possibility that

KEY TERMS

Anorexia—Loss of appetite or unwillingness to eat. Can be caused by medications, depression, or many other factors.

Anorexia nervosa—An eating disorder characterized by an intense fear of weight gain accompanied by a distorted perception of one's own underweight body.

Binge—An excessive amount of food consumed in a short period of time. Usually, while a person binge eats, he or she feels disconnected from reality, and feels unable to stop. The bingeing may temporarily relieve depression or anxiety, but after the binge, the person usually feels guilty and depressed.

Bulimia nervosa—An eating disorder characterized by binges in which large amounts of food are consumed, followed by forced vomiting.

Psychotropic drug—Medication that has an effect on the mind, brain, behavior, perceptions, or emotions. Psychotropic medications are used to treat mental illnesses because they affect a patient's moods and perceptions.

Purge—When a person rids him- or herself of extra food consumed. Purging may be accomplished by induced vomiting, laxative abuse, or excessive exercise.

Relapse—A person experiences a relapse when he or she re-engages in a behavior that is harmful and that he or she was trying to change or eliminate. Relapse is a common occurrence after treatment for many disorders, including addictions and eating disorders.

Thiamin—A B-vitamin that is essential to normal metabolism and nerve function, and whose absorption is affected by alcoholism.

Tyramine—Intermediate product between the chemicals tyrosine and epinephrine in the body and a substance normally found in many foods. Found especially in protein-rich foods that have been aged or fermented, pickled, or bacterially contaminated, such as cheese, beer, yeast, wine, and chicken liver.

hunger and fasting will trigger a binge. Once eating behaviors have been stabilized, energy intake can be gradually adjusted to allow the individual to reach a normal body weight healthfully.

For individuals with either anorexia nervosa and bulimia, continued follow-up and support are required even after normal weight and eating behaviors are restored, particularly since the rate of relapse is quite high. (Relapse occurs when a patient returns to the old behaviors that he or she was trying to change or eliminate.) In addition to dietary changes, **psychotherapy** is an essential part of the treatment of eating disorders and helps the individual deal with fears and misconceptions about body weight and eating behavior.

Attention-deficit/hyperactivity disorder

Attention-deficit/hyperactivity disorder (ADHD) accounts for a substantial portion of referrals to child mental health services. Children with ADHD are inappropriately active, easily frustrated or distracted, impulsive, and have difficulty sustaining concentration. Usual treatment of ADHD involves medication, behavioral management, and education.

Many dietary factors have been proposed as causes of ADHD, including sugar, food additives, and food allergies. In the 1970s the Feingold diet became popular for treatment of ADHD. The Feingold diet excludes artificial colorings and flavorings, natural sources of chemicals called salicylates (found in fruits), and preservatives called BHT and BHA. Although scientific evidence does not support the effectiveness of the Feingold diet, a modified Feingold diet including fruits has been shown to be nutritionally balanced and should not be harmful as long as the child continues to receive conventional ADHD treatment also.

A high intake of sugar and sugary foods has also been implicated as a cause of ADHD. Although carefully controlled studies have shown no association between sugar and ADHD, diets high in sugar should be discouraged because they are often low in other nutrients and can contribute to dental problems.

Food allergies have also been implicated as a cause of ADHD, and some groups have suggested using elimination diets to treat ADHD. Elimination diets omit foods that most commonly cause allergies in children, such as eggs, milk, peanuts, or shellfish. Although research does not support the value of elimination diets for all children with ADHD, children with specific food allergies can become irritable and restless. A child with a suspected food allergy should be evaluated by an allergist.

Stimulant medications used to treat ADHD, such as **methylphenidate** (Ritalin), can cause appetite loss (anorexia) and retard growth, although recent research suggests that a child's ultimate height appears not to be affected by stimulant medications. As a precaution, children on such medicines should receive close monitoring

of growth patterns, and parents should carefully observe their child's appetite and interest in meals and snacks. Providing regular meals and snacks, even when the child is not hungry, can help to assure adequate growth.

Mood disorders

Mood disorders include both depression (unipolar disorder) and episodes of mania followed by depression (**bipolar disorder**). Both types of disorders can affect appetite and eating behavior.

Although some depressed individuals eat more than usual and gain weight, depression more often causes loss of appetite and weight loss. As depressed individuals lose interest in eating and social relationships, they often skip meals and ignore feelings of hunger. Unintentional weight losses of up to 15% of body mass can occur.

Treatment with antidepressant medications often reverses weight loss and restores appetite and interest in eating. If the individual has lost a significant amount of weight, he or she may need to follow a high-calorie diet to restore weight to normal levels and replaced nutritional deficiencies. High-calorie diets usually include three balanced meals from all the food groups and several smaller snacks throughout the day. A protein/calorie supplement may also be necessary for some individuals.

Depression is sometimes treated with medications called monoamine oxidase inhibitors. Individuals on these medications will need to follow a tyramine-restricted diet (see below under monoamine oxidase inhibitors).

Individuals with mania are often treated with lithium. Sodium and caffeine intake can affect lithium levels in the blood, and intake of these should not suddenly be increased or decreased. Weight gain can occur in response to some antidepressant medications and lithium.

Schizophrenia

Individuals with **schizophrenia** can have **hallucinations**, delusional thinking, and bizarre behavior. These distorted behaviors and thought processes can also be extended to **delusions** and hallucinations about food and diet, making people with schizophrenia at risk for poor nutrition.

Individuals with schizophrenia may believe that certain foods are poisonous or have special properties. They may think they hear voices telling them not to eat. Some may eat huge quantities of food thinking that it gives them special powers. Individuals with untreated schizophrenia may lose a significant amount of weight. Delusional beliefs and thinking about food and eating usually improve once the individual is started on medication to treat schizophrenia.

Substance abuse

Substance abuse can include abuse of alcohol, cigarettes, marijuana, cocaine, or other drugs. Individuals abusing any of these substances are at risk for nutritional problems. Many of these substances can reduce appetite, decrease absorption of nutrients into the body, and cause the individual to make poor food choices.

Special diets used for withdrawal from substance abuse are designed to correct any nutritional deficiencies that have developed, aid in the withdrawal of the substance, and prevent the individual from making unhealthful food substitutions as the addictive substance is withdrawn. For example, some individuals may compulsively overeat when they stop smoking, leading to weight gain. Others may substitute caffeine-containing beverages such as soda or coffee for an addictive drug. Such harmful substitutions should be discouraged, emphasizing well-balanced eating combined with adequate rest, **stress** management, and regular exercise. Small, frequent meals and snacks that are rich in vitamins and minerals from healthful foods should be provided. Fluid intake should be generous, but caffeine-containing beverages should be limited.

Individuals withdrawing from alcohol may need extra thiamin supplementation, either intravenously or through a multivitamin supplement because alcohol metabolism in the body requires extra thiamin. Individuals taking drugs to help them avoid alcohol will need to avoid foods with even small amounts of alcohol (see below).

Common withdrawal symptoms and dietary suggestions for coping with these symptoms include:

- Appetite loss: eat small, frequent meals and snacks; limit caffeine; use nutritional supplements if necessary.
- Appetite increase: eat regular meals; eat a variety of foods; limit sweets and caffeine.
- Diarrhea: eat moderate amounts of fresh fruits, vegetables, concentrated sugars, juices, and milk; increase intake of cereal fiber.
- Constipation: drink plenty of fluids; increase fiber in the diet; increase physical activity.
- Fatigue: eat regular meals; limit sweets and caffeine; drink plenty of fluid.

Dietary considerations and medications

Medications that affect body weight

Many medications used to treat mental disorders promote weight gain, including:

- anticonvulsants (divalproex)
- certain types of antidepressants (**amitriptyline**)

- antipsychotic medications (**clozapine**, **olanzapine**, **quetiapine**, and risperidone)

Dietary treatments for individuals taking these medications should focus on a balanced, low-fat diet coupled with an increase in physical activity to counter the side effects of these medications. Nutrient-rich foods such as fruits, vegetables, and whole grain products should be emphasized in the diet, whereas sweets, fats, and other foods high in energy but low in nutrients should be limited. Regular physical activity can help limit weight gain caused by these medications.

Some medications can cause loss of appetite, restlessness, and weight loss. Individuals on such medications should eat three balanced meals and several smaller snacks of protein and calorie-rich foods throughout the day. Eating on a regular schedule rather than depending on appetite can help prevent weight loss associated with loss of appetite.

Medications that affect gastrointestinal function

Many psychiatric medications can affect gastrointestinal functioning. Some drugs can cause dry mouth, difficulty swallowing, constipation, altered taste, heartburn, diarrhea, or nausea. Consuming frequent smaller meals, drinking adequate fluids, modifying texture of foods if necessary, and increasing fiber content of foods can help counter gastrointestinal effects of medications.

Monoamine oxidase inhibitors

Individuals being treated with monoamine oxidase inhibitors (MAOIs) such as **tranylcypromine**, **phenelzine**, and isocarboxazid, must carefully follow a tyramine-restricted diet. Tyramine, a nitrogen-containing substance normally present in certain foods, is usually broken down in the body by oxidases. However, in individuals taking MAOIs, tyramine is not adequately broken down and builds up in the blood, causing the blood vessels to constrict and increasing blood pressure.

Tyramine is normally found in many foods, especially protein-rich foods that have been aged or fermented, pickled, or bacterially contaminated. Cheese is especially high in tyramine. A tyramine intake of less than 5 milligrams daily is recommended. A diet that includes even just 6 milligrams of tyramine can increase blood pressure; a diet that provides 25 milligrams of tyramine can cause life-threatening increases in blood pressure.

TYRAMINE-RESTRICTED DIET. Tyramine is found in aged, fermented and spoiled food products. The tyramine content of a specific food can vary greatly depending on storage conditions, ripeness, or contamination. Reaction to tyramine-containing foods in individuals taking MAOIs can also vary greatly depending on what other foods are eaten with the tyramine-containing food, the length of time between MAOI dose and eating the food, and individual characteristics such as weight, age, etc.

Foods to avoid on a tyramine-controlled diet include:

- all aged and mature cheeses or cheese spreads, including foods made with these cheeses, such as salad dressings, casseroles, or certain breads
- any outdated or nonpasteurized dairy products
- dry fermented sausages such as summer sausage, pepperoni, salami, or pastrami
- smoked or pickled fish
- non-fresh meat or poultry
- leftover foods containing meat or poultry
- tofu and soy products
- overripe, spoiled, or fermented fruits or vegetables
- sauerkraut
- fava or broad beans
- soups containing meat extracts or cheese
- gravies containing meat extracts or nonfresh meats
- tap beer
- nonalcoholic beer
- yeast extracts
- soy sauce
- liquid powdered protein supplements

Perishable refrigerated items such as milk, meat, or fruit should be eaten within 48 hours of purchase. Any spoiled food and food stored in questionable conditions should not be eaten.

Lithium

Lithium is often used to treat individuals with mania. Lithium can cause nausea, vomiting, anorexia, diarrhea, and weight gain. Almost one-half of individuals taking lithium gain weight.

Individuals taking lithium should maintain a fairly constant intake of sodium (found in table salt and other food additives) and caffeine in their diet. If an individual restricts sodium intake, less lithium is excreted in the urine and blood lithium levels rise. If an individual increases caffeine intake, more lithium is excreted in the urine and blood levels of lithium fall.

Anticonvulsant medications

Sodium caseinate and calcium caseinate can interfere with the action and effectiveness of some anticon-

vulsants. Individuals taking these anticonvulsants should read labels carefully to avoid foods containing these additives.

Psychotropic medications

Some psychotropic medications, such as amitriptyline, can decrease absorption of the vitamin riboflavin from food. Good food sources of riboflavin include milk and milk products, liver, red meat, poultry, fish, and whole grain, and enriched breads and cereals. Riboflavin supplements may also be needed.

Other psychotropic drugs, such as **fluvoxamine**, **sertraline**, fesasodone, **alprazolam**, **triazolam**, midazolam, **carbamazepine**, and **clonazepam**, interact with grapefruit juice, so individuals taking these drugs must take care to avoid grapefruit juice. In some cases, apple juice must be avoided, as well. Patients should discuss potential drug interactions with their doctor or pharmacist.

Caffeine-restricted diet

Caffeine is a stimulant and can interfere with the actions of certain medications. As stated, people taking lithium and people recovering from addictions may be asked by their treatment team to monitor (and, in the case of addictions, restrict) their caffeine intake. Foods and beverages high in caffeine include:

- chocolate
- cocoa mix and powder
- chocolate ice cream, milk, and pudding
- coffee
- cola beverages
- tea

Alcohol-restricted diet

Alcohol interacts with some medications used to treat mental disorders. In the case of alcoholism recovery, the negative interaction resulting from the combination of one medication (**disulfiram** or Antabuse) and alcohol consumption is actually part of treatment for some people. (The medication causes an extremely unpleasant reaction to any alcohol consumed, reinforcing or rewarding the avoidance of alcohol.)

When individuals are taking medication that requires that they avoid alcohol, foods containing alcohol must be avoided as well as beverage alcohol. The following foods contain small amounts of alcohol:

- flavor extracts, such as vanilla, almond, or rum flavorings
- cooking wines
- candies or cakes prepared or filled with liqueur
- apple cider
- cider and wine vinegar
- commercial eggnog
- bernaise or bordelaise sauces
- desserts such as crepes suzette or cherries jubilee
- teriyaki sauce
- fondues

Diphenhydramine

Definition

Diphenhydramine is an antihistamine used in psychiatric medicine to treat phenothiazine drug-induced abnormal muscle movement. It is also used in general medicine to treat allergies, allergic reactions, motion

KEY TERMS

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Antihistamine—A medication used to alleviate allergy or cold symptoms such as runny nose, itching, hives, watering eyes, or sneezing.

Extrapyramidal movement disorders—Involuntary movements that occur as a side effect of some psychiatric medications.

Histamine—Substance released during allergic reactions.

Hypokinesia—A condition of abnormally diminished motor activity.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Parkinsonism—A condition caused by the destruction of the brain cells that produce dopamine (a neurotransmitter), and characterized by tremors of the fingers and hands, a shuffling gait, and muscular rigidity.

Phenothiazine—A class of drugs widely used in the treatment of psychosis.

sickness, **insomnia**, cough, and nausea. When diphenhydramine is used for allergy-related symptoms, it is sold in the United States as an over-the-counter medication Benadryl. For use in the treatment of the tremors caused by phenothiazines, diphenhydramine is prescribed in the generic form.

Purpose

Some drugs called phenothiazines are used to treat psychotic disorder such as **schizophrenia**. As a side effect, these drugs may cause tremors and abnormal involuntary movements of the muscles, referred to as extrapyramidal neurologic **movement disorders**. Diphenhydramine is used to control these symptoms. Other uses of the drug include the treatment of nausea, vomiting, and itching. Diphenhydramine is used to help limit allergic reactions to transfused blood products. It can induce sleep. It is sometimes used to treat the stiffness and tremor of Parkinson's disease. In liquid form, it may relieve minor throat irritation.

Description

Diphenhydramine is an antihistamine that is readily distributed throughout the body. It is easily absorbed when taken by mouth. Maximal action occurs approximately one hour after swallowing the drug. The effects continue for four to six hours. Diphenhydramine acts on cells in the **brain**. It seems to compete with the chemical histamine for specific receptor sites on cells in the brain and central nervous system. This means that it achieves its theraputic effect by taking the place of the neurotransmitter histamine on these cells. Diphenhydramine is a useful medication for individuals with mild Parkinsonism when it is used in combination with centrally acting anticholinergic drugs.

Recommended dosage

The dosage of diphenhydramine must be adjusted according to the needs of individuals and their responses. Adults are generally given 25–50 mg orally, three to four times daily. Diphenhydramine may be administered through a vein or injected deep within a muscle. The usual dosage is 10–50 mg per injection, although some people may require 100 mg. The total daily dosage should not exceed 400 mg. People who forget to take a dose of this drug should skip the dose and take the next one at the regularly scheduled time. They should not double up subsequent doses if one is missed.

People should not take diphenhydramine if they are taking other preparations that contain antihistamines unless specifically directed to do so by a physician.

Precautions

People with peptic ulcer disease, bowel obstructions, an enlarged prostate, angle closure glaucoma, or difficulty urinating due to a blockage in the bladder should not use diphenhydramine without close physician supervision and monitoring. People with asthma, heart disease, high blood pressure, or an overactive thyroid should use this drug with caution. Before taking diphenhydramine, people with these conditions should discuss the risks and benefits of this drug with their doctor. Individuals should not take diphenhydramine for several days before an allergy test, as it will interfere with accurate results.

Elderly people are more sensitive to the sedating effects of diphenhydramine. The drug may also cause dizziness and lower blood pressure. Older people should slowly

change position from sitting or lying to standing while taking this medication to prevent dizziness and fainting.

Side effects

Drowsiness commonly occurs after taking diphenhydramine. This effect may be more pronounced if alcohol or any other central nervous system depressant, such as a tranquilizer or a particular medication for pain, is also taken. People taking the drug should not drive, or operate machinery, or perform hazardous tasks requiring mental alertness until the effects of the medication have worn off. In some people, diphenhydramine also may cause dizziness, difficulties with coordination, confusion, restlessness, nervousness, difficulty sleeping, blurry or double vision, ringing in the ears, headache, or convulsions.

Stomach distress is a relatively common side effect of diphenhydramine. Some people may develop poor appetites, nausea, vomiting, diarrhea, or constipation. Individuals also may experience low blood pressure, palpitations, rapid or irregular heartbeats, frequent urination, or difficulty urinating. Urine may be retained in the bladder. Other side effects of diphenhydramine are associated with persons in age groups that are unlikely to use the drug.

Diphenhydramine may also cause hives, a rash, sensitivity to the sun, and a dry mouth and nose. Thickened lung secretions are common among older persons.

Interactions

Alcohol, pain medications, sleeping pills, tranquilizers, and antidepressants may make the drowsiness associated with diphenhydramine more severe. Diphenhydramine should not be used by persons taking hay fever medicines, sedatives, narcotics, anesthetics, **barbiturates** or muscle relaxants.

Disease concept of chemical dependency

Definition

Disease concept of chemical dependency is the concept that a disorder (such as chemical dependency) is like

a disease and has a characteristic set of signs, symptoms, and natural history (clinical course, or outcome).

Description

The disease concept has long been accepted by the medical community. The concept proposes that a disease is characterized by a specific set of signs and symptoms and that the disease, if left untreated, will progress to some endpoint or outcome (clinical course). However, controversy arises when the medical community is faced with new abnormal conditions, owing mostly to the new technologies in genetic engineering. This controversy becomes especially apparent when examining psychological disorders.

In the past, psychological disorders were thought in general to be due to both psychological and social abnormalities. Although these psychosocial problems are still of utmost importance, researchers have since discovered that many psychological disorders, such as alcoholism, also have genetic causes. Recent studies have identified a genetic area (locus) where a gene is located that can transmit alcoholism from affected father to son. Mental health professionals also know from clinical experience that alcoholics demonstrate a characteristic set of specific signs and symptoms. Additionally, it is well established that the ultimate clinical course for untreated alcoholism is death. Therefore alcoholism, once thought to be a disorder of those with a weak will, or "party people" can now be characterized as a disease.

Can it be inferred that other chemical dependencies may also have biological causes? There is compelling evidence that this theory may be correct. It is interesting to note that all psychoactive mood-altering drugs (alcohol, cocaine, marijuana, heroin, etc.) act in specific sites in the **brain** and on a specific neurotransmitter (a chemical that delivers impulses from one nerve cell to another) called dopamine. These mood-altering substances cause dopamine depletion, inducing an abnormality in nerve cells that "hijacks" the cells into chemical dependence. In other words, the substance introduced in the body affects the dopamine in a way that makes the affected individual unable to experience everyday pleasures—the individual instead needs that substance to experience pleasure. Thus the individual's driving force is any drug that can provide some kind of transient happiness (euphoria). In fact, the gene for alcoholism is located in the dopamine molecule. This can further suggest that chemical dependencies may have a medical (biological) cause.

The disease concept of chemical dependency is gaining worldwide acceptance, but does have some critics who argue instead that **addiction** must be understood as a general pattern of behavior, not as a medical problem. Advocates of the disease concept of chemical dependency model maintain that the identification of biological causes or correlations is crucially important for treatment. They argue that if clinicians can understand the intricate details concerning the mechanisms associated with drug effects, then measures to interrupt the effects can be devised. These interventions can be both medical (developing new drugs to chemical block effects of illicit drugs) and psychological.

According to the disease concept model, psychological **intervention** includes a vital educational component that teaches people with chemical dependency the concept of understanding addiction as disease. As a result of this understanding, affected people then view their dependency as a disease, similar to other diseases with a biological cause (heart disease, cancer, high blood pressure), and with a specific set of signs and symptoms and an outcome in the future (clinical course). Proponents of this approach believe that this understanding can help affected people to follow treatment recommendations, and can reduce shame and guilt commonly associated with chemical dependence. Alcoholics Anonymous is a prominent example of an organization that embodies the disease concept of chemical dependency.

Disorder of written expression

Definition

Disorder of written expression, formerly called developmental expressive writing disorder, is a learning disability in which a person's ability to communicate in writing is substantially below the level normally expected based on the individual's age, intelligence, life experiences, educational background, or physical impairments. This disability affects both the physical reproduction of letters and words and the organization of thoughts and ideas in written compositions.

Description

Disorder of written expression is one of the more poorly understood learning disabilities. Learning disabilities that manifest themselves only in written work were first described in the late 1960s. These early studies described three main types of written disorders:

- inability to form letters and numbers correctly, also called dysgraphia
- inability to write words spontaneously or from dictation
- inability to organize words into meaningful thoughts

There are several difficulties in studying disorder of written expression and in implementing a remedial program. Disorder of written expression usually appears in conjunction with other reading or language disabilities, making it hard to separate manifestations of the disability related only to written expression. Delays in attention, visual-motor integration, visual processing, and expressive language may also contribute to writing disorders. Also, there are no standard tests specifically designed to evaluate disorder of written expression.

Causes and symptoms

Causes

The causes of disorder of written expression are unknown. Different manifestations of the disorder may have different causes. For example, people who cannot form letters correctly on the page (dysgraphia) may have delays in hand-eye coordination and difficulties concentrating. People who are unable to write words from memory or dictation appear to have deficits in their visual memory. They cannot remember what the words look like. People who produce legible script but cannot organize their thoughts on paper may be suffering from cognitive processing problems. Because disorder of written expression is a little-studied disorder, specific causes have not yet been determined.

Symptoms

Symptoms that suggest disorder of written expression include:

- poor or illegible handwriting
- poorly formed letters or numbers
- excessive spelling errors
- excessive punctuation errors
- excessive grammar errors
- sentences that lack logical cohesion
- paragraphs and stories that are missing elements and that do not make sense or lack logical transitions
- deficient writing skills that significantly impact academic achievement or daily life.

These symptoms must be evaluated in light of the person's age, intelligence, educational experience, and cultural or life experience. Written expression must be substantially below the level of samples produced by others of the same age, intelligence, and background. Normally, several of the symptoms are present simultaneously.

Demographics

Several studies have estimated that between 3% and 5% of students have disorder of written expression. However, it is difficult to separate this disorder from other **learning disorders**. Deficits in written work may be attributed to a reading, language, or attention disorders, limited educational background, or lack of fluency in the language of instruction. Disorder of written expression unassociated with any other learning disability is rare.

Diagnosis

There are no specific tests to diagnose disorder of written expression. This disorder is not normally diagnosed before age eight because of the variability with which children acquire writing skills. It is most commonly diagnosed in the fourth or fifth grade. Requests for testing usually originate with a teacher or parent who notes multiple symptoms of the disorder in a child's writing.

Several standardized tests accurately reflect spelling abilities, but do not assess other writing skills with the same reliability. Tests that might be helpful in diagnosing disorder of written expression include the Diagnostic Evaluation of Writing Skills (DEWS), the Test of Early Written Language (TEWL) and the Test of Adolescent Language. However, assessment using standardized tests is not enough to make a **diagnosis** of disorder of written expression. In addition, a qualified evaluator should compare multiple samples of the student's written work with the written work normally expected from students of comparable backgrounds. The person being evaluated may also be asked to perform tasks such as writing from dictation or copying written material as part of diagnostic testing. The American Psychiatric Association places disorder of written expression in the miscellaneous category of learning disorders not otherwise specified. It is likely to remain a poorly understood and diagnosed disability until more research findings are available.

Treatments

Little is known about how to treat disorder of written expression. Intense writing remediation may help, but no specific method or approach to remediation has

proved particularly successful. Since disorder of written expression usually occurs in conjunction with other learning disabilities, treatment is often directed at those better-understood learning problems.

Prognosis

Little is known about the long-term outcome for people with disorder of written expression. However, it appears that those who have this disorder may develop low self-esteem and social problems related to their lack of academic achievement. Later in life they may be more likely to drop out of school and find employment opportunities that require writing skills closed to them.

Prevention

There are no known ways to prevent disorder of written expression.

Dissociation and dissociative disorders

Definition

The dissociative disorders are a group of mental disorders that affect consciousness and are defined as causing significant interference with the patient's general functioning, including social relationships and employment.

Description

Dissociation is a mechanism that allows the mind to separate or compartmentalize certain memories or thoughts from normal consciousness. These split-off mental contents are not erased. They may resurface spontaneously or be triggered by objects or events in the person's environment.

Dissociation is a process that occurs along a spectrum of severity. If someone experiences dissociation, it does not necessarily mean that that person has a dissociative disorder or other mental illness. A mild degree of dissociation occurs with some physical stressors; people who have gone without sleep for a long period of time, have had "laughing gas" for dental surgery, or have been in a minor accident often have brief dissociative experiences. Another commonplace example of dissociation is a person becoming involved in a book or movie so completely that the surroundings or the passage of time are not noticed. Another example might be driving on the highway and taking several exits without noticing or remembering. Dissociation is related to hypnosis in that hypnotic trance also involves a temporarily altered state of consciousness. Most patients with dissociative disorders are highly hypnotizable.

People in other cultures sometimes have dissociative experiences in the course of religious (in certain trance states) or other group activities. These occurrences should not be judged in terms of what is considered "normal" in the United States.

Moderate or severe forms of dissociation are caused by such traumatic experiences as childhood **abuse**, combat, criminal attacks, brainwashing in hostage situations, or involvement in a natural or transportation disaster. Patients with **acute stress disorder**, **post-traumatic stress disorder** (PTSD), **conversion disorder,** or **somatization disorder** may develop dissociative symptoms. Recent studies of trauma indicate that the human **brain** stores traumatic memories in a different way than normal memories. Traumatic memories are not processed or integrated into a person's ongoing life in the same fashion as normal memories. Instead they are dissociated, or "split off," and may erupt into consciousness from time to time without warning. The affected person cannot control or "edit" these memories. Over a period of time, these two sets of memories, the normal and the traumatic, may coexist as parallel sets without being combined or blended. In extreme cases, different sets of dissociated memories may cause people to develop separate personalities for these memories— a disorder known as **dissociative identity disorder** (formerly called multiple personality disorder).

Types of dissociative disorders

Dissociative amnesia

Dissociative amnesia is a disorder in which the distinctive feature is the patient's inability to remember important personal information to a degree that cannot be explained by normal forgetfulness. In many cases, it is a reaction to a traumatic accident or witnessing a violent crime. Patients with dissociative **amnesia** may develop **depersonalization** or trance states as part of the disorder, but they do not experience a change in identity.

Dissociative fugue

Dissociative fugue is a disorder in which a person temporarily loses his or her sense of personal identity and travels to another location where he or she may assume a new identity. Again, this condition usually follows a major stressor or trauma. Apart from inability to recall their past or personal information, patients with dissociative fugue do not behave strangely or appear disturbed to others. Cases of dissociative fugue are more common in wartime or in communities disrupted by a natural disaster.

Depersonalization disorder

Depersonalization disorder is a disturbance in which the patient's primary symptom is a sense of detachment from the self. Depersonalization as a symptom (not as a disorder) is quite common in college-age populations. It is often associated with sleep deprivation or "recreational" drug use. It may be accompanied by "derealization" (where objects in an environment appear altered). Patients sometimes describe depersonalization as feeling like a robot or watching themselves from the outside. Depersonalization disorder may also involve feelings of numbness or loss of emotional "aliveness."

Dissociative identity disorder (DID)

Dissociative identity disorder (DID) is considered the most severe dissociative disorder and involves all of the major dissociative symptoms. People with this disorder have more than one personality state, and the personality state controlling the person's behavior changes from time to time. Often, a stressor will cause the change in personality state. The various personality states have separate names, temperaments, gestures, and vocabularies. This disorder is often associated with severe physical or sexual abuse, especially abuse suffered during childhood.

KEY TERMS

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy, as well as by dissociation.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Fugue—A dissociative experience during which a person travels away from home, has amnesia for their past, and may be confused about their identity but otherwise appears normal.

Hypnosis—The means by which a state of extreme relaxation and suggestibility is induced: used to treat amnesia and identity disturbances that occur in dissociative disorders.

Multiple personality disorder (MPD)—An older term for dissociative identity disorder (DID).

Trauma—A disastrous or life-threatening event that can cause severe emotional distress, including dissociative symptoms and disorders.

Dissociative disorder not otherwise specified (DDNOS)

DDNOS is a diagnostic category ascribed to patients with dissociative symptoms that do not meet the full criteria for a specific dissociative disorder.

Rebecca J. Frey, Ph.D.

Dissociative amnesia

Definition

Dissociative **amnesia** is classified by the ***Diagnostic and Statistical Manual of Mental Disorders***, 4th Edition, Text Revision, also known as the

KEY TERMS

Age-associated memory impairment (AAMI)—A condition in which an older person suffers some memory loss and takes longer to learn new information. AAMI is distinguished from dementia because it is not progressive and does not represent a serious decline from the person's previous level of functioning. Benign senescent forgetfulness is another term for AAMI.

Anterograde amnesia—Amnesia for events that occurred after a physical injury or emotional trauma but before the present moment. The type of amnesia that typically occurs in dissociative amnesia is anterograde.

Defense—An unconscious mental process that protects the conscious mind from unacceptable or painful thoughts, impulses, or desires. Examples of defenses include denial, rationalization, projection, and repression.

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from dissociative amnesia by its relatively sudden onset and variation in the severity of the symptoms.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal or dreamlike.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Dissociative amnesia—A dissociative disorder characterized by loss of memory for a period or periods of time in the patient's life. May occur as a result of a traumatic event.

Factitious disorder—A type of mental disturbance in which patients intentionally act physically or mentally ill without obvious benefits. It is distinguished from malingering by the absence of an obvious motive, and from conversion disorder by intentional production of symptoms.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Retrograde amnesia—Amnesia for events that occurred before a traumatic injury. Retrograde amnesia is not usually found in patients with dissociative amnesia.

Supportive—An approach to psychotherapy that seeks to encourage the patient or offer emotional support to him or her, as distinct from insight-oriented or educational approaches to treatment.

DSM-IV-TR as one of the dissociative disorders, which are mental disorders in which the normally well-integrated functions of memory, identity, perception, or consciousness are separated (dissociated). The dissociative disorders are usually associated with trauma in the recent or distant past, or with an intense internal conflict that forces the mind to separate incompatible or unacceptable knowledge, information, or feelings. In dissociative amnesia, the continuity of the patient's memory is disrupted. Patients with dissociative amnesia have recurrent episodes in which they forget important personal information or events, usually connected with trauma or severe **stress**. The information that is lost to the patient's memory is usually too extensive to be attributed to ordinary absentmindedness or forgetfulness related to aging. Dissociative amnesia was formerly called "psychogenic amnesia."

Amnesia is a symptom of other medical and mental disorders; however, the patterns of amnesia are different, depending on the cause of the disorder. Amnesia associated with head trauma is typically both retrograde (the patient has no memory of events shortly before the head injury) and anterograde (the patient has no memory of events after the injury). The amnesia that is associated with seizure disorders is sudden onset. Amnesia in patients suffering from **delirium** or **dementia** occurs in the context of extensive disturbances of the patient's cognition (knowing), speech, perceptions, emotions, and

behaviors. Amnesia associated with substance abuse, which is sometimes called "blackouts" typically affects only short-term memory and is irreversible. In dissociative amnesia, in contrast to these other conditions, the patient's memory loss is almost always anterograde, which means that it is limited to the period following the traumatic event(s). In addition, patients with dissociative amnesia do not have problems learning new information.

Dissociative amnesia as a symptom occurs in patients diagnosed with **dissociative fugue** and **dissociative identity disorder**. If the patient's episodes of dissociative amnesia occur only in the context of these disorders, a separate **diagnosis** of dissociative amnesia is not made.

Description

Patients with dissociative amnesia usually report a gap or series of gaps in their recollection of their life history. The gaps are usually related to episodes or abuse or equally severe trauma, although some persons with dissociative amnesia also lose recall of their own **suicide** attempts, episodes of self-mutilation, or violent behavior.

Five different patterns of memory loss have been reported in patients with dissociative amnesia:

- Localized. The patient cannot recall events that took place within a limited period of time (usually several hours or 1–2 days) following a traumatic event. For example, some survivors of the World Trade Center attacks do not remember how they got out of the damaged buildings or what streets they took to get away from the area.
- Selective. The patient can remember some, but not all of the events that took place during a limited period of time. For example, a veteran of D-Day (June 6, 1944) may recall some details, such as eating a meal on the run or taking prisoners, but not others (seeing a close friend hit or losing a commanding officer).
- Generalized. The person cannot recall anything in his/her entire life. Persons with generalized amnesia are usually found by the police or taken by others to a hospital emergency room.
- Continuous. The amnesia covers the entire period without interruption from a traumatic event in the past to the present.
- Systematized. The amnesia covers only certain categories of information, such as all memories related to a certain location or to a particular person.

Most patients diagnosed with dissociative amnesia have either localized or selective amnesia. Generalized amnesia is extremely rare. Patients with generalized, continuous, or systematized amnesia are usually eventually diagnosed as having a more complex dissociative disorder, such as dissociative identity disorder (DID).

Causes and symptoms

Causes

The primary cause of dissociative amnesia is stress associated with traumatic experiences that the patient has either survived or witnessed. These may include such major life stressors as serious financial problems, the death of a parent or spouse, extreme internal conflict, and guilt related to serious crimes or turmoil caused by difficulties with another person.

Susceptibility to hypnosis appears to be a predisposing factor in dissociative amnesia. As of 2002, however, no specific genes have been associated with vulnerability to dissociative amnesia.

Some personality types and character traits seem to be risk factors for dissociative disorders. A group of researchers in the United States has found that persons diagnosed with dissociative disorders have much higher scores for immature psychological defenses than normal subjects.

Symptoms

The central symptom of dissociative amnesia is loss of memory for a period or periods of time in the patient's life. The memory loss may take a variety of different patterns, as described earlier.

Other symptoms that have been reported in patients diagnosed with dissociative amnesia include the ollowing:

- Confusion.
- Emotional distress related to the amnesia. However, not all patients with dissociative amnesia are distressed. The degree of emotional upset is usually in direct proportion to the importance of what has been forgotten, or the consequences of forgetting.
- Mild depression.

Some patients diagnosed with dissociative amnesia have problems or behaviors that include disturbed interpersonal relationships, sexual dysfunction, employment problems, aggressive behaviors, self-mutilation, or suicide attempts.

Demographics

Dissociative amnesia can appear in patients of any age past infancy. Its true prevalence is unknown. In recent years, there has been an intense controversy

among therapists regarding the increase in case reports of dissociative amnesia and the accuracy of the memories recovered. Some maintain that the greater awareness of dissociative symptoms and disorders among psychiatrists has led to the identification of cases that were previously misdiagnosed. Other therapists maintain that dissociative disorders are overdiagnosed in people who are extremely vulnerable to suggestion.

It should be noted that psychiatrists in the U.S. and Canada have significantly different opinions of dissociative disorder diagnoses. On the whole, Canadian psychiatrists, both French- and English-speaking, have serious reservations about the scientific validity and diagnostic status of dissociative amnesia and dissociative identity disorder. Only 30% of Canadian psychiatrists think that these two dissociative disorders should be included in the *DSM-IV-TR* without reservation; and only 13% think that there is strong scientific support for the validity of these diagnoses.

Diagnosis

The diagnosis of dissociative amnesia is usually a diagnosis of exclusion. The doctor will take a detailed medical history, give the patient a physical examination, and order blood and urine tests, as well as an electroencephalogram (EEG) or head x ray in order to rule out memory loss resulting from seizure disorders, substance abuse (including abuse of inhalants), head injuries, or medical conditions, such as **Alzheimer's disease** or delirium associated with fever.

Some conditions, such as age-related memory impairment (AAMI), may be ruled out on the basis of the patient's age. **Malingering** can usually be detected in patients who are faking amnesia because they typically exaggerate and dramatize their symptoms; they have obvious financial, legal, or personal reasons (such as draft evasion) for pretending loss of memory. In addition, patients with genuine dissociative amnesia usually score high on tests of hypnotizability. The examiner may administer the Hypnotic Induction Profile (HIP) or a similar measure that evaluates whether the patient is easily hypnotized. This enables the examiner to rule out malingering or **factitious disorder**.

There are several standard diagnostic questionnaires that may be given to evaluate the presence of a dissociative disorder. The Dissociative Experiences Scale, or DES, is a frequently administered self-report screener for all forms of dissociation. The Structured Clinical Interview for the *DSM-IV-TR* Dissociative Disorders, or SCID-D, can be used to make the diagnosis of dissociative amnesia distinct from the other dissociative disorders defined by the *DSM-IV-TR*. The SCID-D is a semi-structured interview, which means that the examiner's questions are open-ended and allow the patient to describe experiences of amnesia in some detail, as distinct from simple "yes" or "no" answers.

As of 2002, there are no widely used screeners or diagnostic questionnaires specifically for dissociative amnesia.

Diagnosis of dissociative amnesia in children before the age of puberty is complicated by the fact that inability to recall the first four to five years of one's life is a normal feature of human development. As part of the differential diagnosis, a physician who is evaluating a child in this age group will rule out inattention, **learning disorders**, oppositional behavior, and **psychosis**, and seizure disorders or head trauma. To make an accurate diagnosis, several different people (i.e., teachers, therapists, **social workers**, the child's primary care physician) may be asked to observe or evaluate the child.

Treatments

Treatment of dissociative amnesia usually requires two distinct periods or phases.

Psychotherapy

Psychotherapy for dissociative amnesia is supportive in its initial phase. It begins with creating an atmosphere of safety in the treatment room. Very often, patients gradually regain their memories when they feel safe with and supported by the therapist. This rapport does not mean that they necessarily recover their memories during therapy sessions; one study of 90 patients with dissociative amnesia found that most of them had their memories return while they were at home alone or with family or close friends. The patients denied that their memories were derived from a therapist's suggestions, and a majority of them were able to find independent evidence or corroboration of their childhood abuse.

If the memories do not return spontaneously, hypnosis or sodium amytal (a drug that induces a semi-hypnotic state) may be used to help recover them.

After the patient has recalled enough of the missing past to acquire a stronger sense of self and continuity in their life history, the second phase of psychotherapy commences. During this phase, the patient deals more directly with the traumatic episode(s), and recovery from its aftereffects. Studies of the treatments for dissociative amnesia in combat veterans of World War I (1914–1918) found that recovery and cognitive integration of dissociated traumatic memories within the patient's overall personality were more effective than treatment methods that focused solely on releasing feelings.

Medications

At present, there are no therapeutic agents that prevent amnestic episodes or that cure dissociative amnesia itself. Patients may, however, be given antidepressants or other appropriate medications for treatment of the depression, anxiety, **insomnia**, or other symptoms that may accompany dissociative amnesia.

Legal implications

Dissociative amnesia poses a number of complex issues for the legal profession. The disorder has been cited by plaintiffs in cases of recovered memories of abuse leading to lawsuits against the perpetrators of the abuse. Dissociative amnesia has also been cited as a defense in cases of murder of adults as well as in cases of neonatricide (murder of an infant shortly after birth). Part of the problem is the adversarial nature of courtroom procedure in the U.S., but it is generally agreed that judges and attorneys need better guidelines regarding dissociative amnesia in defendants and plaintiffs.

Prognosis

The prognosis for recovery from dissociative amnesia is generally good. The majority of patients eventually recover the missing parts of their past, either by spontaneous re-emergence of the memories or through hypnosis and similar techniques. A minority of patients, however, are never able to reconstruct their past; they develop a chronic form of dissociative amnesia. The prognosis for a specific patient depends on a combination of his or her present life circumstances; the presence of other mental disorders; and the severity of stresses or conflicts associated with the amnesia.

Prevention

Strategies for the prevention of child abuse might lower the incidence of dissociative amnesia in the general population. There are no effective preventive strategies for dissociative amnesia caused by traumatic experiences in adult life in patients without a history of childhood abuse.

Dissociative fugue

Definition

Dissociative fugue is a rare condition in which a person suddenly, without planning or warning, travels far from home or work and leaves behind a past life. Patients show signs of **amnesia** and have no conscious understanding or knowledge of the reason for the flight. The condition is usually associated with severe **stress** or trauma. Because persons cannot remember all or part of their past, at some point they become confused about their identity and the situations in which they find themselves. In rare cases, they may take on new identities. The American Psychiatric Association (APA) classifies disassociative fugue as one of four dissociative disorders, along with **dissociative amnesia**, **dissociative identity disorder**, and **depersonalization disorder**.

Description

The key feature of dissociative fugue is "sudden, unexpected travel away from home or one's customary place of daily activities, with inability to recall some or all of one's past," according to the APA. The travels associated with the condition can last for a few hours or as long as several months. Some individuals have traveled thousands of miles from home while in a state of dissociative fugue. (The word *fugue* stems from the Latin word for flight—*fugere*.) At first, a person experiencing the condition may appear completely normal. With time, however, confusion appears. This confusion may result from the realization that the person can not remember the past. Victims may suddenly realize that they do not belong where they find themselves.

During an episode of dissociative fugue, a person may take on a new identity, complete with a new name and even establish a new home and ties to their his/her community. More often, however, the victim realizes something is wrong not long after fleeing—in a matter of hours or days. In such cases, the victim may phone home for help, or come to the attention of police after becoming distressed at finding himself/herself unexplainably in unfamiliar surroundings.

Dissociative fugue is distinct from Dissociative Identity disorder (DID). In cases of DID, which previously was called Multiple Personality Disorder (MPD), a person loses memory of events that take place when one of several distinct identities takes control of the person. If a person with dissociative fugue assumes a new identity, it does not co-exist with other identities, as is typical of DID. Repeated instances of apparent dissociative fugue are more likely a symptom of DID, not true dissociative fugue.

Causes and symptoms

Causes

Episodes of dissociative fugue are often associated with very stressful events. Traumatic experiences such a war, or natural disasters, seem to increase the incidence of the disorder. Other, more personal types of stress might also lead to the unplanned travel and amnesia characteristic of dissociative fugue. The shocking death of a loved one or seemingly unbearable pressures at work or home, for example, might cause some people to run away for brief periods and blank out their pasts.

Symptoms

A person in the midst of a dissociative fugue episode may appear to have no psychiatric symptoms at all or to be only slightly confused. Therefore, for a time, it may be very difficult to spot someone experiencing a fugue. After a while, however, the patient shows significant signs of confusion or distress because he or she cannot remember recent events, or realizes a complete sense of identity is missing. This amnesia is a characteristic symptom of the disorder.

Demographics

Dissociative fugue is a rare disorder estimated to affect just 0.2% of the population, nearly all of them

KEY TERMS

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy as well as by dissociation.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

adults. More people may experience dissociative fugue, however, during or in the aftermath of serious accidents, wars, natural disasters, or other highly traumatic or stressful events.

Diagnosis

The ***Diagnostic and Statistical Manual of Mental Disorders***, 4th Edition, Text Revision, also known as the *DSM-IV-TR* lists four criteria for diagnosing dissociative fugue:

- Unexplained and unexpected travel from a person's usual place of living and working along with partial or complete amnesia.
- Uncertainty and confusion about one's identity, or in rare instances, the adoption of a new identity.
- The flight and amnesia that characterize the fugue are not related exclusively to DID, nor is it the result of substance abuse or a physical illness.
- An episode must result in distress or impairment severe enough to interfere with the ability of the patient to function in social, work or home settings.

Accurate **diagnosis** typically must wait until the fugue is over and the person has sought help or has been brought to the attention of mental health care providers. The diagnosis can then be made using the patient's history and reconstruction of events that occurred before, during, and after the patient's excursion.

Treatments

Psychotherapy, sometimes involving hypnosis, is often effective in the treatment of dissociative fugue. Patients, with support from therapists, are encouraged to remember past events by learning to face and cope with the stressful experiences that precipitated the fugue. Since the cause of the fugue is usually a traumatic event, it is often necessary to treat disturbing feelings and emotions that emerge when the patient finally faces the trauma. The troubling events that drove a person to run and forget about his or her past may, when remembered, result in **grief**, depression, fear, anger, remorse, and other psychological states that require therapy.

Prognosis

The prognosis for dissociative fugue is often good. Not many cases last longer than a few months and many people make a quick recovery. In more serious cases, the patient may take longer to recover memories of the past.

Dissociative identity disorder

Definition

Previously known as multiple personality disorder, dissociative identity disorder (DID) is a condition in which a person has more than one distinct identity or personality state. At least two of these personalities repeatedly assert themselves to control the affected person's

KEY TERMS

Alter—An alternate or secondary personality in a person with dissociative identity disorder. Each alter has a unique way of looking at and interacting with the world.

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy as well as by dissociation.

Borderline personality disorder—A severe and usually life-long mental disorder characterized by violent mood swings and severe difficulties in sustaining interpersonal relationships.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal.

Dissociation—A reaction to trauma in which the mind splits off certain aspects of the traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Dissociative identity disorder (DID)—Term that replaced Multiple personality disorder. A condition in which two or more distinctive identities or personality states alternate in controlling a person's consciousness and behavior.

Host—The dominant or main alter in a person with DID.

Hypnosis—The means by which a state of extreme relaxation and suggestibility is induced: used to treat amnesia and identity disturbances that occur in dissociative disorders.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Multiple personality disorder (MPD)—An older term for dissociative identity disorder (DID).

Panic disorder—An anxiety disorder in which an individual experiences sudden, debilitating attacks of intense fear.

Post-traumatic stress disorder—A disorder caused by an extremely stressful or traumatic event (such as rape, act of war, or natural disaster) in which the trauma victim is haunted by flashbacks. In the flashbacks, the event is re-experienced in the present. Other symptoms include nightmares and feelings of anxiety.

Primary personality—The core personality of a DID patient. In women, the primary personality is often timid and passive, and may be diagnosed as depressed.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Shift—The transition of control from one alter to another in a person with DID. Usually shifts occur rapidly, within seconds, but in some cases a more gradual change over is observed. Also referred to as a switch.

Somatization disorder—A type of mental disorder in which the patient suffers from physical complaints that serve as coping strategies for emotional distress.

Trauma—A disastrous or life-threatening event that can cause severe emotional distress. DID is associated with trauma in a person's early life or adult experience.

behavior. Each personality state has a distinct name, past, identity, and self-image.

Psychiatrists and psychologists use a handbook called the *Diagnostic and Statistical Manual of Mental Disorders* , fourth edition text revision or *DSM-IV-TR*, to diagnose mental disorders. In this handbook, DID is classified as a dissociative disorder. Other mental disorders in this category include **depersonalization disorder**, **dissociative fugue**, and **dissociative amnesia**. It should be noted, however, that the nature of DID and even its existence is debated by psychiatrists and psychologists.

Description

"Dissociation" describes a state in which the integrated functioning of a person's identity, including consciousness, memory and awareness of surroundings, is disrupted or eliminated. Dissociation is a mechanism that allows the mind to separate or compartmentalize certain

memories or thoughts from normal consciousness. These memories are not erased, but are buried and may resurface at a later time. Dissociation is related to hypnosis in that hypnotic trance also involves a temporarily altered state of consciousness. Dissociation occurs along a continuum or spectrum, and may be mild and part of the range of normal experience, or may be severe and pose a problem for the individual experiencing the dissociation. An example of everyday, mild dissociation is when a person is driving for a long period on the highway and takes several exits without remembering them. In severe, impairing dissociation, an individual experiences a lack of awareness of important aspects of his or her identity.

The phrase "dissociative identity disorder" replaced "multiple personality disorder" because the new name emphasizes the disruption of a person's identity that characterizes the disorder. A person with the illness is consciously aware of one aspect of his or her personality or self while being totally unaware of, or dissociated from, other aspects of it. This is a key feature of the disorder. It only takes two distinct identities or personality states to qualify as DID but there have been cases in which 100 distinct alternate personalities, or alters, were reported. Fifty percent of DID patients harbor fewer than 11 identities.

Because the alters alternate in controlling the patient's consciousness and behavior, the affected patient experiences long gaps in memory— gaps that far exceed typical episodes of forgetting that occur in those unaffected by DID.

Despite the presence of distinct personalities, in many cases one primary identity exists. It uses the name the patient was born with and tends to be quiet, dependent, depressed and guilt-ridden. The alters have their own names and unique traits. They are distinguished by different temperaments, likes, dislikes, manners of expression and even physical characteristics such as posture and body language. It is not unusual for patients with DID to have alters of different genders, sexual orientations, ages, or nationalities. Typically, it takes just seconds for one personality to replace another but, in rarer instances, the shift can be gradual. In either case, the emergence of one personality, and the retreat of another, is often triggered by a stressful event.

People with DID tend to have other severe disorders as well, such as depression, substance abuse, **borderline personality disorder** and eating disorders, among others. The degree of impairment ranges from mild to severe, and complications may include **suicide** attempts, self-mutilation, violence, or drug abuse.

Left untreated, DID can last a lifetime. Treatment for the disorder consists primarily of individual **psychotherapy**.

Causes and symptoms

Causes

The severe dissociation that characterizes patients with DID is currently understood to result from a set of causes:

- an innate ability to dissociate easily
- repeated episodes of severe physical or sexual **abuse** in childhood
- lack of a supportive or comforting person to counteract abusive relative(s)
- influence of other relatives with dissociative symptoms or disorders

The primary cause of DID appears to be severe and prolonged trauma experienced during childhood. This trauma can be associated with emotional, physical or sexual abuse, or some combination. One theory is that young children, faced with a routine of torture, sexual abuse or **neglect**, dissociate themselves from their trauma by creating separate identities or personality states. A manufactured alter may suffer while the primary identity "escapes" the unbearable experience. Dissociation, which is easy for a young child to achieve, thus becomes a useful defense. This strategy displaces the suffering onto another identity. Over time, the child, who on average is around six years old at the time of the appearance of the first alter, may create many more.

As stated, there is considerable controversy about the nature, and even the existence, of dissociative identity disorder. One cause for the skepticism is the alarming increase in reports of the disorder since the 1980s. An area of contention is the notion of suppressed memories, a crucial component in DID. Many experts in memory research say that it is nearly impossible for anyone to remember things that happened before the age three, the age when some DID patients supposedly experience abuse, but the brain's storage, retrieval, and interpretation of childhood memories are still not fully understood. The relationship of dissociative disorders to childhood abuse has led to intense controversy and lawsuits concerning the accuracy of childhood memories. Because childhood trauma is a factor in the development of DID, some doctors think it may be a variation of **post-traumatic stress disorder** (PTSD). In both DID and PTSD, dissociation is a prominent mechanism.

Symptoms

The major dissociative symptoms experienced by DID patients are **amnesia**, **depersonalization**, derealization, and identity disturbances.

AMNESIA. Amnesia in DID is marked by gaps in the patient's memory for long periods of their past, and, in some cases, their entire childhood. Most DID patients have amnesia, or "lose time," for periods when another personality is "out." They may report finding items in their house that they can't remember having purchased, finding notes written in different handwriting, or other evidence of unexplained activity.

DEPERSONALIZATION. Depersonalization is a dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving. Some DID patients experience depersonalization as feeling to be outside of their body, or as watching a movie of themselves.

DEREALIZATION. Derealization is a dissociative symptom in which the patient perceives the external environment as unreal. Patients may see walls, buildings, or other objects as changing in shape, size, or color. DID patients may fail to recognize relatives or close friends.

IDENTITY DISTURBANCES. Persons suffering from DID usually have a main personality that psychiatrists refer to as the "host." This is generally not the person's original personality, but is rather one developed in response to childhood trauma. It is usually this personality that seeks psychiatric help. DID patients are often frightened by their dissociative experiences, which can include losing awareness of hours or even days, meeting people who claim to know them by another name, or feeling "out of body."

Psychiatrists refer to the phase of transition between alters as the "switch." After a switch, people assume whole new physical postures, voices, and vocabularies. Specific circumstances or stressful situations may bring out particular identities. Some patients have histories of erratic performance in school or in their jobs caused by the emergence of alternate personalities during examinations or other stressful situations. Each alternate identity takes control one at a time, denying control to the others. Patients vary with regard to their alters' awareness of one another. One alter may not acknowledge the existence of others or it may criticize other alters. At times during therapy, one alter may allow another to take control.

Demographics

Studies in North America and Europe indicate that as many as 5% of patients in psychiatric wards have undiagnosed DID. Partially hospitalized and out-patients may have an even higher incidence. For every one man diagnosed with DID, there are eight or nine women. Among children, boys and girls diagnosed with DID are pretty closely matched 1:1. No one is sure why this discrepancy between diagnosed adults and children exists.

Diagnosis

The *DSM-IV-TR* lists four diagnostic criteria for identifying DID and differentiating it from similar disorders:

- Traumatic stressor: The patient has been exposed to a catastrophic event involving actual or threatened death or injury, or a serious physical threat to him- or herself or others. During exposure to the trauma, the person's emotional response was marked by intense fear, feelings of helplessness, or horror. In general, stressors caused intentionally by human beings (genocide, rape, torture, abuse, etc.) are experienced as more traumatic than accidents, natural disasters, or "acts of God."
- The demonstration of two or more distinct identities or personality states in an individual. Each separate identity must have its own way of thinking about, perceiving, relating to and interacting with the environment and self.
- Two of the identities assume control of the patient's behavior, one at a time and repeatedly.
- Extended periods of forgetfulness lasting too long to be considered ordinary forgetfulness.
- Determination that the above symptoms are not due to drugs, alcohol or other substances and that they can't be attributed to any other general medical condition. It is also necessary to rule out fantasy play or imaginary friends when considering a **diagnosis** of DID in a child.

Proper diagnosis of DID is complicated because some of the symptoms of DID overlap with symptoms of other mental disorders. Misdiagnoses are common and include depression, **schizophrenia**, borderline personality disorder, **somatization disorder**, and **panic disorder**.

Because the extreme dissociative experiences related to this disorder can be frightening, people with the disorder may go to emergency rooms or clinics because they fear they are going insane.

When a doctor is evaluating a patient for DID, he or she will first rule out physical conditions that sometimes produce amnesia, depersonalization, or derealization. These conditions include head injuries, **brain** disease (especially seizure disorders), side effects from medications, substance abuse or intoxication, AIDS **dementia** complex, or recent periods of extreme physical **stress** and sleeplessness. In some cases, the doctor may give the patient an electroencephalograph (EEG) to exclude epilepsy or other seizure disorders. The physician also

must consider whether the patient is **malingering** and/or offering fictitious complaints.

If the patient appears to be physically healthy, the doctor will next rule out psychotic disturbances, including schizophrenia. Many patients with DID are misdiagnosed as schizophrenic because they may "hear" their alters "talking" inside their heads. If the doctor suspects DID, he or she can use a screening test called the Dissociative Experiences Scale (DES). If the patient has a high score on this test, he or she can be evaluated further with the Dissociative Disorders Interview Schedule (DDIS) or the Structured Clinical Interview for Dissociative Disorders (SCID-D).

Treatments

Treatment of DID may last for five to seven years in adults and usually requires several different treatment methods.

Psychotherapy

Ideally, patients with DID should be treated by a therapist with specialized training in dissociation. This specialized training is important because the patient's personality switches can be confusing or startling. In addition, many patients with DID have hostile or suicidal alter personalities. Most therapists who treat DID patients have rules or contracts for treatment that include such issues as the patient's responsibility for his or her safety. Psychotherapy for DID patients typically has several stages: an initial phase for uncovering and "mapping" the patient's alters; a phase of treating the traumatic memories and "fusing" the alters; and a phase of consolidating the patient's newly integrated personality.

Most therapists who treat multiples, or DID patients, recommend further treatment after personality integration, on the grounds that the patient has not learned the social skills that most people acquire in adolescence and early adult life. In addition, **family therapy** is often recommended to help the patient's family understand DID and the changes that occur during personality reintegration.

Many DID patients are helped by **group therapy** as well as individual treatment, provided that the group is limited to people with dissociative disorders. DID patients sometimes have setbacks in mixed therapy groups because other patients are bothered or frightened by their personality switches.

Medications

Some doctors will prescribe tranquilizers or antidepressants for DID patients because their alter personalities may have anxiety or mood disorders. However, other therapists who treat DID patients prefer to keep medications to a minimum because these patients can easily become psychologically dependent on drugs. In addition, many DID patients have at least one alter who abuses drugs or alcohol, substances which are dangerous in combination with most tranquilizers.

Hypnosis

While not always necessary, hypnosis (or **hypnotherapy**) is a standard method of treatment for DID patients. Hypnosis may help patients recover repressed ideas and memories. Further, hypnosis can also be used to control problematic behaviors that many DID patients exhibit, such as self-mutilation, or eating disorders like **bulimia nervosa**. In the later stages of treatment, the therapist may use hypnosis to "fuse" the alters as part of the patient's personality integration process.

Prognosis

Unfortunately, no systematic studies of the long-term outcome of DID currently exist. Some therapists believe that the prognosis for recovery is excellent for children and good for most adults. Although treatment takes several years, it is often ultimately effective. As a general rule, the earlier the patient is diagnosed and properly treated, the better the prognosis. Patients may find they are bothered less by symptoms as they advance into middle age, with some relief beginning to appear in the late 40s. Stress or substance abuse, however, can cause a relapse of symptoms at any time.

Prevention

Prevention of DID requires **intervention** in abusive families and treating children with dissociative symptoms as early as possible.

Disulfiram

Definition

Disulfiram is an aldehyde dehydrogenase inhibitor. It prohibits the activity of aldehyde dehydrogenase, an enzyme found in the liver. In the United States, disulfiram is sold under brand name Antabuse.

Purpose

Disulfiram is used as a conditioning treatment for alcohol dependence. When taken with alcohol, disulfiram causes many unwanted and unpleasant effects, and the fear of these is meant to condition the patient to avoid alcohol.

Description

Two Danish physicians who were investigating disulfiram for its potential benefits to destroy parasitic worms took disulfiram and became sick at a cocktail party. After a series of pharmacological and clinical studies, it was determined that disulfiram interacts with alcohol.

Disulfiram by itself is not toxic. If taken with alcohol, however, it alters certain steps in the breakdown of alcohol. When alcohol is ingested, it is converted first to a chemical called acetaldehyde. Acetaldehyde is further broken down into acetate. In order for acetaldehyde to be broken down into acetate, aldehyde dehydrogenase needs to be active. Disulfiram is an aldehyde dehydrogenase inhibitor. Since disulfiram blocks the activity of aldehyde dehydrogenase, acetaldehyde cannot be broken down and the levels of acetaldehyde become five to ten times higher than the normal levels. This causes uncomfortable effects that encourage the person to avoid alcohol.

Disulfiram comes in a 250- and 500-mg tablet.

Recommended dosage

Disulfiram therapy should be started only after the patient has abstained from alcohol for at least 12 hours. The initial dose may be as high as 500 mg taken once daily. If the medication is sedating, the dose can be administered in the evening. Ideally, though, the daily dose should be taken in the morning—the time the resolve not to drink may be strongest. The initial dosing period can last for one to two weeks.

Maintenance dose can range anywhere from 125–500 mg daily with the average dose being 250 mg daily. Disulfiram therapy should continue until full recovery. This may take months to years, depending upon patient's response and motivation to stop using alcohol. The duration of disulfiram's activity is 14 days after discontinuation, and patients need to avoid alcohol for this period of time.

Precautions

Before beginning therapy, patients should be carefully evaluated for their intellectual capacity to understand the goal of therapy, behavioral modification with negative **reinforcement**. Patients with history of **psychosis**, severe myocardial disease, and coronary occlusion should not take disulfiram. People with diabetes taking disulfiram are at an increased risk for complications. Severe liver failure has been associated with the use of disulfiram in patients with or without a prior history of liver problems. People with advanced or severe liver disease should not take disulfiram. Disulfiram should never be given to patients who are in a state of alcohol intoxication or without the patient's knowledge. Those patients with history of **seizures**, hypothyroidism, or nephritis need to use disulfiram with caution and close monitoring.

Besides avoiding alcohol, patients should also avoid any products containing alcohol. This includes many cold syrups, tonics, and mouthwashes. Patients should

KEY TERMS

Coronary occlusion—Blockage of the arteries supplying the blood to the heart.

Hypothyroidism—Thyroid gland that is abnormally low-functioning. A lowered metabolic rate results.

Jaundice—A yellowing of the skin caused by excess bilirubin in the blood; a liver disorder.

MAO inhibitors—A group of antidepressant drugs that decrease the activity of monoamine oxidase, a neurotransmitter found in the brain that affects mood.

Myocardial disease—Disease of the muscular layer of the heart wall.

Nephritis—Inflammation of the kidney.

Psychosis—Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an over-arching disorder, not a disorder in itself. (Plural: psychoses)

not even use topical preparations that contain alcohol such as perfume and after-shave lotion.

Side effects

The most common side effect of disulfiram includes drowsiness and **fatigue**. Many patients experience metallic or garlic-like aftertaste, but most patients develop tolerance to this effect.

In addition, disulfiram is also associated with impotence. This is most common in doses of 500 mg daily. Disulfiram can also cause blurred vision, skin discoloration, inflammation of the skin, increased heart rate, and mental changes.

During the first three months of therapy, patients should have their liver function evaluated. Patients need to be monitored for the signs of jaundice, nausea, vomiting, abdominal pain, light stools and dark urine as these may be the signs of liver damage due to disulfiram. The signs of alcohol ingestion include flushing, headache, nausea, vomiting and abdominal pain.

Interactions

Disulfiram can make cisapride, benzodiazepines, astemizole, cyclosporine, erythromycin, and cholesterol-lowering drugs called statins more toxic. Disulfiram in combination with isoniazid, MAO inhibitors (such as phenelzide and **tranylcypromine**), metronidazole, omeprazole and tricyclic antidepressants may cause adverse central nervous system effects.

In addition, disulfiram may raise the concentrations of the medications theophylline and phenytoin in the body. Disulfiram may put patients on warfarin (a blood-thinning drug) at an increased risk of bleeding. Disulfiram should never be used with tranylcypromine and amprenavir oral solution.

Disulfiram may react even with small amounts of alcohol found in over-the-counter cough and cold preparations and any medication that comes in an elixir form.

Divalproex sodium

Definition

Divalproex sodium is an anticonvulsant (anti-seizure) drug. It is also used to treat mania and to help prevent migraine headaches. It is sold under multiple brand names in the United States, including Depacon, Depakene, Depakote, and Depakote sprinkle.

Purpose

Divalproex sodium is effective in the treatment of epilepsy, particularly for preventing simple, complex (petit mal), absence, mixed, and tonic-clonic (grand mal) **seizures**. Divalproex sodium is also used to treat the manic phase of **bipolar disorder** (also called manic-depressive disorder) in adults, and to prevent migraine headache in adults.

KEY TERMS

Absence seizure—An epileptic seizure characterized by a sudden, momentary loss of consciousness, occasionally accompanied by some minor, jerky movements in the neck or upper arms, a twitching of the face, or a loss of muscle tone.

Addison's disease—Disease caused by malfunctioning adrenal glands that can be treated with cortisol replacement therapy. Symptoms include anemia, low blood pressure, digestive complaints, and diarrhea.

Alzheimer's disease—An incurable dementia marked by the loss of cognitive ability and memory over a period of 10–15 years. Usually affects elderly people.

Complex seizure—In complex seizures, the person experiences impaired consciousness.

Huntington's disease—A hereditary disorder that appears in middle age and is characterized by gradual brain deterioration, progressive dementia, and loss of voluntary movement. It is sometimes called Huntington's chorea.

Multiple sclerosis—A disease characterized by patches of hardened tissue in the brain or spinal cord, paralysis, and/or muscle tremors.

Neurons—Nerve cells in the brain that produce nerve impulses.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Simple seizure—Simple partial seizures occur in patients who are conscious.

Tonic-clonic (grand mal) seizure—This is the most common type of seizure and is categorized into several phases beginning with vague symptoms hours or days before an attack. During the seizure, there is abnormal muscle contraction and relaxation and the individual may lose consciousness.

Description

Divalproex sodium is chemically compounded from sodium valproate and **valproic acid** in a 1:1 ratio.

Divalproex sodium is thought to work by increasing the levels of a **brain** neurotransmitter called gamma-aminobutyric acid (GABA). GABA is an inhibitory neurotransmitter, which means that its presence makes it harder for nerve cells (neurons) in the brain to become activated (fire). It is believed that increasing GABA's inhibitory action on brain neurons accounts for the ability of divalproex sodium to decrease seizures, curb manic behaviors, and decrease the frequency of migraine headaches.

Divalproex sodium was discovered to decrease the likelihood of seizure in 1963. In 1978, the United States Food and Drug Administration approved it for this use. Other uses for divalproex sodium were researched and approved subsequently, including use against mania (1995) and use to decrease migraine headache frequency. Divalproex sodium's 1995 approval as an anti-mania medication was considered an exciting advance, since it represented the first new drug introduced for this use in 25 years.

Recommended dosage

Divalproex sodium is available in tablets of 125 mg, 250 mg, and 500 mg. Divalproex sodium is also available in 125-mg capsules, and in a 500-mg extended release tablet. A syrup is also available, containing 250 mg active drug per 5 mL.

Divalproex sodium therapy is usually started at 10–15 mg per kg of body weight per day. Dosages are then increased until seizures seem to be well controlled. This is usually achieved at averages under 60 mg per kg per day.

To treat mania, divalproex sodium is usually started at a daily dose of about 750 mg.

For migraine prevention, divalproex sodium is started at 250 mg, twice per day. In some patients, this dose will have to be raised to a total of 1,000 mg per day.

Precautions

A greater risk of liver damage exists in patients with kidney disease, known liver disease, Addison's disease, blood diseases, children under the age of two, patients with organic brain diseases (such as Alzheimer's, Parkinson's, slow virus infections, Huntington's chorea, multiple sclerosis, etc.), patients with metabolic disorders present at birth, patients with severe seizure disorders and accompanying **mental retardation**, and patients who are taking several other anticonvulsant drugs.

Because divalproex sodium can affect a patient's blood by dropping the platelet (a type of blood cell that

affects clotting) count and interfering with coagulation (clotting) capability, both platelet count and coagulation parameters should be verified before starting the medication and at intervals throughout its use.

Divalproex sodium is known to cause an increased risk of birth defects when taken during pregnancy. An individual and her health care provider must weigh the potential risks and benefits of using this medication during pregnancy. Women who take this medicine should not breast-feed, since a small amount will pass into the breast milk

Divalproex sodium causes drowsiness and impairs alertness in some individuals. Patients just beginning to use the medication should avoid driving and using dangerous machinery until they determine how the drug affects them. The sedative effects are increased in the presence of alcohol, so patients should avoid drinking while taking medicines containing divalproex sodium.

Side effects

Some of the more common side effects of divalproex sodium include mild stomach cramps, change in menstrual cycle, diarrhea, loss of hair, indigestion, decreased appetite, nausea and vomiting, trembling in the hands and arms, and weight loss or weight gain. These side effects usually go away as the patient's body becomes accustomed to the medication.

Less common side effects include severe stomach cramps or continued nausea and vomiting, changes in mood, behavior, or thinking, double vision or seeing spots, severe **fatigue**, easy bruising or unusual bleeding, yellow cast to the skin or the whites of the eyes (jaundice), odd eye movements, and increased seizures. Patients who notice these symptoms should check with their doctor to see if their dosage or medication needs to be adjusted.

Rare side effects that should be checked out by a doctor include clumsiness, difficulty with balance, constipation, dizziness, drowsiness, headache, skin rash, agitation, restlessness, or irritability.

Interactions

Divalproex sodium is broken down (metabolized) in the liver. Other drugs that are metabolized in the liver can have too low or too high concentrations in the body when taken with divalproex sodium. Levels of divalproex sodium may be increased when taken with felbamate, isoniazid, salicylates (aspirin-containing medications), clarithromycin, erythromycin, and troleandomycin. Divalproex sodium may increase levels of **carbamazepine**, phenytoin, **lamotrigine**, nimodipine, phenobarbital, and zidovudine. Use with **clonazepam** may cause absence seizures. Cholestyramine and colestipol may reduce the absorption and the blood levels of divalproex sodium.

Donepezil

Definition

Donepezil is a drug used to treat **dementia** associated with **Alzheimer's disease**. In the United States, donepezil is sold under the brand name Aricept.

Purpose

Donepezil is used to help treat symptoms of Alzheimer's disease in individuals with mild to moderate illness. The drug may cause small improvements in dementia for a short period of time, but donepezil does not stop the progression of Alzheimer's disease.

Description

The Food and Drug Administration has approved donepezil for treatment of the symptoms of Alzheimer's disease. In Alzheimer's disease, some cells in specific regions of the **brain** die. Because of this cell death, these brain cells lose their ability to transmit nerve impulses. Brain cells normally transmit nerve impulses by secreting various chemicals known as **neurotransmitters**.

Brain cells that make and secrete a neurotransmitter called acetylcholine are affected early in the course of Alzheimer's disease. Donepezil helps prevent the breakdown of acetylcholine in the brain, thus temporarily increasing its concentration. In doing so, donepezil may improve the thinking process by facilitating nerve impulse transmission within the brain.

Donepezil is available as tablets in two different strengths. It is broken down by the liver.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Milligram (mg)—One-thousandth of a gram. A gram is the metric measure that equals about 0.035 ounces.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Recommended dosage

The initial dosage of donepezil is 5 mg taken at bedtime. This dose should be continued for four to six weeks. The dosage may then be increased to 10 mg at bedtime, but there is no clear evidence that the higher dosage is more beneficial. However, the higher dosage is likely to cause more side effects.

Precautions

Donepezil may slow heart rate, increase acid in the stomach, make urination difficult, cause breathing difficulties, and may make it more likely for people to have **seizures**. As a result, it should be used carefully with close physician supervision by people with certain heart conditions, those who are prone to stomach ulcers, people with bladder obstruction, individuals with asthma or chronic obstructive pulmonary disease, and people with a history of seizure disorders.

People taking donepezil should be reassessed periodically to determine whether the drug is providing any benefits. When caregivers feel the drug is no longer beneficial, it may be stopped.

Side effects

More than 5% of people taking donepezil experience difficulty sleeping, dizziness, nausea, diarrhea, muscle cramps, headache, or other pains.

Diarrhea, nausea, and vomiting occur more often with the 10-mg dose than the 5-mg dosage. These adverse effects are usually mild, short-lived, and typically subside when the drug is stopped. Other, less common, side effects are abnormal dreams, depression, drowsiness, fainting, loss of appetite, weight loss, frequent urination, arthritis, and easy bruising.

Interactions

Many drugs may alter the effects of donepezil; likewise, donepezil may alter the action of other drugs. Drugs such as dicylomine, phenytoin, **carbamazepine**, dexamethasone, rifampin, or phenobarbital may lessen the effects of donepezil. Other drugs such as bethanechol, ketoconazole, or quinidine may increase some of the side effects associated with donepezil. When donepezil and nonsteroidal anti-inflammatory drugs such as ibuprofen (Advil) or naproxen are used together, there may be an increased tendency to develop stomach ulcers. Donepezil may increase the side effects associated with use of **fluvoxamine**, an antidepressant. If succinylcholine, a drug commonly used during anesthesia, is used with donepezil, prolonged muscle paralysis may result.

Doxepin

Definition

Doxepin is an oral antidepressant. It is sold in the United States under the brand name Sinequan and is also available under its generic name.

Purpose

Doxepin is used primarily to treat depression and to treat the combination of symptoms of anxiety and depression. Like most antidepressants, doxepin has also been used to treat **panic disorder**, **obsessive-compulsive disorder**, **attention-deficit/hyperactivity disorder**, **enuresis** (bed-wetting), eating disorders such as **bulimia nervosa**, cocaine dependency, and the depressive phase of bipolar (manic-depressive) disorder. It has also been used to support smoking cessation programs.

Description

Doxepin acts to change the balance of naturally occurring chemicals in the **brain** that regulate the transmission of nerve impulses between cells. Its action primarily increases the concentration of norepinephrine and serotonin (both chemicals that stimulate nerve cells) and, to a lesser extent, blocks the action of another brain chemical, acetylcholine. Although not technically a tricyclic antidepressant, doxepin shares most of the properties of these drugs, which include **amitriptyline**, **clomipramine**, **desipramine**, **imipramine**, **nortriptyline**, **protriptyline**, and **trimipramine**. Studies comparing doxepin with these other drugs have shown that doxepin is no more or less effective than other antidepressants of its type. Its choice for treatment is as much a function of physician preference as any other factor.

The therapeutic effects of doxepin, like other antidepressants, appear slowly. Maximum benefit is often not evident for at least two weeks after starting the drug. People taking doxepin should be aware of this and continue taking the drug as directed even if they do not see immediate improvement.

Recommended dosage

As with any antidepressant, doxepin must be carefully adjusted by the physician to produce the desired therapeutic effect. Doxepin is available as 10-mg, 25-mg, 50-mg, 75-mg, 100-mg, and 150-mg oral capsules as well as an oral concentrate solution containing 10 mg of drug in each milliliter of solution.

Therapy is usually started at 30 to 150 mg per day and gradually increased to 300 mg daily if needed. There is little evidence that doses above 300 mg daily provide any additional benefits. Amounts up to 150 mg may be taken as a single dose at bedtime to decrease daytime sleepiness. Doses of more than 150 mg per day should be divided into two or three doses and taken throughout the day.

In patients over age 60, therapy should be maintained at the low end of the dosing range and increased cautiously and with physician supervision. Patients with organic brain syndrome (psychiatric symptoms of **dementia** often seen in elderly patients) generally require daily doses of only 25 to 50 mg.

If the oral concentrate of doxepin is used, each dose should be diluted in at least 4 ounces (120 mL) of milk, orange, prune, tomato, pineapple, or grapefruit juice just before administration. Doxepin is not compatible with many carbonated beverages and should not be diluted in them.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Benign prostate hypertrophy—Enlargement of the prostate gland.

Norepinephrine—A neurotransmitter in the brain that acts to constrict blood vessels and raise blood pressure. It works in combination with serotonin.

Organic brain syndrome—A class of disorders characterized by progressive deterioration of mental processes caused by temporary brain dysfunction or permanent brain damage. Symptoms include delusions, dementia, amnesia, and delirium that are not caused by drugs, alcohol, or as a side effect of medication.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Precautions

As with tricyclic antidepressants, doxepin should be used cautiously and with close physician supervision in people, especially the elderly, who have benign prostatic hypertrophy, urinary retention, and glaucoma, especially angle-closure glaucoma (the most severe form). Before starting treatment, people with these conditions should discuss the relative risks and benefits of treatment with their doctors to help determine if doxepin is the right antidepressant for them.

A common problem with antidepressants is sedation (drowsiness, lack of physical and mental alertness). This side effect is especially noticeable early in therapy. In most patients, sedation decreases or disappears entirely with time, but until then, patients taking doxepin should not perform hazardous activities requiring mental alertness or coordination. The sedative effect is increased when doxepin is taken with other central nervous system depressants, such as alcoholic beverages, sleeping medications, other sedatives, or antihistamines. It may be dangerous to take doxepin in combination with these substances. Doxepin may increase the possibility of having **seizures**. Patients should tell their physician if they have a history of seizures, including seizures brought on by the abuse of drugs or alcohol. These people should use doxepin only with caution and be closely monitored by their physician.

Doxepin may increase heart rate and **stress** on the heart. It may be dangerous for people with cardiovascular disease, especially those who have recently had a heart attack, to take this drug or other antidepressants in the same pharmacological class. In rare cases where patients with cardiovascular disease must receive doxepin, they should be monitored closely for cardiac rhythm disturbances and signs of cardiac stress or damage.

Doxepin should not be taken by nursing mothers because it is secreted into breast milk and may cause side effects in the nursing infant.

Side effects

Doxepin shares the side effects of tricyclic antidepressants. The most frequent of these are dry mouth, constipation, urinary retention, increased heart rate, sedation, irritability, dizziness, and decreased coordination. As with most side effects associated with tricyclic antidepressants, the intensity is highest at the beginning of therapy and tends to decrease with continued use.

Dry mouth, if severe to the point of causing difficulty speaking or swallowing, may be managed by dosage reduction or temporary discontinuation of the drug. Patients may also chew sugarless gum or suck on sugarless candy in order to increase the flow of saliva. Some artificial saliva products may give temporary relief.

Men with prostate enlargement who take doxepin may be especially likely to have problems with urinary retention. Symptoms include having difficulty starting a urine flow and more difficulty than usual passing urine. In most cases, urinary retention is managed with dose reduction or by switching to another type of antidepressant. In extreme cases, patients may require treatment with bethanechol, a drug that reverses this particular side effect. People who think they may be experiencing any side effects from this or any other medication should tell their physicians.

Interactions

Dangerously high blood pressure has resulted from the combination of antidepressants such as doxepin and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Because of this, doxepin should never be taken in combination with MAO inhibitors. Patients taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor then wait at least 14 days before starting doxepin or any tricyclic antidepressant. The same holds true when discontinuing doxepin and starting an MAO inhibitor.

Doxepin may decrease the blood pressure–lowering effects of **clonidine**. Patients who take both drugs should be monitored for loss of blood-pressure control and the dose of clonidine increased as needed.

The sedative effects of doxepin are increased by other central nervous system depressants such as alcohol, sedatives, sleeping medications, or medications used for other mental disorders such as **schizophrenia**. The anticholinergic effects of doxepin are additive with other anticholinergic drugs such as **benztropine**, **biperiden**, **trihexyphenidyl**, and antihistamines.

Dual diagnosis

Definition

Dual **diagnosis** is a term that refers to patients who have both a mental health disorder and substance use disorder. It may be used interchangeably with "co-occurring disorders" or "comorbidity." According to the U.S. Substance Abuse and Mental Health Services Administration (SAMHSA), an estimated 10 million people in the United States will have a combination of at least one mental health and one substance abuse disorder in any twelve-month period. Substance abuse is the most common and significant co-occurring disorder among adults with such severe mental illnesses as **schizophrenia** or **bipolar disorder**. It may also be observed in individuals with mental health diagnoses that include depression, anxiety, **post-traumatic stress disorder**, or eating disorders. The term "substance abuse" refers to substance use disorders that range along a continuum from abuse to dependence or **addiction**.

The term "dual diagnosis" is considered to be misleading by some professionals because most people with this diagnosis actually have many problems rather than just two discrete illnesses. Occasionally, the term is used to describe a person with developmental disabilities and/or a mental health disorder or substance abuse disorder. More commonly, dual diagnosis refers to those with severe mental illness and a drug or alcohol abuse disorder, and who receive therapy in the public treatment systems.

Description

The prevalence of people with dual diagnoses became fully apparent to clinicians in the early 1980s. Initially, dual diagnoses were thought to be most likely in young adults with schizophrenia or bipolar disorder who also had extensive histories of drug or alcohol abuse. There was a widespread belief, often shared by family members of affected patients, that a young person's initiation into illegal drug use actually caused a subsequent mental illness. It is now more commonly thought that symptoms of the mental disorder generally appear first, and that the abuse of drugs or alcohol may represent the patient's attempt to self-medicate and alleviate the troublesome symptoms that accompany mental health disorders.

Today it is clear that the co-occurrence of mental illness and substance abuse is common: about 50% of individuals with severe mental illnesses are affected by substance abuse. A dual diagnosis is also associated with a host of negative outcomes that may include higher rates of relapse, **hospitalization**, incarceration, violence, **homelessness**, and exposure to such serious infections as HIV and hepatitis.

Despite almost twenty years of evidence regarding the prevalence and serious illnesses of people with dual diagnoses, the United States mental health and substance abuse systems continue to operate on parallel tracks, causing additional confusion to those with concurrent disorders. Refusal to combine services to provide better coordinated treatment has meant unnecessary suffering and expense for thousands of patients and their families.

For many people with dual diagnoses, the criminal justice system—juvenile as well as adult— becomes their *de facto* treatment system. Nearly two-thirds of incarcerated youth with substance abuse disorders have at least one other mental health disorder. The common association between **conduct disorder** or **attention-deficit/hyperactivity disorder** and substance abuse are two examples of combinations of serious and disabling disorders. A person in need of treatment for dual diagnoses who is in the current criminal justice system may not be evaluated or assessed, let alone provided with appropriate treatment.

Demographics

Children of alcohol or other drug-addicted parents are at increased risk for developing substance abuse and mental health problems. Disruptive behavior disorders coexist with adolescent substance abuse problems more often than not. Other special groups that may be affected include older adults with mood or anxiety disorders, especially those who are grieving numerous losses. They may drink or misuse or abuse prescription drugs to cope with their lowered quality of life. These factors can often complicate treatment of hypertension, diabetes, arthritis, and other health-related problems that affect the elderly as well.

Abuse of alcohol or other drugs may occur in persons with eating disorders in an effort to deal with guilt, shame, anxiety, or feelings of self-loathing as a result of bingeing and purging food. Many military veterans suffer from anxiety, depression or post-traumatic stress disorder and have histories of substance abuse. Services for veterans are woefully inadequate, adding to the chronic nature of dual diagnosis among them.

Treatment

One of the difficulties in treating patients with dual diagnoses is that most treatments for mental illness are usually developed for and validated by studies of patients with single diagnoses; therefore, many cases of comorbidity may not be well treated by these approaches. Recent research on services provided to people with dual diagnoses, however, indicates that treatment can be successful, provided certain specific components are included in the treatment process. The critical elements identified as part of treatment programs with the most successful outcomes are:

- Staged interventions that begin with engaging the client; persuading him or her to become involved in recovery-focused activities; acquiring skills and support to control the illnesses; and then helping the patient with relapse prevention.
- Assertive outreach that may involve intensive **case management** and meetings in the person's home.
- Motivational interventions to help the client become committed to self-management of their illnesses.
- Counseling that includes cognitive and behavioral skills.
- Social network support and/or family interventions.
- An understanding of the long-term nature of recovery.
- Comprehensive scope to treatment that includes personal habits, stress management, friendship networks, housing, and many other aspects of a person's life.
- Cultural sensitivity and competence.

The success of 12-step programs in the treatment of substance abuse is well-established. Nevertheless, the level of confrontation sometimes found in a traditional 12-step group may feel overwhelming to people with mental illnesses. In addition, the use of psychotropic (mood- or behavior-altering) medications is controversial in some areas of the substance abuse recovery community. As a result, other models of consumer-led **support groups** specifically for people with concurrent disorders, such as Dual Recovery Anonymous and Double Trouble, are being developed.

Dyspareunia

Definition

Dyspareunia is painful sexual intercourse. The same term is used whether the pain results from a medical or a psychosocial problem. Dyspareunia may be diagnosed in men and women, although the **diagnosis** is rare in men; when it does occur in men, it is almost always caused by a medical problem.

This discussion focuses only on pain with intercourse caused by psychosocial problems; therefore, only women's experiences are emphasized in this entry.

The professional's handbook, the ***Diagnostic and Statistical Manual of Mental Disorders***, Fourth edition, text revised (known as the *DSM-IV-TR*) classifies this condition as a sexual dysfunction.

Description

Dyspareunia is any pain experienced any time before, during, or following sexual intercourse. The pain may be located in the genitals or within the pelvis. It is not unusual for women occasionally to experience pain during intercourse. This is not true dyspareunia.

A woman who has dyspareunia often also has **vaginismus**. This is an involuntary tightening of the vaginal muscles in response to penetration. It can make intercourse painful, or impossible.

KEY TERMS

Dyspareunia—Painful sexual intercourse.

Vaginismus—An involuntary tightening of the vaginal muscles that makes sexual intercourse painful, difficult, or impossible.

Vulvar vestibulitis syndrome (VVS)—Vulvar vestibulitis syndrome is thought to be the most frequent cause of dyspareunia in premenopausal women. A chronic, persistent clinical syndrome, vulvar vestibulitis is characterized by severe pain on vestibular touch or attempted vaginal entry.

Causes and symptoms

Causes

Psychosocial causes of dyspareunia include:

- Prior sexual trauma. Many women who have been raped or sexually abused as children have dyspareunia. Even when a woman wishes to have sex with someone later, the act of intercourse may trigger memories of the trauma and interfere with her enjoyment of the act. Vaginismus also often occurs in such women.
- Guilt, anxiety, or tension about sex. Any of these can cause tense vaginal muscles and also prevent arousal from occurring. People who were raised with the idea that sex is bad may be more prone to have this problem. Fear of pregnancy may make arousal difficult.
- Prior physical trauma to the vaginal area. Women who have had an accidental injury or surgery in the vaginal area may become sensitive to penetration. Vaginismus is common in these cases, as well.
- Depression or anxiety in general. Either of these can lead to loss of interest in sex. This can be experienced by either sex.
- Problems in a relationship. Dyspareunia may occur when a woman feels her sexual partner is abusive or emotionally distant, she is no longer attracted to her partner, or she fears her partner is no longer attracted to her. Men, too, can lose interest in sex because of prior emotional trauma in a relationship; however, the result is usually impotence, rather than dyspareunia.
- Vasocongestion. Vasocongestion can occur when either partner frequently becomes aroused but does not reach orgasm. Vasocongestion is a pooling of blood in dilated blood vessels. Normally, the pelvic area becomes congested with blood when a person becomes sexually aroused. This congestion goes away quickly after orgasm. If there is no orgasm, the congestion takes much longer to resolve.

Any of these factors may cause painful sex. The affected person may then associate pain with sex and find it even harder to relax and become aroused in future.

Symptoms

The *DSM-IV-TR* diagnostic criteria for dyspareunia are as follows:

- Recurrent or persistent genital pain related to sexual intercourse that may occur before, during, or after intercourse.
- The affected person is distressed by the pain, or experiences relationship problems as a result of the pain.
- The pain is not caused exclusively by vaginismus or lack of lubrication, is not better accounted for by another disorder, and is not due exclusively to the direct effects of a drug, medication, or a general medical condition. Dyspareunia can occur with other sexual dysfunctions.

The most common symptom of dyspareunia from psychosocial causes is pain at the vaginal opening as the penis enters the vagina. Entry may be difficult, and the pain may be burning, or sharp. The woman may have a sense of being "dry." Pain may continue or ease as thrusting continues.

Vasocongestion can cause an aching pain in the pelvic area that persists for hours after intercourse. Pain with orgasm, or pain deep in the pelvis with thrusting, is more likely to be a sign of a medical problem, but can result from lack of arousal and tension.

A person who experiences pain during sex may feel embarrassed or ashamed. Dyspareunia can cause problems in relationships or lead to the affected person avoiding relationships altogether.

Demographics

About 15% of women may have pain with intercourse at some point in their lives. About 1–2% have true dyspareunia. The incidence is much higher in women who have been raped or otherwise sexually abused. As stated, dyspareunia in men is rare and is almost always caused by a medical problem.

Diagnosis

About 30% to 40% of all women who seek help from a sexual counselor for dyspareunia turn out to have a medical problem that is causing their pain. A full medical examination is necessary to rule out a possible medical cause. This includes a pelvic exam and may also include an ultrasound, as well as other diagnostic tests. Examples of possible physical causes are infections, sexually transmitted diseases (STDs), estrogen deficiencies, and vulvar vestibulitis.

Once a medical cause is ruled out, a full family and sexual history can help pinpoint possible psychosocial causes. A psychological evaluation can determine the cause of the problem. Women who have been raped or abused may also suffer from **post-traumatic stress disorder** (PTSD) or **generalized anxiety disorder**.

There are two types of dyspareunia. Lifelong or primary dyspareunia means that the condition has been present for the entire sexual life of the affected person. This type is usually associated with being raised to believe that sex is bad, sexual abuse, fear of sex, or a painful first sexual experience. Acquired or secondary dyspareunia begins after a period of normal sexual function. It often has a medical cause, but may be a result of some sort of trauma, such as rape.

Treatments

Counseling is often helpful to identify and reframe negative feelings about sex. **Couples therapy** can help improve communication between partners and resolve problems that may be a factor in the sexual relationship. Women who have been abused or raped may benefit from counseling techniques designed to help overcome fears and issues caused by traumatic experiences.

Sex therapy may be offered to provide information about the physical aspects of arousal and orgasm. A sex therapist will also offer suggestions for how to improve sexual technique. For example, increasing time for foreplay and allowing the woman to control when and how penetration occurs can help her to relax and become aroused more easily.

Women who also have vaginismus may be given a set of devices they can use at home to dilate the opening of the vagina. Affected women start with a very small device and gradually work up to a penis-sized device, proceeding to a larger size only when they can use the smaller one without pain or fear. This retrains the vaginal muscles and helps the involuntary muscle tightening of vaginismus.

Use of a vaginal lubricant, at least temporarily, may be helpful in some women to reduce anxiety about possible pain.

There are no specific medications that treat dyspareunia. Medications that increase blood flow or relax muscles may be helpful in some cases.

Prognosis

With treatment, the chance of overcoming dyspareunia and having an enjoyable sexual life is good. Treatment can take several months, particularly in the case of survivors of a violent trauma such as rape.

Dysthymic disorder

Definition

Dysthymic disorder is defined as a mood disorder with chronic (long-term) depressive symptoms that are present most of the day, more days than not, for a period of at least two years.

Description

Everyone experiences feelings of unhappiness and sadness occasionally. When these depressed feelings start to dominate everyday life and cause physical and mental deterioration, the feelings become known as depressive disorders. Depressive disorders can be categorized as **major depressive disorder** or dysthymic disorder. Individuals who suffer from dysthymic disorder have had their depressive symptoms for years— they often cannot pinpoint exactly when they started to feel depressed. People suffering from dysthymic disorder may describe to their doctor feelings of hopelessness, lowered self-esteem, poor concentration, indecisiveness, decreased

motivation, sleeping too much or too little, or eating too much or too little. Symptoms are present often and for the whole day, and are typically present for at least two years.

Causes and symptoms

Causes

The causes of depression are complex and not yet completely understood. Sleep abnormalities, hormones, **neurotransmitters** (chemicals that communicate impulses from one nerve cell to another), upbringing, heredity, and stressors (significant life changes or events that cause **stress**) all have been implicated as causes of depression.

Dysthymic disorder occurs in approximately 25% to 50% of persons who have sleep abnormalities that include reduced rapid eye movement (REM) sleep and impaired sleep continuity. Rapid eye movement sleep is an essential component of the sleep cycle and quality of sleep.

There is some evidence that suggests a correlation with hormonal imbalances of cortisol or thyroid hormones. In many adults, levels of cortisol (a stress hormone) are elevated during acute depressive periods and return to normal when the person is no longer depressed. In children and adolescents, results have been quite inconsistent, although there is some evidence that hypersecretion of cortisol is associated with more severe depressive symptoms and with a higher likelihood of recurrence of depression. A lack of thyroid hormone mimics depression quite well and is routinely checked in patients with recent onset depression.

In depression, there appears to be abnormal excess or inhibition of signals that control mood, thoughts, pain, and other sensations. Some studies suggest an imbalance of the neurotransmitter called serotonin. It is assumed that the reason antidepressants are effective is that they correct these chemical imbalances. For example, the selective serotonin reuptake inhibitors (SSRIs), one class of antidepressant medications that includes **fluoxetine** (Prozac), appears to establish a normal level of serotonin. As the name implies, the drug inhibits the re-uptake of serotonin neurotransmitter from the gaps between the nerve cells, thus increasing neurotransmitter action, alleviating depressive symptoms.

A child's upbringing may also be key in the development of dysthymic disorder. For example, it is speculated that if a person is abused and neglected throughout childhood and adolescence, a pattern of low self-esteem and negative thinking may emerge, and, from that, a lifelong pattern of depression may follow.

Heredity seems to play a role in the development of depressive disorders. People with major depression in their immediate family are up to three times more likely to have the disorder themselves. It would seem that biological and genetic factors may make certain individuals more prone to depressive disorders, but that environmental circumstances, or stressors, may then trigger the disorder.

KEY TERMS

Affect—The expression of emotion displayed to others through facial expressions, hand gestures, tone of voice, etc. Types of affect include: flat (inanimate, no expression), blunted (minimally responsive), inappropriate (incongruous expressions of emotion relative to the content of a conversation), and labile (sudden and abrupt changes in type and intensity of emotion).

Cortisol—A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle, and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Thyroid hormone—A complex hormone that regulates metabolic rate of all cells.

Symptoms

The mental health professional's handbook to aid patient **diagnosis** is the *Diagnostic and Statistical Manual of Mental Disorders,* also called the *DSM.* The 2000 edition of this manual is known as the *DSM-IV-TR* (fourth edition, text revised). The *DSM-IV-TR* has established a list of criteria that can indicate a diagnosis. These criteria include:

- Depressed mood for most of the day, more days than not.
- When depressed, two (or more) of the following are also present: decreased appetite or overeating, too much or too little sleep, low energy level, low self-esteem, decreased ability to concentrate, difficulty making decisions, and/ or feelings of hopelessness.

- During the two years of the disorder, the patient has never been without symptoms listed for more than two months at a time.
- No major depressive episode (a more severe form of depression) has been present during the first two years of the disorder.
- There has never been a manic disorder, and criteria for a less severe depression called **cyclothymic disorder** has never been established.
- The disorder does not exclusively occur with **psychosis**, **schizophrenia** or delusional illnesses.
- The symptoms of depression cause clinically significant impairment and distress in occupational, social, and general functioning. Dysthymic disorder can be described as "early onset" (onset before age 21 years), "late onset" (onset is age 21 years or older), and "with atypical features" (features that are not commonly observed).

Demographics

The lifetime prevalence has been estimated to be 4.1% for women and 2.2% for men. In adults, dysthymic disorder is more common in women than in men and research suggests that the prevalence in the age group 25 to 64 years is 6% for women. In children, dysthymic disorder can occur equally among both genders.

Diagnosis

To diagnose a patient with this disorder, the *DSM-IV-TR* criteria must be established, and this is accomplished through an extensive psychological interview and evaluation. The affected person seeking the clinician's help usually exhibits symptoms of irritability, feelings of worthlessness and hopelessness, crying spells, decreased sex drive, agitation, and thoughts of death. The clinician must rule out any possible medical conditions that can cause depressed **affect**. (Affect can be defined as the expression of emotion displayed to others through facial expressions, hand gestures, tone of voice, etc.) The diagnosis cannot be made if depression occurs during an active course of psychosis, **delusions**, schizophrenia, or **schizoaffective disorder**. If substance abuse is determined as the cause of depression, then a diagnosis of substance-induced mood disorder can be established.

Further psychological tests that can be administered to help in the diagnostic process include the **Beck Depression Inventory** and the **Hamilton Depression Scale**.

Treatments

The goals of treatment include remission of symptoms and psychological and social recovery.

Medications

Studies suggest some treatment success with medications such as tricyclic antidepressants (TCAs) or monoaminoxidase inhibitors (MAOIs). Medications can be effective in patients who have depression due to sleep abnormalities. Some tricyclic antidepressants include **amitriptyline** (Elavil), **imipramine** (Tofranil), and **nortriptyline** (Aventyl, Pamelor), and some MAOIs include **tranylcypromine** (Parnate) and **phenelzine** (Nardil). Selective serotonin reuptake inhibitors (SSRIs) are recommended during initial treatment planning after a definitive diagnosis is well established. The most commonly prescribed SSRIs are fluoxetine (Prozac), **sertraline** (Zoloft), **paroxetine** (Paxil), **fluvoxamine** (Luvox), and **citalopram** (Celexa).

Psychological therapies

Clinical reports suggest that **cognitive-behavioral therapy**, interpersonal **psychotherapy**, or **family therapy** can be effective with concurrent antidepressant medication to treat the symptoms of depression. In these therapies, the goal is to help the patient develop healthy problem-solving and coping skills.

Prognosis

Dysthymic disorder often begins in late childhood or adolescence. The disorder follows a chronic (long-term) course. The development of a more major form of clinical depression called major depressive disorder among children with dysthymic disorder is significant. In other words, childhood onset of dysthymic disorder is considered an early indicator for recurrent mood disorder that may even have more severe clinical symptoms in the patient's future.

Patients with this disorder usually have impaired emotional, social, and physical functioning.

In general, the clinical course of dysthymic disorder is not promising. Causes of a poorer outcome include not completing treatment, noncompliance with medication intake, and lack of willingness to change behaviors that promote a depressed state. However, patients can do very well with a short course of medications if they have a desire to follow psychotherapy treatment recommendations.

If left untreated, dysthymic disorder can result in significant financial and occupational losses. People with

this disorder tend to isolate themselves by restricting daily activities and spending days in bed. Patients often complain of poor health and incur more disability days when compared to the general population. Higher rates of successful outcome occur in people who undergo psychotherapy and treatment with appropriate medications.

Prevention

There is no known prevention for dysthymic disorder. Early **intervention** for children with depression may be effective in arresting the development of more severe problems.

Electroconvulsive therapy

Definition

Electroconvulsive therapy (ECT) is a medical procedure in which a small, carefully controlled amount of electric current is passed through the **brain** to treat symptoms associated with certain mental disorders. The electric current produces a convulsion for the relief of symptoms associated with such mental illnesses as **major depressive disorder**, **bipolar disorder**, acute **psychosis**, and **catatonia**.

Purpose

Also known as electroconvulsive shock therapy or electroshock therapy, ECT is used together with anesthesia, muscle relaxants and oxygen to produce a mild generalized seizure or convulsion. With repeated administration, usually over a period of weeks, ECT is highly effective in relieving symptoms of several mental illnesses.

The American Psychiatric Association's *Practice Guidelines for the Treatment of Psychiatric Disorders* discusses the use of ECT in the treatment of major depressive disorder, bipolar disorder and **schizophrenia**. Electroconvulsive therapy is administered to provide relief from the signs and symptoms of these and occasionally other mental illnesses. ECT is used routinely to treat patients with major depression, delusional depression, mania, and depression associated with bipolar disorder and schizophrenia. It is most closely associated with the treatment of severe depression, for which it provides the most rapid relief available as of 2002. In addition, patients suffering from catatonia, neuroleptic malignant syndrome, and parkinsonism may also benefit from the procedure.

ECT may become the treatment of first choice for depression if a patient with severe depression or psychotic symptoms is at increased risk of committing **suicide** and has not responded to other treatments. Although antidepressant medications are effective in many cases, they may take two to six weeks to begin to work. Some patients with mania and schizophrenia may not be able to tolerate the side effects of the antipsychotic medications used to treat these disorders. In addition, some patients may be unable to take their prescribed medications. For these individuals, ECT is an important option. ECT is also indicated when patients need a treatment that brings about rapid improvement because they are refusing to eat or drink, or presenting some other danger to themselves.

ECT is also recommended for certain subgroups of patients diagnosed with depression. Many elderly patients, for example, respond better to ECT than to antidepressant medications. Pregnant women are another subgroup that may benefit from ECT. Because ECT does not harm a fetus as some medications might, pregnant women suffering from severe depression can safely choose ECT for relief of their depressive symptoms.

Precautions

Candidates for ECT must be carefully screened. Prior to receiving this treatment, patients receive a thorough evaluation to identify any medical conditions they may have that might complicate their response to the procedure. This evaluation includes a complete medical history, a physical examination, and routine laboratory tests. In addition to standard blood tests, the patient should receive an electrocardiogram (EKG) to test for heart abnormalities. Evidence of a recent heart attack would

KEY TERMS

Acute psychosis—A severe mental disorder marked by delusions, hallucinations, and other symptoms that indicate that the patient is not in contact with reality.

Catatonia—Disturbance of motor behavior with either extreme stupor or random, purposeless activity.

Electroencephalography—The measurement and recording of the brain's electrical activity.

Informed consent—A person's agreement to undergo a medical or surgical procedure, or to participate in a clinical study, after being properly advised of the medical facts related to the procedure or study and the risks involved.

Mania—An elevated or euphoric mood or irritable state that is characteristic of bipolar I disorder. This state is characterized by mental and physical hyperactivity, disorganization of behavior, and inappropriate elevation of mood.

Neuroleptic—Another name for the older antipsychotic medications, such as haloperidol (Haldol) and chlorpromazine (Thorazine).

Neuroleptic malignant syndrome (NMS)—An unusual but potentially serious complication that develops in some patients who have been treated with antipsychotic medications. NMS is characterized by changes in blood pressure, altered states of consciousness, rigid muscles, and fever. Untreated NMS can result in coma and death.

Parkinsonism—A condition caused by the destruction of the brain cells that produce dopamine (a neurotransmitter), and characterized by tremors of the fingers and hands, a shuffling gait, and muscular rigidity.

Psychomotor—Referring to a response or reaction that involves both the brain and muscular movements.

Psychotropic—Having an effect on the mind, brain, behavior, perceptions, or emotions. Psychotropic medications are used to treat mental illnesses because they affect a patient's moods and perceptions.

Relapse—A person experiences a relapse when he or she re-engages in a behavior that is harmful and that he or she was trying to change or eliminate. Relapse is a common occurrence after treatment for many disorders, including addictions and eating disorders.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Tourniquet—A rubber tube or length of cloth that is used to compress a blood vessel in order to stop bleeding or to shut off circulation in a part of the body. The tourniquet is wrapped around the arm (or other limb) and tightened by twisting.

disqualify a patient from receiving ECT. Spinal and chest x rays can identify other physical conditions that might complicate a patient's response. Finally, a **computed tomography** (CT) scan should be performed to rule out any structural abnormalities in the brain that might be made worse by the electrical stimulation and resulting convulsions associated with ECT. Signs of a recent **stroke** or a tumor in the brain, for instance, would disqualify a patient as a candidate for ECT therapy.

The doctors who are administering the procedure must receive the **informed consent** of the patient a day before the first treatment is given. In addition, at least two psychiatrists should confirm that ECT is the proper treatment for a specific patient. One of these physicians should serve as the source of a "second opinion" and not be actively involved in treating the patient on a daily basis. This second, or outside, medical consultant should independently determine that ECT is appropriate for a particular patient after conducting a physical examination. The second physician should also confirm that the patient is mentally sound enough to give informed consent to the procedure.

Patients in any age group are eligible for treatment with ECT; however, informed consent for patients under 18 must be given by a parent or legal guardian.

Description

Early history of ECT

Ugo Cerletti and Lucio Bini, who were two Italian physicians working in the 1930s, were the first to use electroconvulsive therapy to treat patients with severe

mental illnesses. Their first patient was a 39-year-old unidentifiable homeless man who had been found wandering through the railroad station in Rome, mumbling incoherently. The doctors were inspired to try the new method by a notion that intrigued psychiatrists in this period, who were desperate for useful therapies— namely, that epilepsy and schizophrenia never appeared in the same person at the same time. (It was later shown, however, that it is possible for the same individual to suffer from both disorders at the same time.) Since epilepsy causes **seizures**, psychiatrists in the 1930s reasoned that artificially induced seizures might cure schizophrenia. Some in the medical community were receptive to this approach because physicians were already using a variety of chemicals to produce seizures in patients. Unfortunately, many of their patients died or suffered severe injuries because the strength of the convulsions could not be well controlled.

As ECT became more widely used, many members of the general public and some in the psychiatric profession were opposed to its use. To them it seemed barbaric and crude. ECT joined **psychosurgery** as one of the most intensely distrusted psychiatric and neurological practices. Many people were frightened simply because ECT was called "shock treatment." Many assumed the procedure would be painful; others thought it was a form of electrocution; and still others believed it would cause brain damage. Unfavorable publicity in newspapers, magazines and movies added to these fears. Indeed, from the 1930s up through the 1960s, doctors and nurses did not explain either ECT or other forms of psychiatric treatment to patients and their families very often. Moreover, many critics had good reasons for opposing the procedure before it was refined. Neither anesthesia nor muscle relaxants were used in the early days of ECT. As a result, patients had violent seizures, and even though they did not remember them, the thought of the procedure itself seemed frightening. Even more unfortunately, this crude, early version of ECT was applied sometimes to patients who could never have benefited from ECT under any conditions.

As the procedures used with ECT became more refined, psychiatrists found that ECT was an effective treatment for schizophrenia and soon after, depression and bipolar disorder. The use of ECT, however, was phased out when antipsychotic and antidepressant drugs were introduced during the 1950s and 1960s. The psychiatric community reintroduced ECT several years later when patients who didn't respond to the new drugs stimulated a search by mental health professionals for effective, and if necessary, non-drug treatments. While the new psychotropic medications provided relief for untold thousands of patients who suffered greatly from their illnesses and would otherwise have been condemned to mental hospitals, the drugs unfortunately produced a number of side effects, some of which are irreversible. Another drawback is that some medications do not have a noticeable effect on the patient's mood for two to six weeks. During this time, the patient may be at risk for suicide. In addition, there are patients who do not respond to any medications or who have severe allergic reactions to them. For these individuals, ECT may be the only treatment that will help.

ECT in contemporary practice

Today, with the introduction of improved safety procedures, ECT is a remarkably safe and highly effective procedure. It is performed in both inpatient and outpatient facilities in specially equipped rooms with oxygen, suction, and cardiopulmonary resuscitation equipment readily available to deal with the rare emergency. A team of health care professionals, including a **psychiatrist**, an anesthesiologist, a respiratory therapist, and other assistants, is present throughout the entire procedure.

As of 2000, the American Psychiatric Association has renewed its set of guidelines, first published in 1990, for determining the appropriate use of ECT in patients suffering from depression. They state that patients qualify for ECT if they:

- cannot tolerate, or receive no significant benefit from, antidepressant medications
- have responded well to ECT treatments during past depressive episodes
- face a greater risk from taking antidepressant drugs than from undergoing ECT
- need treatment without delay to avoid suicide or other self-destructive acts

Administration of ECT

ECT is performed while the patient is unconscious. Unconsciousness is induced by a short-acting barbiturate such as methohexital (Brevital sodium), or another appropriate anesthetic drug. The drug is given intravenously. To prevent the patient from harming themselves during the convulsions or seizures induced by ECT, he or she is given succinylcholine (Anectine) or a similar drug that temporarily paralyzes the muscles. Because the patient's muscles are relaxed, the seizures will not produce any violent contractions of the limbs and torso. Instead, the patient lies quietly on the operating table. One of the patient's hands or feet, however, is tied off with a tourniquet before the muscle relaxant is given. The tourniquet prevents the muscles in this limb from being paralyzed like the muscles in other parts of the

This woman has been prepared to receive electroconvulsive therapy— an effective treatment for depression. This patient has been given a short-acting medication that induces unconsciousness, and another medication was given that relaxes her muscles so that the induced seizures will not produce any violent contractions. Instead, the patient lies quietly on the operating table. The rubber mouthpiece keeps her from biting down on teeth or her tongue during the seizure. *(Photo Reasearchers, Inc. Reproduced by permission.)*

patient's body. The hand or foot is used to monitor muscle movement induced by the electrical current applied to the brain.

A breathing tube is then inserted into the unconscious patient's airway and a rubber mouthpiece is inserted into the mouth to prevent him or her from biting down on teeth or tongue during the electrically induced convulsion. As the current is applied, brain activity is monitored using **electroencephalography**. These brain wave tracings tell the medical team exactly how long the seizure lasts. The contraction of muscles in the arm or leg not affected by the muscle relaxant also provides an indication of the seizure's duration.

The electrodes for ECT may be placed on both sides of the head (bilateral) or one side (unilateral). Physicians often use bilateral electrode placement during the first week or so of treatments. An electric current is passed through the brain by means of a machine specifically designed for this purpose. The usual dose of electricity is 70–150 volts for 0.1–0.5 seconds. In the first stage of the seizure (tonic phase), the muscles in the body that have not been paralyzed by medication contract for a period of 5–15 seconds. This is followed by the second stage of the seizure (clonic phase) that is characterized by twitching movements, usually visible only in the toes or in a non-paralyzed arm or leg. These are caused by alternating contraction and relaxation of these same muscles. This stage lasts approximately 10–60 seconds. The physician in charge will try to induce a seizure that lasts between one-half and two minutes. If the first application of electricity fails to produce a seizure lasting at least 25 seconds, another attempt is made 60 seconds later. The session is stopped if the patient has no seizures after three attempts. The entire procedure, from beginning to end, lasts about 30 minutes.

The absence of seizures is most commonly caused either by the patient's physical condition at the time of treatment or by the individual nature of human responses to drugs and other treatment procedures. Just as there are some patients who do not respond to one type of antidepressant medication but do respond to others, some patients do not respond to ECT.

The total number of ECT treatments that will be given depends on such factors as the patient's age, **diagnosis**, the history of illness, family support and response to therapy. Treatments are normally given every other day with a total of two to three per week. The ECT treatments are stopped when the patient's psychiatric symptoms show significant signs of improvement. Depending on the patient's condition, this improvement may happen in a few weeks or, rarely, over a six-month period. In most cases, patients with depression require between six and twelve ECT sessions.

Only rarely is ECT treatment extended beyond six months. In such infrequent cases, treatments are decreased from two to four per week after the first month to one treatment every month or so.

No one knows for certain why ECT is effective. Because the treatment involves passing an electric current through the brain, which is electrically excitable tissue, it is not surprising that ECT has been shown to affect many neurotransmitter systems. **Neurotransmitters** are chemical messengers in the nervous system that carry signals from nerve cell to nerve cell. The neurotransmitters affected by ECT include dopamine, norepinephrine, serotonin and GABA (gamma-aminobutyric acid).

Preparation

Patients and their relatives are prepared for ECT by viewing a videotape that explains both the procedure and the risks involved. The physician then answers any questions these individuals might have, and the patient is asked to sign an informed consent form. This form gives the doctor and the hospital legal permission to administer the treatment.

After the form has been signed, the doctor performs a complete physical examination and orders a number of tests that can help identify any potential problem. These tests may include a chest x ray; an electrocardiogram (EKG); a CT scan; a urinalysis; a spinal x ray; a brain wave tracing (EEG); and a complete blood count (CBC).

Some medications, such as lithium and a class of antidepressants known as monoamine oxidase inhibitors (MAOIs), should be discontinued for some time before ECT administration. Patients are instructed not to eat or drink for at least eight hours prior to the procedure in order to reduce the possibility of vomiting and choking. During the procedure itself, the members of the health care team closely monitor the patient's vital signs, including blood pressure, heart rate and oxygen content.

Aftercare

The patient is moved to a recovery area after an ECT treatment. Vital signs are recorded every five minutes until the patient is fully awake, which may take 15–30 minutes. The patient may experience some initial confusion, but this feeling usually disappears in a matter of minutes. The patient may complain of headache, muscle pain, or back pain, which can be quickly relieved by aspirin or another mild medication.

Following successful ECT treatments, patients with bipolar disorder may be given maintenance doses of lithium. Similarly, patients with depression may be given antidepressant drugs. These medications are intended to reduce the chance of relapse or the recurrence of symptoms. Some studies have estimated that approximately one-third to one-half of patients treated with ECT relapse within 12 months of treatment. After three years, this figure may increase to two-thirds. Follow-up care with medications for bipolar disorder or depression can reduce the relapse rate in the year following ECT treatment from 50% to 20%. Some patients might relapse because they do not respond well to the medications they take after their ECT sessions are completed. In some cases, patients who relapse may suffer from severe forms of depression that are especially difficult to treat by any method.

Risks

Recent advances in medical technology have substantially reduced the complications associated with ECT. These include memory loss and confusion. Persons at high risk of having complications following ECT include those with a recent heart attack, uncontrolled high blood pressure, brain tumors, and previous spinal injuries.

One of the most common side effects of electroconvulsive therapy is memory loss. Patients may be unable to recall events that occurred before and after treatment. Elderly patients, for example, may become increasingly confused and forgetful as the treatments continue. In a minority of individuals, memory loss may last for months. For the majority of patients, however, recent memories return in a few days or weeks.

Elderly patients receiving ECT may experience disturbances in heart rhythm; slow heartbeat (bradycardia); or rapid heartbeat (tachycardia); and an increased number of falls. As many as one-third of elderly patients may experience such complications following the procedure.

Normal results

ECT often produces dramatic improvement in the signs and symptoms of major depression, especially in

elderly patients. Sometimes the benefits are evident even during the first week of treatment.

A remarkable 90% of patients who receive ECT for depression respond positively. By contrast, only 70% respond as well when treated with antidepressant medications alone. While it is estimated that as many as 50% of successfully treated patients will have future episodes of depression, the prognosis for each episode of illness is good. Mania also often responds well to treatment with ECT. The picture is not as bright for schizophrenia, which is more difficult to treat and is characterized by frequent relapses.

Post-treatment confusion and forgetfulness are common, though disturbing, symptoms associated with ECT. Doctors and nurses must be patient and supportive by providing patients and their families with factual information about the nature and timeframe of the patient's recovery.

A few patients are placed on maintenance ECT. This term means that they must return to the hospital every one to two months as needed for an additional treatment. These persons are thus able to keep their illness under control and lead normal and productive lives.

Abnormal results

If an ECT-induced seizure lasts too long (more than two minutes) during the procedure, physicians will control it with an intravenous infusion of an anticonvulsant drug, usually **diazepam** (Valium).

Overall, ECT is a very safe procedure. The complications encountered are no different from those that may occur with the administration of anesthesia without ECT. There is no convincing evidence of long-term harmful effects from ECT. Researchers are continuing to explore its potential in treating other disorders.

Electroencephalography

Definition

Electroencephalography (EEG) is a neurological diagnostic procedure that records the changes in electrical potentials (**brain** waves) in various parts of the brain.

Purpose

The EEG is an important aid in the **diagnosis** and management of epilepsy and other seizure disorders, as well as in the diagnosis of brain damage related to trauma and diseases such as strokes, tumors, encephalitis, and drug and alcohol intoxication. The EEG is also useful in monitoring brain wave activity and in the determination of brain death. Research is active in determining the role of EEG in the diagnosis and management of **mental retardation**, **sleep disorders**, degenerative diseases such as **Alzheimer's disease** and Parkinson's disease, and in certain mental disorders such as **autism** and **schizophrenia**.

Precautions

The EEG should be administered, monitored, and interpreted only by a specially trained health professional. It is important to recognize that diagnosis should not be based on the EEG alone—the EEG represents an adjunct to the neurological history, examination, and other specialized studies. The EEG is an extremely sensitive instrument, and tracings can be greatly influenced by the actions and the physiologic status of the patient. It is important that the patient be properly prepared physically and psychologically in order to obtain an accurate and reliable record. Medications such as anticonvulsants, tranquilizers, stimulants—including coffee, tea, cola drinks—and alcohol should be withheld for at least 24–48 hours prior to the test. Inasmuch as hypoglycemia affects brain wave patterns, the patient is told not to withhold any meals.

Description

Brain function is associated with electrical activity, which is always accompanied by an electrical field. This field consists of two parts, the electrical field and the magnetic field, and is called an electromagnetic field. The electrical field is measured by surface electrodes and is recorded by the electroencephalogram. Prior to the recording session, approximately 16–20 electrodes are attached to the patient's scalp with a conductive washable paste, or collodion. Depending on the purpose of the EEG, implantable needle electrodes may be utilized, in which case the patient should be informed that there will be mild discomfort.

The patient lies on a bed, padded table, or comfortable reclining chair and is asked to remain quiet and relaxed during the approximately one hour that is usually required. A sleep recording up to three hours in duration is usually obtained if the diagnosis is a seizure disorder. Under certain conditions, various stimuli such as flashing lights or deep breathing may be utilized. In an ambulatory EEG recording, the patient is attached to a portable cassette recorder and goes about regular activities, usually for up to 24 hours.

Magnetoencephalography

Magnetoencephalography, a supplement to EEG, also uses an electroencephalogram to measure the patient's electrical field. In addition, however, the patient's magnetic field is also recorded to measure electrical activity. Every electrical current generates a magnetic field. The magnetic field is detected by an instrument called a biomagnetometer and recorded as a magnetoencephalograph (MEG). The information provided by the MEG is entirely different from that provided by **computed tomography** (CT), topographic encephalography, or **magnetic resonance imaging** (MRI)—imaging instruments that provide still, structural, and anatomical information. The information recorded by the MEG provides important supplemental information to that recorded by the encephalogram and, used together and conjointly, they both provide a much more complete and comprehensive idea of cerebral events. Using MEG, the brain can be observed "in action" rather than just being viewed as a still image.

KEY TERMS

Encephalitis—Inflammation of the brain.

Occipital—The occipital bone forms the back part of the skull.

Magnetoencephalography has been used to map the sensory and motor cortices of the brain, to determine the organization of the auditory center of the brain, and to study cognitive functions such as speech, memory, attention and consciousness. This information is critical for neurosurgical planning such as the removal of brain lesions. Thus, preoperative MEG is valuable in planning the surgical treatment of tumors and malformations. MEG can provide surgeons with real-time computer-generated images of deep-seated lesions that are essential before surgery. The quantitative EEG is also known by the acronym BEAM (brain electrical activity mapping).

Preparation

Prior to the EEG, the patient is given full instructions in the procedure, particularly about the avoidance of certain medications and food. In cases where a sleep EEG is anticipated, the patient may be requested to minimize sleep or stay awake the night before the procedure. Sedatives to induce sleep should be avoided, if possible.

Aftercare

No specific procedures or aftercare are required. Patients are advised to resume their usual activities, especially the resumption of medications that had been temporarily discontinued.

Risks

The primary risk of EEG is the production of a seizure in an epileptic patient. This may result from the

This woman is undergoing an electroencephalogram (EEG) to diagnose Alzheimer's disease. On the computer screen at the right are the colored scans of the electrical activity in her brain. Alzheimer's patients show a specific abnormality in their EEGs. *(Catherine Pouedras. Science Photo Library, National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)*

temporary discontinuation of anticonvulsant medication or from the provocation of a seizure by an epileptogenic stimulus such as flashing lights or deep breathing. Although the provocation of a seizure may serve to substantiate the diagnosis, all potential seizure patients should be carefully monitored to avoid injury in case a seizure does result.

Normal results

The rate, height, and length of brain waves vary depending on the part of the brain being studied, and every individual has an unique and characteristic brainwave pattern. Age and state of consciousness also cause changes in wave patterns. Several wave patterns have been identified:

- Alpha waves: Most of the recorded waves in a normal adult's EEG are the occipital alpha waves, which are best obtained from the back of the head when the subject is resting quietly with the eyes closed but not asleep. These waves, occurring typically in a pattern of eight to 13 cycles per second, are blocked by excitement or by opening the eyes.
- Beta waves: These waves, obtained from the central and frontal parts of the brain, are closely related to the sensory-motor parts of the brain and are also blocked by opening the eyes. Their frequency is in the range of 8–30 hertz (cycles per second).
- Delta waves: These are irregular, slow waves of 2–3 hertz and are normally found in deep sleep and in infants and young children. They indicate an abnormality in an awake adult.
- Theta waves: These are characterized by rhythmic, slow waves of 4–7 hertz.

Abnormal results

EEG readings of patients with epilepsy or other seizure disorders display bursts, or spikes, of electrical activity. In focal epilepsy, spikes are restricted to one hemisphere of the brain. If spikes are generalized to both hemispheres, multifocal epilepsy may be indicated.

Diagnostic brain-wave patterns of other disorders varies widely. The appearance of excess theta waves (four to eight cycles per second) may indicate brain injury. Brain wave patterns in patients with brain disease, mental retardation, and brain injury show overall slowing. A trained medical specialist should interpret EEG results in the context of the patient's medical history and other pertinent medical test results.

Elimination disorders

Definition

Elimination disorders are disorders that concern the elimination of feces or urine from the body. The causes of these disorders may be medical or psychiatric.

KEY TERMS

Constipation—Difficult bowel movements caused by the infrequent production of hard stools.

Feces—Waste products eliminated from the large intestine; excrement.

Incontinence—The inability to control the release of urine or feces.

Laxative—Substance or medication that encourages a bowel movement.

Stools—Feces, bowel movements.

Description

The American Psychiatric Association recognizes two elimination disorders, **encopresis** and **enuresis**. Encopresis is an elimination disorder that involves repeatedly having bowel movements in inappropriate places after the age when bowel control is normally expected. Encopresis is also called fecal incontinence. Enuresis, more commonly called bed-wetting, is an elimination disorder that involves release of urine into bedding, clothing, or other inappropriate places. Both of these disorders can occur during the day (diurnal) or at night (nocturnal). They may be voluntary or involuntary. Encopresis and enuresis may occur together, although most often they occur separately.

Elimination disorders may be caused by a physical condition, a side effect of a drug, or a psychiatric disorder. It is much more common for elimination disorders to be caused by medical conditions than psychiatric ones. In most cases in which the cause is medical, the soiling is unintentional. When the causes are psychiatric, the soiling may be intentional, but it is not always so.

Encopresis

Medical causes of encopresis are usually related to chronic constipation. As hard feces build up in the large intestine, the bowel is stretched out of shape. This allows liquid feces behind the hard stool to involuntarily leak out and stain clothing. Other medical causes of encopresis include malformations of the bowel and side effects of medication. Laxatives (medications that relieve constipation), drugs that kill some of the good bacteria in the intestines, and drugs that increase contractions in the intestines can all cause involuntary encopresis. Pediatricians or family physicians treat almost all cases of encopresis having medical causes. In cases of prolonged involuntary soiling,

children may develop feelings of shame and embarrassment, leading to low self-esteem.

Psychiatric causes of encopresis are not as clear. A few children may experience encopresis because of fear of the toilet or because their toilet training was either overly pressured or irregular and incomplete. Older children may soil intentionally, sometimes smearing the feces on wall or clothing or hiding feces around the house. Children who show this pattern of soiling behavior often have clinical behavior problems such as **conduct disorder** or **oppositional defiant disorder**. About one-quarter of children who soil intentionally also have enuresis.

Enuresis

Enuresis also has both medical and psychiatric causes. Primary enuresis occurs when a child has never established bladder control. Medical causes of primary enuresis are often related to malformations of the urinary system, developmental delays, and hormonal imbalances that affect the ability to concentrate urine. There appears to be a genetic component to primary enuresis, since the condition tends to run in families. Primary enuresis may also be caused by psychological stressors such as family instability or erratic toilet training.

Secondary enuresis occurs when a child has established good bladder control for a substantial period, then begins wetting again. Involuntary secondary enuresis is thought to be brought on by life stresses. For example, it is common for young children to begin wetting the bed after moving to a new house or having a new sibling enter the family. Voluntary enuresis is not common. Like voluntary encopresis, it is associated with psychiatric conditions such as conduct disorder and oppositional defiant disorder.

Treatment and prognosis

Most children outgrow their elimination disorders successfully by the time they are teens, with the exception of those children whose elimination disorders are symptoms of other psychiatric disturbances.

Encopresis is treated with stool softeners or laxatives and by instituting regular bowel evacuation patterns. Enuresis is treated by **behavior modification** including changing nighttime toileting habits. The least expensive and most effective method is by having the child sleep on a special pad that sets off an alarm when the pad becomes wet. This wakes the child and allows him to finish relieving in the toilet. Eventually he awakes without assistance before wetting. Drugs can also help in the treatment of enuresis, although relapse is common after they are stopped. Secondary enuresis caused by **stress** is treated by resolving the stress. **Psychotherapy** is usually not needed, although it may be helpful to children who develop feelings of shame associated with their elimination disorders. Adults can help children avoid shame and embarrassment by treating elimination accidents matter-of-factly and kindly.

Children with voluntary elimination disorders are treated for the diagnosed psychiatric problem associated with the elimination disorder using behavior modification, drugs, and other psychiatric interventions.

Encopresis

Definition

Encopresis is an elimination disorder that involves repeatedly having bowel movements in inappropriate places after the age when bowel control is normally expected. Encopresis is also called "soiling" or "fecal incontinence."

Description

By four years of age, most children are toilet trained for bowel movements. After that age, when inappropriate bowel movements occur regularly over a period of several months, a child may be diagnosed with encopresis. Encopresis can be intentional on unintentional. Intentional soiling is associated with several psychiatric disorders. Involuntary or unintentional soiling is often the result of constipation.

Causes and symptoms

The only symptom of encopresis is that a person has bowel movements in inappropriate places, such as in clothing or on the floor. This soiling is not caused by taking laxatives or other medications, and is not due to a disability or physical defect in the bowel. There are two main types of encopresis, and they have different causes.

Involuntary encopresis

With involuntary encopresis, a person has no control over elimination of feces from the bowel. The feces is semi-soft to almost liquid, and it leaks into clothing without the person making any effort to expel it. Leakage usually occurs during the day when the person is active, and ranges from infrequent or almost continuous.

Involuntary soiling usually results from constipation. A hard mass of feces develops in the large intestine and is not completely expelled during a regular bowel movement in the toilet. This mass then stretches the large intestine out of shape, allowing liquid feces behind it to leak out. Up to 95% of encopresis is involuntary.

Although involuntary encopresis, called by the American Psychiatric Association (APA) encopresis with constipation and overflow incontinence, is caused by constipation, the constipation may be the result of psychological factors. Experiencing a stressful life event, harsh toilet training, toilet fear, or emotionally disturbing events can cause a child to withhold bowel movements or become constipated. Historically, children separated from their parents during World War II are reported to have shown a high incidence of encopresis, indicating that psychological factors play a role in this disorder.

Voluntary encopresis

A person with voluntary encopresis has control over when and where bowel movements occur and chooses to have them in inappropriate places. Constipation is not a factor, and the feces is usually a normal consistency. Often feces is smeared in an obvious place, although sometimes it is hidden around the house. The APA classifies voluntary encopresis as encopresis without constipation and overflow incontinence.

KEY TERMS

Feces—Waste products eliminated from the large intestine; excrement.

Incontinence—The inability to control the release of urine or feces.

Laxative—Substance or medication that encourages a bowel movement.

Stools—Feces; bowel movements.

In young children, voluntary encopresis may represent a power struggle between the child and the caregiver doing the toilet training. In older children, voluntary encopresis is often associated with **oppositional defiant disorder** (ODD), **conduct disorder**, sexual **abuse**, or high levels of psychological stressors.

Demographics

Encopresis occurs in 1–3% of children and is seen more often in boys than in girls. The frequency of encopresis appears to be independent of social class, and there is no evidence that it runs in families.

Diagnosis

To receive an APA **diagnosis** of encopresis, a child must have a bowel movement, either intentional or accidental, in an inappropriate place at least once a month for a minimum of three months. In addition, the child must be chronologically or developmentally at least four years old, and the soiling cannot be caused by illness, medical conditions (such as chronic diarrhea, spina bifida, anal stenosis, etc.), medications, or disabilities. However, it may be caused by constipation.

Treatments

Involuntary encopresis is treated by addressing the cause of the constipation and establishing soft, pain-free stools. This can include:

- increasing the amount of liquids a child drinks
- adding high-fiber foods to the diet
- short-term use of laxatives or stool softeners
- emptying the large intestine by using an enema
- establishing regular bowel habits

Once the constipation is resolved, involuntary encopresis normally stops.

Treatment of voluntary encopresis depends on the cause. When voluntary encopresis results from a power struggle between child and adult, it is treated with **behavior modification**. In addition to taking the steps listed above to ensure a soft, pain-free stool, the adult should make toileting a pleasant, pressure-free activity. Some experts suggest transferring the initiative for toileting to the child instead of constantly asking him/her to use the toilet. Others recommend toileting at scheduled times, but without pressure to perform. In either case, success should be praised and failure treated in a matter-of-fact manner. If opposition to using the toilet continues, the family may be referred to a child **psychiatrist** or a pediatric **psychologist**.

With older children who smear or hide feces, voluntary encopresis is usually a symptom of another more serious disorder. When children are successfully treated for the underlying disorder with psychiatric interventions, behavior modification, and education, the encopresis is often resolved.

Prognosis

Since 80–95% of encopresis is related to constipation, the success rate in resolving involuntary encopresis is high, although it may take time to establish good bowel habits and eliminate a reoccurrence of constipation. The success rate is also good for younger children in a power struggle with adults over toileting, although the results may be slow. The prognosis for older children with associated behavioral disorders is less promising and depends more on the success of resolving those problems than on direct treatment of the symptoms of encopresis.

Prevention

Power struggles during toilet training that lead to encopresis can be reduced by waiting until the child is developmentally ready and interested in using the toilet. Toilet training undertaken kindly, calmly, and with realistic expectations is most likely to lead to success. Successes should be rewarded and failures accepted. Once toilet training has been established, encopresis can be reduced by developing regular bowel habits and encouraging a healthy, high-fiber diet.

Energy therapies

Definition

Energy therapies is a collective term used to refer to a variety of alternative and complementary treatments based on the use, modification, or manipulation of energy fields. Most energy therapies presuppose or accept the theory that matter and energy are not exclusive opposites, but that matter is simply a denser form of energy that is more easily perceived by the senses. Some energy therapies are associated with systems of traditional Indian or Chinese medicine that are thousands of years old; others draw upon contemporary scientific theories. Energy therapies can be divided for purposes of discussion into two groups: those that utilize energy fields located in, affecting, or emanating from the human body (biofield therapies); and those that use electromagnetic fields in unconventional ways. In addition, there are energy therapies that combine biofield therapy with some aspects of bodywork— Breema, polarity therapy, and qigong are examples of this combined approach.

Energy therapies vary widely in their understanding of qualifications to be a healer. Some have credentialing or training programs; others do not. Some practitioners of energy therapy believe that all or most people have the capacity to be healers; others regard the ability to use or direct healing energies as a gift or charism that is given only to people who are "chosen" or unusually spiritual.

Although energy therapies are often associated with either Eastern or so-called "New Age" belief systems, most do not expect people in need of healing to give up mainstream Western religious practice or allopathic medical/psychiatric treatments.

KEY TERMS

Aura—An energy field that is thought to emanate from the human body and to be visible to people with special psychic or spiritual powers.

Ayurvedic medicine—The traditional medical system of India. Ayurvedic treatments include diet, exercises, herbal treatments, meditation, massage, breathing techniques, and exposure to sunlight.

Biofield therapies—A subgroup of energy therapies that make use of energy fields (biofields) thought to exist within or emanate from the human body. Biofield therapies include such approaches as Reiki, therapeutic touch, qigong, and polarity balancing.

Bodywork—Any technique involving hands-on massage or manipulation of the body.

Breema—An alternative therapy that originated in California in the 1980s. Breema combines biofield therapy with certain elements of chiropractic and bodywork.

Chakra—One of the seven major energy centers in the body, according to traditional Indian yoga.

Endorphins—A group of peptide compounds released by the body in response to stress or traumatic injury. Endorphins react with opiate receptors in the brain to reduce or relieve pain.

Kundalini—In Indian yoga, a vital force or energy at the base of the spine that is activated or released by certain yoga postures or breathing techniques. This release is called the "awakening" of the kundalini. Some Westerners have had kundalini experiences that were diagnosed as psychotic episodes or symptoms of schizophrenia.

Meridians—In traditional Chinese medicine, a network of pathways or channels that convey qi, or vital energy, through the body.

Polarity therapy—A form of energy therapy influenced by Ayurvedic medicine that integrates bodywork with diet, home exercises, and self-awareness techniques. It is sometimes called polarity balancing.

Prana—The Sanskrit word for vital energy, roughly equivalent to qi in traditional Chinese medicine.

Qi—The traditional Chinese term for vital energy or the life force. The word is also spelled "ki" or "chi" in English translations of Japanese and Chinese medical books.

Qigong—A traditional form of Chinese energy therapy that includes physical exercises, breathing techniques, postures, and mental discipline. Internal qigong refers to exercises practiced to maintain one's own health and vitality; external qigong refers to the transfer of energy from a qigong master to another person for healing purposes. External qigong is also known as medical qigong.

Reiki—A form of energy therapy that originated in Japan. Reiki practitioners hold their hands on or slightly above specific points on the patient's body in order to convey universal life energy to that area for healing.

Therapeutic touch (TT)—An American form of energy therapy based on the ancient tradition of the laying-on of hands. TT is thought to work by removing energy blockages or disturbances from the patient's aura.

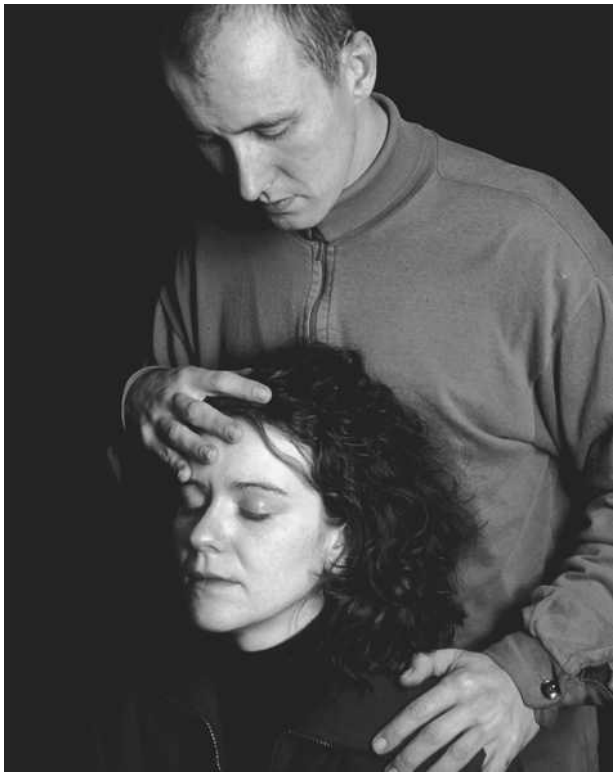
Purpose

The purpose of energy therapies can be broadly defined as the healing of mental or physical disorders by rebalancing the energy fields in the human body or by drawing upon spiritual energies or forces for such healing. Some energy therapies include internal **detoxification** or release of trauma-related memories as additional purposes.

Precautions

In general, persons who are interested in Breema, qigong, or any form of energy therapy that involves vigorous physical exercise or bodywork should seek the advice of a qualified medical practitioner before starting such a program. This precaution is particularly important for persons with chronic heart or lung disease, persons recovering from surgery or acute illness, or persons with arthritis or other disorders that affect the muscles and joints.

Some forms of energy therapy may produce unexpected or startling psychological reactions. For example, a type of psychospiritual energy referred to as Kundalini in Indian **yoga** sometimes produces experiences of spiritual crisis that may be interpreted by mainstream psychiatrists as symptoms of **schizophrenia** or another psychotic disorder. Practitioners of Reiki healing have reported instances of patients feeling tingling sensations, "spaciness," an "out of body" sensation, sudden warmth,



Woman undergoing therapeutic touch. In this form of healing, the therapist channels healing energy into the patient in order to cure the imbalances that cause physical or mental illness. *(Cordelia Molloy/ Science Photo Library. Photo Researchers, Inc. Reproduced by permission.)*

or similar experiences. As a rule, people in treatment for any mental condition or disorder should consult their therapist before beginning any form of energy treatment. This precaution is particularly important for patients diagnosed with **post-traumatic stress disorder** or a dissociative disorder, and for those who are easily hypnotized. It is also a good idea to find out as much as possible about the background and basic beliefs associated with a specific energy therapy, including the training or credentialing of its practitioners.

Description

Brief descriptions of some of the better known energy therapies follow.

Therapeutic touch

Therapeutic touch, or TT, is a form of energy therapy that developed in the United States. It is a noninvasive method of healing derived from an ancient laying-on of hands technique. In TT, practitioners alter the patient's energy field through a transfer of energy from their hands to the patient. Therapeutic touch was developed in 1972 by Dora Kunz, a psychic healer, and Dolores Krieger, a professor of nursing at New York University. The principle behind TT is restoration of balance or harmony to the human energy field, or aura, that is thought to extend several inches to several feet from the body. When illness occurs, it creates a disturbance or blockage in the vital energy field. The TT practitioner uses her/his hands to discern the blockage or disturbance. Although the technique is called "therapeutic touch," there is generally no touching of the client's physical body, only his or her energetic body or field. TT is usually performed on fully clothed patients who are either lying down on a flat surface or sitting up in a chair.

A therapeutic touch session consists of five steps or phases. The first step is a period of **meditation** on the practitioner's part, to become spiritually centered and energized for the task of healing. The second step is assessment or discernment of the energy imbalances in the patient's aura. In this step, the TT practitioner holds his or her hands about 2–3 inches above the patient's body and moves them in long, sweeping strokes from the patient's head downward to the feet. The practitioner may feel a sense of warmth, heaviness, tingling, or similar cues, as they are known in TT. The cues are thought to reveal the location of the energy disturbances or imbalances. In the third step, known as the unruffling process, the practitioner removes the energy disturbances with downward sweeping movements. In the fourth step, the practitioner serves as a channel for the transfer of universal energy to the patient. The fifth step consists of smoothing the patient's energy field and restoring a symmetrical pattern of energy flow. After the treatment, the patient rests for 10–15 minutes.

Although therapeutic touch has become a popular alternative or complementary approach in some schools of nursing in the United States and Canada, acceptance by the mainstream medical community varies. Many hospitals permit nurses and staff to perform TT on patients at no extra charge. On the other hand, however, therapeutic touch became national news in April 1998 when an elementary-school student carried out research for a science project that questioned its claims. Twenty-one TT practitioners with experience ranging from one to 27 years were blindfolded and asked to identify whether the investigator's hand was closer to their right hand or their left. Placement of the investigator's hand was determined by flipping a coin. The TT practitioners were able to identify the correct hand in only 123 (44%) of 280 trials, a figure that could result from random chance alone. Debate about the merits of TT filled the editorial pages of the *Journal of the American Medical Association* for nearly a year after the news reports, and continues to this day.

Qigong

Qigong is a form of Chinese energy therapy that is usually considered a martial art by most Westerners. It is better understood, however, as an ancient Chinese system of postures, exercises, breathing techniques and meditations. Its techniques are designed to improve and enhance the body's *qi*. According to traditional Chinese philosophy and medicine, qi is the fundamental life energy responsible for human health and vitality. Qi travels through the body along channels called meridians. There are twelve main meridians in humans. Each major body organ has qi associated with it, and each organ interacts with particular emotions on the mental level. Qigong techniques are designed to improve the balance and flow of energy throughout the meridians, and to increase the overall quantity and volume of a person's qi.

In the context of energy therapy, qigong is sometimes divided into internal and external qigong. Internal qigong refers to a person's practice of qigong exercises to maintain his or her own health and vitality. Some qigong master teachers are renowned for their skills in external qigong, in which the energy from one person is passed on to another for healing. Chinese hospitals use medical qigong along with herbs, **acupuncture** and other techniques of traditional Chinese medicine. In these hospitals, qigong healers use external qigong and also design specific internal qigong exercises for the patients' health problems.

Reiki

Reiki is a holistic alternative therapy based on Eastern concepts of energy flow and the seven chakras (energy centers) in the human body. Reiki was formulated by a Japanese teacher, Mikao Usui, around 1890, based on Vajrayana (Tibetan) Buddhism, but incorporates meditation techniques, beliefs, and symbols that are considerably older. It is distinctive among energy therapies in its emphasis on self-healing, its spiritual principles, and its accreditation of healers through a system of initiation. Reiki practitioners participate in the healing of emotional and spiritual as well as physical pain through the transmission of universal life energy, called "rei-ki" in Japanese. It is believed that ki flows throughout the universe, but that Reiki connects humans in a more direct way to the universal source. Reiki is used for the healing of animals as well as people. As of 2002, a research team at the University of Michigan is studying the effectiveness of Reiki in treating chronic pain in patients with diabetic neuropathy. Various other studies are also underway in the United States and Canada, some examining the efficacy of the therapy in coping with pain and anxiety.

Although Reiki involves human touch, it is not massage therapy. The patient lies on a table fully clothed except for shoes while the practitioner places her or his hands over the parts of the body and the chakras in sequence. The hands are held palms downward with the fingers and thumbs extended. If the person is in pain or cannot turn over, the practitioner may touch only the affected part(s). Silence or music appropriate for meditation is considered essential to the treatment. Reiki healers practice daily self-healing, in which they place their hands in traditional positions on their own bodies. They may use touch, or distant/non-touch.

Reiki healers are initiated into three levels of practice through attunements, which are ceremonies in which teachers transmit the hand positions and "sacred" symbols. Reiki I healers learn the basic hand positions and can practice direct physical, emotional or mental healing on themselves and others. Reiki II healers are taught the symbols that empower them to do distance or absentee healing. In Reiki III the healer makes a commitment to become a master teacher and do spiritual healing.

Polarity therapy

Polarity therapy, which is sometimes called polarity balancing, is a biofield therapy that resembles Reiki in its emphasis on energy flow, human touch, and the energy centers (chakras) in the human body. Polarity therapy was developed by Dr. Randolph Stone (1890-1981), an American chiropractor and naturopath. It integrates bodywork with diet, yoga-based exercise, and self-awareness techniques to release energy blockages in the patient's body, mind, or feelings. Polarity theory divides the body into three horizontal and four vertical zones (right, left, front, and back), each having a positive, negative, or neutral charge. Energy currents in the zones are correlated with five energy centers in the body corresponding to the five elements (ether, air, fire, water, and earth) of Ayurvedic medicine.

Polarity therapy can be done one-on-one or with a group of practitioners working on the patient. The therapist as well as the patient removes shoes. The patient lies fully dressed except for shoes on a massage table or bed, or on the floor. The practitioner takes the patient's history, checks reflexes and touches body parts to determine energy blocks. Polarity therapy uses three levels of touch: no touch (hands held above the body, touching only the energy fields); light touch; and a deep, massaging touch. The therapist balances energy currents in the patient's body by placing his or her "plus" hand on "negative" body parts and vice versa. Polarity therapy involves rocking the patient's body and holding the head as well as more usual massage techniques. It takes about four polarity sessions

In this Reiki treatment, the therapist is channelling energy into the head of the woman being treated. *(Roger Ressmeyer/Corbis. Reproduced by permission.)*

to treat most conditions, with each session lasting about an hour. After a course of treatment, the polarity practitioner usually suggests drinking plenty of liquids for one to two weeks together with other dietary changes as part of a general internal cleansing or detoxification program. Polarity yoga (stretching exercises) is prescribed for the patient's regular workouts at home.

Breema

Breema is a form of body movement energy therapy that combines elements of bodywork, yoga, chiropractic, and New Age philosophy. Breema began in California in 1980. Its founder is Dr. Jon Schreiber, a graduate of Palmer College of Chiropractic. The Breema Health and Wellness Center was opened in Oakland, California, in 1981. The principles of Breema are intended to free people from the conceptual body, defined as "the ideas and images of our body that we carry in our mind." The aim of Breema "is to increase vitality, not to fight sickness, and to create an atmosphere which allows the body to move toward a natural state of balance." A person receiving a Breema treatment works with an instructor or practitioner through a series of individualized exercises on a padded floor. The instructors and practitioners are certified by the Breema Center in Oakland.

Decrystallization is an important part of Breema therapy. According to Breema, decrystallization is a process in which the body is helped to release deeply held, or "crystallized," patterns of chronic discomfort, tension, or emotional pain. As the body releases its crystallizations, its "core energetic patterns" are balanced and realigned. A decrystallization program consists of one or more Breema treatments per week for a year. It includes a set of personalized self-Breema exercises.

Electromagnetic therapies

Electromagnetic therapies cover a variety of treatments that use a source of physical energy outside the body— most often magnets or electromagnetic field stimulation— to treat a range of musculoskeletal disorders. Some forms of magnetic therapy, such as bracelets, gloves, shoe inserts, and similar items containing small magnets meant to be worn near the affected body part, can be self-administered. This form of magnetic therapy

has become quite popular among professional athletes and "weekend warriors" to relieve soreness in joints and muscles from over exercise. At present, there are two hypothetical explanations of the effectiveness of magnetic therapy. One theory maintains that the magnets stimulate nerve endings in the skin surface to release endorphins, which are pain-relieving chemicals produced by the body in response to **stress** or injury. According to the second hypothesis, the magnets attract certain ions (electrically charged molecules) in the blood, which serves to increase the blood flow in that area of the body. The increased blood flow then relieves the tissue swelling and other side effects of over exercise that cause pain.

Other forms of electromagnetic therapy require special equipment and cannot be self-administered. These forms of treatment are most commonly used by naturopathic practitioners. One form, called transcranial magnetic stimulation, is used in the treatment of depression. Another form, called pulsed electromagnetic field stimulation, has been shown to be effective in the treatment of osteoarthritis.

Preparation

Most forms of energy therapy require little preparation on the patient's part except for the wearing of loose and comfortable clothes. Patients are asked to remove jewelry before a polarity balancing treatment and to remove eyeglasses and shoes prior to Reiki treatment. Qigong should not be practiced on either a full or a completely empty stomach.

Aftercare

Aftercare for therapeutic touch and Reiki usually involves a few moments of quiet rest to maximize the benefits of treatment. Aftercare for polarity therapy includes increased fluid intake for one to two weeks and other dietary adjustments that may be recommended by the practitioner.

Risks

There are no known risks associated with therapeutic touch, or polarity balancing. Using Reiki, precautions should be taken clients diagnosed with schizophrenia, **psychosis**, dissociative disorder, manic/depressive (bipolar) or borderline personality. The risk of physical injury from the exercises involved in Breema or qigong are minimal for patients who have consulted their primary physician beforehand and are working with a qualified instructor.

Mild headache has been reported as a side effect of transcranial magnetic stimulation. No side effects have been associated with self-administered magnetic therapy.

Normal results

Normal results for energy therapies include increased physical vitality, lowered blood pressure, a sense of calm or relaxation, improved sleep at night, and a strengthened immune system. Some persons report pain relief and speeded-up healing of wounds from magnetic therapy, Reiki, and qigong.

Abnormal results

Abnormal results from energy therapies include physical injury, severe headache, dizziness, depressed mood, or increased anxiety.

Enuresis

Definition

Enuresis, more commonly called bed-wetting, is a disorder of elimination that involves the voluntary or involuntary release of urine into bedding, clothing, or other inappropriate places. In adults, loss of bladder control is often referred to as urinary incontinence rather than enuresis; it is frequently found in patients with late-stage Alzheimer's disease or other forms of **dementia**.

Description

Enuresis is a condition that has been described since 1500 B.C. People with enuresis wet their bed or release urine at other inappropriate times. Release of urine at night (nocturnal enuresis) is much more common than daytime, or diurnal, wetting. Enuresis commonly affects young children and is involuntary. Many cases of enuresis clear up by themselves as the child matures, although some children need behavioral or physiological treatment in order to remain dry.

There are two main types of enuresis in children. Primary enuresis occurs when a child has never established bladder control. Secondary enuresis occurs when a person has established bladder control for a period of six months, then relapses and begins wetting. To be diagnosed with enuresis, a person must be at least five years old or have reached a developmental age of five years. Below this age, problems with bladder control are considered normal.

Causes and symptoms

Symptoms

The symptoms of enuresis are straightforward—a person urinates in inappropriate places or at inappropriate times. The causes of enuresis are not so clear. A small number of children have abnormalities in the anatomical structure of their kidney or bladder that interfere with bladder control, but normally the cause is not the physical structure of the urinary system. A few children appear to have to have a lower-than-normal ability to concentrate urine, due to low levels of antidiuretic hormone (ADH). This hormone helps to regulate fluid balance in the body. Large amounts of dilute urine cause the bladder to overflow at night. For the majority of bedwetters, there is no single clear physical or psychological explanation for enuresis.

Causes in children

The fourth edition of the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revision, or (*DSM-IV-TR*), does not distinguish between children who wet the bed involuntarily and those who voluntarily release urine. Increasingly, however, research findings suggest that voluntary and involuntary enuresis have different causes.

Involuntary enuresis is much more common than voluntary enuresis. Involuntary enuresis may be categorized as either primary or secondary. Primary enuresis occurs when young children lack bladder control from infancy. Most of these children have urine control problems only during sleep; they do not consciously, intentionally, or maliciously wet the bed. Research suggests that children who are nighttime-only bed wetters may have a nervous system that is slow to process the feeling of a full bladder. Consequently, these children do not wake up in time to relieve themselves. In other cases, the child's enuresis may be related to a sleep disorder.

Children with diurnal enuresis wet only during the day. There appear to be two types of daytime wetters. One group seems to have difficulty controlling the urge to urinate. The other group consciously delays urinating until they lose control. Some children have both diurnal and nocturnal enuresis.

Secondary enuresis occurs when a child has stayed dry day and night for at least six months, then returns to wetting. Secondary enuresis usually occurs at night. Many studies have been done to determine if there is a psychological component to enuresis. Researchers have found that secondary enuresis is more likely to occur after a child has experienced a stressful life event such as the birth of a sibling, divorce or death of a parent, or moving to a new house.

Several studies have investigated the association of primary enuresis and psychiatric or behavior problems. The results suggest that primary nocturnal enuresis is *not* caused by psychological disorders. Bed-wetting runs in families, however, and there is strong evidence of a genetic component to involuntary enuresis.

Unlike involuntary enuresis, voluntary enuresis is not common. It is associated with such psychiatric disorders as **oppositional defiant disorder**, and is substantially different from ordinary nighttime bed-wetting. Voluntary enuresis is always secondary.

Causes in adults

Enuresis or urinary incontinence in elderly adults may be caused by loss of independent control of body functions resulting from dementia, bladder infections, uncontrolled diabetes, side effects of medications, and weakened bladder muscles. Urinary incontinence in adults is managed by treatment of the underlying medical condition, if one is present; or by the use of adult briefs with disposable liners.

KEY TERMS

Bladder—A muscular sac in the lower abdomen that holds urine until it is discharged from the body.

Elimination—The medical term for expelling waste from the body.

Enuresis—The inability to control urination; bed-wetting.

Primary enuresis—Bed-wetting in a child who has not yet developed bladder control.

Secondary enuresis—Bed-wetting in a child who has established bladder control but has begun to wet the bed again, usually as the result of emotional stress.

Urinary incontinence—A term that is sometimes used for enuresis in adults. Urinary incontinence is often found in patients with late-stage Alzheimer's disease or other adult-onset dementias.

Urinary system—The kidney, urethra, bladder, and associated organs that process urine and eliminate it from the body.

Demographics

Enuresis is a problem of the young and is more common in boys than girls. At age five, about 7% of boys and 3% of girls have enuresis. This number declines steadily in older children; by age 18, only about 1% of adolescents experience enuresis. Studies done in several countries suggest that there is no apparent cultural influence on the incidence of enuresis in children. On the other hand, the disorder does appear to run in families; children with one parent who wet the bed as a child are five to seven times more likely to have enuresis than children whose parents did not have the disorder in childhood.

Diagnosis

Enuresis is most often diagnosed in children because the parents express concern to the child's doctor. The pediatrician or family physician will give the child a physical examination to rule out medical conditions that may be causing the problem, including structural abnormalities in the child's urinary tract. The doctor may also rule out a sleep disorder as a possible cause. In many cases the pediatrician can reassure the child's parents and give them helpful advice.

According to the American Psychiatric Association, to make a **diagnosis** of enuresis, a child must have reached the chronological or developmental age of five. Inappropriate urination must occur at least twice a week for three months; or the frequency of inappropriate urination must cause significant distress and interfere with the child's school and/or social life. Finally, the behavior cannot be caused exclusively by a medical condition or as a side effect of medication.

Treatments

Treatment for enuresis is not always necessary. About 15% of children who have enuresis outgrow it each year after age six. When treatment is desired, a physician will rule out obvious physical causes of enuresis through a physical examination and medical history. Several different treatment options are then available.

Behavior modification

Behavior modification is often the treatment of choice for enuresis. It is inexpensive and has a success rate of about 75%. The child's bedding includes a special pad with a sensor that rings a bell when the pad becomes wet. The bell wakes the child, who then gets up and goes to the bathroom to finish emptying his bladder. Over time, the child becomes conditioned to waking up when the bladder feels full.

Once this response is learned, some children continue to wake themselves help from without the alarm, while others are able to sleep all night and remain dry. A less expensive behavioral technique involves setting an alarm clock to wake the child every night after a few hours of sleep, until the child learns to wake up spontaneously. In trials, this method was as effective as the pad-and-alarm system. A newer technique involves an ultrasound monitor worn on the child's pajamas. The monitor can sense bladder size, and sets off an alarm once the bladder reaches a predetermined level of fullness. This technique avoids having to change wet bed pads.

Other behavior modifications that can be used alone or with the pad-and-alarm system include:

- restricting liquids starting several hours before bedtime
- waking the child up in the night to use the bathroom
- teaching urinary retention techniques
- giving the child positive **reinforcement** for dry nights and being sympathetic and understanding about wet nights

Treatment with medications

There are two main drugs for treating enuresis. **Imipramine**, a tricyclic antidepressant, has been used since the early 1960s. It is not clear why this antidepressant is effective in treating enuresis when other antidepressants are not. Desmopressin acetate (DDAVP) has been widely used to treat enuresis since the 1990s. It is available as a nasal spray or tablet. Both imipramine and DDAVP are very effective in preventing bed-wetting, but have high relapse rates if medication is stopped.

Alternative therapies

Some success in treating bed-wetting has been reported using hypnosis. When hypnosis works, the results are seen within four to six sessions. **Acupuncture** and massage have also been used to treat enuresis, with inconclusive results.

Psychotherapy

Primary enuresis does not require **psychotherapy**. Secondary enuresis, however, is often successfully treated with therapy. The goal of the treatment is to resolve the underlying stressful event that has caused a relapse into bed-wetting. Unlike children with involuntary enuresis, children who intentionally urinate in inappropriate places often have other serious psychiatric disorders. Enuresis is usually a symptom of another disorder. Therapy to treat the underlying disorder is essential to resolving the enuresis.

Prognosis

Enuresis is a disorder that most children outgrow. For those who do receive treatment, the overall success rate of behavioral therapy is 75%. The short-term success rate with drug treatments is even higher than with behavioral therapy. Drugs do not, however, eliminate the enuresis. Many children who take drugs to control their bed-wetting relapse when the drugs are stopped.

Prevention

Although enuresis cannot be prevented, one side effect of the disorder is the shame and social embarrassment it causes. Children who wet may avoid sleepovers, camp, and other activities where their bed-wetting will become obvious. Loss of these opportunities can cause a loss of self-esteem, social isolation, and adjustment problems. A kind, low-key approach to enuresis helps to prevent these problems.

Erectile dysfunction

Definition

Erectile dysfunction (ED) may be defined as the consistent inability to achieve or maintain an erection sufficient to permit satisfactory sexual intercourse. The word "consistent" is included in the definition because most men experience transient episodes of ED that are temporary and usually associated with **fatigue**, anger, depression or other stressful emotions. The use of the formerly used term "impotence" has been virtually abandoned because of its inherent **stigma** of weakness and lack of power.

Erectile dysfunction can occur as part of several mental disorders recognized by the mental health professional's manual, the *Diagnostic and Statistical Manual of Mental Disorders,* often shortened to the *DSM.* ED is the main symptom in the disorder the manual calls "male erectile disorder." ED can also be a symptom of other disorders, such as sexual dysfunction due to a general medical condition or substance-induced sexual dysfunction. In this entry, however, ED is examined and discussed as its own medical entity, and not within the strict guidelines of the *DSM*.

Description

First, it may be useful to understand the mechanisms of normal penile erection. Penile erection occurs essentially when the penis becomes engorged with blood. The anatomical compartments (two corpora cavernosa and one corpus spongiosum) are capable of being distended with seven times their normal amount of blood. When this occurs in association with relaxation of the penile muscles, erection results.

The sequence of events resulting in penile erection is complex. It is usually initiated by sexual arousal stimuli arising in the **brain** as a result of visual, auditory or olfactory sensations or erotic thoughts. Tactile (touch) sensations of the penis acting through the spinal cord play a similar role. Sexual arousal results in the release of a chemical (nitric oxide) from specialized cells. Nitric oxide causes the formation of a substance (cyclic glutamine monophosphate or cGMP) that is responsible for dilating the blood vessels of the penis and relaxing its muscles, thus allowing for an increase in blood flow and resultant penile erection. Compression of the dilated blood vessels against the firm outer lining of the penis prevents the blood from escaping and perpetuates the erection. A specialized substance (phosphodiesterase 5 or PDE-5), causes the breakdown of cGMP and, with the help of nerves from the sympathetic nervous system, allows the penis to return to its flaccid relaxed state.

Any defect in this complex cascade of events can result in erectile dysfunction.

Different men experience varying patterns of ED. Men with ED may report the inability to experience any erection from the beginning of a sexual experience, while others experience an erection that is not maintained at penetration. Other men may lose the erection during sexual intercourse, and others can only experience erection upon awakening or during self-masturbation.

KEY TERMS

Diabetes mellitus—A chronic disease affecting the metabolism of carbohydrates that is caused by insufficient production of insulin in the body.

Hypertension—High blood pressure, often brought on by smoking, obesity, or other causes; one of the major causes of strokes.

Hypogonadism—Abnormally decreased gonad function with retardation of sexual development.

Priapism—Persistent abnormal erection of the penis, usually without sexual desire, and accompanied by pain and tenderness.

Prostate gland—The gland at the base of a male's urethra that produces a component of semen.

Impact of ED

It is well-recognized that adults of all ages view sex as an important quality-of-life issue, and that the imposition of ED usually results in a reduced quality of life. In spite of this and for a number of reasons— most of them unfounded— the victims often suffer in silence. Included among the reasons for their silence are the following conceptions:

- ignorance of the availability of safe and effective therapy for ED
- inadequate information provided by the physician concerning timing of medication, need for preliminary sexual arousal, etc.
- undue concern about the irreversibility of marital discord and lack of partner support
- concerns about administration of invasive therapies, adverse effects of therapy, discomfort, inconvenience and cost of therapy
- high rates of discontinuation of therapy due to inadequacy of therapeutic response and associated adverse effects.

Causes and symptoms

Causes

A precise determination of the cause of any individual case of ED is often difficult and may be impossible because ED is often due to multiple factors. This is a consequence of the complicated nature of the human sexual response and the complex physiology of penile erection and relaxation. Normal erectile function requires the coordination of vascular, neurologic, hormonal and psychological factors and any condition that interferes with one or more of these processes may result in ED.

Attitudes concerning age and psychological factors, commonly associated with ED in the past, have changed in the last two decades. Although the prevalence of ED increases with advancing age, ED is no longer regarded as an inevitable consequence of aging. Whereas most cases of ED were once considered primarily psychological and/or psychiatric in origin, it is now well-recognized that organic, non-psychological causes of ED play a much more significant role in the development of ED. Most researchers agree that pure psychological (emotional) mechanisms are causative in 15% to 20% of cases with organic causes responsible for at least 80% of ED cases. In a number of cases, the situation is "mixed," with significant secondary psychological and social components such as guilt, depression, anxiety, tension or marital discord being present in addition to one or more underlying organic components.

Causes of ED may be grouped into those factors that arise within the individual (endogenous) and those factors arising from sources outside the body (exogenous). Endogenous factors include endocrine imbalances, cardiovascular and other medical conditions, and emotional causes. Included among exogenous factors are medications, surgery, trauma and irradiation, smoking, and alcohol and substance abuse. Many of these causes are discussed in more detail in the following list of causes:

- Diabetes mellitus. This is the single most common cause of ED by virtue of its combined nerve and blood vessel damage. At least 40% of male diabetics have ED.
- Circulation abnormalities. Vascular (circulation-related) causes include diseases of the aorta or the arteries supplying the pelvis and penis. Hardening of the arteries (arteriosclerosis) is the most common vascular cause, but damage to the arteries may result from trauma, surgery, or irradiation. Surgery involving the prostate gland may involve both the arteries and nerves in that region.
- Neurological causes, including diseases of the brain (such as **Alzheimer's disease**) and spinal cord (multiple sclerosis, for example).
- Hormonal or endocrine causes. These are uncommon causes for ED, however. ED may occur in males with deficient testicular function and low circulating levels of the male sex hormone, testosterone. These cases are referred to as hypogonadism and may be due to congenital abnormalities or testicular disease such as that accompanying mumps.

- Penile diseases: Organic causes of ED may be related to diseases of the penis. Many factors influence penile circulation. For instance, Peyronie's disease, a condition characterized by fibrous tissue and a downward bowing of the penis, limits the expandability of the penile tissues, thus preventing venous compression and allowing blood to leave the penis. Similarly, arteriosclerotic plaque, injury to blood vessels' inner lining due to trauma, surgery, or irradiation, or even aortic occlusion (blockage in a main artery leading out of the heart) can be the cause of compromised penile blood flow and prevent penile erection.
- Medications: A number of classes of medications can cause ED. Not all agents within each drug class produce the same effects. For example, some antidepressants are associated with ED, whereas an antidepressant called **trazodone** hydrochloride (Desyrel) has been used in institutional studies for the treatment of ED because of its tendency to produce priapism. Some medication classes that can cause ED include (but are not limited to): medications that reduce high blood pressure, medications taken for central nervous system diseases like Parkinson's disease (methyldopa), antidepressants, sedatives or tranquilizers like **barbiturates**, anti-anxiety medications like **diazepam** (Valium), common, non-prescribed drugs such as tobacco and alcohol, and drugs of abuse including heroin.
- Psychological factors that can precipitate ED include **stress**, fatigue, depression, guilt, low self-esteem and negative feelings for or by a sexual partner. Depressive symptoms and/or difficulty coping with anger may be particularly influential, and ED may be related to a "submissive personality."
- Lifestyle: **Obesity**, physical inactivity, cigarette smoking, and excessive intake of alcohol are risk factors for the development of ED. These suggest that changes in lifestyle may constitute an important aspect of both the therapy and prevention of ED.

The identification of risk factors for ED has an important impact not only on the treatment, but on the prevention of ED as well. For example, if a doctor is treating a patient for high blood pressure who is also at risk for ED, the doctor may make an informed decision to prescribe an effective medication that is not associated with ED instead of one that is.

ED AS A MARKER FOR OTHER DISEASES. The frequent association between ED and a number of important vascular conditions such as hypertension and coronary artery heart disease has raised the possibility that ED may serve as an important marker for the detection of these vascular disorders. Additionally, an increased incidence of depression has been noted in men with ED that is believed to be distinct from the reactive type of depression that might occur because of ED. This has led to the recognition of a possible syndrome linking depression and ED. Thus, the presence of depression should be investigated in men presenting with ED.

Symptoms

The main symptom is the inability to attain or maintain adequate erection to complete sexual activity.

As a result of this symptom, affected men may also experience depression and distress, and this symptom can cause interpersonal (including marital) issues.

Demographics

Studies indicate that in the United States at least 30 million American men suffer from some degree of erectile dysfunction (ED). Of these, 10 to 20 million have a severe degree of ED resulting in the complete inability to attain or maintain a penile erection. The number of ED victims in the U.S. is projected to increase by nearly 10 million by the year 2025. With the advancement of men's median age in western industrial countries and the general population growth in developing nations, the worldwide incidence is projected to increase to greater than 320 million by 2025. ED accounts for more than 500,000 annual visits to health care professionals.

As with other chronic disorders and the conditions that are commonly associated with ED (diabetes, hypertension, cardiovascular disease), the prevalence of ED increases with advancing age, with an estimated prevalence of 39% in men aged 40 and 67% in those aged 70. These figures may actually underestimate the true dimensions of the problem since ED is notoriously underreported, undiagnosed and under-treated because of the perceived stigma associated with the **diagnosis** of ED. It is reported that 70% of ED remains undiagnosed and in a survey of general medical practice less than 12% of men with ED reported having received treatment for it.

Diagnosis

Interview

An essential first step in the diagnosis of ED is the taking of a thorough sexual, medical, and psychosocial (both psychological and social) history. The sexual history should include information such as the frequency of sexual intercourse, its duration, the quality and degree of penile erection, the presence or absence of nocturnal erections, and the success or failure of penetration. Any sexual dysfunction on the part of the partner, such as painful intercourse (**dyspareunia**) or vaginal dryness,

should be ascertained. The use of one of several available self-directed patient questionnaires may be a useful adjunct to the sexual history. The sexual history helps in distinguishing ED from other abnormalities in sexual function such as ejaculatory and orgasmic disturbances and loss of sexual desire.

The general medical history may disclose one or more distinct causes of ED including the presence of associated conditions, the use of medications that can cause the disorder, and/or a history of substance abuse.

A psychosocial history, preferably with the participation of the patient's sexual partner, should include current sexual practices, the presence or absence of stress and performance anxiety, and any special circumstances under which ED occurs.

Physical examination

For a patient with ED, the physical examination should not differ substantially from that performed routinely by a primary care physician. The doctor looks for evidence of hypogonadism or congenital conditions in which there is defective testicular function. The examination of the genitourinary, circulatory and neurologic systems might be especially emphasized. The patient's genitalia are carefully examined for testicular size and consistency and penile deformities. A rectal examination is needed to evaluate the size and consistency of the prostate gland and for the performance of certain muscular reflexes. Vital signs such as blood pressure and pulse would be recorded. Because the presence of ED may serve as a marker for high blood cholesterol, hypertension, coronary artery heart disease, and depression, the physician may also request blood work and/or may perform other assessments to check for these conditions.

Other diagnostic methods that may be performed

Laboratory tests may be performed to evaluate levels of hormones including testosterone and prolactin.

Nocturnal studies present a true picture of erectile dysfunction due to organic causes. The most complete evaluation of nocturnal erectile function is obtained in a sleep laboratory, where patients are monitored for rapid eye movement (REM) sleep.

Duplex Doppler ultrasonography has been used extensively in the evaluation of erectile function. It provides information about both arterial and venous blood flow.

Pharmacological testing involves intracavernosal injection of a small amount of an active agent (such as 10 micrograms of alprostadil [prostaglandin E1]) that would produce a normal or priapic erection in a patient with normal erectile function but a poor response in a patient with erectile dysfunction.

There are several patient self-administered questionnaires available to assist in the evaluation of sexual function in men with erectile dysfunction. The best known and most widely used is the International Index of Erectile Function (IIEF). The IIEF addresses the five relevant domains of male sexual function: erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction.

Treatment

The first step in the treatment of ED includes the elimination or alteration of modifiable risk factors or causes, such as lifestyle or psychosocial factors including smoking, obesity, substance and alcohol abuse, and the alteration of prescription and over-the-counter medications if necessary.

Recommended treatment options for ED include the following medications:

- Oral erectogenic medications
- PDE-5 inhibitors. Sildenafil (Viagra) is an example. It works by blocking PDE-5 thereby allowing cGMP to have a longer effect, increasing penile blood flow and producing erection.
- Yohimbine
- Apomorphine
- Alpha adrenergic blockers

Vacuum constriction device therapy, which involves a mechanical device to increase penile blood flow and erection may also be recommended. Psychosexual therapy is also recommended so that any psychological causes for ED can be detected and therapy can be instituted. Individual **psychotherapy** or **couples therapy** may be helpful. These various treatment methods can be used alone or in combination.

If those therapies are unsuccessful, the following treatment options may be recommended:

- Intracavernous therapy (ICIT). This therapy involves injection of the penile structures with substances that promote blood flow and produce erection.
- Intraurethral therapy. Medications are inserted into the urethra and act to increase blood flow and muscle relaxation, allowing for erection.
- Penile prostheses. These are various devices inserted surgically into the penis to produce the erect state.
- Surgery. In rare cases, surgery may be used to correct a defect that interferes with penile erection.

Regardless of the therapy chosen, follow-up at regular intervals and good communication between the patient and the doctor is essential. Patients need to keep their doctors informed about adverse reactions, and patients need to be informed about drug interactions. The doctor may adjust the dosage of medication, or may substitute or add a therapeutic agent into the treatment, as necessary.

The patient and his sexual partner can work with their treatment team so that they are both well-informed about various treatment options and can maximize treatment results.

Prognosis

The combination of the increased understanding of ED, an improved approach to the problem and the development of newer and more effective therapies has resulted in a marked improvement in the prognosis of ED. It is estimated that at least 65% of all cases of ED currently have a satisfactory therapeutic outcome. However, several factors affect individual prognostic forecasts. Risk factors that cannot be changed and that have a negative effect on individual prognoses include: increasing age, the presence of comorbid (co-occurring) conditions such as diabetes, and pelvic surgery in which the nerves were not spared. In contrast, potentially modifiable risk factors such as physical inactivity, smoking, excessive alcoholic intake, certain medications, and obesity improve prognosis when treated effectively.

Estazolam

Definition

Estazolam is a sedative-hypnotic drug belonging to the class of drugs known as benzodiazepines. It is sold in the United States under the names ProSom and Sedarest.

Purpose

Estazolam is used as a short-term treatment for **insomnia**. Given at bedtime, estazolam can help patients who have trouble falling asleep, staying asleep, or who have unwanted early morning awakening.

Description

Estazolam belongs to a group of drugs called benzodiazepines. Benzodiazepines are sedative-hypnotic drugs that help to relieve nervousness, tension, and other anxiety symptoms by slowing the central nervous system. To do this, they block the effects of a specific chemical involved in the transmission of nerve impulses in the **brain**, decreasing the excitement level of the nerve cells.

Estazolam, like other benzodiazepines, can be habit-forming and can cause tolerance. Tolerance occurs when a given dosage has less and less effect when the drug is taken over a long time. Therefore, estazolam is recommended only for short-term use.

Estazolam is available in 1- and 2-mg tablets, for oral use.

Recommended dosage

Adults are usually prescribed a single 1–2 mg dose of estazolam to be taken at bedtime. The elderly (over

KEY TERMS

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Delusion—A false belief that is resistant to reason or contrary to actual fact.

Depressant—Something that slows down functioning.

Glaucoma—A group of eye diseases characterized by increased pressure within the eye significant enough to damage eye tissue and structures. If untreated, glaucoma results in blindness.

Hallucinations—False sensory perceptions. A person experiencing a hallucination may "hear" sounds or "see" people or objects that are not really present. Hallucinations can also affect the senses of smell, touch, and taste.

Sleep apnea—Short periods where a person stops breathing during sleep. Breathing re-starts spontaneously, however, this condition can lead a lack of oxygen in the body.

age 60) or people with serious health problems require much smaller doses, and are usually started at 0.5 mg at bedtime.

Precautions

Care must be taken when prescribing this medication to anyone with decreased liver or kidney functioning, the elderly, those with a history of substance abuse, depression, respiratory depression (such as asthma, chronic obstructive pulmonary disease, chronic bronchitis, or other chronic respiratory diseases), narrow-angle glaucoma or known sleep apnea. People with these health conditions should discuss the risks and benefits of using estazolam with their doctor before starting treatment.

Pregnant women should not use estazolam, because it causes damage to the developing fetus. Because estazolam shows up in breast milk, women who are breastfeeding a baby should not take this drug.

Because estazolam is a nervous system and respiratory depressant, it should not be taken with other such depressants, such as alcohol or other sedatives, sleeping pills, or tranquilizers. Furthermore, patients should not drive, operate dangerous machinery, or engage in hazardous activities until the drug's effects have worn off.

Suddenly discontinuing estazolam after several weeks of use may cause uncomfortable symptoms of withdrawal. Patients should discuss with their doctor how to discontinue estazolam gradually use to avoid such symptoms.

Side effects

The most common side effects of estazolam include sleepiness, slowness of movement, dizziness, and difficulty with coordination.

Less common side effects include anxiety, confusion, depression, memory loss for events occurring after the drug is taken, increased heart rate, and pounding or irregular heartbeat.

Rare side effects include confused thinking, disorientation, **delusions**, irritability, agitation, **hallucinations**, **seizures**, bizarre and/or aggressive behavior, a drop in blood pressure, weak muscles, skin rash or itching, sores in mouth or throat, fever and chills, difficulty sleeping, odd body and/or eye movements, unusual bruising or easy bleeding, severe **fatigue** or weakness, and yellow eyes or skin (jaundice).

Interactions

Cimetidine (Tagamet), **disulfiram** (Antabuse), and erythromycin (an antibiotic) may increase estazolm's sedative effects.

Rifampin may decrease the effects of estazolam.

Evening primrose oil

Definition

Evening primrose oil is a dietary supplement derived from the seeds of the evening primrose plant, *Oenothera biennis*. Its Latin name is derived from the Greek word for wine, reflecting the folk belief that the plant could

relieve the symptoms of a hangover. Other names for the plant are tree primrose and sundrop. Native Americans used the leaves and bark of evening primrose as a sedative and astringent; it was given for stomach and liver complaints as well as disorders of the female reproductive system. More recently, the discovery of antioxidant and other properties of the seed oil has focused attention on its usefulness in treating a range of diseases and disorders, including as an anti-inflammatory, and for premenstrual syndrome (PMS), rheumatoid arthritis, diabetes, osteoporosis, ulcerative colitis, menopausal problems, and heart disease.

Purpose

Evening primrose oil is given by contemporary naturopaths and other alternative practitioners to relieve the discomfort of symptoms associated with PMS, eczema, sunburn, fibrocystic breast disease, arthritis, and diabetes. It is also given to lower the risk of preeclampsia and eclampsia in pregnancy and osteoporosis in older women.

Description

Evening primrose oil is obtained from the seeds of the plant by pressing. The oil can be taken directly as a liquid or in the form of capsules.

Evening primrose oil is considered a useful dietary supplement because it is a good source of essential fatty acids (EFAs), Omega 6 predominantly. EFAs are called essential fatty acids because the human body cannot produce them; they must be obtained from the diet. EFAs maintain the function of cell membranes, regulate pain and inflammation, prevent blood clots, regulate blood pressure and cholesterol levels, and help to produce hormone-like substances known as prostaglandins. Prostaglandins function as inflammation mediators in the short-term regulation of glands and other body organs. It is thought that evening primrose oil relieves the symptoms of PMS by preferentially stimulating anti-inflammatory prostaglandins.

Under normal conditions, the body uses an EFA called linoleic acid to produce a compound called gamma linoleic acid, or GLA. Evening primrose oil contains both linoleic acid (74%) and GLA (9%), making it the most familiar and popular source of GLA. The other compounds contained in evening primrose oil are oleic acid (11%) and palmitic acid (6%).

KEY TERMS

Antioxidant—Substance that protects the body from damaging reactive oxygen molecules in the body. These reactive oxygen molecules can come from inside the body or from environmental pollution and are thought to play a role in the aging process and the development of degenerative disease.

Astringent—A substance or compound that causes contraction or constriction of soft tissue.

Eczema—An inflammation of the skin characterized by itching and oozing of a clear fluid.

Essential fatty acids (EFAs)—a group of polyunsaturated fats that are essential to life and growth but cannot be produced by the body.

Fibrocystic breast disease—A benign disorder of breast tissue characterized by fibrous saclike growths (cysts) that cause pain and tenderness.

Preeclampsia—A complication of pregnancy characterized by high blood pressure, fluid retention, and protein in the urine. If the patient develops convulsions, the condition is called eclampsia.

Prostaglandins—A group of unsaturated fatty acids involved in the contraction of smooth muscle, control of inflammation, and many other body processes.

Topical—A type of medication or preparation intended for use on the skin or external suface of the body. Evening primrose oil is used in topical preparations to soothe sunburn and relieve the itching of eczema.

Recommended dosage

Evening primrose oil can be obtained in health food stores in either liquid or capsule form. Consumers are advised to look for that which is organic and cold-pressed (not oxidized by heating), and to store it in the refrigerator. Standard dosage varies according to the condition being treated. The dosage for breast pain from fibrocystic disease is 3 g per day. For sunburn, patients may take up to 8 capsules daily until the symptoms subside. Dosages for eczema and rheumatoid arthritis depend on the concentration of GLA in the preparation of evening primrose oil, and should be decided in consultation with a physician, or naturopathic practitioner.

Evening primrose oil can also be used as a topical preparation to treat sunburn and eczema. One recipe for a homemade topical preparation calls for mixing one part of diced plant with four parts of heated petroleum jelly. The mixture is stored in a tightly closed container and refrigerated, as well.

All parts of the evening primrose plant are safe to eat. The roots can be boiled and eaten like parsnips. The seeds were roasted and used as a coffee substitute when food rationing was in effect during World War II.

Precautions

Evening primrose oil should not be given to patients with epilepsy, and only after a consultation with a physician should it be given to children.

Side effects

Evening primrose oil has not been reported as having toxic or severe side effects. Some patients, however, have reported nausea, headache, and softening of the stools.

Reports of side effects from using evening primrose oil in topical preparations for sunburn and other skin problems are the same as with any EFA supplement. Bruising due to damage of the blood platelet function is possible.

Interactions

Experts in pharmacology advise against using evening primrose oil with phenytoin (Dilantin) and other anticonvulsant medications, as the oil may lower the threshold for **seizures**. No other significant drug interactions have been reported.

Executive function

Definition

The term executive function describes a set of cognitive abilities that control and regulate other abilities and behaviors. Executive functions are necessary for goal-directed behavior. They include the ability to initiate and stop actions, to monitor and change behavior as needed, and to plan future behavior when faced with novel tasks and situations. Executive functions allow us to anticipate outcomes and adapt to changing situations. The ability to form concepts and think abstractly are often considered components of executive function.

Description

As the name implies, executive functions are high-level abilities that influence more basic abilities like attention, memory and motor skills. For this reason, they can be difficult to assess directly. Many of the tests used to measure other abilities, particularly those that look at more complex aspects of these abilities, can be used to evaluate executive functions. For example, a person with executive function deficits may perform well on tests of basic attention, such as those that simply ask the individual to look at a computer screen and respond when a particular shape appears, but have trouble with tasks that require divided or alternating attention, such as giving a different response depending on the stimulus presented. Verbal fluency tests that ask people to say a number of words in a certain period of time can also reveal prob-

lems with executive function. One commonly used test asks individuals to name as many animals or as many words beginning with a particular letter as they can in one minute. A person with executive function deficits may find the animal naming task simple, but struggle to name words beginning with a particular letter, since this task requires people to organize concepts in a novel way. Executive functions also influence memory abilities by allowing people to employ strategies that can help them remember information. Other tests are designed to assess cognitive function more directly. Such tests may present a fairly simple task but without instructions on how to complete it. Executive functions allow most people to figure out the task demanded through trial and error and change strategies as needed.

Executive functions are important for successful adaptation and performance in real-life situations. They allow people to initiate and complete tasks and to persevere in the face of challenges. Because the environment can be unpredictable, executive functions are vital to human ability to recognize the significance of unexpected situations and to make alternative plans quickly when unusual events arise and interfere with normal routines. In this way, executive function contributes to success in work and school and allows people to manage the stresses of daily life. Executive functions also enable people to inhibit inappropriate behaviors. People with poor executive functions often have problems interacting with other people since they may say or do things that are bizarre or offensive to others. Most people experience impulses to do or say things that could get them in trouble, such as making a sexually explicit comment to a stranger, commenting negatively on someone's appearance, or insulting an authority figure like a boss or police officer; but most people have no trouble suppressing these urges. When executive functions are impaired, however, these urges may not be suppressed. Executive functions are thus an important component of the ability to fit in socially.

Executive function deficits are associated with a number of psychiatric and developmental disorders, including **obsessive-compulsive disorder**, Tourette's syndrome, depression, **schizophrenia**, **attention-deficit/hyperactivity disorder**, and **autism**. Executive function deficits also appear to play a role in antisocial behavior. Chronic heavy users of drugs and alcohol show impairments on tests of executive function. Some of these deficits appear to result from heavy substance use, but there is also evidence suggesting that problems with executive functions may contribute to the development of substance use disorders.

Because executive functions govern so many lower-level abilities, there is some controversy about their physiological basis. Nevertheless, most people who study these abilities agree that the frontal lobes of the **brain** play a major role in executive function. The frontal lobes are the large portions of the brain cortex that lie near the front of the brain. The cortex is the site in the brain where lower level processes like sensation and perception are processed and integrated into thoughts, memories and abilities, and actions are planned and initiated. People with frontal lobe injuries have difficulty with the higher

KEY TERMS

Autism—A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

Cognitive—Pertaining to the mental processes of memory, perception, judgment, and reasoning.

Cortex—Region in the brain where sensation and perception are processed and integrated into thoughts, memories, and abilities; also where actions are planned and initiated.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Executive—Pertaining to supervision, planning and carrying out duties or actions.

Frontal lobes—A region of the brain that influences higher mental functions often associated with intelligence, such as the ability to foresee the consequences of actions, planning, comprehension, and mood.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, language and communication disturbances, and withdrawal from people and social activities.

Tourette syndrome—Neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics that come and go over years, usually beginning in childhood and becoming chronic. Sometimes the tics include inappropriate language.

level processing that underlies executive functions. Because of its complexity, the frontal cortex develops more slowly than other parts of the brain, and not surprisingly, many executive functions do not fully develop until adolescence. Some executive functions also appear to decline in old age, and some executive function deficits may be useful in early detection of mild **dementia**.

Exhibitionism

Definition

Exhibitionism is a mental disorder characterized by a compulsion to display one's genitals to an unsuspecting stranger. The ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM-IV-TR,* classifies exhibitionism under the heading of the "paraphilias," a subcategory of sexual and gender identity disorders. The **paraphilias** are a group of mental disorders marked by **obsession** with unusual sexual practices or with sexual activity involving nonconsenting or inappropriate partners (such as children or animals). The term *paraphilia* is derived from two Greek words meaning "outside of" and "friendship-love."

In the United States and Canada, the slang term "flasher" is often used for exhibitionists.

Description

Exhibitionism is described in the *DSM-IV-TR* as the exposure of one's genitals to a stranger, usually with no intention of further sexual activity with the other person. For this reason, the term exhibitionism is sometimes grouped together with expression, "voyeurism," ("peeping," or watching an unsuspecting person or people, usually strangers, undressing or engaging in sexual activity) as a "hands-off" paraphilia. This contrasts with the "hands-on disorders" which involve physical contact with other persons.

In some cases, the exhibitionist masturbates while exposing himself (or while fantasizing that he is exposing himself) to the other person. Some exhibitionists are aware of a conscious desire to shock or upset their target; while others fantasize that the target will become sexually aroused by their display.

Causes and symptoms

Causes

Several theories have been proposed regarding the origins of exhibitionism. As of 2002, however, none are considered conclusive They include:

- Biological theories. These generally hold that testosterone, the hormone that influences the sexual drive in both men and women, increases the susceptibility of

KEY TERMS

Aversion therapy—An approach to treatment in which an unpleasant or painful stimulus is linked to an undesirable behavior in order to condition the patient to dislike or avoid the behavior.

Castration—Desexing a person or animal by surgical removal of the testes (in males) or ovaries (in females). Castration is sometimes offered as a treatment option to violent rapists and pedophiles who are repeat offenders.

Comorbidity—Association or presence of two or more mental disorders in the same patient. A disorder that is said to have a high degree of comorbidity is likely to occur in patients diagnosed with other disorders that may share or reinforce some of its symptoms.

Compliance—In medicine or psychiatry, cooperation with a treatment plan or schedule of medications.

Denial—A psychological defense mechanism that reduces anxiety by excluding recognition of an addiction or similar problem from the conscious mind.

Double-blind placebo-controlled study—A study in which patients are divided into two groups—those who will recive a medication, and those who will receive a placebo (a pill that looks like the medication but has no active ingredients). Neither the patients nor their physicians know which pill any specific patient is receiving.

Klinefelter's syndrome—A genetic disorder in males characterized by the presence of an extra X chromosome in addition to the normal XY. Most men with Klinefelter's syndrome have learning problems, are sterile, and have a shortened life expectancy.

Paraphilias—A group of mental disorders that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Placebo—An inactive substance or preparation used as a control in experiments with human subjects to test the effectiveness of a medication.

Recidivism—A tendency to return to a previously treated activity, or repeated relapse into criminal or deviant behavior.

Sequela (plural, sequelae)—An abnormal condition resulting from a previous disease or disorder.

Serotonin—A chemical produced by the brain that functions as a neurotransmitter. Low serotonin levels are associated with the paraphilias as well as with mood disorders. Medications known as selective serotonin reuptake inhibitors (SSRIs) can be used to treat exhibitionism and other paraphilias.

Voyeurism—A paraphilia that involves watching unsuspecting people, usually strangers, undress or engage in sexual activity.

males to develop deviant sexual behaviors. Some medications used to treat exhibitionists are given to lower the patients' testosterone levels.

- Learning theories. Several studies have shown that emotional **abuse** in childhood and family dysfunction are both significant risk factors in the development of exhibitionism.
- Psychoanalytical theories. These are based on the assumption that male gender identity requires the male child's separation from his mother psychologically so that he does not identify with her as a member of the same sex, the way a girl does. It is thought that exhibitionists regard their mothers as rejecting them on the basis of their different genitals. Therefore, they grow up with the desire to force women to accept them by making women look at their genitals.
- Head trauma. There are a small number of documented cases of men becoming exhibitionists following traumatic **brain** injury (TBI) without previous histories of alcohol abuse or sexual offenses.
- A childhood history of attention-deficit/hyperactivity disorder (ADHD). The reason for the connection is not yet known, but researchers at Harvard have discovered that patients with multiple paraphilias have a much greater likelihood of having had ADHD as children than men with only one paraphilia.

In general, psychiatrists disagree whether exhibitionism should be considered a disorder of impulse control or whether it falls within the spectrum of obsessive-compulsive disorders (OCDs). Further research into the anatomical structure and neurochemistry of the brain may help to settle this question.

As of 2002, there are no genes that have been associated with an increased risk of exhibitionism or other paraphilias. Such chromosomal abnormalities as Klinefelter's syndrome (where males have an extra X chromosome and are usually sterile) were at one time thought to be a risk factor for the development of paraphilias, but research has not yet proved a connection.

Symptoms

One expert in the field of treating paraphilias has suggested classifying the symptoms of exhibitionism according to level of severity, based on criteria from the *DSM-III-R* (1987):

- Mild. The person has recurrent fantasies of exposing himself, but has rarely or never acted on them.
- Moderate.The person has occasionally exposed himself (three targets or fewer) and has difficulty controlling urges to do so.
- Severe. The person has exposed himself to more than three people and has serious problems with control.
- A fourth level of severity, catastrophic, would not be found in exhibitionists without other paraphilias. This level denotes the presence of sadistic fantasies which, if acted upon, would result in severe injury or death to the victim.

Because exhibitionism is a hands-off paraphilia, it rarely rises above the level of moderate severity in the absence of other paraphilias.

Demographics

The incidence of exhibitionism in the general population is difficult to estimate because persons with this disorder do not usually seek counseling by their own free will. Exhibitionism is one of the three most common sexual offenses in police records (the other two are **voyeurism** and **pedophilia**). It is rarely diagnosed in general mental health clinics, but most professionals believe that it is probably underdiagnosed and underreported.

In terms of the technical definition of exhibitionism, almost all reported cases involve males. A number of mental health professionals, however, have noted that gender bias may be built into the standard definition. Some women engage in a form of exhibitionism by undressing in front of windows as if they are encouraging someone to watch them. In addition, wearing the low-cut gowns favored by some models and actresses have been described as socially sanctioned exhibitionism. One textbook description of exhibitionism says "women exhibit everything but the genitals; men, nothing but."

Although the stereotype of an exhibitionist is a "dirty old man in a raincoat," most males arrested for exhibitionism are in their late teens or early twenties. The disorder appears to have its onset before age 18. Like most paraphilias, exhibitionism is rarely found in men over 50 years of age.

In the U.S., most exhibitionists are Caucasian males. About half of exhibitionists are married.

Diagnosis

Diagnosis of exhibitionism is complicated by several factors. For example, most persons with the disorder come to therapy because of court orders. Some are motivated by fear of discovery by employers or family members, and a minority of exhibitionists enter therapy because their wife or girlfriend is distressed by the disorder. Emotional attitudes toward the disorder vary; some men maintain that the only problem they have with exhibitionism is society's disapproval of it; others, however, feel intensely guilty and anxious.

A second complication of diagnosing exhibitionism is the high rate of comorbidity among the paraphilias as a group and between the paraphilias as a group and other mental disorders. In other words, a patient in treatment for exhibitionism is highly likely to engage in other forms of deviant sexual behavior and to suffer from depression (an anxiety or substance-abuse disorder). In addition, many patients with paraphilias do not cooperate with physicians, who may have considerable difficulty making an accurate diagnosis of other disorders that may also exist.

A diagnosis of exhibitionism follows a somewhat different pattern from the standard procedures for diagnosing most mental disorders. A thorough workup in a clinic for specialized treatment of sexual disorders includes the following components:

- A psychiatric evaluation and mental status examination to diagnose concurrent psychiatric and medical conditions, and to rule out **schizophrenia**, **post-traumatic stress disorder** (PTSD), **mental retardation**, and depression.
- A neurologic examination to rule out head trauma, **seizures**, or other abnormalities of brain structure and function, followed by a **computed tomography** (CT) scan or **magnetic resonance imaging** (MRI), if needed.
- Blood and urine tests for substance abuse and sexually transmitted diseases, including an HIV screen.
- Assessment of sexual behaviors. This includes creation of a sex hormone profile and responses to questionnaires. The questionnaires are intended to measure cog-

nitive distortions regarding rape and other forms of coercion, pedophilia, aggression, and impulsivity.

Treatments

Exhibitionism is usually treated with a combination of **psychotherapy**, medications, and adjunctive treatments.

Psychotherapy

Several different types of psychotherapy have been found helpful in treating exhibitionism:

- **Cognitive-behavioral therapy** (CBT). This approach is generally regarded as the most effective form of psychotherapy for exhibitionism. Patients are encouraged to recognize the irrational justifications that they offer for their behavior, and to alter other distorted thinking patterns.
- Orgasmic reconditioning. In this technique, the patient is conditioned to replace fantasies of exposing himself with fantasies of more acceptable sexual behavior while masturbating.
- **Group therapy.** This form of therapy is used to get patients past the **denial** frequently associated with paraphilias, and as a form of relapse prevention.
- Twelve-step groups for sexual addicts. Exhibitionists who feel guilty and anxious about their behavior are often helped by the social support and emphasis on healthy spirituality found in these groups, as well as by the cognitive restructuring that is built into the twelve steps.
- **Couples therapy** or **family therapy**. This approach is particularly helpful for patients who are married and whose marriages and family ties have been strained by their disorder.

Medications

There are several different classes of drugs used to treat the patient with exhibitionism and the other paraphilias. However, one difficulty in evaluating the comparative efficacy of different medications should be noted: ethical limitation. Double-blind placebo-controlled studies of medication treatment of sexually deviant men raises the ethical question of the possibility of relapse in the subjects who receive the placebo. Withholding a potentially effective drug in circumstances that might lead to physical or psychological injury to a third party is difficult to justify.

As of 2002, medications are the only form of treatment for patients with exhibitionism that have the capability to suppress deviant behaviors. The categories of drugs used to treat exhibitionism are as follows:

- Selective serotonin reuptake inhibitors (SSRIs). The SSRIs show promise in treating the paraphilias, as well as depression and other mood disorders. It has been found that decreased levels of serotonin in the brain result in an increased sex drive. The SSRIs are appropriate for patients with mild- or moderate-level paraphilias; these patients include the majority of exhibitionists.
- Female hormones. Estrogens have been used to treat sexual offenders since the 1940s. Medroxyprogesterone acetate, or MPA, is the most widely used hormonal medication in the U.S. for the treatment of people with exhibitionism. Medroxyprogesterone acetate works by stimulating the liver to produce a chemical that speeds up the clearance of testosterone from the bloodstream. It is effective as long as patients are take their MPA as prescribed by their physicians. Unfortunately, MPA can cause several troublesome side effects in some patients. These include nausea, vomiting, weight gain, and headache.
- Luteinizing hormone-releasing hormone (LHRH) agonists. These drugs are sometimes described to be the equivalent of pharmacologic castration. They work by reducing the release of gonadotropin hormones. The LHRH agonists include such drugs as triptorelin (Trelstar), leuprolide acetate, and goserelin acetate.
- Antiandrogens. These drugs block the uptake and metabolism of testosterone and reduce the blood levels of testosterone. The antiandrogens include cyproterone acetate (CPA) and flutamide. Cyproterone acetate has been used in Germany to treat exhibitionists since the early 1970s, and most long-term studies of the CPA have been done by German psychiatrists. The drug appears to have minimal side effects in long-term use and significantly reduces recidivism (relapse and repetition of the deviant behavior).

Surgery

Surgical castration, which involves removal of the testes, is effective in significantly reducing levels of testosterone in blood plasma. This form of treatment for paraphilias, however, is generally reserved for more serious offenders than exhibitionists (violent rapists and pedophiles with a history of repeated offenses, for example).

Other treatment methods

Another method of treating patients with exhibitionism disorder, used more frequently in the 1970s and 1980s than today, is electroshock aversion. While a mild electric shock was administered, the patient was shown pictures, projected onto a screen, of men exposing them-

selves. In 2002, **aversion therapy** involves asking the patient to fantasize a sequence of events leading up to his exhibitionism. Then, a very unpleasant scene is inserted at a crucial point in the sequence. The patient might, for example, be asked to imagine a police officer approaching as he exposes himself, or to think of his target fighting back or laughing at him.

Another treatment method that is often offered to people with exhibition disorder is **social skills training**. It is thought that some men develop paraphilias partially because they do not know how to form healthy relationships, whether sexual or nonsexual, with other people. Although social skills training is not considered a substitute for medications or psychotherapy, it appears to be a useful adjunctive treatment for exhibitionism disorder.

Legal considerations

People with exhibitionism disorder are at risk for lifetime employment problems if they acquire a police record. An attorney who specializes in employment law has pointed out that the Americans with Disabilities Act (ADA), enacted by Congress in 1990 to protect workers against discrimination on grounds of mental impairment or physical disability, does not protect persons with paraphilias. People with exhibitionism disorder were specifically excluded by Congress from the provisions of the ADA, along with voyeurs and persons with other sexual behavior disorders.

Prognosis

The prognosis for people with exhibition disorder depends on a number of factors, including the age of onset, the reasons for the patient's referral to psychiatric care, degree of his cooperation with the therapist, and comorbidity with other paraphilias or other mental disorders. For some patients, exhibitionism is a temporary disorder related to sexual experimentation during their adolescence. For others, however, it is a lifelong problem with potentially serious legal, interpersonal, financial, educational, and occupational consequences. People with exhibition disorder have the highest recidivism rate of all the paraphilias; between 20% and 50% of men arrested for exhibitionism are re-arrested within two years.

Prevention

One important preventive strategy includes the funding of programs for the treatment of paraphilias in adolescents. According to one expert in the field, males in this age group have not been studied and are undertreated, yet it is known that paraphilias are usually established before age 18. Recognition of paraphilias in adolescents and treatment for those at risk would lower the risk of recidivism. A second important preventive approach is early recognition and appropriate treatment of people who have committed child abuse.

Exposure treatment

Definition

Exposure treatment is a technique that is widely used in **cognitive-behavioral therapy** (CBT). Exposure treatment is used for a variety of anxiety disorders, and it has also recently been extended to the treatment of substance-related disorders. Generally speaking, exposure treatment involves presenting a patient with anxiety-producing material for a long enough time to decrease the intensity of their emotional reaction. As a result, the feared situation or thing no longer makes the patient anxious. Exposure treatment can be carried out in real situations, which is called in vivo exposure; or it can be done through imagination, which is called imaginal exposure. The category of imaginal exposure includes **systematic desensitization**, which asks the patient to imagine certain aspects of the feared object or situation combined with relaxation. Graded or graduated exposure refers to exposing the patient to the feared situation in a gradual manner. Flooding refers to exposing the patient to the anxiety-provoking or feared situation all at once and kept in it until the anxiety and fear subside. There are several variations in the delivery of exposure treatment: patient-directed exposure instructions or self-exposure; therapist-assisted exposure; group exposure; and exposure with response prevention.

Purpose

The basic purpose of exposure treatment is to decrease a person's anxious and fearful reactions (emotions, thoughts, or physical sensations) through repeated exposures to anxiety-producing material. This reduction of the patient's anxiety response is known as habituation. A related purpose of exposure treatment is to eliminate the anxious or fearful response altogether so that the patient can face the feared situation repeatedly without

KEY TERMS

Cognitive restructuring—An approach to psychotherapy that focuses on helping the patient examine distorted patterns of perceiving and thinking in order to change their emotional responses to people and situations.

Cue—Any behavior or event in a person's environment that serves to stimulate a particular response. For example, the smell of liquor may be a cue for some people to pour themselves a drink.

Desensitization—The reduction or elimination of an overly intense reaction to a cue by controlled repeated exposures to the cue.

Extinction—The elimination or removal of a person's reaction to a cue as a result of exposure treatment.

Flooding—A type of exposure treatment in which the patient is exposed to an anxiety-provoking or feared situation all at once and kept in it until the anxiety and fear subside.

Habituation—The reduction of a person's emotional or behavioral reaction to a cue by repeated or prolonged exposure.

Hierarchy—In exposure therapy, a list of feared items or situations, ranked from least fearsome to most fearsome.

In vivo—A Latin phrase that means "in life." In modeling and exposure therapies, it refers to practicing new behaviors in a real setting, as distinct from using imagery or imagined settings.

Interoceptive—Referring to stimuli or sensations that arise inside the body. In interoceptive exposure treatment, the patient is asked to exercise or perform other actions that produce feared internal physical sensations.

Modality—The medical term for a method of treatment.

Subjective units of distress (SUDS) scale—A scale used by patients during exposure treatment to rate their levels of fear and anxiety with numbers from zero to 100.

Virtual reality—A realistic simulation of an environment, produced by a computer system using interactive hardware and software.

experiencing anxiety or fear. This elimination of the anxiety response is known as extinction.

Precautions

Exposure treatment is generally a safe treatment method; however, some patients may find that the level of anxiety that occurs during treatment sessions is higher than they can handle. Some studies of exposure treatment have reported a high dropout rate, perhaps because the method itself produces anxiety. In addition, exposure treatment is not effective for all patients; after treatment, some continue to experience anxiety symptoms.

Description

Exposure treatment usually begins with making a list or hierarchy of situations that make the patient anxious or fearful. The situations are ranked on a scale of zero (representing the situation producing the least anxiety) to ten (representing the situation of highest anxiety). In addition, patients are usually asked to rate their level of anxiety in each situation on a scale from zero (no anxiety or discomfort) to 100 (extreme anxiety and discomfort). This scale is called the subjective units of distress scale, or SUDS. Patients may be asked to provide SUDS ratings at regular intervals during exposure treatment, for example every five minutes.

Methods of delivering exposure treatment

PATIENT-DIRECTED EXPOSURE. Patient-directed exposure is the simplest variation of exposure treatment. After the patient makes his or her hierarchy list with the therapist, he or she is instructed to move through the situations on the hierarchy at his or her own rate. The patient starts with the lowest anxiety situation on the list, and keeps a journal of his or her experiences. Patient-directed exposure is done on a daily basis until the patient's fears and anxiety have decreased. For example, if a patient is afraid of leaving the house, the first item on the hierarchy might be to stand outside the front door for a certain period of time. After the patient is able to perform this action without feeling anxious, he or she would move to the next item on the hierarchy, which might be walking to the end of the driveway. Treatment would proceed in this way until the patient has completed all the items on the hierarchy. During therapy sessions, the therapist reviews the patient's journal; gives the patient positive feedback for any progress that he or she has made; and discusses any obstacles that the patient encountered during exposures to the feared situation.

THERAPIST-ASSISTED EXPOSURE. In this form of exposure treatment, the therapist goes with the patient to the feared location or situation and provides on-the-spot coaching to help the patient manage his or her anxiety. The therapist may challenge the patient to experience the maximum amount of anxiety. In prolonged in vivo exposure, the therapist and patient stay in the situation as long as it takes for the anxiety to decrease. For example, they might remain in a crowded shopping mall for four or more hours. The therapist also explores the patient's thoughts during this exposure so that any irrational ways of thinking can be confronted.

GROUP EXPOSURE. In group exposure, self-exposure and practice are combined with group education and discussion of experiences during exposure to feared situations. These sessions may last as long as three hours and include 30 minutes of education, time for individual exposure practice, and 45 minutes of discussion. Group sessions may be scheduled on a daily basis for 10–14 days.

Exposure treatment for specific anxiety disorders

AGORAPHOBIA. Many research studies have shown that graded exposure treatment is effective for **agoraphobia**. Long-term studies have shown that improvement can be maintained for as long as seven years. Exposure treatment for agoraphobia is best done in vivo, in the actual feared situation, for example entering a packed subway car. Exposure treatment for agoraphobia is likely to be more effective when the patient's spouse or friend is involved, perhaps because of the support a companion can offer the patient during practice sessions.

PANIC DISORDER. Exposure treatment is the central component of cognitive-behavioral treatment for **panic disorder**. Treatment for this disorder involves identifying specific fears within the patient's experience of panic, such as fears of being sick, fears of losing control, and fears of embarrassment. Once these fears are identified, the patient is instructed to expose himself or herself to situations in which the fearful thoughts arise (walking away from a safe person or place, for example). The rationale behind this instruction is that enduring the anxiety associated with the situation will accustom the patient to the situation itself, so that over time the anxiety will diminish or disappear. In this way, the patient discovers that the feared consequences do not happen in real life.

In some patients, physical symptoms of panic lead to fears about the experience of panic itself. Fears related to the physical symptoms associated with panic can be targeted for treatment by inducing the bodily sensations that mimic those experienced during a **panic attack**. This technique is called interoceptive exposure. The patient is asked to induce the feared sensations in a number of ways. For example, the patient may spin in a revolving chair to induce dizziness or run up the stairs to induce increased heart rate and shortness of breath. The patient

is then instructed to notice what the symptoms feel like, and allow them to remain without doing anything to control them. With repeated exposure, the patient learns that the bodily sensations do not signal harm or danger, and therefore need not be feared. The patient is taught such strategies as muscle relaxation and slow breathing to control anxiety before, during, and after the exposure.

Interoceptive exposure treatment for panic usually begins with practice sessions in the therapist's office. The patient may be instructed to practice at home and then practice in a less "safe" environment, such as the patient's work setting or a nearby park. The next step is the addition of the physical activities that naturally produce the feared symptoms. Situational or in vivo exposure would then be introduced for patients with agoraphobia combined with panic disorder. The patient would be instructed to go back into a situation that he or she has been avoiding, such as an elevator or busy railroad terminal. If the patient develops symptoms of anxiety, he or she is instructed to use the techniques for controlling anxiety that were previously learned.

The effectiveness of exposure treatment for decreasing panic attacks and avoidance has been well demonstrated. In research studies, 50%–90% of patients experience relief from symptoms.

SPECIFIC PHOBIA AND SOCIAL PHOBIA. Graded exposure is used most often to treat **specific phobia** or simple phobia. In graded exposure, the patient approaches the feared object or situation by degrees. For example, someone afraid of swimming in the ocean might begin with looking at photographs of the ocean, then watch movies of people swimming, then go to the beach and walk along the water's edge, and then work up to a full swim in the ocean. Graded exposure can be done through patient-directed instruction or therapist-assisted exposure. Research studies indicate that most patients respond quickly to graded exposure treatment, and that the benefits of treatment are well maintained.

Treatment for **social phobia** usually combines exposure treatment with cognitive restructuring. This combination seems to help prevent a recurrence of symptoms. In general, studies of exposure treatment for social phobia have shown that it leads to a reduction of symptoms. Since cognitive restructuring is usually combined with exposure, it is unclear which component is responsible for the patients' improvement, but there is some indication that exposure alone may be sufficient.

Exposure treatment can be more difficult to arrange for treating social phobia, however, because the patient has less control over social situations, which are unpredictable by their nature and can unexpectedly become more intense and anxiety-provoking. Furthermore, social exchanges usually last only a short time; therefore, they may not provide the length of exposure that the patient needs.

OBSESSIVE-COMPULSIVE DISORDER. The most common non-medication treatment for **obsessive-compulsive disorder** (OCD) is exposure to the feared or anxiety-producing situation plus response prevention (preventing the patient from performing a compulsive behavior, such as hand washing after exposure to something thought to be contaminated). This form of treatment also uses a hierarchy, and begins with the easiest situation and gradually moves to more difficult situations. Research has shown that exposure to contamination situations leads to a decrease in fears of contamination, but does not lead to changes in the compulsive behavior. In a similar fashion, the response prevention component leads to a decrease in compulsive behavior, but does not affect the patient's fears of contamination. Since each form of treatment affects different OCD symptoms, a combination of exposure and response prevention is more effective than either modality by itself. Exposure combined with response prevention also appears to be effective for treating OCD in children and adolescents.

Prolonged continuous exposure is better than short, interrupted periods of exposure in treating OCD. On average, exposure treatment of OCD requires 90-minute sessions, although the frequency of sessions varies. Some studies have shown good results with 15 daily treatments spread over a period of three weeks. This intensive treatment format may be best suited for cases that are more severe and complex, as in patients suffering from depression as well as OCD. Patients who are less severely affected and are highly motivated may benefit from sessions once or twice a week. Treatment may include both therapist-assisted exposure and self-exposure as homework between sessions. Imaginal exposure may be useful for addressing fears that are hard to include in vivo exposure, such as fears of a loved one's death. Patients usually prefer gradual exposure to the most distressing situation in their hierarchy; however, gradual exposure does not appear to be more effective than flooding or immediate exposure to the situation.

POST-TRAUMATIC STRESS DISORDER. Exposure treatment has been used successfully in the therapy of **post-traumatic stress disorder** (PTSD) resulting from such traumatic experiences as combat, sexual assault, and motor vehicle accidents. Research studies have reported encouraging results for exposure treatment in reducing PTSD or PTSD symptoms in children, adolescents, and adults. Such intrusive symptoms of PTSD as nightmares and flashbacks may be reduced by having the patient relive the emotional aspects of the trauma in a safe therapeutic environment. It may take 10–15 exposure sessions to decrease the negative physical sensations associated with PTSD. These sessions

may range from one to two hours in length and may occur once or twice a week. Relaxation techniques are usually included before and after exposure. The exposure may be therapist-assisted or patient-directed.

A recent study showed that imaginal exposure and cognitive treatment are equally effective in reducing symptoms associated with chronic or severe PTSD, but that neither brought about complete improvement. In addition, more patients treated with exposure worsened over the course of treatment than patients treated with cognitive approaches. This finding may have been related to the fact that the patients receiving exposure treatment had less frequent sessions with long periods of time between sessions. Some patients diagnosed with PTSD, however, do not seem to benefit from exposure therapy. They may have difficulty tolerating exposure, or have difficulty imagining, visualizing, or describing their traumatic experiences. The use of cognitive therapy to help the patient focus on thoughts may be a useful adjunctive treatment, or serve as an alternative to exposure treatment.

Many persons who have undergone sexual assault or rape meet *DSM-IV-TR* criteria for PTSD. They may re-experience the traumatic event, avoid items or places associated with the trauma, and have increased levels of physical arousal. Exposure treatment in these cases involves using either imaginal or in vivo exposure to reduce anxiety and any tendencies to avoid aspects of the situation that produce anxiety (also known as avoidance behavior). Verbal description of the event (imaginal exposure) is critical for recovery, although it usually feels painful and threatening to patients. It is important that the patient's verbal description of the traumatic event, along with the expression of thoughts and feelings related to it, occur as early in the treatment process as possible. It is in the patient's "best long-term interest to experience more discomfort temporarily in order to suffer less in the long run."

Prolonged exposure is the most effective non-medical treatment for reducing traumatic memories related to PTSD. It combines flooding with systematic desensitization. The goal is to expose patients using both imaginal and in vivo exposure techniques in order to reduce avoidance behavior and decrease fears. Prolonged exposure may occur over nine to 12 ninety-minute sessions. During the imaginal exposure phase of treatment, the patient is asked to describe the details of the traumatic experience repeatedly, in the present tense. The patient uses the SUDS scale to monitor levels of fear and anxiety. The in vivo component occurs outside the therapist's office; it involves the client exposing himself or herself to cues in the environment that he or she has been avoiding— for example, the place where the motor vehicle accident or rape occurred. The patient is instructed to stay in the fear-producing situation for at least 45 minutes, or until their anxiety levels have gone down significantly on the SUDS rating scale. Often patients will use a coach or someone who will stay with them at the beginning of in vivo practice. The coach's role gradually decreases over time as the patient experiences less anxiety.

Recent innovations in exposure treatment

VIRTUAL REALITY EXPOSURE TREATMENT. Virtual reality is a technique that allows a person to participate actively in a computer-generated (or virtual) scenario or environment. The participant has the sense of being present in the virtual environment. Virtual reality uses a device mounted on the participant's head that shows computer graphics and visual displays in real time, and tracks the person's body movements. Some forms of virtual reality also allow participants to hold a second device in their hands that enables them to interact more fully with the virtual environment, such as opening a car door.

Virtual reality has been proposed as a new way of conducting exposure therapy because it can provide a sense of being present in a feared situation. Virtual reality exposure may be useful for treating such phobias as fear of heights, flying, or driving, as well as for treating PTSD. This method appears to have several advantages over standard exposure therapy. First, virtual reality may offer patients a greater sense of control because they can instantly turn the device on and off or change its level of intensity. Second, virtual reality would protect patients from harm or social embarrassment during their practice sessions. Third, it could be implemented regardless of the patient's ability to imagine or to remain with prolonged imaginal exposure. These proposed advantages of virtual reality over standard exposure therapy have yet to be tested, however.

Some studies have been conducted using virtual reality in the treatment of patients with fear of heights and fear of flying, and in a sample of Vietnam veterans diagnosed with PTSD. These studies of virtual reality exposure therapy have limitations in terms of study design and small sample size, but their positive results suggest that virtual reality exposure therapy deserves further investigation.

CUE EXPOSURE TREATMENT FOR ALCOHOL DEPENDENCE. Cue exposure is a relatively new approach to treating substance-related disorders. It is designed to recreate real-life situations in a safe therapeutic environment that expose patients repeatedly to alcohol-related cues, such as the sight or smell of alcohol. It is thought that this repeated exposure to cues, plus prevention of the usual response (drinking alcohol) will reduce and possibly eliminate urges experienced in reaction to the cues.

Persons diagnosed with alcohol dependence face a number of alcohol-related cues in their environment, including moods associated with previous drinking pat-

terns; people, places, times, and objects associated with the pleasurable effects of alcohol; and the sight or smell of alcoholic beverages. Exposure to these cues increases the patient's risk of relapse, because the cues can interfere with a person's use of coping skills to resist the urge to drink. The purpose of cue exposure is to teach patients coping skills for responding to these urges. It is thought that a person who practices coping skills in the presence of cues will find the coping skills strengthened, along with the conviction that he or she can respond effectively when confronted by similar cues in real-life situations.

There are various approaches to cue exposure. The choice of cues is usually based on treatment philosophy and goals, which may require abstinence from alcohol or permit moderate drinking. In abstinence-only programs, patients may be exposed to actual alcohol cues and/or imagined high-risk situations. This imaginal exposure is useful for dealing with cues and circumstances that cannot be reproduced in treatment settings, such as fights. Patients learn and practice urge-specific coping skills. While a patient may learn to cope successfully with one cue (such as the smell of alcohol), the urge to drink may reappear in response to another cue, such as seeing a friend with whom they used to go to bars. The patient would then learn how to manage this particular cue. This program may take six to eight individual or group sessions and may occur on an inpatient or outpatient basis. Often patients remain in the treatment setting for several hours after the exposure to ensure that any lasting urges are safely managed with the therapist's help.

More specifically, cue exposure focuses on the aspect of alcohol consumption that produces the strongest urge. The patient would report each change in their level of urgency, using a scale of zero to ten that resembles the SUDS scale. The urge to drink usually peaks after one to five minutes. When the desire for a drink arises, the patient is instructed to focus on the cue to see what happens to their desire. In most cases the urge subsides within 15 minutes, which is often different from what the patient expected. In later sessions, the patient is instructed when the urge peaks to imagine using the coping skills that he or she was recently taught. The patient may also be instructed to imagine being in high-risk situations and using the coping skills. Some examples of these coping skills include telling oneself that the urge will go away; picturing the negative consequences of drinking alcohol; and thinking of the positive consequences of staying sober.

Although there has been little research on cue exposure, available studies show positive outcomes in terms of decreasing the patients' consumption of alcohol. There have been, however, few outcome studies comparing cue exposure treatment to other treatment approaches. It may be hard to separate the benefits due to exposure from the benefits due to coping skills training. In any event, cue exposure treatment is a promising approach that deserves further study to determine if either component alone is sufficient or if a combination of the two is more effective.

Normal results

Progress in exposure therapy is often slow in the beginning, and occasional setbacks are to be expected. As the patient gains experience with various anxiety-producing situations, his or her rate of progress may increase. While flooding can produce positive results more quickly than graded exposure, it is rarely used because of the high level of discomfort associated with it.

Expressive language disorder

Definition

Expressive language disorder occurs when an individual has problems expressing him or herself using spoken language.

Description

Expressive language disorder is generally a childhood disorder. There are two types of expressive language disorder: the developmental type and the acquired type. Developmental expressive language disorder does not have a known cause and generally appears at the time a child is learning to talk. Acquired expressive language disorder is caused by damage to the **brain**. It occurs suddenly after events such as **stroke** or traumatic head injury. The acquired type can occur at any age.

Causes and symptoms

Causes

There is no known cause of developmental expressive language disorder. Research is ongoing to determine which biological or environmental factors may be the cause. Acquired expressive language disorder is caused by damage to the brain. Damage can be sustained during a stroke, or as the result of traumatic head injury, **seizures**, or other medical conditions. The way in which acquired expressive language disorder manifests itself in a specific person depends on which parts of the brain are injured and how badly they are damaged.

Symptoms

Expressive language disorder is characterized by a child having difficulty expressing him- or herself using speech. The signs and symptoms vary drastically from child to child. The child does not have problems with the pronunciation of words, as occurs in **phonological disorder**. The child does have problems putting sentences together coherently, using proper grammar, recalling the appropriate word to use, or other similar problems. A child with expressive language disorder is not able to communicate thoughts, needs, or wants at the same level or with the same complexity as his or her peers. The child often has a smaller vocabulary than his or her peers.

Children with expressive language disorder have the same ability to understand speech as their peers, and have the same level of intelligence. Therefore, a child with this disorder may understand words that he or she cannot use in sentences. The child may understand complex spoken sentences and be able to carry out intricate instructions, although he or she cannot form complex sentences.

There are many different ways in which expressive language disorder can manifest itself. Some children do not properly use pronouns, or leave out functional words such as "is" or "the." Other children cannot recall words that they want to use in the sentence and substitute general words such as "thing" or "stuff." Some children cannot organize their sentences so that the sentences are easy to understand. These children do comprehend the material

they are trying to express—they just cannot create the appropriate sentences with which to express their thoughts.

Demographics

Expressive language disorder is a relatively common childhood disorder. Language delays occur in 10–15% of children under age three, and in 3–7% of school-age children. Expressive language disorder is more common in boys that in girls. Studies suggest that developmental expressive language disorder occurs two to five times more often in boys as girls. The developmental form of the disorder is far more common than the acquired type.

Diagnosis

To diagnose expressive language disorder, children must be performing below their peers at tasks that require communication in the form of speech. This can be hard to determine because it must be shown that an individual understands the material, but cannot express that comprehension. Therefore, non-verbal tests must be used in addition to tests that require spoken answers. Hearing should also be evaluated, because children who do not hear well may have problems putting together sentences similar to children with expressive language disorder. In children who are mildly hearing impaired, the problem can often be resolved by using hearing aids to enhance the child's hearing. Also, children who speak a language other than English (or the dominant language of their society) in the home should be tested in that language if possible. The child's ability to communicate in English may be the problem, not the child's ability to communicate in general.

The ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revised (known as the *DSM-IV-TR*), states that there are four general criteria for diagnosing expressive language disorder. The first is that the child communicates using speech at a level that is less developed than expected for his or her intelligence and ability to understand spoken language. This problem with communication using speech must create difficulties for the child in everyday life or in achieving goals. The child must understand what is being said at a level that is age-appropriate, or at a developmental level consistent with the child's. Otherwise the diagnoses should be **mixed receptive-expressive language disorder**. If the child has **mental retardation**, poor hearing, or other problems, the difficulties with speech must be greater than is generally associated with the handicaps that the child has.

Treatment

There are two types of treatment used for expressive language disorder. The first involves the child working one-on-one with a speech therapist on a regular schedule and practicing speech and communication skills. The second type of treatment involves the child's parents and teachers working together to incorporate spoken language that the child needs into everyday activities and play. Both of these kinds of treatment can be effective, and are often used together.

Prognosis

The developmental form of expressive language disorder generally has a good prognosis. Most children develop normal or nearly normal language skills by high school. In some cases, minor problems with expressive language may never resolve. The acquired type of expressive language disorder has a prognosis that depends on the nature and location of the brain injury. Some people get their language skills back over days or months. For others it takes years, and some people never fully recover expressive language function.

Prevention

There is no known way to prevent developmental expressive language disorder. Because acquired language disorder is caused by damage to the brain, anything that would help to prevent brain damage may help to prevent that type of the disorder. This can include such things ranging from lowering cholesterol in order to prevent stroke to wearing a bicycle helmet to prevent traumatic brain injury.

F

Factitious disorder

Definition

Factitious disorder (FD) is an umbrella category that covers a group of mental disturbances in which patients intentionally act physically or mentally ill without obvious benefits. According to one estimate, the unnecessary tests and waste of other medical resources caused by FD cost the United States $40 million per year. The name factitious comes from a Latin word that means "artificial" or "contrived."

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-TR*, fourth edition) distinguishes factitious disorder from **malingering**, which is defined as pretending illness when the individual has a clear motive—usually to benefit economically or to avoid legal trouble.

Factitious disorder is sometimes referred to as hospital **addiction**, pathomimia, or polysurgical addiction. Variant names for individuals with FD include hospital vagrants, hospital hoboes, peregrinating patients, problem patients, and professional patients.

Description

Cases of factitious disorder appear in the medical literature as early as Galen, a famous Roman physician of the second century A.D. The term factitious is derived from a book by an English physician named Gavin, published in 1843, entitled *On Feigned and Factitious Diseases*. The modern study of factitious disorder, however, began with a 1951 article in *Lancet* by a British **psychiatrist**, Richard Asher, who also coined the term Munchausen's syndrome to describe a chronic subtype of FD. The name comes from an eighteenth-century German baron who liked to embellish stories of his military exploits in order to impress his listeners. In 1977, it was Gellengerg who first reported a case of FD with primarily psychological symptoms. Factitious disorder was recognized as a formal diagnostic category by *DSM-III* in 1980.

DSM-IV-TR defines factitious disorder as having three major subtypes: FD with predominantly psychological signs and symptoms; FD with predominantly physical signs and symptoms; and FD with combined psychological and physical signs and symptoms. A fourth syndrome, known as Ganser syndrome, has been classified in the past as a form of factitious disorder, although *DSM-IV-TR* groups it with the dissociative disorders.

DSM-IV-TR specifies three criteria for factitious disorder:

- The patient is intentionally producing or pretending to have physical or psychological symptoms or signs of illness.
- The patient's motivation is to assume the role of a sick person.
- There are no external motives (as in malingering) that explain the behavior.

Psychological FD

Factitious disorder with predominantly psychological signs and symptoms is listed by *DSM-IV-TR* as the first subcategory of the disorder. It is characterized by the individual feigning psychological symptoms.

Some researchers have suggested adding the following criteria for this subtype of FD:

- The symptoms are inconsistent, changing markedly from day to day and from one **hospitalization** to the next.
- The changes are influenced by the environment (as when the patient feels observed by others) rather than by the treatment.
- The patient's symptoms are unusual or unbelievable.
- The patient has a large number of symptoms that belong to several different psychiatric disorders.

Physical FD

Factitious disorder wih predominantly physical signs and symptoms is the most familiar to medical per-

KEY TERMS

Conversion disorder—A type of somatoform disorder in which unconscious psychological conflicts or other factors take the form of physical symptoms that are produced unintentionally. Conversion disorder is part of the differential diagnosis of factitious disorder.

Forensic—Pertaining to courtroom procedure or evidence used in courts of law.

Ganser syndrome—A rare subtype of factitious disorder accompanied by dissociative symptoms. It is most often seen in male patients under severe stress in prison or courtroom settings.

Gridiron abdomen—An abdomen with a network of parallel scars from repeated surgical operations.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Masochism—A mental disorder in which a person obtains sexual satisfaction through pain or humiliation inflicted by the self or by another person. The term is sometimes used more generally to refer to a tendency to find pleasure in submissiveness or self-denial.

sonnel. Chronic FD of this type is often referred to as Munchausen's syndrome. The most common ways of pretending illness are: presenting a factitious history (claiming to have had a seizure that never happened); combining a factitious history with external agents that mimic the symptoms of disease (adding blood from a finger prick to a urine sample); or combining a factitious history with maneuvers that produce a genuine medical condition (taking a psychoactive drug to produce psychiatric symptoms). In most cases, these patients sign out of the hospital when they are confronted by staff with proof of their pretending, usually in the form of a laboratory report. Many individuals with Munchausen's syndrome move from hospital to hospital, seeking treatment, and thus are known commonly as "hospital hoboes."

FD with mixed symptoms

Factitious disorder in this category is characterized by a mix of psychological and physical signs and symptoms.

FD not otherwise specified

Factitious disorder not otherwise specified is a category that *DSM-IV* included to cover a bizarre subtype in which one person fabricates misleading information about another's health or induces actual symptoms of illness in the other person. First described in 1977 by an American pediatrician, this syndrome is known as Munchausen syndrome by proxy (MSBP) and almost always involves a parent (usually the mother) and child. MSBP is now understood as a form of child **abuse** involving premeditation rather than impulsive acting out. Many pediatricians in the United States believe that MSBP is underdiagnosed.

Ganser syndrome

Ganser syndrome is a rare disorder (about a 100 documented cases worldwide) that has been variously categorized as a factitious disorder or a dissociative disorder. It is named for a German psychiatrist named Sigbert Ganser, who first described it in 1898 from an examination of male prisoners who were thought to be psychotic. Ganser syndrome is used to describe dissociative symptoms and the pretending of **psychosis** that occur in forensic settings.

There are four symptoms regarded as diagnostic of Ganser syndrome:

- *Vorbeireden*: A German word that means "talking beside the point," it refers to a type of approximate answer to an examiner's questions that may appear silly but usually indicates that the patient understands the question. If examiner asks how many legs a dog has, the patient may answer, "Five."
- Clouding of consciousness: The patient is drowsy or inattentive.
- Conversion symptoms: These are physical symptoms produced by unconscious psychological issues rather than diagnosable medical causes. A common conversion symptom is temporary paralysis of an arm or leg.
- Hallucinations.

Virtual FD

Although virtual factitious disorder does not appear as a heading in any present diagnostic manual, it is a phenomenon that has appeared with increasing frequency with the spread of the Internet. The growing use of the personal computer has affected presentations of factitious disorder in two important ways. First, computers allow people with sufficient technical skills to access medical records from hospital databases and cut-and-paste changes into their own records in order to falsify their medical histories. Second, computers allow people to enter Internet chat rooms for persons with serious illnesses and pretend to be a patient with that illness in order to obtain attention and sympathy. "Munchausen by

Internet" can have devastating effects on chat groups, destroying trust when the hoax is exposed.

Causes and symptoms

Causes

The causes of factitious disorder, whether physical or psychiatric, are difficult to determine because these patients are often lost to follow-up when they sign out of the hospital. **Magnetic resonance imaging** (MRI) has detected abnormalities in the **brain** structure of some patients with chronic FD, suggesting that there may be biological or genetic factors in the disorder. PET scans of patients diagnosed with Ganser syndrome have also revealed brain abnormalities. The results of EEG (**electroencephalography**) studies of these patients are nonspecific.

Several different psychodynamic explanations have been proposed for factitious disorder. These include:

- Patients with FD are trying to re-enact unresolved childhood issues with parents.
- They have underlying problems with masochism.
- They need to be the center of attention and feel important.
- They need to receive care and nurturance.
- They are bothered by feelings of vulnerability.
- Deceiving a physician allows them to feel superior to an authority figure.

There are several known risk factors for factitious disorder, including:

- The presence of other mental or physical disorders in childhood that resulted in the patient's getting considerable medical attention.
- A history of significant past relationships with doctors, or of grudges against them.
- Present **diagnosis** of borderline, narcissistic, or antisocial personality disorder.

Symptoms

SYMPTOMS OF FACTITIOUS DISORDER IN ADULTS OR ADOLESCENTS. Reasons for suspecting factitious disorder include:

- The individual's history is vague and inconsistent; or the individual has a long medical record with many admissions at different hospitals in different cities.
- The patient has an unusual knowledge of medical terminology or describes the illness as if they are reciting a textbook description of it.
- The patient is employed in a medical or hospital-related occupation.
- *Pseudologia fantastica*, a Latin phrase for "uncontrollable lying," is a condition in which the individual provides fantastic descriptions of events that never took place.
- The patient visits emergency rooms at times such as holidays or late Friday afternoons when experienced staff are not usually present and obtaining old medical records is difficult.
- The patient has few visitors even though he or she claims to be an important person.
- The patient is unusually accepting of surgery or uncomfortable diagnostic procedures.
- The patient's behavior is controlling, attention-seeking, hostile, or disruptive.
- The symptoms are present only when the patient thinks he or she is being watched.
- The patient is abusing substances, particularly prescription pain-killers or tranquilizers.
- The course of the "illness" fluctuates, or complications develop with unusual speed.
- The patient has multiple surgical scars, a so-called "gridiron abdomen," or evidence of self-inflicted wounds or injuries.

SYMPTOMS OF MUNCHAUSEN SYNDROME BY PROXY. Factors that suggest MSBP include:

- The victim is a young child; the average age of MSBP victims is 40 months.
- There is a history of long hospitalizations and frequent emergency room visits.
- Siblings have histories of MSBP, failure to thrive, or death in early childhood from an unexplained illness.
- The mother is employed in a health care profession.
- The mother has been diagnosed with depression or histrionic or borderline personality disorder.
- There is significant dysfunction in the family.

Demographics

The demographics of factitious disorder vary considerably across the different subtypes. Most individuals with the predominantly psychological subtype of FD are males with a history of hospitalizations beginning in late adolescence; few of these people, however, are older than 45. For non-chronic factitious disorder with predominantly physical symptoms, women outnumber men by a 3:1 ratio. Most of these women are between 20 and 40

years of age. Individuals with Munchausen syndrome are mostly middle-aged males who are unmarried and estranged from their families. Mothers involved in MSBP are usually married, educated, middle-class women in their early 20s.

Little is known about the rates of various subcategories of factitious disorder in different racial or ethnic groups.

The prevalence of factitious disorder worldwide is not known. In the United States, some experts think that FD is underdiagnosed because hospital personnel often fail to spot the deceptions that are symptomatic of the disorder. It is also not clear which subtypes of factitious disorders are most common. Most observers in developed countries agree, however, that the prevalence of factitious physical symptoms is much higher than the prevalence of factitious psychological symptoms. A large teaching hospital in Toronto reported that 10 of 1,288 patients referred to a consultation service had FD (0.8%). The National Institute for Allergy and Infectious Disease reported that 9.3% of patients referred for fevers of unknown origin had factitious disorder. A clinic in Australia found that 1.5% of infants brought in for serious illness by parents were cases of Munchausen syndrome by proxy.

Diagnosis

Diagnosis of factitious disorder is usually based on a combination of laboratory findings and the gradual exclusion of other possible diagnoses. In the case of MSBP, the abuse is often discovered through covert video surveillance.

The most important differential diagnoses, when factitious disorder is suspected, are malingering, **conversion disorder**, or another genuine psychiatric disorder.

Treatments

Medications

Medications have not proved helpful in treating factitious disorder by itself, although they may be prescribed for symptoms of anxiety or depression if the individual also meets criteria for an anxiety or mood disorder.

Psychotherapy

As of 2002, knowledge of the comparative effectiveness of different psychotherapeutic approaches is limited by the fact that few people diagnosed with FD remain in long-term treatment. In many cases, however, the factitious disorder improves or resolves if the individual receives appropriate therapy for a co-morbid psychiatric disorder. Ganser syndrome usually resolves completely with supportive **psychotherapy**.

One approach that has proven helpful in confronting patients with an examiner's suspicions is a supportive manner that focuses on the individual's emotional distress as the source of the illness rather than on the anger or righteous indignation of hospital staff. Although most individuals with FD refuse psychiatric treatment when it is offered, those who accept it appear to benefit most from supportive rather than insight-oriented therapy.

Family therapy is often beneficial in helping family members understand the individual's behavior and their need for attention.

Legal considerations

In dealing with cases of Munchausen syndrome by proxy, physicians and hospitals should seek appropriate legal advice. Although covert video surveillance of parents suspected of MSBP is highly effective (between 56% and 92%) in exposing the fraud, it may also be considered grounds for a lawsuit by the parents on grounds of entrapment. Hospitals can usually satisfy legal concerns by posting signs stating that they use hidden video monitoring.

All 50 states presently require hospitals and physicians to notify law enforcement authorities when MSBP is suspected, and to take steps to protect the child. Protection usually includes removing the child from the home, but it should also include an evaluation of the child's sibling(s) and long-term monitoring of the family. Criminal prosecution of one or both parents may also be necessary.

Prognosis

The prognosis of factitious disorder varies by subcategory. Males diagnosed with the psychological subtype of FD are generally considered to have the worst prognosis. Self-mutilation and **suicide** attempts are common in these individuals. The prognosis for Munchausen's syndrome is also poor; the statistics for recurrent episodes and successful suicides range between 30% and 70%. These individuals do not usually respond to psychotherapy. The prognosis for non-chronic FD in women is variable; some of these patients accept treatment and do quite well. This subcategory of FD, however, often resolves itself after the patient turns 40. MSBP involves considerable risks for the child; 9–10% of these cases end in the child's death.

Ganser syndrome is the one subtype of factitious disorder with a good prognosis. Almost all patients recover

within days of the diagnosis, especially if the **stress** that precipitated the syndrome is resolved.

Prevention

As of 2002, factitious disorder is not sufficiently well understood to allow for effective preventive strategies—apart from protection of child patients and their siblings in cases of MSBP.

Family education

Definition

Family education is the ongoing process of educating family members about a serious mental illness in order to improve their coping skills and their ability to help a relative affected by the illness.

Purpose

When someone is diagnosed with a chronic illness, such as diabetes or heart disease, efforts are typically made by his/her doctor not only to educate the individual directly affected by the illness, but to educate and involve his/her family in treatment and care. Historically, this has not been the case with severe mental illnesses such as **schizophrenia**, major depression, **bipolar disorder**, or **schizoaffective disorder**.

More often than not, mental health professionals did not educate families about what to expect or how to care for their loved one. In fact, for much of the twentieth century it was believed that mental illness was caused by overly strict or overly permissive parenting styles, and families were unfairly blamed for causing these disorders. Mothers were labeled "schizophrenogenic" and even well-meaning clinicians tried to keep them and other fam-

ily members at a distance. Bateson's "double-bind" theory suggested that contradictory messages and communications by parents were the root cause of the problem. Because of these ideas and the **stigma** associated with mental illness, families felt isolated and alone, with few resources to assist them. After **diagnosis**, the only recourse for most families was to go to public libraries to read and learn as much as they could on their own.

Over the last 20 years, advances in genetics, neuroscience, and imaging techniques have provided new evidence that severe mental illnesses are neurobiological in origin. With this scientific knowledge has come greater awareness and understanding that these are "no-fault" **brain** illnesses, and that neither families nor patients should be blamed. Rather, they both should receive the necessary information and support to help them better cope with these complex disorders.

Description

In the United States and elsewhere, the large majority of individuals with severe mental illness live with their families and depend on them for housing, financial assistance, advocacy, and support. For this reason families require knowledge and skills to actively help their relative avoid relapse, benefit from treatment, and achieve recovery. Specifically, family caregivers require information about: the illness and its symptoms, how to better communicate with their family member and professionals, pros and cons of different treatment options, medications and their therapeutic uses and their adverse side effects, signs of relapse, availability of community services and supports, how to access benefits and entitlements, and how to handle crises or bizarre and troubling behaviors. Because living with an individual with a serious mental disorder can be very stressful, family education must also focus on teaching families about the importance of taking care of themselves.

The National Alliance for the Mentally Ill (NAMI) is an umbrella organization of more than 1,100 local support and advocacy groups in 50 states. The organization comprises families and individuals affected by serious mental illness who come together for family education, mutual support, and advocacy. Through conferences, **support groups**, and newsletters, family members have opportunities to educate one another and exchange experiences. The organization has also made great inroads in educating mental health professionals about the importance of educating family members and involving them in plans for the patient's treatment and rehabilitation. On a more formal level, NAMI has sponsored "Family to Family" a 12-week education course that has been taught to 50,000 family members in more than 42 states. Taught by family volunteers, this is the first peer program in family education in the United States.

Family education is slowly becoming an integral part of treatment, as the recommendation for this has been incorporated into practice guidelines for professionals. Families are also making use of a new generation of books about mental illness—some written by professionals, and others written by, and for, family members. Families are also increasingly using the internet to learn more about mental disorders. The 2002 film, "A Beautiful Mind" was the story about Nobel-prize-winning mathematician John Nash, who suffered from schizophrenia. The film won an Oscar for best picture of the year. This reflects a changing attitude toward mental illness, which in the past was only discussed behind closed doors.

Family education for parents of children and adolescents

Because major mental illnesses tend to occur in adolescence or early adulthood, most family interventions focus on parents of adult children. However, any parent of a younger child with an emotional or behavioral disturbance can testify to the extraordinary challenges involved in coordinating care for their family member. For this reason, more public and private agencies are beginning to provide training, information, education, and financial assistance to family members of children and adolescents with emotional disturbances. The results of research about family education interventions for parents of children with serious emotional disturbances are just beginning to emerge. Some research suggests that family participation improves service delivery and patient outcomes for this group. In a randomized controlled trial of the training of 200 parents who did or did not receive training, while there were no significant effects on child mental health status, those family members who were trained showed significant knowledge enhancement and increased effectiveness.

Results

Research conducted over the past decade has provided evidence that family education and support leads to improved patient outcome. For example, **family psychoeducation** provided by mental health professionals, has such a compelling research base that it is considered a practice based on the findings of real-life studies of family education and support.

Another type of therapy discussed in the scientific literature has been used in China and India. The "family consultation" model uses individualized, private consultations between the family and a trained consultant to assist the family on an as-needed basis.

Family psychoeducation

Definition

Family psychoeducation is a method based on clinical findings for training families to work together with mental health professionals as part of an overall clinical treatment plan for their family members. Family psychoeducation has been shown to improve patient outcomes for persons with **schizophrenia** and other major mental illnesses.

Purpose

The goal of family psychoeducation is to prevent patients with severe mental illnesses from relapsing, and to promote their re-entry into their home communities, with particular regard for their social and occupational functioning. To achieve that goal, family psychoeducation programs seek to provide families with the information they need about mental illness and the coping skills that will help them deal with their loved one's psychiatric disorder.

An associated goal of these programs is support for the patients' families. Families experience many burdens (financial, social, and psychological) in serving as long-term caregivers for their loved ones. Although the primary focus of family psychoeducation groups is improved patient outcomes, an essential intermediate goal is to promote the well-being of the family.

Description

There are several different models of family psychoeducation. Although they include many common elements, these different models include: single- and multiple-family groups; mixed groups that include family members and consumers (patients); groups of varying duration ranging from nine months to more than five years; and groups that focus on patients and families at different phases in the illness. Family psychoeducation programs have been studied extensively and refined by a number of researchers, including Drs. Ian Falloon, Gerald Hogarty, William McFarlane, and Lisa Dixon.

The evidence suggests that multi-family groups, which bring together several patients and their families, lead to better outcomes than single-family psychoeducation groups. The origins of multiple-family **group therapy** go back as far as 1960, when these groups were first assembled to solve ward-management problems in a psychiatric hospital. Lasting a minimum of nine months, the programs provided their participants with information about mental illness, its symptoms and treatment; med-

KEY TERMS

Burden—First described by Treudley in 1946, this term generally refers to the consequences for the family of close contact with a person who is severely mentally ill.

Meta-analysis—The statistical analysis of a large collection of analyses from individual studies for the purpose of integrating the findings.

ication and its side effects; how to communicate with a person with mental illness; and techniques for **crisis intervention** and mutual problem-solving.

Dixon recently outlined the characteristics of successful family psychoeducation programs. They include:

- The programs consider schizophrenia an illness like any other.
- They are led by mental health professionals.
- They are part of a total treatment plan that includes medication.
- Families are treated as partners rather than patients.
- The programs focus primarily on patient outcomes, secondarily on family outcomes.
- The programs differ from traditional **family therapy** in that they do not treat families as part of the problem; they see them as part of the solution.

It is also important that **family education** programs take into account the phase of the patient's illness; the life cycle of both the patient and the family; and the family's cultural context.

Results

A large body of evidence supports the use of family psychoeducation as a "best practice" for young adults with schizophrenia and their families. Because of this compelling evidence, researchers at the University of Maryland, as part of the Schizophrenia Patient Outcomes Research Team (PORT), identified family psychoeducation as an evidence-based practice that should be offered to all families. This and other research studies have shown reduced rates of relapse and lower rates of **hospitalization** among consumers and families involved in these programs. Other outcomes included increased rates of patient participation in **vocational rehabilitation** programs and employment; decreased costs of care; and improved well-being of family members.

A meta-analysis of 16 individual studies found that family interventions of fewer than 10 sessions have no effect on the reduction of family burden. There are also several controlled studies that support the effectiveness of single-and multiple-family interventions for **bipolar disorder**, major depression, **obsessive-compulsive disorder**, **anorexia nervosa**, and **borderline personality disorder**. Studies of family psychoeducation have been conducted outside the United States in China, Norway, and the Netherlands; and with a Hispanic population in Los Angeles, California.

Unfortunately, putting family psychoeducation into effect in clinical settings has not kept pace with research. The PORT study found that only 31% of patients studied reported that their families received information about their illness. One recent strategy to expand these programs includes integrating family psychoeducation into assertive community treatment (ACT) programs.

Family therapists *see* **Marital and family therapists**

Family therapy

Definition

Family therapy is a form of **psychotherapy** that involves all the members of a nuclear or extended family. It may be conducted by a pair of therapists—often a man and a woman—to treat gender-related issues or serve as role models for family members. Although some types of family therapy are based on behavioral or psychodynamic principles, the most widespread form is based on family systems theory, an approach that regards the entire family as the unit of treatment, and emphasizes such factors as relationships and communication patterns rather than traits or symptoms in individual members.

Purpose

The purpose of family therapy is to identify and treat family problems that cause dysfunction. Therapy focuses on improvement in specific areas of functioning for each member, including communication and problem-solving skills.

Family therapy is often recommended when:

- A family member has schizophrenia or suffers from another severe **psychosis**; the goal in these cases is to help other family members understand the disorder and adjust to the psychological changes that may be occurring in the patient.
- Problems cross generational boundaries, such as when parents share a home with grandparents, or children are being raised by grandparents.
- Families deviate from social norms (unmarried parents, gay couples rearing children, etc.). These families may or may not have internal problems, but could be troubled by societal attitudes.
- Members come from mixed racial, cultural, or religious backgrounds.
- One member is being scapegoated, or their treatment in individual therapy is being undermined.
- The identified patient's problems seem inextricably tied to problems with other family members.
- A blended (i.e. step-) family is having adjustment difficulties.

Precautions

Before family therapy begins, family members are required to undergo a comprehensive clinical evaluation (interview) that includes questions of a personal and sensitive nature. Honest communication between the family members and the therapist is essential; people who are not willing to to discuss and change behaviors may not benefit from therapy.

Families that may not be considered suitable candidates for family therapy include those in which:

- One or both parents is psychotic or has been diagnosed with antisocial or paranoid personality disorder.
- Cultural or religious values are opposed to, or suspicious of, psychotherapy.
- Some family members cannot participate in treatment sessions because of illness or other physical limitations.
- Individuals have very rigid personality structures and might be at risk for an emotional or psychological crisis.
- Members cannot or will not be able to meet regularly for treatment.
- The family is unstable or on the verge of break-up.

Intensive family therapy may be difficult for psychotic family members.

Description

Family therapy is a relatively recent development in psychotherapy. It began shortly after World War II, when doctors who were treating schizophrenic patients noticed that the patients' families communicated in disturbed ways. The doctors also found that patients' symptoms rose or fell according to the level of tension between their parents. These observations led to considering a family as an organism (or system) with its own internal rules, patterns of functioning, and tendency to resist change. When the therapists began to treat the families as whole units instead of focusing solely on the hospitalized member, they found that in many cases the schizophrenic family member improved. (This does not mean that **schizophrenia** is caused by family problems, although they may aggravate its symptoms.) This approach was then applied to families

with problems other than schizophrenia. Family therapy is becoming an increasingly common form of treatment as changes in American society are reflected in family structures; it is also helpful when a child or other family member develops a serious physical illness.

Family therapy tends to be short term, usually several months in length, aimed at resolving specific problems such as eating disorders, difficulties with school, or adjustments to bereavement or geographical relocation. It is not normally used for long-term or intensive restructuring of severely dysfunctional families.

In therapy sessions, all members of the family and both therapists (if there is more than one) are present. The therapists try to analyze communication and interaction between all members of the family; they do not side with specific members, although they may make occasional comments to help members become more conscious of patterns previously taken for granted. Therapists who work as a team also model new behaviors through their interactions with each other.

Family therapy is based on systems theory, which sees the family as a living organism that is more than the sum of its individual members and evaluates family members in terms of their position or role within the system. Problems are treated by changing the way the system works rather than trying to "fix" a specific member.

Family systems theory is based on several major concepts:

The identified patient

The identified patient (IP) is the family member with the symptom that has brought the family into treatment. The concept of the IP is used to keep the family from scapegoating the IP or using him or her as a way of avoiding problems in the rest of the system.

Homeostasis

This concept presumes that the family system seeks to maintain its customary organization and functioning over time. It tends to resist change. The family therapist can use homeostasis to explain why a certain family symptom has surfaced at a given time, why a specific member has become the IP, and what is likely to happen when the family begins to change.

The extended family field

The extended family field is the nuclear family plus the network of grandparents and other members of the extended family. This concept is used to explain the intergenerational transmission of attitudes, problems, behaviors, and other issues.

Differentiation

Differentiation refers to each family member's ability to maintain his or her own sense of self while remaining emotionally connected to the family; this is the mark of a healthy family.

Triangular relationships

Family systems theory maintains that emotional difficulties in families are usually triangular—whenever any two persons have problems with each other, they will "triangle in" a third member to stabilize their own relationship. These triangles usually interlock in a way that maintains homeostasis. Common family triangles include a child and its parents; two children and one parent; a parent, a child, and a grandparent; three siblings; or, husband, wife, and an in-law.

Preparation

Families are often referred to a specialist by a pediatrician or other primary care provider. (Some estimates suggest that as many as 50% of pediatric office visits concern developmental problems in children that are affecting their families.) Physicians may use symptom checklists or psychological screeners to assess a family's need for therapy.

Family therapists can be psychiatrists, clinical psychologists, or other professionals certified by a specialty board in marriage and family therapy. They will usually evaluate a family for treatment by scheduling a series of interviews with members of the immediate family, including young children, as well as significant or symptomatic members of the extended family. This allows the therapist(s) to learn how each family member sees the problem and provides a first impression of the family's functioning. Therapists typically evaluate the level and types of emotions expressed, patterns of dominance and submission, roles played by family members, communication styles, and the existence of emotional triangles. They also note whether these patterns are rigid or relatively flexible.

Preparation also usually includes creating a genogram, a diagram that depicts significant persons and events in the family's history. They include annotations about the medical history and major personality traits of each member and help uncover intergenerational patterns of behavior, marriage choices, family alliances and conflicts, the existence of family secrets, and other information that sheds light on the family's present situation.

Risks

There are no major risks involved in receiving family therapy, especially if family members seek the therapy with honesty, openness, and a willingness to change. Changes that result from the therapy may be seen by some as "risks"—the possible unsettling of rigid personality defenses in individuals, or the unsettling of couple relationships that had been fragile before the beginning of therapy, for example.

Normal results

The goal of therapy is the identification and resolution of the problem that is causing the family's unhealthy interactions. Results vary, but in good circumstances they include greater insight, increased differentiation of individual family members, improved communication within the family, and loosening of previously automatic behavior patterns.

Fatigue

Introduction

Fatigue may be defined as a subjective state in which one feels tired or exhausted, and in which the capacity for normal work or activity is reduced. There is, however, no commonly accepted definition of fatigue when it is considered in the context of health and illness. This lack of definition results from the fact that a person's experience of fatigue depends on a variety of factors. These factors include culture; personality; the physical environment (light, noise, vibration); availability of social support through networks of family members and friends; the nature of a particular fatiguing disease or disorder; and the type and duration of work or exercise. For example, the experience of fatigue associated with disease will be different for someone who is clinically depressed, is socially isolated, and is out of shape, as compared to another person who is not depressed, has many friends, and is aerobically fit.

Fatigue is sometimes characterized as normal or abnormal. For example, the feeling of tiredness or even exhaustion after exercising is a normal response and is relieved by resting; many people report that the experience of ordinary tiredness after exercise is pleasant. Moreover, this type of fatigue is called *acute* since the onset is sudden and the desired activity level returns after resting. On the other hand, there is a kind of fatigue that is not perceived as ordinary; that may develop insidiously over time; is unpleasant or seriously distressing; and is not resolved by rest. This kind of fatigue is abnormal and is called *chronic*.

Some researchers regard fatigue as a defense mechanism that promotes the effective regulation of energy expenditures. According to this theory, when people feel tired they take steps to avoid further **stress** (physical or emotional) by resting or by avoiding the stressor. They are then conserving energy. Since chronic fatigue is not normal, however, it is an important symptom of some mental disorders; of a variety of physical diseases with known etiologies (causes); and of medical conditions that have no biological markers although they have recognizable syndromes (patterns of symptoms and signs).

Fatigue is sometimes described as being primary or secondary. Primary fatigue is a symptom of a disease or mental disorder, and may be part of a cluster of such symptoms as pain, fever, or nausea. As the disease or disorder progresses, however, the fatigue may be intensified by the patient's worsening condition, by the other disease symptoms, or by the surgical or medical treatment given to the patient. This subsequent fatigue is called secondary.

KEY TERMS

Biological marker—An indicator or characteristic trait of a disease that facilitates differential diagnosis (the process of distinguishing one disorder from other, similar disorders).

Deconditioning—Loss of physical strength or stamina resulting from bed rest or lack of exercise.

Electrolytes—Substances or elements that dissociate into electrically charged particles (ions) when dissolved in the blood. The electrolytes in human blood include potassium, magnesium, and chloride.

Metabolism—The group of biochemical processes within the body that release energy in support of life.

Stress—A physical and psychological response that results from being exposed to a demand or pressure.

Syndrome—A group of symptoms that together characterize a disease or disorder.

Risk factors

Fatigue is a common experience. It is one of the top ten symptoms that people mention when they visit the doctor. Some people, however, are at higher risk for developing fatigue. For example, the risk for women is about 1.5 times the risk for men, and the risk for people who don't exercise is twice that of active people. Some researchers question whether women really are at higher risk, since they are more likely than men to go to the doctor with health problems; also, men are less likely to admit they feel fatigued. Other risk factors include **obesity**; smoking; use of alcohol; high stress levels; depression; anxiety; and low blood pressure. Having low blood pressure is usually considered desirable in the United States, but is regarded as a treatable condition in other countries. Low blood pressure or postural hypotension (sudden lowering of blood pressure caused by standing up) may cause fatigue, dizziness, or fainting.

Major sources of chronic fatigue

Disease

There are many diseases and disorders in which fatigue is a major symptom— for example, cancer, cardiovascular disease, emphysema, multiple sclerosis, rheumatic arthritis, systemic lupus erythematosus, HIV/AIDS, infectious mononucleosis, chronic fatigue syndrome, and fibromyalgia. The reasons for the fatigue, however, vary according to the organ system or body function affected by the disease. Physical reasons for fatigue include:

- Circulatory and respiratory impairment. When the patient's breathing and blood circulation are impaired, or when the patient has anemia (low levels of red blood cells), body tissues do not receive as much oxygen and energy. Hence, the patient experiences a general sense of fatigue. Fatigue is also an important warning sign of heart trouble because it precedes 30%–55% of myocardial infarctions (heart attacks) and sudden cardiac deaths.
- Infection. Microorganisms that disturb body metabolism and produce toxic wastes cause disease and lead to fatigue. Fatigue is an early primary symptom of chronic, nonlocalized infections found in such diseases as acquired immune deficiency syndrome (AIDS), Lyme disease, and tuberculosis.
- Nutritional disorders or imbalances. Malnutrition is a disorder that promotes disease. It is caused by insufficient intake of important nutrients, vitamins, and minerals; by problems with absorption of food through the digestive system; or by inadequate calorie consumption. Protein-energy malnutrition (PEM) occurs when people do not consume enough protein or calories; this condition leads to wasting of muscles and commonly occurs in developing countries. In particular, young children who are starving are at risk of PEM, as are people recovering from major illness. In general, malnutrition damages the body's immune function and thereby encourages disease and fatigue. Taking in too many calories for the body's needs, on the other hand, results in obesity, which is a predictor of many diseases related to fatigue.
- Dehydration. Dehydration results from water and sodium imbalances in body tissues. The loss of total body water and sodium may be caused by diarrhea, vomiting, bed rest, exposure to heat, or exercise. Dehydration contributes to muscle weakness and mental confusion; it is a common and overlooked source of fatigue. Once fatigued, people are less likely to consume enough fluids and nutrients, which makes the fatigue and confusion worse.
- Deconditioning. This term refers to generalized organ system deterioration resulting from bed rest and lack of exercise. In the 1950s and 1970s, the National Aeronautics and Space Administration (NASA) studied the effects of bed rest on healthy athletes. The researchers found that deconditioning set in quite rapidly (within 24 hours) and led to depression and weakness. Even mild exercise can counteract deconditioning, however, and has become an important means of

minimizing depression and fatigue resulting from disease and hospitalization.

- Pain. When pain is severe enough, it may disrupt sleep and lead to the development of such **sleep disorders** as **insomnia** or **hypersomnia**. Insomnia is the term for having difficulty falling and/or staying asleep. Hypersomnia refers to excessive sleeping. In general, disrupted sleep is not restorative; people wake up feeling tired, and as a result their pain is worsened and they may become depressed. Furthermore, pain may interfere with movement or lead to too much bed rest, which results in deconditioning. Sometimes pain leads to social isolation because the person cannot cope with the physical effort involved in maintaining social relationships, or because family members are unsympathetic or resentful of the ill or injured person's reduced capacity for work or participation in family life. All of these factors worsen pain, contributing to further sleep disruption, fatigue, and depression.
- Stress. When someone experiences ongoing pain and stress, organ systems and functional processes eventually break down. These include cardiovascular, digestive, and respiratory systems, as well as the efficient elimination of body wastes. According to the American Psychiatric Association, various chronic diseases are related to stress, including regional enteritis (intestinal inflammation); ulcerative colitis (a disease of the colon); gastric ulcers; rheumatoid arthritis; cardiac angina, and dysmenorrhea (painful menstruation). These diseases deplete the body's levels of serotonin (a neurotransmitter important in the regulation of sleep and wakefulness, as well as depression), and endorphins (opiate-like substances that moderate pain). Depletion of these body chemicals leads to insomnia and chronic fatigue.
- Sleep disorders. There are a variety of sleep disorders that cause fatigue, including insomnia, hypersomnia, sleep apnea, and restless legs syndrome. For example, hypersomnia may be the result of **brain** abnormalities caused by viral infections. Researchers studying the aftermath of infectious mononucleosis proposed that exposure to viral infections might change brain function with the effect of minimizing restorative sleep; hence, some people developed hypersomnia. Another common disorder is sleep apnea, in which the patient's breathing stops for at least ten seconds, usually more than 20 times per hour. Snoring is common. People may experience choking and then wake up gasping for air; they may develop daytime hypersomnia (daytime sleepiness) to compensate. Sleep apnea is associated with aging, weight gain, and depression. It is also a risk factor for **stroke** and myocardial infarctions. Restless legs syndrome is a condition in which very uncomfortable sensations in the patient's legs cause them to move and wake up from sleep, or keep them from falling asleep. All of these disorders reduce the quality of a person's sleep and are associated with fatigue.

Fibromyalgia and chronic fatigue syndrome

Fibromyalgia (also known as myofascial syndrome or fibrositis) is characterized by pain and achiness in muscles, tendons, and ligaments. There are 18 locations on the body where patients typically feel sore. These locations include areas on the lower back and along the spine, neck, and thighs. A diagnostic criterion for fibromyalgia (FM) is that at least 11 of the 18 sites are painful. In addition to pain, people with FM may experience sleep disorders, fatigue, anxiety, and irritable bowel syndrome. Some researchers maintain, however, that when fatigue is severe, chronic, and persistent, FM is indistinguishable from chronic fatigue syndrome (CFS). The care that patients receive for FM or CFS depends in large measure on whether they were referred to a rheumatologist (a doctor who specializes in treating diseases of the joints and muscles), neurologist, or **psychiatrist**.

Some doctors do not accept CFS (also known as myalgic encephalomyelitis in Great Britain) as a legitimate medical problem. This refusal is stigmatizing and distressing to the person who must cope with disabling pain and fatigue. It is not uncommon for people with CFS to see a number of different physicians before finding one who is willing to diagnose CFS. Nevertheless, major health agencies, such as the Centers for Disease Control (CDC) in the United States, have studied the syndrome. As a result, a revised CDC case definition for CFS was published in 1994 that lists major and minor criteria for **diagnosis**. The major criteria of CFS include the presence of chronic and persistent fatigue for at least six months; fatigue that does not improve with rest; and fatigue that causes significant interference with the patient's daily activities. Minor criteria include such flu-like symptoms as fever; sore throat; swollen lymph nodes; myalgia (muscle pain); difficulty with a level of physical exercise that the patient had performed easily before the illness; sleep disturbances; and headaches. Additionally, people often have difficulty concentrating and remembering information; they experience extreme frustration and depression as a result of the limitations imposed by CFS. The prognosis for recovery from CFS is poor, although the symptoms are manageable.

Psychological disorders

While fatigue may be caused by many organic diseases and medical conditions, it is a chief complaint for several mental disorders, including **generalized anxiety**

disorder and clinical depression. Moreover, mental disorders may coexist with physical disease. When there is considerable symptom overlap, the differential diagnosis of fatigue is especially difficult.

GENERALIZED ANXIETY DISORDER. People are diagnosed as having generalized anxiety disorder (GAD) if they suffer from overwhelming worry or apprehension that persists, usually daily, for at least six months; and if they also experience some of the following symptoms: unusual tiredness, restlessness and irritability, problems with concentration, muscle tension, and disrupted sleep. Such stressful life events as divorce, unemployment, illness, or being the victim of a violent crime are associated with GAD, as is a history of psychiatric problems. Some evidence suggests that women who have been exposed to danger are at risk of developing GAD; women who suffer loss are at risk of developing depression, and women who experience danger and loss are at risk of developing a mix of both GAD and depression.

While the symptoms of CFS and GAD overlap, the disorders have different primary complaints. Patients with CFS complain primarily of tiredness, whereas people with GAD describe being excessively worried. In general, some researchers believe that anxiety contributes to fatigue by disrupting rest and restorative sleep.

DEPRESSION. In the fourth edition of the ***Diagnostic and Statistical Manual of Mental Disorders*** (*DSM-IV*), the presence of depressed mood or sadness, or loss of pleasure in life, is an important diagnostic criterion for depression. Daily fatigue, lack of energy, insomnia and hypersomnia are indicators of a depressed mood. The symptoms of depression overlap with those of CFS; for example, some researchers report that 89% of people with depression are fatigued, as compared to 86%–100% of people with CFS. The experience of fatigue, however, seems to be more disabling with CFS than with depression. Another difference between CFS and depression concerns the onset of the disorder. Most patients with CFS experience a sudden or acute onset, whereas depression may develop over a period of weeks or months. Also, while both types of patients experience sleep disorders, CFS patients tend to have difficulty falling asleep, whereas depressed patients tend to wake early in the morning.

Some researchers believe that there is a link between depression, fatigue, and exposure to too much REM sleep. There are five distinct phases in human sleep. The first two are characterized by light sleep; the second two by a deep restorative sleep called slow-wave sleep; and the last by rapid eye movement or REM sleep. Most dreams occur during REM sleep. Throughout the night, the intervals of REM sleep increase and usually peak around 8:30 A.M. A sleep deprivation treatment for depression involves reducing the patient's amount of REM sleep by waking him or her around 6:00 A.M. Researchers think that some fatigue associated with disease may be a form of mild depression and that reducing the amount of REM sleep will reduce fatigue by moderating depression.

Managing fatigue

The management of fatigue depends in large measure on its causes and the person's experience of it. For example, if fatigue is acute and normal, the person will recover from feeling tired after exertion by resting. In cases of fatigue associated with influenza or other infectious illnesses, the person will feel energy return as they recover from the illness. When fatigue is chronic and abnormal, however, the doctor will tailor a treatment program to the patient's needs. There are a variety of approaches that include:

- Aerobic exercise. Physical activity increases fitness and counteracts depression.
- Hydration (adding water). Water improves muscle turgor or tension and helps to carry electrolytes.
- Improving sleep patterns. The patient's sleep may be more restful when its timing and duration are controlled.
- Pharmacotherapy (treatment with medications). The patient may be given various medications to treat physical diseases or mental disorders; to control pain; or to manage sleeping patterns.
- Psychotherapy. There are several different treatment approaches that help patients manage stress; understand the motives that govern their behavior; or change maladaptive ideas and negative thinking patterns.
- Physical therapy. This form of treatment helps patients improve or manage functional impairments or disabilities.

In addition to seeking professional help, people can understand and manage fatigue by joining appropriate **self-help groups**; reading informative books; seeking information from clearinghouses on the Internet; and visiting web sites maintained by national organizations for various diseases.

Feeding disorder of infancy or early childhood

Definition

Feeding disorder of infancy or early childhood is characterized by the failure of an infant or child under six years of age to eat enough food to gain weight and grow normally over a period of one month or more. The disorder can also be characterized by the loss of a significant amount of weight over one month. Feeding disorder is similar to failure to thrive, except that no medical or physiological condition can explain the low food intake or lack of growth.

Description

Infants and children with a feeding disorder fail to grow adequately, or even lose weight with no underlying medical explanation. They do not eat enough energy or nutrients to support growth and may be irritable or apathetic. Factors that contribute to development of a feeding disorder include lack of nurturing, failure to read the child's hunger and satiety cues accurately, poverty, or parental mental illness. Successful treatment involves dietary, behavioral, social, and psychological **intervention** by a multidisciplinary team of health professionals.

Causes and symptoms

Causes

Feeding disorder of infancy or early childhood can occur with inappropriate parent-child interactions, such as failure to read the child's hunger cues or forcing food when the child is not hungry. Lack of nurturing and/or parental aggression, anger, or **apathy** can make eating a negative experience for the child, increasing the risk of feeding disorders.

Feeding disorders are more common in infants and children who are born prematurely, had a low birth weight, or who are developmentally delayed. Many medical (or physiological) causes can contribute to eating difficulties, eating aversions, or failure to thrive, including:

- diseases of the central nervous system
- metabolic diseases
- sensory defects
- anatomical abnormalities, such as cleft palate
- muscular disorders, such as cerebral palsy
- heart disease
- gastrointestinal diseases, such as Crohn's disease

To meet criteria for a true feeding disorder of infancy or childhood, these medical conditions must be ruled out.

Symptoms

Because the child or infant with a feeding disorder is not consuming enough energy, vitamins, or minerals to support normal growth, symptoms resemble those seen in malnourished or starving children. The infant or child may be irritable, difficult to console, apathetic, withdrawn, and unresponsive.

Delays in development, as well as growth, can occur. In general, the younger the child, the greater the risk of developmental delays associated with the feeding disorder.

Laboratory abnormalities may also be associated with the disorder. Blood tests may reveal a low level of protein or hemoglobin in the blood. Hemoglobin is an iron-containing substance in blood that carries oxygen to body cells.

This mother is consoling her new baby. Infants who are not nurtured, or whose caregiver becomes angry or are apathetic at feedings are more likely to develop feeding disorders. *(Laura Dwight/CORBIS. Reproduced by permission.)*

Demographics

Although minor feeding problems are common in infancy and childhood, true feeding disorder of infancy or early childhood is estimated to occur in 1% to 3% of infants and children. Children separated from their families or living in conditions of poverty or **stress** are at greater risk. Mental illness in a parent, or child **abuse** or **neglect**, may also increase the risk of the child developing a feeding disorder.

Diagnosis

Between 25% and 35% of normal children experience minor feeding problems. In infants born prematurely, 40% to 70% experience some type of feeding problem. For a child to be diagnosed with feeding disorder of infancy or early childhood, the disorder must be severe enough to affect growth for a significant period of time. Generally, growth failure is considered to be below the fifth percentile of weight and height.

Feeding disorder of infancy or early childhood is diagnosed if all four of the following criteria are present:

- Failure to eat adequately over one month or more, with resultant weight loss or failure to gain weight.
- Inadequate eating and lack of growth not explained by any general medical or physiological condition, such as gastrointestinal problems, nervous system abnormalities, or anatomical deformations.
- The feeding disorder cannot be better explained by lack of food or by another mental disorder, such as rumination disorder.
- The inadequate eating and weight loss or failure to gain weight occurs before the age of six years. If feeding behavior or weight gain improves when another person feeds and cares for the child, the existence of a true feeding disorder, rather than some underlying medical condition, is more likely.

Treatments

Successful treatment of feeding disorders requires a multidisciplinary team approach to assess the child's needs and to provide recommendations and education to improve feeding skills, behavior, and nutrient intake. The multidisciplinary team for treatment of feeding disorders in childhood usually includes physicians specializing in problems of the gastrointestinal tract or of the ear, nose, and throat; a dietitian, a **psychologist**, a speech pathologist, and an occupational therapist. Support from **social workers** and physicians in related areas of medicine is also helpful.

An initial evaluation should focus on feeding history, including detailed information on type and timing of food intake, feeding position, meal duration, energy and nutrient intake, and behavioral and parental factors that influence the feeding experience. Actual observation of a feeding session can give valuable insight into the cause of the feeding disorder and appropriate treatments. A medical examination should also be conducted to rule out any potential medical problems or physical causes of the feeding disorder.

After a thorough history is taken and assessment completed, dietary and behavioral therapy is started. The goal of diet therapy is to gradually increase energy and nutrient intake as tolerated by the child to allow for catch up growth. Depending on the diet history, energy and nutrient content of the diet may be kept lower initially to avoid vomiting and diarrhea. As the infant or child is able to tolerate more food, energy and nutrient intake is gradually increased over a period of one to two weeks, or more. Eventually, the diet should provide about 50% more than normal nutritional needs of infants or children of similar age and size.

Behavioral therapy can help the parent and child overcome conditioned feeding problems and food aversions. Parents must be educated to recognize their child's hunger and satiety cues accurately and to promote a pleasant, positive feeding environment. Changing the texture of foods, the pace and timing of feedings, the position of the body, and even feeding utensils can help the child overcome aversions to eating. If poverty, abuse, or parental mental illness contribute to the feeding disorder, these issues must also be addressed.

Prognosis

If left untreated, infants and children with feeding disorders can have permanent physical, mental, and behavioral damage. However, most children with feeding disorders show significant improvements after treatment, particularly if the child and parent receive intensive nutritional, psychological, and social intervention.

Prevention

Providing balanced, age-appropriate foods at regular intervals—for example, three meals and two or three snacks daily for toddlers—can help to establish healthy eating patterns. If a child is allowed to fill up on soft drinks, juice, chips, or other snacks prior to meals, appetite for other, more nutritious foods will decrease.

Positive infant and childhood feeding experiences require the child to communicate hunger and satiety effectively and the parent or caregiver to interpret these signals accurately. This set of events requires a nurturing environment and an attentive, caring adult. Efforts should be made to establish feeding as a positive, pleasant experience. Further, forcing a child to eat or punishing a child for not eating should be avoided.

Female orgasmic disorder

Definition

Female orgasmic disorder (FOD) is the persistent or recurrent inability of a woman to have an orgasm (climax or sexual release) after adequate sexual arousal and sexual stimulation. According to the handbook used by mental health professionals to diagnose mental disorders, the ***Diagnostic and Statistical Manual of Mental Disorders***, 4th Edition, Text Revision (also known as the *DSM-IV-TR)*, this lack of response can be primary (a woman has never had an orgasm) or secondary (acquired after trauma), and can be either general or situation-specific. There are both physiological and psychological causes for a woman's inability to have an orgasm. To receive the **diagnosis** of FOD, the inability to have an orgasm must not be caused only by physiological problems or be a symptom of another major mental health problem. FOD may be diagnosed when the disorder is caused by a combination of physiological and psychological difficulties. To be considered FOD, the condition must cause personal distress or problems in a relationship. In earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders,* FOD was called "inhibited sexual orgasm."

Description

FOD is the persistent or recurrent inability of a woman to achieve orgasm. This lack of response affects the quality of the woman's sexual experiences. To understand FOD, it is first necessary to understand the physiological changes that normally take place in a woman's body during sexual arousal and orgasm.

Normally, when a woman is sexually excited, the blood vessels in the pelvic area expand, allowing more blood to flow to the genitals. This is followed by the seepage of fluid out of blood vessels and into the vagina to provide lubrication before and during intercourse. These events are called the "lubrication-swelling response."

Body tension and blood flow to the pelvic area continue to build as a woman receives more sexual stimulation; this occurs either by direct pressure on the clitoris or as pressure on the walls of the vagina and cervix. This tension builds as blood flow increases. When tension is released, pleasurable rhythmic contractions of the uterus and vagina occur; this release is called an "orgasm." The contractions carry blood away from the genital area and back into general circulation.

It is normal for orgasms to vary in intensity, length, and number of contractions from woman to woman, as

KEY TERMS

Cervix—The neck or narrow lower end of a woman's uterus.

Clitoris—The most sensitive area of the external genitals. Stimulation of the clitoris causes most women to reach orgasm.

Uterus—The hollow muscular sac in which a fetus develops; sometimes called the womb.

Vagina—The part of the female reproductive system that opens to the exterior of the body and into which the penis is inserted during sexual intercourse.

well as in a single individual from experience to experience. Unlike men, woman can have multiple orgasms in a short period of time. Mature women, who may be more sexually experienced than younger women, may find it easier to have orgasms than adolescents or the sexually inexperienced.

In FOD, sexual arousal and lubrication occur. Body tension builds, but the woman is unable or has extreme difficulty reaching climax and releasing the tension. This inability can lead to frustration and unfulfilling sexual experiences for both partners. FOD often occurs in conjunction with other **sexual dysfunctions**. Also, lack of orgasm can cause anger, frustration, and other problems in the relationship.

Causes and symptoms

With FOD, a woman either does not have an orgasm or has extreme difficulty regularly reaching climax. It is normal for women to lack this response occasionally, or to have an orgasm only with specific types of stimulation. The occasional failure to be reach orgasm or dependence on a particular type of stimulation is not the same as FOD.

The causes of FOD can be both physical and psychological. FOD is most often a primary or lifelong disorder, meaning that a woman has never achieved orgasm under any type of stimulation, including self-stimulation (masturbation), direct stimulation of the clitoris by a partner, or vaginal intercourse. Some women experience secondary, or acquired FOD. These women have had orgasms, but lose the ability after illness, emotional trauma, or as a side effect of surgery or medication. Acquired FOD is often temporary.

FOD can be generalized or situation-specific. In generalized FOD, the failure to have an orgasm occurs with different partners and in many different settings. In situational FOD, inability to reach climax occurs only with specific partners or under particular circumstances. FOD may be due either to psychological factors or a combination of physiological and psychological factors, but not due to physiological factors alone.

Physiological causes of FOD include:

- damage to the blood vessels of the pelvic region
- spinal cord lesions or damage to the nerves in the pelvic area
- side effects of medications (antipsychotics, antidepressants, narcotics) or illicit substance abuse
- removal of the clitoris (also called female genital mutilation, a cultural practice in parts of Africa, the Middle East, and Asia)

Psychological causes of FOD include:

- past sexual abuse, rape, incest, or other traumatic sexual experience
- emotional abuse
- fear of becoming pregnant
- fear of rejection by partner
- fear of loss of control during orgasm
- self-image problems
- relationship problems with partner
- life stresses, such as financial worries, job loss, or divorce
- guilt about sex or sexual pleasure
- religious or cultural beliefs about sex
- other mental health disorders such as major depression

FOD is more likely to have a psychological, rather than a physical cause. Inadequate time spent in foreplay, inadequate arousal, lack of appropriate sexual stimulation, poor sexual communication with a partner, and failure to continue with stimulation for an adequate length of time may cause failure to climax, but are not considered causes of FOD.

Demographics

Inability to have an orgasm, discontent with the quality of orgasms, and the ability to have orgasms only with one type of stimulation are common sexual complaints among women. Some studies have found that about half of all women experience some orgasmic difficulties, but not of all these difficulties are considered FOD. About 50% of women experience orgasm through direct clitoral stimulation but not during intercourse, thus not meeting the criteria for a diagnosis of FOD. About 10% of women

never experience an orgasm, regardless of the situation or stimulation. These women are more likely to be unmarried, young, and sexually inexperienced.

Diagnosis

FOD is diagnosed through a medical and psychological history and history of the conditions under which orgasm fails to occur. It is especially helpful for the clinician or sex therapist to understand how long the problem has persisted, and whether it is general or situational. FOD is sometimes found in conjunction with **sexual aversion disorder** and **female sexual arousal disorder**, making the diagnosis complex. To be diagnosed with FOD, the lack of orgasmic response must occur regularly over an extended period of time; based on the clinician's judgment, it must be less than would be reasonable based on age, sexual experience, and the adequacy of sexual stimulation. The lack of orgasm must cause emotional distress or relationship difficulties for the woman and be caused either only by psychological factors alone or by a combination of psychological and physical factors. According to the American Psychiatric Association (APA), a diagnosis of FOD is not appropriate if failure to climax is due only to physiological factors. FOD is also not diagnosed if it is a symptom of another major psychological disorder, such as depression.

Treatments

When failure to reach orgasm is caused by a physical problem, the root problem is treated. In other cases, a combination of education, counseling, **psychotherapy**, and sex therapy are used—often along with directed exercises to increase stimulation and decrease inhibitions—either for the individual or for the couple. As of 2002, clinical trials are under way to investigate the effect of sildenafil (Viagra) on women's sexual response. Sildenafil has already been proved effective in helping men to attain and maintain an erection.

Sex therapists have special training to help individuals and couples focus on overcoming specific sexual dysfunctions. In **couples therapy**, they often assign "homework" that focuses on relaxation techniques, sexual exploration, improving sexual communication, decreasing inhibitions, and increasing direct clitoral stimulation. Individually, a woman might be encouraged to masturbate either through self-stimulation or with a vibrator. In addition, Kegel exercises, which improve the strength and tone of the muscles in the genital area, may be recommended.

Traditional psychotherapy, or **talk therapy** alone or in conjunction with sex therapy, can be effective in resolving psychological causes of FOD, especially when those causes are rooted in past sexual or emotional exploitation or cultural taboos. Psychotherapy is also helpful in resolving relationship tensions that develop as a result of frustration from FOD.

Prognosis

Many women with FOD can be helped to achieve orgasm through a combination of psychotherapy and guided sexual exercises. However, this does not mean that they will be able to achieve orgasm all the time or in every situation, or that they will always be satisfied with the strength and quality of their climax. Couples often need to work through relationship issues that have either caused or resulted from FOD before they see improvement. This process takes time and requires a joint commitment to problem solving.

Prevention

There are no sure ways to prevent FOD. However, reducing life factors that cause **stress** can be effective. Seeking counseling or psychotherapy for past trauma, or when problems begin to appear in a relationship, can help minimize sexual dysfunction problems.

Female sexual arousal disorder

Definition

Female sexual arousal disorder (FSAD) refers to the persistent or recurrent inability of a woman to achieve or maintain an adequate lubrication-swelling response during sexual activity. This lack of physical response may be either lifelong or acquired, and either generalized or situation-specific. FSAD has both physiological and psychological causes. The results of FSAD are often sexual avoidance, painful intercourse, and sexual tension in relationships.

Description

FSAD results from the body's inability to undergo specific physiological changes, called the lubrication-swelling response, in response to sexual desire and stimulation. This lack of response then affects the woman's desire for and satisfaction obtained from intercourse. To understand FSAD, it is helpful to have an outline of the physiological changes that normally take place in a woman's body during sexual arousal.

William Masters and Virginia Johnson were the first researchers to examine extensively the physical components of human sexual arousal. They recorded four stages of sexual response: excitement, plateau, climax (or orgasm), and resolution. Since then, other models have been suggested that include the emotional aspects of arousal. One model suggests three stages: desire, arousal, and orgasm. FSAD affects the excitement or arousal stage of sexual activity.

Normally, when a woman is aroused and sexually excited, the first physiological change that she experiences is expansion of the blood vessels in the pelvic region, allowing more blood to flow to her lower abdomen and genitals. Some women notice this as a feeling of fullness in the pelvis and either consciously or involuntarily contract the muscles in the genital area.

The increased blood flow also causes a phenomenon called transudation, which refers to the seepage of fluid through the walls of the blood vessels. In this case, the fluid seeps into the vagina to provide lubrication before and during intercourse. Often this moisture is noticeable to the woman and her partner. Lubrication of the vagina can happen very rapidly, within a minute.

The increase in blood flow produces other changes in the tissues of the female genitals. The upper part of the vagina, the uterus, the cervix, and the clitoris all expand. At the same time, the lower third of the vagina and the outer labia swell, so that the opening to the vagina becomes smaller. The inner labia also swell, and push apart the opening to the vagina. These changes taken together make up the lubrication-swelling response and are designed to facilitate the entry of the penis into the vagina.

A woman with FSAD either does not have these physical responses or does not maintain them through completion of sexual activity. The lack of arousal and lubrication may result in painful intercourse (**dyspareunia**), emotional distress, or relationship problems.

Causes and symptoms

The symptoms of FSAD include lack of or insufficient transudation. A woman diagnosed with FSAD does not produce enough fluid to lubricate the vagina. As a result, intercourse is often painful and unsatisfactory. The woman may then avoid sexual activity and intimacy, creating relationship difficulties.

The causes of FSAD are quite complex. For some women, FSAD is a lifelong disorder; they have never experienced a normal lubrication-swelling response. For other women FSAD develops after illness or emotional trauma, through physiological changes, or as a side effect of surgery, radiation therapy for cancer, or medication. FSAD can be generalized, occurring with different partners and in many different settings, or it can be situation-specific, occurring only with certain partners or under particular circumstances. In addition, FSAD may be due either to psychological factors or to a combination of physiological and psychological factors.

Physiological causes of FSAD include:

- damage to the blood vessels of the pelvic region resulting in reduced blood flow
- damage to the nerves in the pelvic area resulting in diminished arousal
- general medical conditions that damage blood vessels (coronary artery disease, high blood pressure, diabetes mellitus)
- nursing a baby (lactation)
- general medical conditions that cause changes in hormone levels (thyroid disorders, adrenal gland disorders, removal of the ovaries)
- lower levels of sex hormones due to aging (menopause)
- side effects of medications (antidepressants, antipsychotic drugs, drugs to lower blood pressure, sedatives, birth control pills, or other hormone-containing pills)

Psychological causes of FSAD include:

- chronic mild depression (dysthymia)

- emotional **stress**
- past sexual **abuse**
- emotional abuse
- bereavement
- self-image problems
- relationship problems with partner
- other mental health disorders (major depression, **post-traumatic stress disorder** or **obsessive-compulsive disorder**)

The physical and psychological factors leading to FSAD often appear together. For example, a woman who does not experience arousal because of illness or the side effects of medication may then develop self-image and relationship problems that reinforce her difficulty in reaching arousal.

Demographics

It is difficult to determine the incidence of FSAD, because many women are reluctant to seek help for this problem. FSAD may also be present concurrently with other female **sexual dysfunctions** and be difficult to distinguish from them. In addition, there is some disagreement in the medical community on the exact descriptions of different female sexual dysfunctions. A recent review of the medical literature, however, found that 22–43% of women experience some form of sexual dysfunction. One study that looked specifically at lubrication found that about 20% of women reported problems in this area. Both of these estimates include women whose dysfunction arises from physiological and psychological causes.

Diagnosis

FSAD is usually diagnosed when a woman reports her concerns to her doctor, usually a gynecologist (a doctor who specializes in women's health issues); although she may also discuss it with a family doctor or a psychotherapist. The doctor will take a complete medical and psychological history, including a list of the medications that the patient is currently taking. The doctor will then give the patient a physical examination to evaluate medical aspects of the disorder; if necessary, blood and urine samples may be taken for laboratory testing to rule out previously undiagnosed diabetes or other medical conditions. In order to be diagnosed with FSAD, the lack of lubrication-swelling response must happen persistently or intermittently over an extended period. It is normal for women to have occasional problems with arousal, and these occasional difficulties are not the same as FSAD. The lack of sexual response must cause emotional distress or relationship difficulties for the woman and be caused either only by psychological factors or by a combination of psychological and physical factors to meet the criteria for a **diagnosis** of FSAD.

According to the mental health professional's handbook, the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition, text revision (2000), which is also called *DSM-IV-TR*, a diagnosis of FSAD is not appropriate if problems with arousal are caused only by physiological factors. These factors may include injuries to the genital area, illness, or menopause. When the causes are only physiological, a diagnosis of sexual dysfunction due to a general medical condition is appropriate. If lack of arousal is caused by the side effects of medication or substance abuse, a diagnosis of substance-induced sexual dysfunction would be made. FSAD is also not diagnosed if it

KEY TERMS

Adrenal gland—A small organ located above each kidney that produces hormones related to the sex drive.

Cervix—The neck or narrow lower end of a woman's uterus.

Clitoris—The most sensitive area of the external genitals. Stimulation of the clitoris causes most women to reach orgasm.

Labia—The outside folds of tissue that surround the clitoris and the opening of the urethra in women.

Menopause—A period of decreasing hormonal activity in women, when ovulation stops and conception is no longer possible.

Pelvis—The basin-like cavity in the human body below the abdomen, enclosed by a framework of four bones.

Penis—The external male sex organ.

Thyroid—A gland in the neck that produces the hormone thyroxin, which is responsible for regulating metabolic activity in the body. Supplemental synthetic thyroid hormone is available as pills taken daily when the thyroid fails to produce enough hormone.

Uterus—The hollow muscular sac in which a fetus develops; sometimes called the womb.

Vagina—The part of the female reproductive system that opens to the exterior of the body and into which the penis is inserted during sexual intercourse.

is a symptom of another major psychological disorder. If a woman receives inadequate sexual stimulation from a partner, that also is not considered a cause of FSAD.

Treatments

Treatment varies depending on the cause of FSAD. When there are physical causes, the root problem or disease is treated. Many women who have difficulties with lubrication due to naturally decreasing hormone levels associated with aging are helped by hormone replacement therapy (HRT). There are also nonprescription preparations available in pharmacies for supplementing the woman's natural lubricant. Many women find these preparations quite satisfactory, particularly if they have only occasional problems with arousal.

The United States Food and Drug Administration has approved one medical device for treating FSAD. The Eros-Clinical Therapy Device (Eros-CTD) is a small vacuum pump that fits over the clitoral area. The pump produces a gentle sucking action that stimulates blood flow in the area. In clinical trials the device proved safe and effective in increasing blood flow, sensation, and vaginal lubrication. In May 2000, it was approved for the treatment of FSAD. As of 2002, clinical trials are underway to investigate whether sildenafil (Viagra) can increase blood flow to the genital area in women as it does in men.

Psychotherapy, or **talk therapy**, is most commonly used to treat the psychosocial aspects of FSAD. Sex therapy focuses primarily on the sexual dysfunction. Sex therapists have special training to help individuals and couples overcome their sexual difficulties. Traditional psychotherapy focuses on problems in relationships, seeking to clarify problems, identify emotions, improve communication, and promote problem-solving strategies. Therapy can involve either the woman alone or the woman and her partner (**couples therapy**). Many couples experiencing sexual dysfunction develop relationship problems related to sexual expectations, and benefit from traditional psychotherapy even when difficulties with sexual arousal are resolved.

Prognosis

Because FSAD has multiple causes, individual response to treatment varies widely. Difficulties with lubrication related to the menopause generally have a good prognosis. Stress-related difficulties with arousal typically resolve when the stressor is no longer present. Couples often need to work through relationship issues that have either caused or resulted from sexual dysfunction before they see an improvement in sexual arousal. This process takes time and a joint commitment to problem-solving.

Prevention

There are no sure ways to prevent FSAD. Eating a healthy, well-balanced diet, getting enough rest, having regular gynecological check-ups, and seeking counseling or psychotherapy when problems begin to appear in a relationship can help minimize sexual arousal problems.

Fetishism

Definition

Fetishism is a form of paraphilia, a disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving non-human objects, the suffering or humiliation of oneself or one's partner (not merely simulated), or children or other non-

consenting persons. The essential feature of fetishism is recurrent intense sexual urges and sexually arousing fantasies involving specific objects. While any object may become a fetish, the distinguishing feature is its connection with sex or sexual gratification. A **diagnosis** of fetishism is made only if an individual has acted on these urges, is markedly distressed by them, or if the fetish object is required for gratification.

For some people with a paraphilia such as fetishism, paraphilic fantasies or stimuli may be necessary for erotic arousal and are always included in sexual activity, or the presence of the fetish object may occur only episodically. For example, the fetish object may only be necessary for arousal during periods of **stress**, and at other times, the person is able to function sexually without the fetish or stimuli related to the fetish.

Description

As stated, a fetish is a form of paraphilia, and in fetishism, the affected person has created a strong association between an object and sexual pleasure or gratification. A fetish is not simply a pleasant memory—it is a dominant component of most sexual situations. Most fetishes are objects or body parts. Common fetishes involve items of clothing, stuffed animals, or other non-sexual objects. Body fetishes may involve breasts, legs, buttocks, or genitals.

A person with a fetish often spends significant amounts of time thinking about the object of the fetish. Further, the object is intimately related to sexual pleasure or gratification. In the extreme, the presence of the fetish object is required for sexual release and gratification.

Causes and symptoms

Causes

The cause of the association between an object and sexual arousal may be adolescent curiosity or a random association between the object and feelings of sexual pleasure. A random association may be innocent or unappreciated for its sexual content when it initially occurs. For example, a male may enjoy the texture or tactile sensation of female undergarments or stockings. At first, the pleasurable sensation occurs randomly, and then, in time and with experience, the behavior of using female undergarments or stockings as part of sexual activity is reinforced, and the association between the garments and the sexual arousal is made. A person with a fetish may not be able to pinpoint exactly when his or her fetish began. A fetish may be related to activities associated with sexual **abuse**.

KEY TERMS

Paraphilia—A disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Symptoms

Early symptoms for a fetish involve touching the object of desire. The amount of time spent thinking about the fetish object may increase. Over time, the importance of the fetish object expands. In the extreme, it becomes a requirement for achieving sexual pleasure and gratification.

Demographics

How many people have a fetish and the extent to which the fetish influences their lives and sexual activities are not accurately known. In some rare instances, people with fetishes may enter the legal system as a result of their fetishes, and those cases may be counted or tracked.

Paraphilias such as fetishism are uncommon among females, but some cases have been reported. Females may attach erotic thoughts to specific objects such as items of clothing or pets, but these are uncommon elements in sexual activity. Virtually no information is available on family patterns.

Diagnosis

A diagnosis of a paraphilia involving a fetish is most commonly made by taking a detailed history or by direct observation. The diagnosis is made only if a person has actually obtained sexual gratification by using the fetish object, or has been markedly distressed by the inability to use such an object if contact with the fetish object is needed for sexual success. Occasionally discussing admiration for a particular object or finding an object to be arousing does not indicate a diagnosis of fetishism.

Treatments

In the earliest stages of behavior therapy, fetishes were narrowly viewed as attractions to inappropriate objects. Aversive stimuli such as shocks were administered to persons undergoing therapy. This approach was not successful. People with fetishes have also been

behaviorally treated by orgasmic reorientation, which attempts to help them develop sexual responses to culturally appropriate stimuli that have been otherwise neutral. This therapy has had only limited success.

Most persons who have a fetish never seek treatment from professionals. Most are capable of achieving sexual gratification in culturally appropriate situations. As of 2002, American society seems to have developed more tolerance for persons with fetishes than in the past, thus further reducing the already minimal demand for professional treatment.

Prognosis

The prognosis for eliminating a fetish is poor because most people with a fetish have no desire to change or eliminate it. Most cases in which treatment has been demanded as a condition of continuing a marriage have not been successful. Most fetishes are relatively harmless in that most do not involve other persons or endanger the person with the fetish. Persons with a fetish rarely involve non-consenting partners.

The personal prognosis for a person with a fetish is good if the fetish and related activities do not impact others or place the person with the fetish in physical danger.

Prevention

Most experts agree that providing gender-appropriate guidance in culturally appropriate situations will prevent the formation of a fetish. The origin of some fetishes may be random associations between a particular object or situation and sexual gratification. There is no way to predict such as association.

Figure drawings

Definition

Figure drawings are projective diagnostic techniques in which an individual is instructed to draw a person, an object, or a situation so that cognitive, interpersonal, or psychological functioning can be assessed.

Purpose

A projective test is one in which a test taker responds to or provides ambiguous, abstract, or unstructured stimuli, often in the form of pictures or drawings. While other projective tests, such as the **Rorschach Technique** and **Thematic Apperception Test**, ask the test taker to interpret existing pictures, figure drawing tests require the test taker to create the pictures themselves. In most cases, figure drawing tests are given to children. This is because it is a simple, manageable task that children can relate to and enjoy.

Some figure drawing tests are primarily measures of cognitive abilities or cognitive development. In these tests, there is a consideration of how well a child draws and the content of a child's drawing. In some tests, the child's self-image is considered through the use of the drawings. In other figure drawing tests, interpersonal relationships are assessed by having the child draw a family or some other situation in which more than one person is present. Some tests are used for the evaluation of child **abuse**. Other tests involve personality interpretation through drawings of objects, such as a tree or a house, as well as people. Finally, some figure drawing tests are used as part of the diagnostic procedure for specific types of psychological or neuropsychological

impairment, such as central nervous system dysfunction or **mental retardation**.

Precautions

Despite the flexibility in administration and interpretation of figure drawings, these tests require skilled and trained administrators familiar with both the theory behind the tests and the structure of the tests themselves. Interpretations should be made with caution and the limitations of projective tests should be considered. It is generally a good idea to use projective tests as part of an overall test battery. There is little professional support for the use of figure drawing, so the examples that follow should be interpreted with caution.

Description

The Draw-A-Man Test, developed by Goodenough in 1926 was the first formal figure drawing test. It was used to estimate a child's cognitive and intellectual abilities reflected in the drawing's quality. The test was later revised by Harris in 1963 as the Goodenough Harris Drawing Test (GHDT), which included a detailed scoring system and allowed for drawings of men, women, and the self. The scoring system primarily reflected the way in which the child is maturing cognitively. The GHTD is appropriate for children between the ages of three and 17, although it has been found to be most useful for children between three and 10.

The Draw-A-Person test (DAP) was developed by Machover in 1948 and used figure drawings in a more projective way, focusing on how the drawings reflected the anxieties, impulses, self-esteem, and personality of the test taker. In this test, children are first asked to draw a picture of a person. Then, they are asked to draw a picture of a person of the sex opposite of the first drawing. Sometimes, children are also asked to draw a picture of the self and/or family members. Then, they are asked a series of questions about themselves and the drawings. These questions can be about the mood, the ambitions, and the good and bad qualities of the people in the drawings. The pictures and the questions on the DAP are meant to elicit information about the child's anxieties, impulses, and overall personality. The DAP is the most frequently used figure drawing test today. A scoring system appropriate for adults was developed in 1993 by Mitchel, Trent, and McArthur.

In 1992, Naglieri and his colleagues created a more specific scoring system for figure drawing tests called the Draw-A-Person: Screening Procedure of Emotional Disturbance (DAP:SPED), based on a large standardization sample. This scoring method includes 55 items rated by the test administrator and based on the child's drawings and responses to questions. The DAP:SPED is appropriate for children aged six to 17. It is often used as a screening method for children who may be having difficulties with regard to social adjustment and require further evaluation.

KEY TERMS

Projective test—A psychological test in which the test taker responds to or provides ambiguous, abstract, or unstructured stimuli, often in the form of pictures or drawings.

Reliability—The ability of a test to yield consistent, repeatable results.

Standardization—The administration of a test to a sample group of people for the purpose of establishing scoring norms. The DAP:SPED structured scoring system was standardized using a sample of over 2,300 children and adolescents.

Validity—The ability of a test to measure accurately what it claims to measure.

The **House-Tree-Person** (HTP) **test**, created by Buck in 1948, provides a measure of a self-perception and attitudes by requiring the test taker to draw a house, a tree, and a person. The picture of the house is supposed to conjure the child's feelings toward his or her family. The picture of the tree is supposed to elicit feelings of strength or weakness. The picture of the person, as with other figure drawing tests, elicits information regarding the child's self-concept. The HTP, though mostly given to children and adolescents, is appropriate for anyone over the age of three.

The Kinetic Family Drawing technique (KFD), developed in 1970 by Burns and Kaufman, requires the test taker to draw a picture of his or her entire family. Children are asked to draw a picture of their family, including themselves, "doing something." This picture is meant to elicit the child's attitudes toward his or her family and the overall family dynamics. The KFD is sometimes interpreted as part of an evaluation of child abuse.

The Kinetic School Drawing technique (KSD), developed in 1974 by Prout and Phillips, requires the child to draw a picture of himself or herself, a teacher, and one or more classmates. This picture is meant to elicit the child's attitudes toward people at school and his or her functioning in the school environment.

Results

As with all projective measures, scoring on figure drawing tests is more subjective. Specific scoring systems, such as the DAP:SPED can be used to provide more objective information. Most figure drawing tests have some sort of objective scoring system; however, the instructions given to the child, the questions asked by the test administrator, and the administrator's interpretations of the drawings are flexible and this makes it difficult to compare results between children, even on the same measure. Also, many clinicians choose not to rely on the scoring systems and rely entirely on their own intuitive judgments regarding their interpretation of picture content.

Figure drawings are often interpreted with regard to appropriate cognitive development. Naglieri's DAP:SPED scoring system includes a consideration of what features in a drawing are appropriate for children of various ages. For example, five-year old children are expected to make fairly basic drawings of people, consisting of a head, eyes, nose, mouth, body, arms, and legs. An 11-year-old, on the other hand is expected to have more details in the picture, such as a more defined neck, clothes, and arms in a particular direction.

Sometimes, figure drawings are assessed with regard to self-image. Children often project themselves in the drawings. For example, females with body image concerns may reflect these concerns in their drawings. Victims of sexual abuse may stress sexual characteristics in their drawings.

Psychological, neuropsychological, or emotional dysfunction can also be considered in figure drawing interpretation. This type of interpretation is often done with figure drawings made by adults. For example, a person who omits or distorts body parts may suffer from emotional impairment. Excessive detail with regard to the sexual nature of the drawing may indicate sexual maladjustment.

Family dynamics are also interpreted through figure drawings. For example, in the Kinetic Family Drawing test, a picture where family members are in separate rooms may indicate isolation or a lack of interaction between family members.

Figure drawings are also interpreted with regard to child abuse. In 1994, Von Hutton developed a scoring system for both the HTP and DAP focusing on indicators of child abuse that may be present in drawings. The drawing of the family in the KFD test may also provide indicators of abuse.

There has been much debate over the overall reliability and validity of figure drawing tests (and projective tests in general). For example, when structured scoring systems are used, the DAP has been found to be a reliable measure, especially for cognitive development in children. However, with regard to specific personality characteristics, self-image issues, or personality dysfunctions, there has been relatively little support for the use of figure drawings.

Fluoxetine

Definition

Fluoxetine is an antidepressant of the type known as selective serotonin reuptake inhibitors (SSRI). It is sold in the United States under the brand names Prozac and Sarafem.

Purpose

Fluoxetine is used to treat depression, premenstrual syndrome, bulimia, and **obsessive-compulsive disorder**.

Description

Serotonin is a **neurotransmitter**—a **brain** chemical that carries nerve impulses from one nerve cell to another. Researchers think that depression and certain other mental disorders may be caused, in part, because there is not enough serotonin being released and transmitted in the brain. Like the other SSRI antidepressants, **fluvoxamine** (Luvox), **sertraline** (Zoloft), and **paroxetine** (Paxil), fluoxetine increases the level of brain serotonin (also known as 5-HT). Increased serotonin levels in the brain may be beneficial in patients with obsessive-compulsive dirder, alcoholism, certain types of headaches, **post-traumatic stress disorder** (PTSD), pre-menstrual tension and mood swings, and **panic disorder**.

Fluoxetine was the first of the class of antidepressants called selective serotonin reuptake inhibitors (SSRIs) to be approved for use in the United States. In 2000, fluoxetine was approved by the FDA for use in treating premenstrual dysphoric disorder.

The benefits of fluoxetine develop slowly over a period of several weeks. Patients should be aware of this and continue to take the drug as directed, even if they feel no immediate improvement.

Fluoxetine (marketed as Prozac) is available in 10-, 20-, and 40-mg capsules, 10-mg tablets, and in a liquid solution with 20 mg of active drug per 5 ml. Prozac Weekly capsules are a time-release formula containing 90 mg of active drug. Sarafem is available in 10- and 20-mg capsules.

Recommended dosage

Fluoxetine therapy in adults is started as a single 20-mg dose, initially taken in the morning. Depending on the patient's response after four to six weeks of therapy, this dose can be increased up to a total of 80 mg per day. Doses over 20 mg per day can be given as equally divided morning and afternoon doses.

Precautions

Patients taking fluoxetine should be monitored closely for **insomnia**, anxiety, mania, significant weight loss, **seizures**, and thoughts of **suicide**.

Caution should also be exercised when prescribing fluoxetine to patients with impaired liver or kidney function, the elderly (over age 60) children, individuals with known manic-depressive disorder or a history of seizures, people with diabetes, and individuals expressing ideas of committing suicide.

Individuals should not take MAO inhibitors during fluoxetine therapy, for two weeks prior to beginning fluoxetine therapy, and for five weeks after stopping fluoxetine therapy.

Care should be taken to weigh the risks and benefit of this drug in women who are, or wish to become, pregnant, as well as in breast-feeding mothers.

People with diabetes should monitor their blood or urine sugar more carefully, since fluoxetine can affect blood sugar.

Until an individual understands the effects that fluoxetine may have, he or she should avoid driving, operating dangerous machinery, or participating in hazardous activities. Alcohol should not be used while taking fluoxetine.

KEY TERMS

Bulimia—An eating disorder characterized by binges in which large amounts of food are consumed, followed by forced vomiting.

Obsessive-compulsive disorder—Disorder in which the affected individual has an obsession (such as a fear of contamination, or thoughts he or she doesn't like to have and can't control) and feels compelled to perform a certain act to neutralize the obsession (such as repeated handwashing).

Pre-menstrual syndrome—A severe change in mood that occurs in women immediately prior to, and during, their menstrual period.

Side effects

More common side effects include decrease sexual drive, restlessness, difficulty sitting still, skin rash, hives, and itching.

Less common side effects include fever and/or chills, and pain in joints or muscles.

Rare side effects include pain or enlargement of breasts and/or abnormal milk production in women, seizures, fast heart rate, irregular heartbeats, red or purple spots on the skin, low blood sugar and its symptoms (anxiety, chills, cold sweats, confusion, difficulty concentrating, drowsiness, excess hunger, rapid heart rate, headache, shakiness or unsteadiness, severe **fatigue**), low blood sodium and its symptoms (including confusion, seizures, drowsiness, dry mouth, severe thirst, decreased energy), serotonin syndrome (usually at least three of the following: diarrhea, fever, sweatiness, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking), excitability, agitation, irritability, pressured talking, difficulty breathing, and odd body or facial movements.

Interactions

Fluoxetine interacts with a long list of other medications. People starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all of their health care providers, including dentists, that they are taking fluoxetine.

When taken with fluoxetine, blood levels of the following drugs may increase: benzodiazepines, **beta blockers**, **carbamazepine**, dextromethorphan, **haloperidol**,

atorvastatin, lovastatin, simvastatin, phenytoin, and tricyclic antidepressants.

The following drugs may increase the risk of serotonin syndrome: dexfenfluramine, fenfluramine, and tryptophan.

When **buspirone** is taken with fluoxetine, the therapeutic effect of buspirone may be impaired.

Low blood sodium may occur when fluoxetine is taken along with diuretics.

Increased risk of mania and high blood pressure occurs when selegiline is taken along with fluoxetine.

Severe, fatal reactions have occurred when fluoxetine is given along with MAO inhibitors.

Fluphenazine

Definition

Fluphenazine is a phenothiazine antipsychotic sold under the brand names Permitil and Prolixin in the United States. It is also available under its generic name.

Purpose

Fluphenazine is a drug used to treat psychotic disorders, agitation, and **dementia**.

Description

Fluphenazine is one of many drugs in the group called the phenothiazines. Phenothiazines work by inhibiting the actions of the **brain** chemicals, dopamine and norepinephrine, which are overproduced in individuals with **psychosis**.

Fluphenazine is available in 1-mg, 2.5-mg, 5-mg, and 10-mg tablets, a liquid concentrate containing 5 mg per 1 mL, a rapid-onset injectable form containing 2.5 mg per 1 mL, and a long-acting injectable form containing 25 mg per 1 mL.

Recommended dosage

In children over age 16 and in adults, fluphenazine is usually given in oral dosages ranging from 0.5–10 mg daily. The total dosage is usually divided and taken two to four times throughout the day. The dosage is typically reduced at a gradual pace over time to a range between 1 mg and 5 mg. Older adults usually receive lower doses that begin in the range of 1 mg–2.5 mg per day. In children under age 16, the usual range is 0.25–3.5 mg per day divided into several doses. Maximum dosage is normally 10 mg per day for this age group.

This drug is also available by injection. In adults, injections into the muscle range from 1.25–10 mg per day divided into several doses. A long-acting injectable form can also be administered to patients who have been stabilized on the drug. The dose for the long-acting preparation ranges from 12.5–25 mg given every one to four weeks in adults. The dosage for children is lower in all cases.

Precautions

People with a history of depression, lung problems, heart disease, glaucoma, **seizures**, and kidney disease should take fluphenazine only after careful evaluation by their physician. In addition, those undergoing alcohol withdrawal and those who have received **electroconvulsive therapy** should take this drug with great caution and close physician supervision after discussing the risks and benefits with their doctor. Those over age 60 and children under age 12 should take fluphenazine only after a thorough assessment from their physician. Pregnant women should use fluphenazine with great caution.

Fluphenazine may cause drowsiness. People who take this drug should not drive, operate heavy machinery, or perform other hazardous tasks requiring mental alertness until they see how the drug affects them. People taking fluphenazine should avoid significant exposure to sunlight, as the drug may cause people to sunburn more easily. This drug can sometimes change the color of urine to a pinkish or reddish-brown color. Fluphenazine use can make people more susceptible to heat and increase the risk of heatstroke. People taking fluphenazine should get up slowly after being in a reclining position because of potential dizziness.

Side effects

Relatively common side effects that accompany fluphenazine include drowsiness, dizziness, rash, dry mouth, **insomnia**, **fatigue**, muscular weakness, anorexia, blurred vision, some loss of muscular control, and amenorrhea (lack of menstruation) in women.

Dystonia (difficulty walking or moving) may occur with fluphenazine use. This condition may subside in 24 to 48 hours even when the person continues taking the drug and usually disappears when fluphenazine is discontinued.

Fluphenazine use may lead to the development of symptoms that resemble Parkinson's disease. These symptoms may include a tight or mask-like expression on the face, drooling, tremors, pill-rolling motions in the hands, cogwheel rigidity (abnormal rigidity in muscles characterized by jerky movements when the muscle is passively stretched), and a shuffling gait. Taking anti-Parkinson drugs **benztropine** mesylate or **trihexyphenidyl** hydrochloride along with the fluphenazine usually controls these symptoms.

Fluphenazine has the potential to produce a serious side effect called **tardive dyskinesia**. This syndrome consists of involuntary, uncoordinated movements that may appear late in therapy and may not disappear even after the drug is stopped. Tardive dyskinesia involves involuntary movements of the tongue, jaw, mouth or face or other groups of skeletal muscles. The incidence of tardive dyskinesia increases with increasing age and with increasing dosage of fluphenazine. Women are at greater risk than men for developing tardive dyskinesia. There is no known effective treatment for tardive dyskinesia, although gradual (but rarely complete) improvement may occur over a long period.

An occasionally reported side effect of fluphenazine is neuroleptic malignant syndrome. This is a complicated and potentially fatal condition characterized by muscle rigidity, high fever, alterations in mental status, and cardiac symptoms such as irregular pulse or blood pressure, sweating, tachycardia (fast heartbeat), and arrhythmias (irregular heartbeat). People who think they may be experiencing any side effects from this or any other medication should talk to their physician promptly.

KEY TERMS

Agitation—Excessive restlessness or emotional disturbance that is often associated with anxiety or psychosis.

Anticholinergic—Related to the ability of a drug to block the nervous system chemical acetylcholine. When acetylcholine is blocked, patients often experience dry mouth and skin, increased heart rate, blurred vision, and difficulty in urinating. In severe cases, blocking acetylcholine may cloud thinking and cause delirium.

Dementia—A group of symptoms (syndrome) associated with a progressive loss of memory and other intellectual functions that is serious enough to interfere with a person's ability to perform the tasks of daily life. Dementia impairs memory, alters personality, leads to deterioration in personal grooming, impairs reasoning ability, and causes disorientation.

Psychosis—Severe state that is characterized by loss of contact with reality and deterioration in normal social functioning; examples are schizophrenia and paranoia. Psychosis is usually one feature of an over-arching disorder, not a disorder in itself. (Plural: psychoses)

Interactions

Barbiturates lower the level of fluphenazine in the blood. The blood pressure drugs known as beta-blockers tend to decrease the level of fluphenazine in the blood. Bromocriptine, a drug used for Parkinson's disease, also lowers the level of fluphenazine in the blood. Conversely, antimalarial drugs can increase the level of fluphenazine in the blood.

The combination of fluphenazine with the drugs known as cyclic antidepressants lowers the concentrations of both drugs in the blood. Fluphenazine inhibits the blood pressure-lowering effects of the drug called guanadrel. Levodopa, a drug given to patients with Parkinson disease, is less effective when combined with fluphenazine. The combination of fluphenazine with meperidine can cause very low blood pressure and significant depression of the central nervous system. The use of the muscle relaxant, orphenadrine, can lower the effective levels of fluphenazine in the blood.

Flurazepam

Definition

Flurazepam is a benzodiazepine hypnotic (sleeping medication) that is given by mouth. It is sold in the United States under the brand name of Dalmane, but is also manufactured and sold by several companies under its generic name.

Purpose

Flurazepam is used for the short-term treatment of **insomnia**, which is a sleep disorder characterized by difficulty in falling or staying asleep.

Description

Flurazepam is a benzodiazepine, which means that it belongs to a class of drugs whose primary action is to reduce the patient'sanxiety, relax the skeletal muscles, and bring on sleep. Flurazepam is chemically and pharmacologically related to such other benzodiazepine hypnotics as **temazepam** (Restoril), **triazolam** (Halcion), **quazepam** (Doral), and **estazolam**. All the benzodiazepines work by enhancing the effects of a naturally occurring chemical in the body called gamma-aminobutyric acid (GABA). GABA is a neurotransmitter, or chemical that helps to conduct nerve impulses across the tiny gaps between nerve cells. GABA acts to lower the level of activity in the central nervous system; it is involved in muscle relaxation, sedation, and sleep, and plays a role in preventing seizure activity.

Flurazepam decreases the time it takes the patient to fall asleep, thus reducing the number of nighttime awakenings and increasing the length of total sleep time. The difference between a benzodiazepine like flurazepam that is used to help patients fall asleep and those that are used as tranquilizers is the way that each type acts in the **brain**. The sleep-inducing benzodiazepines are faster in getting to the part of the brain that controls sleep. They also reach higher levels of concentration there than the benzodiazepines that are used as tranquilizers.

Flurazepam is available in 15- and 30-mg capsules.

Recommended dosage

The usual dose of flurazepam is 15–30 mg taken by mouth at bedtime. Older or physically weakened patients are usually given the lower dose. Women who are pregnant or nursing a baby, and children younger than 15 should not be given flurazepam. In addition, the drug should not be used for longer than four weeks.

KEY TERMS

Benzodiazepines—A group of central nervous system depressants used to relieve anxiety or to induce sleep.

Central nervous system depressant—Any drug that lowers the level of stimulation or excitement in the central nervous system.

Central nervous system stimulant—Any drug that raises the level of activity in the central nervous system.

Gamma-aminobutyric acid (GABA)—A neurotransmitter that helps to lower or reduce the level of excitement in the nerves, leading to muscle relaxation; calmness; sleep; and prevention of seizures.

Hypnotic—A type of medication that induces sleep.

Metabolism—The group of biochemical processes within the body that release energy in support of life.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Rebound effect—A physical reaction to stopping a medication characterized by the reappearance of the symptom that the medication was given to suppress. For example, people who stop taking flurazepam may experience rebound insomnia.

Precautions

Some of the flurazepam is metabolized (broken down) in the body to form another compound called desalkylflurazepam, which can also cause drowsiness the next day because it remains in the body for hours. This "hangover" effect is most common in people who are taking flurazepam on a daily basis. People who are taking flurazepam may not be able to operate machinery safely or drive a car the next day.

Patients who take flurazepam for several days or weeks may experience a reaction called rebound insomnia when they stop taking it. When a person takes a medication for sleep on a regular basis, the body adjusts to the presence of the drug. It tries to counteract the effects of the medication. As a result, when the person stops taking the sleeping medication, the body will take a few nights to return to its normal condition. During this period of readjustment, the person may experience a few sleepless hours each night.

The sleepiness that flurazepam brings about may be intensified if the patient drinks alcoholic beverages or takes other medications that contain central nervous system depressants. Common types of medications that may cause problems when combined with flurazepam include tranquilizers and antihistamines.

Elderly patients who are taking flurazepam should be monitored for signs of dizziness or loss of coordination. They are at increased risk of falling if they wake up and get out of bed during the night to get a drink of water or use the bathroom.

Side effects

Some people experience dizziness, daytime drowsiness, and loss of coordination while they are taking flurazepam. Elderly patients may lose their balance and fall. Less common side effects include blurred vision, nausea and vomiting, diarrhea or constipation, nightmares, and a feeling of depression.

Interactions

The effects of flurazepam are increased by other central nervous system depressants. These types of chemicals include alcohol, sedatives, and antihistamines (allergy medications). In addition, flurazepam may interact with anti-seizure medications.

Fluvoxamine

Definition

Fluvoxamine is an antidepressant of the type known as selective serotonin reuptake inhibitors (SSRI). It is marketed in the United States under the brand name Luvox.

Purpose

Fluvoxamine is used to treat depression. It is also the first SSRI to be approved by the United States Food and Drug Administration (FDA) for use in **obsessive-compulsive disorder** in children, adolescents, and adults.

Description

Serotonin is a **brain** chemical that carries nerve impulses from one nerve cell to another. Researchers think that depression and certain other mental disorders may be caused, in part, because there is not enough serotonin being released and transmitted in the brain. Like the other SSRI antidepressants, **fluoxetine** (Prozac), **sertraline** (Zoloft), and **paroxetine** (Paxil), fluvoxamine increases the level of brain serotonin (also known as 5-HT). Increased serotonin levels in the brain may be beneficial in patients with obsessive-compulsive dirder, alcoholism, certain types of headaches, **post-traumatic stress disorder** (PTSD), pre-menstrual tension and mood swings, and **panic disorder**.

Fluvoxamine was approved for use in adults in 1993. In 1997, the United States Food and Drug Administration (FDA) approved this medication for the treatment of obsessive-compulsive disorder in children and adolescents.

Fluvoxamine is available in 25-, 50- and 100-mg tablets.

Recommended dosage

Fluvoxamine therapy in adults is started as a single 50-mg dose taken at bedtime. Based on the patient's response to the medication, the dosage can be increased by 50 mg every four to seven days, until maximum benefit is achieved. Maximum dosage is 300 mg per day. Dosage over 100 mg per day should be given as equally divided morning and afternoon doses.

Fluvoxamine therapy in children is started as a single 25-mg dose, initially taken at bedtime. Based on the patient's response to the medication, the dosage can be increased by 25 mg every four to seven days, until maximum benefit is achieved. Maximum dosage in children is 200 mg per day. Dosage over 100 mg per day should be given as equally divided morning and afternoon doses.

Precautions

Patients taking fluvoxamine should be monitored closely for the onset of mania, **seizures**, thoughts of **suicide**, and skin problems (including itching, hives, rashes).

People with impaired liver function, **bipolar disorder** (manic depression), a history of seizures, or individuals contemplating suicide should take fluvoxamine only under close physician supervision.

A group of serious side effects, called serotonin syndrome, has resulted from the combination of SSRI drugs such as fluvoxamine and members of another class of antidepressants known as monoamine oxidase (MAO) inhibitors. Serotonin syndrome usually consists of at least three of the following symptoms: diarrhea, fever, extreme perspiration, mood or behavior changes, overactive reflexes, fast heart rate, restlessness, shivering or shaking. Because of this, fluvoxamine should never be taken in combination with MAO inhibitors. People taking any MAO inhibitors, for example Nardil (**phenelzine** sulfate) or Parmate (**tranylcypromine** sulfate), should stop the MAO inhibitor and wait at least 14 days before starting fluvoxamine or any other antidepressant. The same holds true when discontinuing fluvoxamine and starting an MAO inhibitor.

Physicians and their patients should weigh the risks and benefits of this drug for women who are or wish to become pregnant, as well as in breast-feeding mothers.

Until an individual understands the effects that fluvoxamine may have on them, he or she should avoid driving, operating dangerous machinery, or participating in hazardous activities.

People should not use alcohol while taking fluvoxamine.

Side effects

Common side effects of fluvoxamine therapy include decreased sex drive or decreased sexual performance.

Less common side effects of fluvoxamine therapy include changes in mood, behavior, or thinking, difficulty breathing, difficulty urinating, and twitches or uncontrollable movements of the face or body.

Rare side effects include difficulty moving, blurred vision, clumsiness or problems with balance, seizures, difficulty moving the eyes, increased uncontrollable movements of the body or face, changes in the menstrual period, redness or irritation of the eyes or skin, peeling, itching or burning sensation of the skin, sore throat, fever and/or chills, easy bruising, nosebleeds, abnormal milk production in women, and symptoms of serotonin syndrome (usually at least three of the following: restlessness, overexcitement, irritability, confusion, diarrhea, fever, overactive reflexes, difficulty with coordination, uncontrollable shivering or shaking, trembling or twitching).

Interactions

Fluvoxamine interacts with a long list of other medications. Anyone starting this drug should review the other medications they are taking with their physician and pharmacist for possible interactions. Patients should always inform all their health care providers, including dentists, that they are taking fluvoxamine.

When taken together with fluvoxamine, the effect of the following drugs may be enhanced: benzodiazepines, **beta blockers**, **clozapine**, cholesterol-lowering drugs such as atorvastatin, lovastatin, and simvastatin, antiseizure drugs phenytoin and **carbamazepine**, tricyclic antidepressants, and **pimozide**.

The diet pills dexfenfluramine and fenfluramine may increase the incidence of serotonin syndrome when taken with fluvoxamine.

When **buspirone** is given with fluvoxamine, the therapeutic effect of buspirone may be decreased and the risk of seizures increased.

Increased risk of mania and high blood pressure occurs with selegiline.

Severe, fatal reactions mentioned above have occurred when fluvoxamine is given along with MAO inhibitors.

Fluvoxamine given with warfarin (a blood thinner) may increase the possibility of bleeding.

Frotteurism

Definition

Frotteurism is a disorder in which a person derives sexual pleasure or gratification from rubbing, especially the genitals, against another person, usually in a crowd. The person being rubbed is a victim. Frotteurism is a paraphilia, a disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving objects, the suffering or humiliation of oneself or one's partner (not merely simulated), or children or other nonconsenting persons.

Description

The primary focus of frotteurism is touching or rubbing one's genitals against the clothing or body of a nonconsenting person. This behavior most often occurs in situations that allow rapid escape. Frottage (the act of rubbing against the other person) is most commonly practiced in crowded places such as malls, elevators, on busy sidewalks, and on public transportation vehicles.

The most commonly practiced form of frotteurism is rubbing one's genitals against the victim's thighs or buttocks. A common alternative is to rub one's hands over the victim's genitals or breasts.

Most people who engage in frottage (sometimes called frotteurs) usually fantasize that they have an exclusive and caring relationship with their victims during the moment of contact. However, once contact is made and broken, the frotteur realizes that escape is important to avoid prosecution.

Causes and symptoms

Causes

There is no scientific consensus concerning the cause of frotteurism. Most experts attribute the behavior to an initially random or accidental touching of another's genitals that the person finds sexually exciting. Successive repetitions of the act tend to reinforce and perpetuate the behavior.

Symptoms

In order for the disorder to be clinically diagnosed, the symptoms must meet the diagnostic criteria as listed in the professional's handbook, the ***Diagnostic and Statistical Manual of Mental Disorders***. These symptoms include:

- Recurrent, intense, or sexually arousing fantasies, sexual urges, or behaviors that involve touching and rubbing against a nonconsenting person.
- The person has acted on these sexual urges, or the fantasies or urges cause significant distress to the individual or are disruptive to his everyday functioning.

Demographics

Males are much more likely to engage in frotteurism than are females. Females are the most common victims of frotteurism. Most acts of frottage are peformed by those between 15 to 25 years of age. After the age of 25, the acts decline.

KEY TERMS

Frottage—The act of touching or rubbing against the body or genitals of a non-consenting individual.

Medroxyprogesterone—A progestin, a female hormone.

Paraphilia—A disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Diagnosis

Most people with frotteurism never seek professional help, but people with the disorder may come into the mental health system as a result of a court order. The **diagnosis** is established in an interview between the person accused of frotteurism and the mental health professional (a **psychiatrist** or a **psychologist**, for example). In the interview, the individual acknowledges that touching others is a preferred or exclusive means of sexual gratification. Because this acknowledgment can bring criminal charges, the disorder is underdiagnosed and its prevalence is largely unknown. In some cases, other people besides the accused may be interviewed, including observers or the victim.

Treatments

For treatment to be successful, the frotteur must want to modify existing patterns of behavior. This initial step is difficult for most people with this disorder to take.

Behavior therapy is commonly used to try to treat frotteurism. The frotteur must learn to control the impulse to touch nonconsenting victims. Medroxyprogesterone, a female hormone, is sometimes prescribed to decrease sexual desire.

Frotteurism is a criminal act in many jurisdictions. It is usually classified as a misdemeanor. As a result, legal penalties are often minor. It is also not easy to prosecute frotteurs as intent to touch is difficult to prove. In their defense statements, the accused often claim that the contact was accidental.

The primary goal of frotteurism is to touch the clothing or body of a non-consenting person. This behavior most often occurs in situations that allow rapid escape, and frotteurism is most commonly practiced in crowded places such as public transportation vehicles. *(Patrik Giardino/CORBIS. Photo reproduced by permission.)*

Prognosis

The prognosis for eliminating frotteurism is poor as most frotteurs have no desire to change their behavior. Since frotteurism involves nonconsenting partners and is against the law in many jurisdictions, the possibility of embarrassment may deter some individuals.

Prevention

Most experts agree that providing guidance as to behavior that is culturally acceptable will prevent the development of a paraphilia such as frotteurism. The origin of some instances of frotteurism may be a truly accidental contact that becomes associated with sexual gratification. There is no way to predict when such an association will occur.

Fugue *see* **Dissociative fugue**

G

Gabapentin

Definition

Gabapentin is an anti-seizure medication. It is sold in the United States under the trade name Neurontin.

Purpose

Gabapentin is used in combination with other anti-seizure (anticonvulsant) drugs to manage partial **seizures** with or without generalization in individuals over the age of 12. Gabapentin can also be used to treat partial seizures in children between the ages of three and 12. Off-label uses (legal uses not specifically approved by the United States Food and Drug Administration [FDA]) include treatment of severe, chronic pain caused by nerve damage (such as occurs in shingles, diabetic neuropathy, multiple sclerosis, or post-herpetic neuralgia). Studies are also looking at using gabapentin to treat **bipolar disorder** (also known as manic-depressive disorder).

Description

Brain cells normally transmit nerve impulses from one cell to another by secreting chemicals known as **neurotransmitters**.

Gabapentin is chemically related to a naturally occurring neurotransmitter called GABA (gamma-amino butyric acid). The actual mechanism of action by which gabapentin acts in the brain to control seizures and treat pain is not known, although it appears to alter the action of nerve cells.

Gabapentin was approved for use in the United States in 1993. A liquid formulation was approved for use in 2000. Use in children ages three to 12 was also approved by the FDA in 2000.

Gabapentin is available in 100-, 300-, and 400-mg capsules; in 600- and 800- mg tablets; and in a liquid solution containing 250 mg per 5 ml.

Recommended dosage

People over the age of 12 should be started on 300 mg gabapentin taken three times a day. The dose can be increased up to a total of 1,800 mg per day. In some instances, doses of up to 3,600 mg per day have been tolerated.

Children should receive a dosage of 10–15 mg per kg of body weight per day, divided into three equal doses.

Chronic pain may be treated with 300–3,600 mg per day, divided into three equal doses.

When gabapentin is used for bipolar disorder, the starting dose is usually 300 mg taken at bedtime. Depending on the patient's response, the dose can be increased every four to seven days. Many people receive maximum therapeutic benefit at 600 mg per day, although some people have required up to 4,800 mg per day.

Precautions

Women who are breast-feeding and people who have decreased kidney functioning should discuss the risks and benefits of this drug with their physician. Women who are or wish to become pregnant will also require a careful assessment of the risks and benefits of gabapentin.

Patients should not suddenly discontinue gabapentin, as this can result in an increased risk of seizures. If the medication needs to be discontinued, the dosage should be reduced gradually over a week.

Until an individual understands the effects that gabapentin may have, he or she should avoid driving, operating dangerous machinery, or participating in hazardous activities. Alcohol should be avoided while taking gabapentin.

Side effects

Patients who experience the following side effects of gabapentin should check with their doctor immediately.

KEY TERMS

Diabetic neuropathy—A condition in which the nerve endings, particularly in the legs and feet, become less sensitive. Minor injuries, such as blisters or callouses, are not felt and can thus become infected and become more serious problems.

Multiple sclerosis—A disease characterized by patches of hardened tissue in the brain or spinal cord, paralysis, and/or muscle tremors.

Neuralgia—Pain that extends along the course of a nerve.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

These include more common side effects, such as unsteadiness, clumsiness, and uncontrollable back-and-forth eye movements or eye rolling. Less common side effects include depression, irritability, other mood changes or changes in thinking, and decreased memory. Rare side effects include pain in the lower back or side, difficulty urinating, fever and/or chills, cough, or hoarseness.

Children under age 12 who have the following more common side effects should also check with their doctor immediately: aggressive behavior, irritability, anxiety, difficulty concentrating and paying attention, crying, depression, mood swings, increased emotionality, hyperactivity, suspiciousness or distrust.

Multiple side effects often occur when a patient starts taking gabapentin. While these side effects usually go away on their own, if they last or are particularly troublesome, the patient should consult a doctor. More common side effects that occur when first starting to take gabapentin include blurred or double vision, muscle weakness or pain, swollen hand, feet, or legs, trembling or shaking, and increased **fatigue** or weakness. Less common side effects that occur when initiating gabapentin treatment include back pain, constipation, decreased sexual drive, diarrhea, dry mouth and eyes, frequent urination, headache, indigestion, low blood pressure, nausea, ringing in the ears, runny nose, slurred speech, difficulty thinking and sleeping, weight gain, twitching, nausea and/or vomiting, weakness.

Interactions

Antacids can decrease gabapentin levels in the blood. They should be taken at least two hours before taking gabapentin.

Galantamine

Definition

Galantamine belongs to a class of drugs called acetylcholinesterase inhibitors. In the United States galantamine is sold under brand name Reminyl.

Purpose

Galantamine is used to treat the symptoms of **Alzheimer's disease**. Galantamine is also being evaluated for the treatment of respiratory depression, mania, **vascular dementia** due to **stroke** or cardiac arrest that causes **brain** lesions, and reversal of side effects, such as blurred vision and mental changes caused by medications such as scopolamine.

Description

Alzheimer's disease develops when brain cells, called neurons, undergo an early, and selective death. It is believed that the premature death of these neurons may be prevented if stimulated by a brain chemical called acetylcholine. Acetylcholine is recycled by an enzyme called acetylcholinesterase. Galantamine works by inhibiting this enzyme. The inhibition of acetylcholinesterase increases the concentration of available acetylcholine.

Galantamine has only been studied, and is only used, in patients with mild-to-moderate Alzheimer's disease according to the Alzheimer's Disease Assessment Scale.

Galantamine is available in 4-mg, 8-mg, and 12-mg tablets.

Recommended dosage

The recommended initial dose of galantamine in adults is 4 mg twice daily. After a minimum of four weeks of treatment with galantamine, it may be increased to 8 mg twice daily. Further increases to 12 mg twice

daily should be initiated only after a minimum of four weeks at the previous dose.

Increased side effects associated with higher doses may prevent the increase in dose in some patients. Patients with moderate liver or kidney problems should not exceed 16 mg of galantamine daily.

Precautions

Galantamine should not be used in patients with severe liver or kidney problems. Since there are no well-controlled studies for the use of galantamine in pregnancy, galantamine should only be used if the potential benefits justify the potential risks to the fetus.

Patients who are undergoing anesthesia or bladder or gastrointestinal surgery should take galantamine only after a discussion with their physician. Patients with gastrointestinal problems should be closely monitored if it is decided that they should take galantamine. Galantamine should be used under close physician supervision in patients who have Parkinson's disease, severe asthma, or obstructive pulmonary disease. Because galantamine may slow down the heart, patients with any heart condition, and especially patients taking other medications that slow down the heart, should be evaluated before starting galantamine.

Side effects

The most common side effects reported with the use of galantamine are nausea, vomiting, diarrhea, anorexia, and abdominal pain. These occur most often at dosage-escalation periods. The average duration of nausea is five to seven days. These side effects tend to be less frequent if the patient is taking a total daily dosage of 16 mg. Eleven percent of patients receiving 24 mg daily lose weight, while 6% of patients receiving 16 mg daily experience weight loss.

Other common side effects include dizziness, headache, tremor, **fatigue**, depression, agitation, irritation, and **insomnia**. These side effects have a higher incidence and severity if higher doses are used. If side effects become severe, the dosage should be adjusted downward under physician supervision.

Interactions

There is currently little data regarding potential drug interactions with galantamine. Medications that are known to increase levels of galantamine in the body include cimetidine, erythromycin, ketoconazole, and **paroxetine**.

KEY TERMS

Acetylcholine—A naturally occurring chemical in the body that transmits nerve impulses from cell to cell. Generally, it has opposite effects from dopamine and norepinephrine; it causes blood vessels to dilate, lowers blood pressure, and slows the heartbeat. Central nervous system well-being is dependent on a balance among acetylcholine, dopamine, serotonin, and norepinephrine.

Acetylcholinesterase—The chemical responsible for the breakdown of acetylcholine

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness.

Ganser's syndrome

Definition

Ganser's syndrome is a rare disorder in which the affected person gives approximate answers to questions that have right and wrong answers, such as "What is 5 minus 3?"

KEY TERMS

Factitious disorder—A type of mental disturbance in which patients intentionally act physically or mentally ill without obvious benefits. It is distinguished from malingering by the absence of an obvious motive, and from conversion disorder by intentional production of symptoms.

Malingering—Knowingly pretending to be physically or mentally ill to avoid some unpleasant duty or responsibility, or for economic benefit.

Description

Although this disorder was previously classified as a **factitious disorder**, the American Psychiatric Association has redefined Ganser's syndrome and placed it in the category called "Dissociative Disorder Not Otherwise Specified." Sometimes called "the syndrome of approximate answers," Ganser's syndrome is most often seen in male prisoners. In the past, this was so much the case that early clinicians called the syndrome "prison psychosis," despite the fact that it is not a true **psychosis**. (Psychosis is characterized by a radical change in personality and a distorted sense of reality.) The disorder has also been referred to as hysterical pseudodementia, due to the resemblance of responses to those of demented patients. However, data on the prevalence of the syndrome and on links within families have not been gathered and analyzed.

Ganser's syndrome is usually sudden in onset and, like **malingering**, seems to arise in response to an opportunity for personal gain or the avoidance of some responsibility. The patient will offer nearly correct replies when asked questions about facts of common knowledge, such as the number of days in a year, the number of months in a year, subtracting seven from 100, the product of four times five, etc. To such questions, the patient may respond by stating that there are 360 days in a year, 11 months in a year, 94 for the result of subtracting seven from 100, and that 21 is the product of four times five. These persons appear to have no difficulty in understanding questions asked, but appear to provide incorrect answers deliberately.

This syndrome is seen in conjunction with a preexisting severe personality disorder. However, unless the patient is willing to admit to the manufactured nature of the symptoms, or unless there is conclusive objective evidence contradicting the syndrome, determining whether the patient has a true disorder may be impossible. As with its sudden onset, disappearance of the symptoms can be just as fast. However, symptoms can also appear to worsen if the patient believes someone is watching. When reviewing a case of Ganser's syndrome, the clinician must consider factitious disorder and malingering as alternative diagnoses.

Gender dysphoria *see* **Gender identity disorder**

Gender identity disorder

Definition

Gender identity disorder is a condition characterized by a persistent feeling of discomfort or inappropriateness concerning one's anatomic sex. The disorder typically begins in childhood with gender identity problems and is manifested in adolescence or adulthood by a person dressing in clothing appropriate for the desired gender, as opposed to one's birth gender. In extreme cases, persons with gender identity disorder may seek gender reassignment surgery, also known as a sex-change operation.

Description

Gender identity disorder is distressing to those who have it. It is especially difficult to cope with because it remains unresolved until gender reassignment surgery has been performed. Most people with this disorder grow up feeling rejected and out of place. **Suicide** attempts and substance abuse are common. Most adolescents and adults with the disorder eventually attempt to pass or live as members of the opposite sex.

Gender identity disorder may be as old as humanity. Cultural anthropologists and other scientists have observed a number of cross-gender behaviors in classical and Hindu mythology, Western and Asian classical history, and in many late nineteenth- and early twentieth-cen-

tury pre-literate cultures. This consistent record across cultures and time lends support to the notion that the disorder may be, at least in part, biological in origin. Not all behavioral scientists share this conclusion, however.

Gender identity and gender-appropriate behaviors are generally learned. This learning first occurs at home and later outside the home. Behavioral experimentation, particularly when a child is young, is considered normal. As they grow, children will often experiment with a variety of gender role behaviors as they learn to make the fine distinctions between masculine and feminine role expectations of the society in which they live. Some young boys occasionally exhibit behaviors that Western culture has traditionally labeled "feminine." Examples of these behaviors include wearing a dress, using cosmetics, or playing with dolls.

In a similar manner, some young girls will occasionally assume masculine roles during play. An example of this behavior includes pretending to be the father when playing house. Some girls temporarily adopt a cluster of masculine behaviors. These youngsters are often designated as tomboys. Most experts agree that such temporary or episodic adopting of behaviors opposite to one's gender is normal and usually constitute learning experiences in the acquisition of normal sex role socialization.

In pathological cases, however, children deviate from the normal model of exploring masculine and feminine behaviors. Such children develop inflexible, compulsive, persistent, and rigidly stereotyped patterns. On one extreme are boys who become excessively masculine. The opposite extreme is seen in effeminate boys who reject their masculinity and rigidly insist that they are really girls or that they want to become mothers and bear children.

Such males frequently avoid playing with other boys, dress in girls' clothing, play predominantly with girls, try out cosmetics and wigs, and display stereotypically feminine gait, arm movements, and body gestures. Although much less common, some girls may similarly reject traditionally feminine roles and mannerisms in favor of masculine characteristics. Professional **intervention** is required for both extremes of gender behavior.

This disorder is different from transvestitism or **transvestic fetishism**, in which cross-dressing occurs for sexual pleasure. Furthermore, the transvestite does not identify with the other sex.

Adults with gender identity disorder sometimes live their lives as members of the opposite sex. They often cross-dress and prefer to be seen in public as a member of the other sex. Some people with the disorder request sex-change or sex reassignment surgery.

KEY TERMS

Cross-dressing—Wearing clothing and other attire appropriate to the opposite sex.

Paraphilia—A disorder that is characterized by recurrent intense sexual urges and sexually arousing fantasies generally involving (1) non-human objects, (2) the suffering or humiliation of oneself or one's partner (not merely simulated), or (3) children or other non-consenting persons.

Transsexual—A person whose gender identity is opposite his or her biologic sex.

Transvestite—A person who derives sexual pleasure or gratification from dressing in clothing of the opposite sex.

Persons with gender identity disorder frequently complain that they were born the wrong sex. They may describe their sexual organs as being ugly and may refrain from touching their genitalia. People with gender identity disorder may try to hide their secondary sex characteristics. For instance, males may try to shave off or pluck their body hair. Many elect to take female hormones in an effort to enlarge their breasts. Females may try to hide their breasts by binding them.

Causes and symptoms

Causes

There is no clearly understood or universally agreed-upon cause for gender identity disorder. However, most experts agree that there may be a strong biological basis for the disorder.

The sex of a human baby is determined by chromosomes. Males have a Y chromosome, in addition to a X chromosome, while females have two X chromosomes. The Y chromosome contains a gene known as the testes determining factor. This gene causes cells in an embryo to differentiate and develop male genitals. Embryos without the testes determining factor continue to develop undifferentiated as females.

The newly formed male testes release significant quantities of male hormones during the third month of pregnancy, further enhancing male differentiation. This sudden surge of hormones occurs again in males sometime between the second and twelfth week after birth. It is important to note that there is no corresponding feminizing hormonal surge sequence observed in females at this age.

These facts provide the biological basis for gender identity disorder. Male hormonal surges must occur not only in sufficient amounts, but also during a short window of time to cause masculinization of the developing infant. If there is insufficient androgen, the hormone primarily responsible for masculinization, or the surge comes too early or too late, the developing infant may be incompletely masculinized.

Disruptions of hormonal surges may come from a variety of sources. A partial list includes a disorder in the mother's endocrine system, common maternal **stress**, or maternal medications or some other toxic substances yet to be identified.

Recent post-mortem studies conducted on male-to-female transsexuals, non-transsexual men, and non-transsexual women show a significant difference in the volume of a portion of the hypothalamus that is essential for sexual behavior. While further investigations are needed, these initial studies seem to confirm that one's sense of gender resides in the **brain** and that it may be chemically determined.

In addition to biological factors, environmental conditions, such as socialization, seem to contribute to gender identity disorder. Social learning theory, for example, proposes that a combination of observational learning and different levels and forms of **reinforcement** by parents, family, and friends determine a child's sense of gender, which, in turn, leads to what society considers sex-appropriate or inappropriate behavior.

Symptoms

The onset of puberty increases the difficulties for people with gender identity disorder. The subsequent development of unwanted secondary sex characteristics, especially in males, increases a person's anxiety and frustrations. In an effort to cope with their feelings, some men with gender identity disorder may engage in stereotypical, or even super-masculine, activities. For example, a man struggling with the disorder may engage in such "macho" sports as wrestling and football in order to feel more "male." Unfortunately, the result is usually an increase in anxiety.

This anxious state is characterized by feelings of confusion, shame, guilt, and fear. These individuals are confused over their inability to handle their problem. They feel shame over their inability to control what society considers "perverse" activities. Even though cross-dressing and cross-gender fantasies provide relief, the respite is temporary. These activities often leave individuals with a profound shame over their thoughts and activities.

Closely associated with shame is guilt, particularly about being dishonest with family and friends. Sometimes people with gender identity disorder get married and have children without telling their spouse about their disorder. Typically, it is kept secret because they have the mistaken conviction that participation in marriage and parenting will eliminate or cure their gender identity problems. The fear of being discovered further raises their anxiety. With some justification, people with gender identity disorder fear being labeled "sick," and being rejected and abandoned by people they love.

If an individual's gender identity disorder is profound, a lifestyle change such as occasional cross-dressing may be insufficient. In such a case, gender expression may move from a lifestyle problem to a life-threatening imperative. The result can be extreme depression that requires medical treatment. If sufficiently severe, the imperative may result in gender reassignment surgery. If an individual lacks the psychological commitment to undertake surgery, the result may be suicide.

Demographics

Gender identity disorder is more prevalent in males than in females. Accurate estimates of prevalence for either males or females are not available.

Diagnosis

A mental health professional makes a **diagnosis** of gender identity disorder by taking a careful personal history. He or she obtains the age of the patient and determines whether the patient's sexual attraction is to males, females, both, or neither. Laboratory tests are neither available nor required to make a diagnosis of gender identity disorder. However, it is very important not to overlook a physical illness such as a tumor that might mimic or contribute to a psychological disorder. If there is any question that a physical problem might be the underlying cause of an apparent gender identity disorder, a mental health professional should recommend a complete physical examination by a medical doctor. Laboratory tests might be necessary as components of the physical evaluation.

According to the clinician's handbook for diagnosing mental disorders, the ***Diagnostic and Statistical Manual of Mental Disorders***, fourth edition text revised *(DSM-IV-TR)*, the following criteria must be met to establish a diagnosis of gender identity disorder. More specific descriptions and examples of the first two criteria follow the list.

- A strong and persistent cross-gender identification.

- Persistent discomfort with his or her sex or having a sense of inappropriateness in the gender role of one's birth sex.
- The disturbance is not concurrent with a physical intersex condition, such as hermaphroditism in which a person is born with the genitalia of both male and female.
- The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

A strong and persistent cross-gender identification

In children, the disturbance is manifested by four (or more) of the following:

- Repeatedly stating a desire to be, or insistence that he or she is, a member of the other sex.
- Strong preference for wearing clothes of the opposite gender. In boys, displaying a preference for cross-dressing or simulating female attire; in girls, insistence on wearing only stereotypical masculine clothing.
- Displaying strong and persistent preferences for cross-sex roles in make-believe play or experiencing persistent fantasies of being a member of the other sex.
- Having an intense desire to participate in the games and pastimes that are stereotypical of the other sex.
- Exhibiting a strong preference for playmates of the other sex.

Among adolescents and adults, the disturbance is manifested by symptoms such as a stated desire to become a member of the other sex, frequent passing as a person of the other sex, a desire to live or be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex. These characteristics cannot be merely from a desire for any perceived cultural advantages of being the other sex.

Persistent discomfort with his or her sex or having a sense of inappropriateness in the gender role of one's birth sex

Among children, the disturbance is manifested by any of the following:

- Among boys, asserting that his penis or testes are disgusting or will disappear, asserting that it would be better not to have a penis, or having an aversion toward rough-and-tumble play and rejecting male stereotypical toys, games, and activities.
- Among girls, rejecting the gender-typical practice of urinating in a sitting position, asserting that she has or will grow a penis, or stating that she does not want to grow breasts or menstruate, or having a marked aversion toward normative feminine clothing.

Among adolescents and adults, the disturbance is manifested by symptoms such as preoccupation with getting rid of primary and secondary sex characteristics (request for hormones, surgery, or other procedures to alter sexual characteristics to simulate the other sex, for example) or a belief that he or she was born the wrong sex.

Treatments

One common form of treatment for gender identity disorder is **psychotherapy**. The earlier the intervention, the greater likelihood of success. Early intervention can lead to reduced levels of transsexual behavior later in life. The initial aim of treatment is to help individuals function in their biologic sex roles to the greatest degree possible.

Adults who have had severe gender identity disorder for many years sometimes request reassignment of their sex, or sex-change surgery. Before undertaking such surgery, they usually undergo hormone therapy to suppress same-sex characteristics and to accentuate other-sex characteristics. For instance, the female hormone estrogen is given to males to make breasts grow, reduce facial hair, and widen hips. The male hormone testosterone is administered to females to suppress menstruation, deepen the voice, and increase body hair. Following the hormone treatments, pre-operative candidates are usually required to live in the cross-gender role for approximately a year before surgery is performed.

Prognosis

If gender identity disorder persists into adolescence, it tends to be chronic in nature. There may be periods of remission. However, adoption of characteristics and activities appropriate for one's birth sex is unlikely to occur.

Prevention

Providing gender-appropriate clothing and toys in infancy and early childhood is helpful in preventing or mitigating gender identity disorder. Avoiding derogatory comments about a child's toy, clothing, or activity preference reduces the potential for inadvertent psychic harm.

Most individuals with gender identity disorder require and appreciate support from several sources. Families, as well as the person with the disorder, need and appreciate both information and support. Local and national **support groups** and informational services exist, and health care providers and mental health professionals can provide referrals.

Gender issues in mental health

Defining gender

The term *gender* is often used to classify the anatomy of a person's reproductive system as either male or female. In the social sciences, however, the concept of gender means much more than biological sex. It refers to socially constructed expectations regarding the ways in which one should think and behave, depending on sexual classification. These stereotypical expectations are commonly referred to as gender roles. Attitudes toward gender roles are thought to result from complex interactions among societal, cultural, familial, religious, ethnic, and political influences.

Gender affects many aspects of life, including access to resources, methods of coping with **stress**, styles of interacting with others, self-evaluation, spirituality, and expectations of others. These are all factors that can influence mental health either positively or negatively. Psychological gender studies seek to better understand the relationship between gender and mental health in order to reduce risk factors and improve treatment methods.

Traditional gender roles define masculinity as having power and being in control in emotional situations, in the workplace, and in sexual relationships. Acceptable male behaviors include competitiveness, independence, assertiveness, ambition, confidence, toughness, anger, and even violence (to varying degrees). Males are expected to avoid such characteristics associated with femininity as emotional expressiveness, vulnerability (weakness, helplessness, insecurity, worry), and intimacy (especially showing affection to other males).

Traditional femininity is defined as being nurturing, supportive, and assigning high priority to one's relationships. Women are expected to be emotionally expressive, dependent, passive, cooperative, warm, and accepting of subordinate status in marriage and employment. Competitiveness, assertiveness, anger, and violence are viewed as unfeminine and are not generally tolerated as acceptable female behavior.

Gender theories

Differences in gender roles have existed throughout history. Evolutionary theorists attribute these differences to the physiological characteristics of men and women that prescribed their best function for survival of the species. In primitive societies, men adopted the roles of hunting and protecting their families because of their physical strength. Women's ability to bear and nurse children led them to adopt the roles of nurturing young, as well as the less physically dependent roles of gathering and preparing food. These gender-dependent labor roles continued into the period of written human history, when people began to live in cities and form the earliest civilized societies.

In the 1800s, the industrial movement marked a prominent division of labor into public and private domains. Men began leaving home to work, whereas women worked within the home. Previously, both men

KEY TERMS

Active coping strategies—Ways of handling stress that affect the problem or situation in some way.

Androgyny—A way of behaving that includes high levels of both masculinity and femininity.

Antisocial behavior—Behavior characterized by high levels of anger, aggression, manipulation, or violence.

Avoidant coping strategies—Ways of coping with stress that do not alter the problem in any way, but instead provide temporary relief or distraction.

Externalizing disorders—Mental disorders with primary symptoms that involve outward behavior as opposed to inner emotions.

Femininity—Prescribed behavior for females, characterized by interpersonal warmth, passivity, and lack of aggression.

Gender role conflict or stress—A negative psychological state resulting from a discrepancy between gender role expectations and how one actually thinks, feels, or behaves.

Gender roles—Stereotypical expectations regarding how one should think, behave, and feel depending on whether one is male or female.

Internalizing disorders—Mental disorders with primary symptoms that involve inner emotions as opposed to outward behavior.

Machismo—The Latino image of extreme masculinity that includes such qualities as concern for personal honor, virility, physical strength, heavy drinking, toughness, aggression, risk taking, authoritarianism, and self-centeredness.

Masculinity—Prescribed behavior for males, characterized by independence, strength, control, and avoidance of emotional expressiveness.

Masochistic tendencies—Tendencies to direct harm or hatred towards oneself.

Object-relations theory—An approach to psychological development that includes Nancy Chodorow's stating that children develop according to interactions with their primary caregivers.

Psychoanalytic theory—A psychological theory proposed by Sigmund Freud involving unconscious conflicts and specific stages of development; central themes include sexuality and male superiority.

Socialization—The process whereby social influences and demands shape one's values, beliefs, or behavior.

and women frequently engaged in comparably respected, productive activities on their homestead. When men began working in the public domain, they acquired money, which was transferable for goods or services. Women's work, on the other hand, was not transferable. Men's relative economic independence contributed to their power and influence, while women were reduced to an image of frailty and emotionality deemed appropriate only for domestic tasks and child-rearing.

Sigmund Freud's psychoanalytic theory of human development, which emerged from Freud's late-nineteenth-century European setting and medical training, reflected an attitude of male superiority. Freud asserted that as children, boys recognize they are superior to girls when they discover the difference in their genitals. Girls, on the other hand, equate their lack of a penis with inferiority. This feeling of inferiority causes girls to idolize and desire their fathers, resulting in passivity, masochistic tendencies, jealousy and vanity—all seen by Freud as feminine characteristics.

Other developmental theorists rejected Freud's notions. Eric Erikson (in 1950) and Lawrence Kohlberg (in 1969) theorized that all humans begin as dependent on caregivers and gradually mature into independent and autonomous beings. Such theories, however, still favored males because independence has historically been considered a masculine trait. By such a standard, males would consistently achieve greater levels of maturity than females.

Nancy Chodorow's object-relations theory (in 1978) favored neither sex. She proposed that children develop according to interactions with their primary caregivers, who tend to be mothers. Mothers identify with girls to a greater extent, fostering an ability to form rich interpersonal relationships, as well as dependency traits. Mothers push boys toward independence, helping them to adjust to the male-dominated work environment, but rendering them unaccustomed to emotional connection. Chodorow's theory suggests both strengths and weaknesses inherent in male and female development, with neither deemed superior. Around that same time (1974), Sandra Bem advocated for

androgyny, or high levels of both masculinity and femininity, as the key to mental health.

In the 1980s, such psychologists as Carol Gilligan sought to build respect for stereotypically feminine traits. They introduced the notion that women function according to an ethic of care and relatedness that is not inferior to men—just different. In 1985, Daniel Stern's developmental theory favored traditional femininity, suggesting that humans start out as unconnected to others and gradually form more complex interpersonal connections as they mature.

Current gender studies appear less concerned with establishing male or female superiority. The general consensus seems to be that gender is socially constructed rather than biologically determined. The process of learning gender roles is known as socialization. Children learn which behaviors are acceptable or not acceptable for their sex by observing other people. They may also be shamed by caregivers or peers when they violate gender role expectations. As a result, gender roles usually become an internal guide for behavior early in childhood. Current studies focus on the ways in which extreme notions of masculinity or femininity affect mental health, and the social processes that shape one's concept of maleness or femaleness.

Gender role conflict

In current research, gender is viewed as an artificial (humanly constructed) concept that may not be related to biological sex at all. For example, masculinity and femininity may simply be sets of personality traits that can be exhibited by either sex. Individuals vary in degree of adherence to gender roles, resulting in large amounts of behavioral variation within the sexes.

Although attitudes toward gender roles are now much more flexible, different cultures retain varying degrees of expectations regarding male and female behavior. An individual may personally disregard gender expectations, but society may disapprove of his or her behavior and impose external social consequences. On the other hand, an individual may feel internal shame if he or she experiences emotions or desires characteristic of the opposite sex. Gender role conflict, or gender role stress, results when there is a discrepancy between how one believes he or she should act—based on gender role expectations learned in childhood—and how one actually thinks, feels, or behaves. If these discrepancies are unresolved, gender role conflict contributes to poor mental health.

Women's issues

Typical stressors

Women are often expected to occupy a number of roles at the same time: wife, mother, homemaker, employee, or caregiver to an elderly parent. Meeting the demands of so many roles simultaneously leads to stressful situations in which choices must be prioritized. Women are often forced to choose whether to pursue or further a career versus whether to devote more time to home and family.

Many women prefer to work outside the home because it gives them a greater sense of life satisfaction. For other women, such as those who run single-parent households, employment is not an option—it is a necessity. Compared with men, women are frequently given jobs with less autonomy or creativity, which decreases their level of job satisfaction. Women may also have more difficultly being accepted in the workplace because of hierarchical structures preferring men. Documentation repeatedly shows that women's salaries are lower than those of men in comparable positions; women tend to be paid less even when performing the same job as a man.

When women do choose or are required to work outside the home, they continue to perform the bulk of household duties as well. Sarah Rosenfield reported that compared to men, women perform 66% more of the domestic work, sleep one-half hour less per night, and perform an extra month of work each year. Needless to say, increased workloads and decreased attention to rest and relaxation are stressful and pose obstacles to women's mental health.

Divorce results in more severe consequences for women who choose or are able to stay home in deference to child-rearing. Such women depend on marriage for financial security. Such domestic skills as childcare and housecleaning are not highly valued by society, and thus are poorly compensated in terms of money. Women who have never been employed and then experience divorce often have few options for securing adequate income.

Although women's ability to form meaningful relationships is a buffer against stress, it can also be a source of stress. Caring about another person can be stressful when that person is not doing well physically or emotionally. Many families take for granted that the female members will care for elderly parents who are no longer self-sufficient. As a result, many women in their forties or fifties are caught between the needs of their college-age offspring and the needs of dependent parents or parents-in-law. Interpersonal conflicts resulting from these heavy burdens may cause stress or lower self-esteem. Women may also view unsuccessful relationships as rep-

resenting failure on their part to fulfill traditional feminine qualities such as nurturance, warmth, and empathy.

Additional sources of stress common to women include victimization, assertiveness, and physical unattractiveness. Victimization is a constant concern due to the power differential between men and women. Assertiveness may be stressful for women who have had little experience in competitive situations. Physical unattractiveness may cause some women who adhere to unrealistic standards of feminine beauty to experience shame, or place them at risk for developing eating disorders. Women considered unattractive may also suffer discrimination in the workplace or in admission to higher education. In addition, the double standard of aging in contemporary society means that all women will eventually have to cope with the **stigma** of unattractiveness simply through growing older.

Typical coping strategies

Studies suggest that women typically react to stress by seeking social support, expressing feelings, or using distraction. These strategies might include praying, worrying, venting, getting advice, or engaging in behaviors that are not related to the problem at all (including such antisocial behaviors as drinking alcohol). Seeking social support and distraction are considered avoidant coping strategies because they do not focus on solving or overcoming a problem, only on alleviating the stress associated with the problem. Research is inconclusive regarding whether men or women are more likely to use problem-solving, which is considered an active coping strategy.

Typical patterns of psychopathology

Women are more likely than men to experience internalizing disorders. Primary symptoms of internalizing disorders involve negative inner emotions as opposed to outward negative behavior. Depression (both mild and severe) and anxiety (generalized or "free-floating" anxiety, phobias, and panic attacks) are internalizing disorders common to women. Symptoms include sadness; a sense of loss, helplessness, or hopelessness; doubt about one's ability to handle problems; high levels of worry or nervousness; poor self-esteem; guilt, self-reproach, and self-blame; decreased energy, motivation, interest in life, or concentration; and problems with sleep or appetite.

Men's issues

Typical stressors

Situations that typically produce stress for men are those which challenge their self-identity and cause them to feel inadequate. If their identity closely matches a traditional male role, they will experience stress in situations requiring subordination to women or emotional expressiveness. They will also experience stress if they feel they are not meeting expectations for superior physical strength, intellect, or sexual performance. Research indicates that men who strictly adhere to extreme gender roles are at higher risk for mental disorders.

Certain cultures are thought to adhere more strictly to traditional male gender roles. In a study by Jose Abreu and colleagues, Latino men were identified as adopting the most exaggerated form of masculinity, followed by European Americans, and then African Americans. The Latino image of masculinity is often referred to as *machismo* and includes such qualities as concern for personal honor, virility, physical strength, heavy drinking, toughness, aggression, risk-taking, authoritarianism, and self-centeredness. African American males are also thought to have a unique image of masculinity; however, Abreu's study showed that African Americans are more egalitarian in terms of gender roles than European Americans.

Typical coping strategies

Men typically respond to stress by putting on a tough image, keeping their feelings inside, releasing stress through such activities as sports, actively attempting to solve the problem, denying the problem, abusing drugs or alcohol, or otherwise attempting to control the problem. As stated previously, research is inconclusive regarding whether males or females use problem-solving strategies more often. This type of coping strategy, however, has more frequently been attributed to males. Problem-solving is seen as an active coping strategy, which is more effective than such avoidant strategies as **denial**, abuse of drugs or alcohol, or refusing to talk about problems.

Typical patterns of psychopathology

Men are more likely than women to experience externalizing disorders. Externalizing disorders are characterized by symptoms involving negative outward behavior as opposed to internal negative emotions. Such externalizing disorders as substance abuse (both drugs and alcohol) and antisocial behavior (such as anger, hostility, aggression, violence, stealing, etc.) are common to men. Substance abuse results in such negative physical and social consequences as **hallucinations**, blackouts, physical dependency, job loss, divorce, arrests, organ and **brain** damage, and financial debt. Antisocial behavior impairs interpersonal relationships and can also result in negative consequences in other areas of life, such as run-ins with the criminal justice system.

Men are not exempt from such internalizing disorders as anxiety and depression. In fact, one study found that high levels of masculinity appear to be related to depression in males. Some researchers feel that men's abuse of substances could be considered the male version of depression. Because male gender roles discourage admitting vulnerability, men may resort to substance abuse as a way of covering their feelings.

Men who adhere to rigid gender roles are also at a disadvantage in interpersonal relationships, especially intimate relationships. They may avoid emotional expressiveness, or may behave in domineering and hostile ways. These behaviors increase their risk of social isolation, disconnection from nurturance, and participation in unhealthy relationships.

Mental health

Research indicates that, overall, neither males nor females are at greater risk for developing mental disorders as such. Being male or female may indicate susceptibility to certain types of disorders, however. Neither masculinity nor femininity is uniformly positive; both gender identifications have strengths and weaknesses. For example, femininity appears to be protective against antisocial behaviors and substance abuse, but is associated with high levels of avoidant coping strategies and low levels of achievement. Masculinity appears to be protective against depression, but is high in antisocial behavior and substance abuse.

Information about gender roles has implications for treatment. Women may not seek treatment because of lack of such resources as money, transportation, or time away from childcare duties. A treatment center sensitive to women's issues should seek to provide these resources in order to facilitate access to treatment. Men, on the other hand, may not seek treatment because it is incongruent with their image of masculinity. Therapists may need to offer men less threatening forms of treatment, such as those that focus on cognitive problem-solving rather than on emotions.

The focus of therapy may differ according to one's gender issues. Therapists should recognize the potential for shame and defensiveness when exploring gender norms. Externalizing behaviors may point to underlying hidden shame. For women, the importance placed on various roles in their lives and how closely those roles are tied to their self-identity is relevant. Men may be encouraged to connect to the spiritual aspects of their being and to consider less stringent views of masculinity. Therapists should also consider the associated influences of generation, culture, class, occupation, and educational level when exploring gender role issues.

Mental health is best achieved by maintaining a balance between masculine and feminine qualities. Taking either set of qualities to an extreme and to the exclusion of the other is detrimental. A non-traditional gender role orientation would combine the best of both genders: a social focus (reciprocally supportive relationships and a balance between interests of self and others) and active coping strategies.

Flexibility in using coping strategies is also important. Active, problem-focused coping strategies help to change the situation that is causing the problem. Avoidant or emotion-focused coping strategies manage or reduce emotional distress. Avoidant and emotion-focused strategies may be helpful for the immediate crisis, but should be used in combination with more active strategies for complete problem resolution.

Generalized anxiety disorder

Definition

Generalized anxiety disorder, or GAD, is a disorder characterized by diffuse and chronic worry. Unlike people with phobias or post-traumatic disorders, people with GAD do not have their worries provoked by specific triggers; they may worry about almost anything having to do with ordinary life. It is not unusual for patients diagnosed with GAD to shift the focus of their anxiety from one issue to another as their daily circumstances change. For example, someone with GAD may start worrying about finances when several bills arrive in the mail, and then fret about the state of his or her health when it is noticed that one of the bills is for health insurance. Later in the day he or she may read a newspaper article that moves the focus of the worry to a third concern.

A manual commonly used by mental health professionals is the ***Diagnostic and Statistical Manual of Mental Disorders***, also known as the *DSM*. This manual may also be identified more specifically by edition, such as the *DSM,* fourth edition text revised, or *DSM-IV-TR*. The *DSM-IV-TR* classifies GAD as an anxiety disorder.

Description

Generalized anxiety disorder is characterized by persistent worry that is excessive and that the patient finds hard to control. Common worries associated with generalized anxiety disorder include work responsibilities, money, health, safety, car repairs, and household chores. The *ICD-10,* which is the European equivalent of *DSM-IV-TR,* describes the anxiety that typifies GAD as "free-floating," which means that it can attach itself to a wide number of issues or concerns in the patient's environment.

DSM-IV-TR specifies that the worry must occur "more days than not for a period of at least six months"; *ICD-10* states only that the patient "must have primary symptoms of anxiety most days for at least several weeks at a time, and usually for several months." The patient usually recognizes that his or her worry is out of proportion in its duration or intensity to the actual likelihood or impact of the feared situation or event. For example, a husband or wife may worry about an accident happening to a spouse who commutes to work by train, even though the worried partner knows objectively that rail travel is much safer than automobile travel on major highways. The anxiety level of a patient with GAD may rise and fall somewhat over a period of weeks or months but tends to become a chronic problem. The disorder typically becomes worse during stressful periods in the patient's life.

DSM-IV-TR specifies interference with work, family life, social activities, or other areas of functioning as a criterion for generalized anxiety disorder; *ICD-10* does not mention interference with tasks or other activities as a criterion for the disorder. Both diagnostic manuals mention such physical symptoms as **insomnia**, sore muscles, headaches, digestive upsets, etc. as common accompaniments of GAD, but only *DSM-IV-TR* specifies that an adult patient must experience three symptoms out of a list of six (restlessness, being easily fatigued, having difficulty concentrating, being irritable, high levels of muscle tension, and sleep disturbances) in order to be diagnosed with the disorder.

Patients diagnosed with GAD have a high rate of concurrent mental disorders, particularly major depres-

KEY TERMS

Anxiolytic—A preparation or substance given to relieve anxiety; a tranquilizer.

Ataque de nervios—A culture-specific anxiety syndrome found among some Latino groups in the United States and in Latin America. It resembles panic disorder in some respects but also includes dissociative symptoms, and frequently occurs in response to a stressful event.

Autonomic nervous system—The part of the nervous system that governs the heart, involuntary muscles, and glands.

Double anxiety—Acute anxiety from a recent stressful event combined with underlying persistent anxiety associated with generalized anxiety disorder.

Free-floating—A term used in psychiatry to describe anxiety that is unfocused or lacking an apparent cause or object.

Insidious—Proceeding gradually and inconspicuously but with serious effect.

Social modeling—A process of learning behavioral and emotional response patterns from observing one's parents or other adults. Some researchers think that social modeling plays a part in the development of generalized anxiety disorder in women.

Temperament—A person's natural disposition or inborn combination of mental and emotional traits.

Temporomandibular joint dysfunction—Condition resulting in pain in the head, face, and jaw. Muscle tension or abnormalities of the bones in the area of the hinged joint (the temporomandibular joint) between the lower jaw and the temporal bone are usually the cause.

Trait anxiety—A type of persistent anxiety found in some patients with generalized anxiety disorder. Trait anxiety is regarded as a feature (trait) of a person's temperament.

sion disorder, other anxiety disorders, or a substance abuse disorder. They also frequently have or develop such stress-related physical illnesses and conditions as tension headaches, irritable bowel syndrome (IBS), temporomandibular joint dysfunction (TMJ), bruxism (grinding of the teeth during sleep), and hypertension. In addition, the discomfort or complications associated with arthritis, diabetes, and other chronic disorders are often intensified by GAD. Patients with GAD are more likely to seek help from a primary care physician than a **psychiatrist**; they are also more likely than patients with other disorders to make frequent medical appointments, to undergo extensive or repeated diagnostic testing, to describe their health as poor, and to smoke tobacco or abuse other substances. In addition, patients with anxiety disorders have higher rates of mortality from all causes than people who are less anxious.

In many cases, it is difficult for the patient's doctor to determine whether the anxiety preceded the physical condition or followed it; sometimes people develop generalized anxiety disorder after being diagnosed with a chronic organic health problem. In other instances, the wear and tear on the body caused by persistent and recurrent worrying leads to physical diseases and disorders. There is an overall "vicious circle" quality to the relationship between GAD and other disorders, whether mental or organic.

Children diagnosed with GAD have much the same anxiety symptoms as adults. The mother of a six-year-old boy with the disorder told his pediatrician that her son "acted like a little man" rather than a typical first-grader. He would worry about such matters as arriving on time for school field trips, whether the family had enough money for immediate needs, whether his friends would get hurt climbing on the playground jungle gym, whether there was enough gas in the tank of the family car, and similar concerns. The little boy had these worries in spite of the fact that his family was stable and happy and had no serious financial or other problems.

GAD often has an insidious onset that begins relatively early in life, although it can be precipitated by a sudden crisis at any age above six or seven years. The idea that GAD often begins in the childhood years even though the symptoms may not become clearly noticeable until late adolescence or the early adult years is gaining acceptance. About half of all patients diagnosed with the disorder report that their worrying began in childhood or their teenage years. Many will say that they cannot remember a time in their lives when they were not worried about something. This type of persistent anxiety can be regarded as part of a person's temperament, or inborn disposition; it is sometimes called trait anxiety. It is not unusual, however, for people to develop the disorder in their early adult years or even later in reaction to chronic **stress** or anxiety-producing situations. For example, there are instances of persons developing GAD after several years of taking care of a relative with **dementia**, living with domestic violence, or living in close contact with a friend or relative with **borderline personality disorder**.

The specific worries of a person with GAD may be influenced by their ethnic background or culture. *DSM-IV-TR's* observation that being punctual is a common concern of patients with GAD reflects the value that Western countries place on using time as efficiently as possible. One study of worry in college students from different ethnic backgrounds found that Caucasian and African American students tended to worry a variable amount about a wider range of concerns whereas Asian Americans tended to worry more intensely about a smaller number of issues. Another study found that GAD in a community sample of older Puerto Ricans overlapped with a culture-specific syndrome called *ataque de nervios*, which resembles **panic disorder** but has features of other anxiety disorders as well as dissociative symptoms. (People experience dissociative symptoms when their perception of reality is temporarily altered—they may feel as if they were in a trance, or that they were observing activity around them instead of participating.) Further research is needed regarding the relationship between people's ethnic backgrounds and their outward expression of anxiety symptoms.

Causes and symptoms

Causes

The causes of generalized anxiety disorder appear to be a mixture of genetic and environmental factors. It has been known for some years that the disorder runs in families. Recent twin studies as well as the ongoing mapping of the human genome point to a genetic factor in the development of GAD. A gene related to panic disorder was identified in late 2001, which increases the likelihood that there is a gene or genes that govern susceptibility to generalized anxiety. The role of the family environment (social **modeling**) in an individual's susceptibility to GAD is uncertain. Social modeling, the process of learning behavioral and emotional response patterns from observing one's parents or other adults, appears to be a more important factor for women than for men.

Another factor in the development of GAD is social expectations related to gender roles. A recent Swiss study corroborated earlier findings that women have higher levels of emotional distress and lower quality of life than men. The higher incidence of GAD in women has been linked to the diffuse yet comprehensive expectations of women as caregivers. Many women assume responsibility for the well-being and safety of other family members in addition to holding a job or completing graduate or professional school. The global character of these responsibilities as well as their unrelenting nature has been described as a mirror image of the persistent but nonspecific anxiety associated with GAD.

Socioeconomic status may also contribute to generalized anxiety. One British study found that GAD is more closely associated with an accumulation of minor stressors than with any demographic factors. Persons of lower socioeconomic status, however, have fewer resources for dealing with minor stressors and so appear to be at greater risk for generalized anxiety.

One additional factor may be the patient's level of muscle tension. Several studies have found that patients diagnosed with GAD tend to respond to physiological stress in a rigid, stereotyped manner. Their autonomic reactions (reactions in the part of the nervous system that governs involuntary bodily functions) are similar to those of people without GAD, but their muscular tension shows a significant increase. It is not yet known, however, whether this level of muscle tension is a cause or an effect of GAD.

Symptoms

The symptomatology of GAD has changed somewhat over time with redefinitions of the disorder in successive editions of *DSM.* The first edition of *DSM* and *DSM-II* did not make a sharp distinction between generalized anxiety disorder and panic disorder. After specific treatments were developed for panic disorder, GAD was introduced in *DSM-III* as an anxiety disorder without panic attacks or symptoms of major depression. This definition proved to be unreliable. As a result, *DSM-IV* constructed its definition of GAD around the psychological symptoms of the disorder (excessive worrying) rather than the physical (muscle tension) or autonomic symptoms of anxiety. *DSM-IV-TR* continued that emphasis.

According to the *DSM-IV-TR,* the symptoms of GAD are:

- excessive anxiety and worry about a number of events or activities, occurring more days than not for at least six months
- worry that cannot be controlled
- worry that is associated with several symptoms such as restlessness, **fatigue**, irritability, or muscle tension
- worry that causes distress or impairment in relationships, at work, or at school

In addition, to meet the diagnostic criteria for GAD, the content or focus of the worry cannot change the **diagnosis** from GAD to another anxiety disorder such as panic disorder, **social phobia**, or **obsessive-compulsive disorder**, and the anxiety cannot be caused by a substance (a drug or a medication).

One categorization of GAD symptoms that some psychiatrists use in addition to the *DSM* framework consists of three symptom clusters:

- symptoms related to high levels of physiological arousal: muscle tension, irritability, fatigue, restlessness, insomnia
- symptoms related to distorted thinking processes: poor concentration, unrealistic assessment of problems, recurrent worrying
- symptoms associated with poor coping strategies: procrastination, avoidance, inadequate problem-solving skills

Demographics

It is difficult to compare present statistics for generalized anxiety disorder with those of the 1980s and early 1990s because of changes in the diagnostic criteria for GAD in successive editions of *DSM*. The National Institute of Mental Health (NIMH) states that as of 2000, 2.8% of the general United States population, or about four million people, have GAD during the course of a given year. One study that used *DSM-III-R* criteria concluded that 5% of the United States population, or one person in every 20, will develop GAD at some point in their lives. Another range of figures given for the lifetime prevalence of GAD in the American population is 4.1%–6.6%. The figure given for children in the United States is also 5%. Women develop generalized anxiety disorder more frequently than men; the sex ratio is variously given as 3:2 or 2:1. Prevalence across races and ethnic groups is more difficult to determine because of cultural influences on expressions of anxiety.

Some psychiatrists think that generalized anxiety disorder is overdiagnosed in both adults and children. One reason for this possibility is that diagnostic screening tests used by primary care physicians for mental disorders produce a large number of false positives for GAD. One study of the PRIME-MD, a screening instrument for mental disorders frequently used in primary care practices, found that 7% of patients met the criteria for GAD. Follow-up in-depth interviews with the patients, however, revealed that only a third of the GAD diagnoses could be confirmed.

Diagnosis

Diagnosis of GAD, particularly in primary care settings, is complicated by several factors. One is the high level of comorbidity (co-occurrence) between GAD and other mental or physical disorders. Another is the considerable overlap between anxiety disorders in general and depression. Some practitioners believe that depression and GAD may not be separate disorders after all, because studies have repeatedly confirmed the existence and common occurrence of a "mixed" anxiety/depression syndrome.

Evaluating a patient for generalized anxiety disorder includes the following steps:

- Patient interview. The doctor will ask the patient to describe the anxiety, and will note whether it is acute (lasting hours to weeks) or persistent (lasting from months to years). If the patient describes a recent stressful event, the doctor will evaluate him or her for "double anxiety," which refers to acute anxiety added to underlying persistent anxiety. The doctor may also give the patient a diagnostic questionnaire to evaluate the presence of anxiety disorders. The **Hamilton Anxiety Scale** is a commonly used instrument to assess anxiety disorders in general. The Generalized Anxiety Disorder Questionnaire for DSM-IV (GAD-Q-IV) is a more recent diagnostic tool, and is specific to GAD.
- Medical evaluation. Nonpsychiatric disorders that are known to cause anxiety (hyperthyroidism, Cushing's disease, mitral valve prolapse, carcinoid syndrome, and pheochromocytoma) must be ruled out, as well as certain medications (steroids, digoxin, thyroxine, theophylline, and selective serotonin reuptake inhibitors) that may also cause anxiety as a side effect. The patient should be asked about his or her use of herbal preparations as well.
- Substance abuse evaluation. Because anxiety is a common symptom of substance abuse and withdrawal syndrome, the doctor will ask about the patient's use of caffeine, nicotine, alcohol, and other common substances (including prescription medications) that may be abused.
- Evaluation for other psychiatric disorders. This step is necessary because of the frequent overlapping between GAD and depression or between GAD and other anxiety disorders.

In some instances the doctor will consult the patient's family for additional information about the onset of the patient's anxiety symptoms, dietary habits, etc.

Treatments

There are several treatment types that have been found effective in treating GAD. Most patients with the disorder are treated with a combination of medications and **psychotherapy**.

Medications

Pharmacologic therapy is usually prescribed for patients whose anxiety is severe enough to interfere with daily functioning. Several different groups of medications have been used to treat generalized anxiety disorder.

These medications include the following:

- Benzodiazepines. This group of tranquilizers does not decrease worry, but lowers anxiety by decreasing muscle tension and hypervigilance. They are often prescribed for patients with double anxiety because they act very quickly. The benzodiazepines, however, have several disadvantages: they are unsuitable for long-term therapy because they can cause dependence, and GAD is a long-term-disorder; they cannot be given to patients who abuse alcohol; and they cause short-term memory loss and difficulty in concentration. One British study found that benzodiazepines significantly increased a patient's risk of involvement in a traffic accident.
- **Buspirone** (BuSpar). Buspirone appears to be as effective as benzodiazepines and antidepressants in controlling anxiety symptoms. It is slower to take effect (about two–three weeks), but has fewer side effects. In addition, it treats the worry associated with GAD rather than the muscle tension.
- Tricyclic antidepressants. **Imipramine** (Tofranil), **nortriptyline** (Pamelor), and **desipramine** (Norpramin) have been given to patients with GAD. They have, however, some problematic side effects; imipramine has been associated with disturbances in heart rhythm, and the other tricyclics often cause drowsiness, dry mouth, constipation, and confusion. They increase the patient's risk of falls and other accidents.
- Selective serotonin reuptake inhibitors. **Paroxetine** (Paxil), one of the SSRIs, was approved by the Food and Drug Administration (FDA) in 2001 as a treatment for GAD. **Venlafaxine** (Effexor) appears to be particularly beneficial to patients with a mixed anxiety/depression syndrome; it is the first drug to be labeled by the FDA as an antidepressant as well as an anxiolytic. Venlafaxine is also effective in treating patients with GAD whose symptoms are primarily somatic (manifesting as physical symptoms, or bodily complaints).

Psychotherapy

Some studies have found cognitive therapy to be superior to medications and **psychodynamic psychotherapy** in treating GAD, but other researchers disagree with these findings. As a rule, GAD patients who have **personality disorders**, who are living with chronic social stress (are caring for a parent with **Alzheimer's disease**, for example), or who don't trust psychotherapeutic approaches require treatment with medications. The greatest benefit of cognitive therapy is its effectiveness in helping patients with the disorder to learn more realistic ways to appraise their problems and to use better problem-solving techniques.

Family therapy is recommended insofar as family members can be helpful in offering patients a different perspective on their problems. They can also help the patient practice new approaches to problem-solving.

Alternative and complementary therapies

Several alternative and complementary therapies have been found helpful in treating patients with generalized anxiety disorder. These include **hypnotherapy**; music therapy; Ayurvedic medicine; **yoga**; religious practice; and guided imagery **meditation**.

Biofeedback and relaxation techniques are also recommended for GAD patients in order to lower physiologic arousal. In addition, massage therapy, hydrotherapy, shiatsu, and **acupuncture** have been reported to relieve muscle spasms or soreness associated with GAD.

One herbal remedy that has been used in clinical trials for treating GAD is **passionflower** (*Passiflora incarnata*). One team of researchers found that passionflower extract was as effective as **oxazepam** (Serax) in relieving anxiety symptoms in a group of 36 outpatients diagnosed with GAD according to *DSM-IV* criteria. In addition, the passionflower extract did not impair the subjects' job performance as frequently or as severely as the oxazepam.

Prognosis

Generalized anxiety disorder is generally regarded as a long-term condition that may become a lifelong problem. Patients frequently find their symptoms resurfacing or getting worse during stressful periods in their lives. It is rare for patients with GAD to recover spontaneously.

Prevention

As of 2002, the genetic factors involved in generalized anxiety disorder have not been fully identified. In addition, the many stressors of modern life that raise people's anxiety levels are difficult to escape or avoid. The best preventive strategy, given the early onset of GAD, is the modeling of realistic assessment of stressful events by parents, and the teaching of effective coping strategies to their children.

Genetic factors and mental disorders

Introduction and overview

In recent years, mental health professionals have become increasingly aware of the importance of genetic factors in the etiology (causes) of mental disorders. Since the Human Genome Project began its mapping of the entire sequence of human DNA in 1990, the implications of its findings for psychiatric **diagnosis** and treatment have accumulated rapidly. A new subspecialty known as biological psychiatry (also called physiological psychology or psychiatric genetics) has emerged from the discoveries of the last two decades. Biological psychiatry got its start in the late 1980s, when several research groups identified genes associated with manic depression and **schizophrenia** respectively. These studies ran into difficulties fairly quickly, however, because of the com-

plexity of the relationship between genetic factors and mental illness.

The ongoing search for genes related to psychiatric symptoms and disorders is complicated by several factors:

- Psychiatric diagnosis relies on a doctor's human judgment and evaluation of a patient's behavior or appearance to a greater degree than diagnosis in other fields of medicine. For example, there is no blood or urine test for schizophrenia or a personality disorder. Diagnostic questionnaires for mental disorders are helpful in trimming the list of possible diagnoses but do not have the same degree of precision or objectivity as laboratory findings.
- Mental disorders almost always involve more than one gene. Studies have shown that one mental disorder can be caused by different genes on different chromosomes in different populations. For example, one study in the late 1980s found two genes on two different chromosomes among two populations that caused manic depression. Studies of schizophrenia done in the late 1980s and early 1990s revealed the same finding— different genes on different chromosomes produced schizophrenia in different populations. It now appears that specific mental disorders are related to different sets of genes that vary across family and ethnic groups.
- Genes associated with mental disorders do not always show the same degree of *penetrance*, which is defined as the frequency with which a gene produces its effects in a specific group of people. Penetrance is expressed as a percentage. For example, a gene for manic depression may have 20% penetrance, which means that 20% of the members of the family being studied are at risk of developing the disorder.
- Genetic factors in mental disorders interact with a person's family and cultural environment. A person who has a gene associated with susceptibility to alcohol abuse, for example, may not develop the disorder if he or she grows up in a family that teaches effective ways to cope with **stress** and responsible attitudes toward drinking.

There are several terms in biological psychiatry that are important to understand:

- Genotype: A person's *genotype* is the sum total of the genetic material transmitted from his or her parents.
- Phenotype: A person's *phenotype* is the observable signs, symptoms, and other aspects of his or her appearance. The term is also used sometimes to refer to a person's outward appearance and behavior as these result from the interaction between the person's genotype and his or her environment.
- Behavioral phenotype: The concept of a *behavioral phenotype* is used most often with reference to patterns of behavior found in certain developmental disorders of childhood, such as Down syndrome or Prader-Willi syndrome. Behavioral phenotype refers to the greater likelihood that people with a specific genetic syndrome will have certain behavioral or developmental characteristics compared to people who do not have the syndrome; it does not mean that every person diagnosed with a given genetic syndrome will invariably develop these characteristics.

Genetic causality in mental disorders

As of 2002, genes appear to influence the development of mental disorders in three major ways: they may govern the organic causes of such disorders as **Alzheimer's disease** and schizophrenia; they may be responsible for abnormalities in a person's development before or after birth; and they may influence a person's susceptibility to anxiety, depression, **personality disorders**, and substance abuse disorders.

One technological development that has contributed to the major advances in biological psychiatry in the last twenty years is high-speed computing. Faster computers have enabled researchers to go beyond rough estimates of the heritability of various disorders to accurate quantification of genetic effects. In some cases the data have led to significant reappraisals of the causes of specific disorders. As recently as the 1960s and 1970s, for example, schizophrenia was generally attributed to "refrigerator mothers" and a chilly emotional climate in the patients' extended families. As of 2002, however, the application of computer models to schizophrenia indicates that the heritability of the disorder may be as high as 80%. Another instance is **autism**, which was also blamed at one time on faulty parenting but is now known to be 90+% heritable.

Mental disorders with organic causes

The two most important examples of mental disorders caused by organic changes or abnormalities in the **brain** are late-onset Alzheimer's disease and schizophrenia. Both disorders are *polygenic*, which means that their expression is determined by more than one gene. Another disorder that is much less common, Huntington's disease, is significant because it is one of the few mental disorders that is *monogenic*, or determined by a single gene.

SCHIZOPHRENIA. Researchers have known for many years that first-degree biological relatives of patients with schizophrenia have a 10% risk of developing the disorder, as compared with 1% in the general population. The identical twin of a person with schizophrenia has a

KEY TERMS

Anticipation—In medicine, a phenomenon in which certain diseases manifest at earlier ages or in more severe phenotypes in each successive generation of an affected family.

Apolipoprotein E—A protein that transports cholesterol through the body. One form of this protein, apoE4, is associated with a 60% risk of late-onset AD.

Behavioral phenotype—A term that refers to the greater likelihood that people with a specific genetic syndrome will have certain behavioral or developmental characteristics, compared to people who do not have the syndrome.

Beta amyloid protein—A starchy substance that builds up in the brains of people with AD to form the plaques that are characteristic of the disease. Beta amyloid is formed when amyloid precursor protein, or APP, is not broken down properly by the body.

Bleomycin hydrolase—An enzyme involved in the body's processing of amyloid precursor protein. If the gene that governs production of BH mutates, the APP accumulates, producing the plaques in the brains of patients with AD.

Codon—A three-member nucleotide sequence in messenger RNA that codes for a specific amino acid in synthesizing protein molecules.

Cytogenetics—The branch of biology that combines the study of genetic inheritance with the study of cell structure.

Dizygotic—Developed from two fertilized ova. Dizygotic twins are sometimes called fraternal twins.

Down syndrome—A genetic disorder characterized by an extra chromosome 21 (trisomy 21), mental retardation, and susceptibility to early-onset Alzheimer's disease.

Epidemiology—The study of the causes, incidence, transmission, and control of diseases.

Etiology—The cause or origin of a disease or disorder. The word is also used to refer to the study of the causes of disease.

Exon—A segment of DNA that is transcribed to RNA and encodes information about the protein sequence.

Expansion mutation—A genetic mutation caused by additional repetitions of a triplet, or trinucleotide sequence, during the process of genetic transmission. In Huntington's disease, the expansion mutation produces more of a toxic gene product.

Genome—The total genetic makeup of a cell or organism. The human genome is the complete genetic constitution of a human being.

40%–50% risk. The first instance of a specific genetic linkage for schizophrenia, however, was discovered in 1987 by a group of Canadian researchers at the University of British Columbia. A case study that involved a Chinese immigrant and his 20-year-old nephew, both diagnosed with schizophrenia, led the researchers to a locus on the short arm of chromosome 5. In 1988, a study of schizophrenia in several Icelandic and British families also pointed to chromosome 5. Over the course of the next decade, other studies of families with a history of schizophrenia indicated the existence of genes related to the disorder on other chromosomes. In late 2001, a multidisciplinary team of researchers reported positive associations for schizophrenia on chromosomes 15 and 13. Chromosome 15 is linked to schizophrenia in European American families as well as some Taiwanese and Portuguese families. A recent study of the biological pedigrees found among the inhabitants of Palau (an isolated territory in Micronesia) points to chromosomes 2 and 13. Still another team of researchers has suggested that a disorder known as 22q deletion syndrome may actually represent a subtype of schizophrenia, insofar as people with this syndrome have a 25% risk of developing schizophrenia.

ALZHEIMER'S DISEASE. Late-onset Alzheimer's disease (AD) is unquestionably a polygenic disorder. It has been known since 1993 that a specific form of a gene for apolipoprotein E (apoE4) on human chromosome 19 is a genetic risk factor for late-onset Alzheimer's. People who have the apoE4 gene from one parent have a 50% chance of developing AD; a 90% chance if they inherited the gene from both parents. They are also likely to develop AD earlier in life. One of the remaining puzzles about this particular gene, however, is that it is not a consistent marker for AD. In other words, some people who have the apoE4 gene do not develop Alzheimer's, and some who do not have the gene do develop the disorder.

KEY TERMS CONTINUED

Genomic imprinting—The process in which specific genes or DNA segments are modified during the development of sperm or egg cells in a parent-specific fashion. The modification is reversible and appears to include the addition or removal of methyl groups to specific areas within the DNA sequence.

Genotype—The genetic makeup of an organism or a set of organisms.

Huntington's disease—A hereditary disorder that appears in middle age and is characterized by gradual brain deterioration, progressive dementia, and loss of voluntary movement. It is sometimes called Huntington's chorea.

Hyperphagia—An abnormally large appetite for food. Hyperphagia is one of the symptoms of Prader-Willi syndrome.

Intron—A segment of DNA that interrupts an exon and that does not encode any information about the protein sequence.

Monogenic—Determined or controlled by a single gene. Huntington's disease is one of the few psychiatric disorders that is monogenic.

Monozygotic—Developed from a single fertilized ovum. Monozygotic twins are sometimes called identical twins.

Nosology—The branch of medicine that deals with the systematic classification of diseases and disorders.

Nucleotide—One of the molecules that form the building blocks of DNA or RNA. The nucleotides of DNA include a phosphate group, four chemical bases (adenine, cytosine, guanine, and thymine), and a sugar containing five carbon atoms. In RNA the thymine base is replaced by uracil.

Penetrance—In genetics, the frequency with which a specific gene produces its effects in a group of people or other organisms. Penetrance is expressed as a percentage.

Phenotype—The observable signs, symptoms, and other aspects of the makeup of an organism. The term is also used sometimes to refer to the appearance of an organism resulting from the interaction between its genotype and its environment.

Polygenic—A trait or disorder that is determined by a group of genes acting together. Most human characteristics, including height, weight, and general body build, are polygenic. Schizophrenia and late-onset Alzheimer's disease are considered polygenic disorders.

Prader-Willi syndrome—A developmental disorder of childhood characterized by mental retardation; poor muscle tone; delayed growth and sexual maturation; and childhood onset of an abnormally large appetite for food.

In 1998, another gene on chromosome 12 that controls the production of bleomycin hydrolase (BH) was identified as a second genetic risk factor that acts independently of the apoE gene. In December 2000, three separate research studies reported that a gene on chromosome 10 that may affect the processing of amyloid-beta protein is also involved in the development of late-onset AD.

There are two other forms of AD, early-onset AD and familial Alzheimer's disease (FAD), which have different patterns of genetic transmission. Early-onset AD is caused by a defect in one of three genes known as APP, presenilin-1, and presenilin-2, found on human chromosomes 21, 14, and 1, respectively. Early-onset AD is also associated with Down syndrome, in that persons with trisomy 21 (three forms of human chromosome 21 instead of a pair) often develop this form of Alzheimer's. The brains of people with Down syndrome age prematurely, so that those who develop early-onset AD are often only in their late 40s or early 50s when the symptoms of the disease first appear. Familial Alzheimer's disease appears to be related to abnormal genes on human chromosomes 21 and 14.

HUNTINGTON'S DISEASE. Huntington's disease, or Huntington's chorea, is a neurological disorder that kills the cells in the caudate nucleus, the part of the brain that coordinates movement. It also destroys the brain cells that control cognitive functions. In 1983, the gene that causes Huntington's disease was discovered on the short arm of human chromosome 4. Ten years later, the gene was identified as an instance of a triplet or trinucleotide repeat. Nucleotides are the molecular "building blocks" of DNA and RNA. Three consecutive nucleotides form a codon, or triplet, in messenger RNA that codes for a specific amino acid. In 1991, researchers discovered not only that nucleotide triplets repeat themselves, but that these repetitions sometimes expand in number during the

process of genetic transmission. This newly discovered type of mutation is known as a dynamic or expansion mutation. Since 1991, more than a dozen diseases have been traced to expansion mutations. Eight of them are caused by repeats of the triplet cytosine-adenine-guanine (CAG), which codes for an amino acid called glutamine. In 1993, Huntington's disease was identified as a CAG expansion mutation disorder. Where the genetic material from a normal chromosome 4 has about 20 repeats of the CAG triplet, the Huntington's gene has a minimum of 45 repeats, sometimes as many as 86. The higher the number of CAG triplet repeats in a Huntington's gene, the earlier the age at which the symptoms will appear. The expansion mutation in Huntington's disease results in the production of a toxic protein that destroys the cells in the patient's brain that control movement and cognition.

Childhood developmental disorders

Developmental disorders of childhood are another large category of mental disorders caused by mutations, deletions, translocations (rearrangements of the arms of chromosomes) and other alterations in genes or chromosomes.

TRIPLET REPEAT DISORDERS. Since 1991, expansion mutations have been identified as the cause of thirteen different diseases. Some, like Huntington's disease, are characterized by long expansion mutations of the trinucleotide sequence CAG, which in effect adds so much glutamine to the protein being synthesized that it becomes toxic to the nervous system. A second category of triplet repeat disorders contains extra triplets that add an amino acid called alanine to the protein. The sequence of nucleotides is cytosine-guanine-N, where N stands for any of the four basic nucleotides. Although the proteins produced by this type of expansion mutation are not toxic, their normal function in the body is disrupted. The developmental disorders related to these CGN triplets are characterized by abnormalities of the skeleton. One of these disorders is synpolydactyly, in which the patient has more than the normal number of fingers or toes. Another is cleidocranial dysplasia, a disorder marked by abnormal development of the skull.

Other developmental disorders are caused by expansion mutations outside the regions of the gene that code for proteins. The segments of DNA that specify the sequence of a portion of a protein are known as *exons*, while the stretches of DNA that lie between the exons and do not code for proteins are called *introns*. The CAG and CGN groups of triplet disorders described in the preceding paragraph are expansion mutations that occur within exons. A third group of triplet disorders results from expansion mutations in introns. Expansions in this third group are usually much longer than those in the first two categories; some repeat several hundred or even several thousand times. The best-known expansion mutation in this group causes the disorder known as fragile X syndrome. Fragile X syndrome is the most common inherited form of **mental retardation** and should be considered in the differential diagnosis of any child with developmental delays, mental retardation, or learning difficulties. The syndrome is caused by a large expansion of a cytosine-guanine-guanine (CGG) repeat which interferes with normal protein transcription from a gene called the FMR1 gene on the X chromosome. Males with the mutation lack a second normal copy of the gene and are more severely affected than females who have a normal FMR1 gene on their second X chromosome. In both sexes there is a correlation between the length of the expansion mutation and the severity of the syndrome.

The discovery of expansion mutations was the solution to a long-standing genetic riddle. Clinicians had noticed as early as 1910 that some disorders produce a more severe phenotype or occur at earlier and earlier ages in each successive generation of an affected family. This phenomenon is known as *anticipation*, but its biological basis was not understood until recently. It is now known that triplet repeats that are long enough to cause disorders are unstable and tend to grow longer from generation to generation. For example, an expansion mutation of the cytosine-thymine-guanine (CTG) triplet causes a potentially life-threatening developmental disorder known as myotonic dystrophy. Repeats of the CTG triplet that are just above the threshold for myotonic dystrophy itself may produce a relatively mild disorder, namely eye cataracts in later life. Within two to three generations, however, the CTG repeats become longer, producing a fatal congenital illness. In addition to developmental disorders of childhood, expansion mutations may also be involved in other psychiatric disorders. Anticipation has been found in some families affected by **bipolar disorder** and schizophrenia, and some researchers think that it may also be present in some forms of autism.

GENOMIC IMPRINTING. Another recent discovery in the field of biological psychiatry is the phenomenon of genomic imprinting, which distinguishes between chromosomes derived from a person's father and those derived from the mother. Genomic imprinting was discovered in the late 1980s as an exception to Gregor Mendel's laws of biological inheritance. A small subset of human genes are expressed differently depending on the parent who contributes them to a child's genetic makeup. This phenomenon has helped researchers understand the causation of three well-known genetic disorders— Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes.

In the 1980s, researchers studying Prader-Willi syndrome and Angelman syndrome noticed that both disor-

ders were caused by a deletion on the long arm of chromosome 15 in the very same region, extending from 15q11 to 15q13. This finding was surprising, because the two syndromes have markedly different phenotypes. Children with Prader-Willi syndrome have severe mental retardation, poor muscle tone, small hands and feet, and a voracious appetite (hyperphagia) that begins in childhood. As a result, they are often obese by adolescence. Children with Angelman syndrome, on the other hand, do not speak, are often hyperactive, and suffer from **seizures** and sleep disturbances. In the late 1980s, advances in molecular genetics revealed that the different expressions of the same deletion on the same chromosome were determined by the sex of the parent who contributed that chromosome. Children with Prader-Willi syndrome had inherited their father's copy of chromosome 15 while the children with Angelman syndrome had inherited their mother's. Highly specific diagnostic tests for these two disorders have been developed within the past decade.

Beckwith-Wiedemann syndrome is an overgrowth condition in which patients develop abnormally large bodies. They often have low blood sugar at birth and are at high risk for developing Wilms tumor, a childhood form of kidney cancer. Beckwith-Wiedemann syndrome is caused by several different genetic mutations that affect imprinted genes on chromosome 11p15. One of these imprinted genes governs the production of a growth factor that is responsible for the children's large body size.

BEHAVIORAL PHENOTYPES. Although medical professionals are familiar with the physical phenotypes associated with genetic disorders, the notion of behavioral phenotypes is still controversial. A behavioral phenotype is the characteristic set of behaviors found in patients with a genetic disorder. Behavioral phenotypes include patterns of language usage, cognitive development, and social adjustment as well as behavioral problems in the narrow sense. It is important for psychiatrists who treat children and adolescents to understand behavioral phenotypes, because they are better able to identify problem behaviors as part of a genetic syndrome and refer children to a geneticist for an accurate genetic diagnosis.

Examples of behavioral phenotypes are those associated with Down, Prader-Willi, and Williams syndromes. Children with Down syndrome have an increased risk of developing early-onset Alzheimer's disease. They are usually quiet and good-tempered, but may also be hyperactive and impulsive. Their behavioral phenotype includes delayed language development and moderate to severe mental retardation.

Children with Prader-Willi syndrome are often quiet in childhood but develop stubborn, aggressive, or impulsive patterns of behavior as they grow older. The onset of their hyperphagia is often associated with temper tantrums and other behavioral problems. They are typically obsessed with food, frequently hoarding it, stealing it, or stealing money to buy food. About 50% of children diagnosed with Prader-Willi syndrome meet the criteria for **obsessive-compulsive disorder** (OCD).

Williams syndrome is a genetic disorder that results from a deletion of locus 23 on chromosome 7q11. Children with this syndrome often have an "elf-like" face with short upturned noses and small chins. Their behavioral phenotype includes talkativeness, friendliness, and a willingness to follow strangers. They are also hyperactive and easily distracted from tasks. The personality profile of children with Williams syndrome is so distinctive that many are diagnosed on the basis of the behavioral rather than the physical phenotype.

Psychological/behavioral vulnerability in adults

Although psychiatrists at one time regarded emotional wounds in early childhood as the root cause of anxiety and depressive disorders in later life, inherited vulnerability to these disturbances is the subject of intensive study at the present time. In the past two decades, genetic factors have been shown to influence the likelihood of a person's developing mood disorders or post-traumatic syndromes in adult life. A study done in 1990 showed that first-degree relatives of a person diagnosed with major depression were two to four times as likely to develop depression themselves as people in the general population. As of 2002, however, the genetic patterns involved in depression appear to be quite complex; there is some evidence that both genomic imprinting and the phenomenon of anticipation may be present in some families with multigenerational histories of depression. In addition, the evidence indicates that susceptibility to major depression is governed by several different genes on several different chromosomes. At present, genetic factors are thought to account for about 40% of a person's risk of depression, with environmental factors and personal temperament accounting for the remaining 60%.

With regard to manic depression, twin studies have shown that the twin of a patient diagnosed with manic depression has a 70%–80% chance of developing the disorder. As of January 2002, a team of German researchers studying 75 families with a total of 275 members diagnosed with manic depression (out of 445 persons) has narrowed its search for genes for manic depression to one locus on human chromosome 10 and another on the long arm of chromosome 8.

POST-TRAUMATIC SYNDROMES. Researchers have found that some persons are more vulnerable than others to developing dissociative and anxiety-related symptoms

following a traumatic experience. Vulnerability to trauma is affected by such inherited factors as temperament as well as by family or cultural influences; shy or introverted persons are at greater risk for developing **post-traumatic stress disorder** (PTSD) than their extroverted or outgoing peers. In addition, twin studies indicate that certain abnormalities in brain hormone levels and brain structure are inherited, and that these increase a person's susceptibility to developing **acute stress disorder** (ASD) or PTSD following exposure to trauma.

ANXIETY DISORDERS. It has been known for some time that anxiety disorders tend to run in families. Recent twin studies as well as the ongoing mapping of the human genome point to a genetic factor in the development of **generalized anxiety disorder** (GAD). One study determined the heritability of GAD to be 0.32.

Recent research has also confirmed earlier hypotheses that there is a genetic component to **agoraphobia**, and that it can be separated from susceptibility to **panic disorder** (PD). In 2001 a team of Yale geneticists reported the discovery of a genetic locus on human chromosome 3 that governs a person's risk of developing agoraphobia. Panic disorder was found to be associated with two loci, one on human chromosome 1 and the other on chromosome 11q. The researchers concluded that agoraphobia and PD are common, heritable anxiety disorders that share some but not all of their genetic loci for susceptibility.

BEHAVIORAL TRAITS. There has been considerable controversy in the past decade concerning the mapping of genetic loci associated with specific human behaviors, as distinct from behavioral phenotypes related to developmental disorders. In 1993 a group of Dutch researchers at a university-affiliated hospital in Nijmegen reported that a mutation in a gene that governs production of a specific enzyme (monoamine oxidase A or MAOA) appeared to be the cause of violent antisocial behavior in several generations of males in a large Dutch family. At least fourteen men from this family had been in trouble with the law for unprovoked outbursts of aggression, ranging from arson and attacks on employers to sexual assaults on female relatives. Tests of the men's urine indicated that **neurotransmitters** secreted when the body responds to stress were not being cleared from the bloodstream, which is the normal function of MAOA. In other words, the genetic mutation resulted in an overload of stress-related neurotransmitters in the men's bodies, which may have primed them to act out aggressively. As of 2002, however, the Dutch findings have not been replicated by other researchers.

Another controversial study in the early 1990s concerned the possible existence of "gay genes" as a factor in human homosexuality. A researcher at the Salk Institute found that cells in the hypothalamus, a structure in the brain associated with the regulation of temperature and sleep cycles, were over twice as large in heterosexual males as in homosexual men. Although the researcher acknowledged that the structural differences may have arisen in adult life and were not necessarily present at birth, he raised the possibility that sexual orientation may have a genetic component. Another study of affected sibling pairs reported a possible locus for a "gay gene" on the X chromosome, but as of 2002 the results have not been replicated elsewhere.

In general, however, research into the genetic component of human behavior is presently conducted with one eye, so to speak, on the social and political implications of its potential results. Given contemporary concerns about the misuse of findings related to biological race or sex, investigators are usually careful to acknowledge the importance of environmental as well as genetic factors.

Genetic epidemiology

Genetic epidemiology is the branch of medicine that investigates the incidence and prevalence of genetic disorders in specific populations. Researchers in this field make use of specific types of studies in order to assess the relative importance of genetic and environmental factors in families with a history of inherited disorders.

Twin studies

Twin studies are based on the assumption that twins reared in the same family share a common environment. Monozygotic (identical) twins have all their genes in common, whereas dizygotic (fraternal) twins share only half their genes. If a certain disorder appears more frequently in monozygotic twins of affected persons than in dizygotic twins, one may assume that the difference is due to genetic factors rather than the family environment. Some phenotypes show clear differences between identical and fraternal twins, including schizophrenia, childhood autism, **attention-deficit/hyperactivity disorder**, unipolar depression, manic depressive disorder, and cognitive abilities as measured by IQ tests.

Twin studies have proved to be particularly important in genetic research into autism. Until the early 1970s, autism was assumed to be caused primarily by parental coldness toward the child. In part, the lack of interest in genetic aspects of the disorder was due to the fact that cytogenetic research (research that studies the links between genetic inheritance and cell structure) was not sufficiently advanced in the late 1960s to have demonstrated any chromosomal abnormalities in people diag-

nosed with autism. The first small-scale twin study of children with autism was done in 1977; its findings showed, first, that there is a significant difference between monozygotic and dizygotic twin pairs with regard to the appearance of the disorder in siblings. More importantly, the study showed that the similarities within monozygotic pairs of twins included a range of social and cognitive disabilities, not just autism itself. This finding implied that the phenotype of autism is broader than the older diagnostic categories implied. In the 1970s and 1980s, advances in cytogenetic techniques led to the discovery that autism is associated with several different chromosomal abnormalities, including the defect that produces fragile X syndrome. A much larger British twin study done in 1995 confirmed earlier findings in the United States: a monozygotic twin of a child diagnosed with autism was 12 times more likely to have the disorder than a dizygotic twin (60% vs 5%). Secondly, the British study confirmed the hypothesis that the genetic risk of autism extends to a broader phenotype; over 90% of the monozygotic twin pairs in the British study shared social and intellectual disabilities similar to those found in patients with autism, but less severe.

Adoption studies

Adoption studies are used less frequently than twin studies, but are crucial in researching such conditions as schizophrenia and alcoholism. Studies of schizophrenia done in Denmark, for example, showed that the frequency of schizophrenia was 16% in the biological relatives of patients with schizophrenia who had been adopted as infants, compared with 1.8% in the adoptive relatives and the relatives of a group of adopted children who did not have schizophrenia.

Family studies

Family studies are important tools for evaluating environmental effects on children with genetic disorders— and also for evaluating the impact of the disorder on the family environment. Family studies have indicated that families may develop problems in response to a child's illness as well as affecting the child's prognosis for recovery.

Family factors fall into three categories: shared genetic material; shared environment; and nonshared environment. These three categories are complicated, however, by the fact that genetic as well as environmental factors affect interactions between parents and children. For example, a parent's behavior toward a child diagnosed with depression is partly shaped by the parent's genetic vulnerability to depression.

In general, much of the impact of a family's environment on a child with a mental disorder is due to nonshared rather than shared interactions. A clinical research measurement called expressed emotion, or EE, originally developed to study young adults with schizophrenia, is now used to study families with younger children with mental disorders. EE measures three primary aspects of family members' attitudes toward the child with the illness: criticism, hostility, and emotional overinvolvement. A growing number of research studies indicate that EE is a good predictor of the outcome of the child's illness; high EE is a marker of a more difficult course of the disorder and a poorer prognosis.

Clinical applications of biological psychiatry

As of 2002, recent advances in genetics have affected the practice of psychiatry in several ways:

- Genetic counseling. Genetic counseling is recommended when a couple has already produced a child with mental retardation, dysmorphic (malformed) features, or developmental delays; when either parent is suspected or known to have a genetic disorder; when the mother is over 35; when there is a family history of a genetic disorder, especially if several members are affected; or if the mother has been exposed during pregnancy to drugs or environmental toxins known to cause birth defects. Genetic counselors do not try to control the couple's decision about a present or future pregnancy; rather, they offer information about the disorder, including treatment options as well as the risk of recurrence. They discuss possible reproductive choices available to the couple and help them adjust to caring for a child who is already affected.
- Medication selection and dosage. Preliminary studies of patients with schizophrenia indicate that DNA testing of the gene for a specific serotonin receptor can predict the patient's response to antipsychotic drugs. A similar form of gene testing can predict which children with asthma will respond to an inhaled medication known as albuterol and which will not. In the near future, researchers hope to devise genetic tests that will measure patients' responsiveness to specific antidepressant and anti-anxiety medications. Such tests would greatly simplify the present process of trial-and-error prescribing of drugs for psychiatric disorders.
- Psychiatric nosology. Nosology is the branch of psychiatry that deals with the classification of mental disorders. Some current diagnostic labels, including autism and attention-deficit/hyperactivity disorder, may represent groups of related syndromes rather than a single diagnostic entity. In other instances, genetic

studies may lead to eventual reclassification of certain disorders. Some studies, for example, suggest that **body dysmorphic disorder** is more closely related to obsessive-compulsive disorder than to the somatoform disorders with which it is presently grouped.

- Diagnosis of disorders with major psychological consequences. As of 2002, it is possible for people to find out whether they have the gene for Huntington's disease or the BRCA1 or BRCA2 genes for breast cancer. Although some people may choose not to know, others may prefer the possibility of bad news to years of chronic uncertainty and anxiety.

Ethical concerns

As the number of tests available for determining genetic markers for mental disorders continues to increase, ethical issues are being debated. These concerns include:

- Regulation of genetic testing. Some companies have started to market tests for the apoE4 Alzheimer's gene even though the present benefits of such testing are not clear. The Department of Health and Human Services has established an advisory committee to study the question of government regulation of genetic testing.
- Confidentiality. The fear of losing health insurance is a major barrier to acceptance of genetic testing in the general population. Many people do not trust hospitals or research laboratories to keep test results confidential.
- Discrimination. Others are concerned that genetic findings could be used to deny college or graduate school admission to persons at risk for certain disorders, or to restrict their access to employment opportunities.
- Reproductive issues. A recent controversy in the *British Medical Journal* erupted over the question of using genetic testing for "social engineering" by forcing couples to abort fetuses with "undesirable" psychological characteristics or restricting people's right to have children. As more and more human traits are found to have a genetic component, questions inevitably arise regarding the possibility of government control over reproduction. But while few people would want to preserve the gene for Huntington's disease, for example, they are likely to disagree about the desirability of other human traits, such as a tendency toward short stature.

Geriatric Depression Scale

Definition

The Geriatric Depression Scale (GDS) is a 30-item self-report assessment designed specifically to identify depression in the elderly. The items may be answered yes or no, which is thought to be simpler than scales that use a five-category response set. It is generally recommended as a routine part of a comprehensive geriatric assessment. One point is assigned to each answer and corresponds to a scoring grid. A score of 10 or 11 or lower is the usual threshold to separate depressed from nondepressed patients. However, a **diagnosis** of clinical depression should not be made on the GDS results alone. Although the test has well-established reliability and validity, responses should be considered in conjunction with other results from a comprehensive diagnostic work-up. A short version of the GDS containing 15 questions has been developed. The GDS is also available in a number of languages other than English.

Purpose

Depression is widespread among elderly persons, affecting one in six patients treated in general medical practice and an even higher percentage of those in hospitals and nursing homes. Older people have the highest **suicide** rate of any group, and many medical problems common to older people may be related to, or intensified by, a depressive disorder. Recognition of the prevalence of depression among older people prompted the development of the geriatric depression scale in 1982-83. Yes/no responses are thought to be more easily used than the graduated responses found on other standard assessment scales such as the **Beck Depression Inventory**, the

KEY TERMS

Low affect—Severe lack of interest and emotions; emotional numbness.

Somatic concern—Excessive concern about the body, particularly in relation to illness.

Hamilton rating scale for depression, or the Zung self-rating depression scale.

While it is not found in the ***Diagnostic and Statistical Manual of Mental Disorders*** (*DSM-IV-TR*) produced by the American Psychiatric Association, the GDS is widely recommended for clinical use and is included as a routine part of a comprehensive geriatric assessment. It is also increasingly being used in research on depression in the elderly.

Precautions

Depression scales are either interviewer-administered or by self-report means. The GDS is a self-report assessment developed in 1982 by J. A. Yesavitch and colleagues. A self-report assessment is easier and quicker to administer, though an interviewer-administered test is generally more sensitive and specific—another reason for using more than one tool to obtain an accurate diagnosis.

There is some controversy over whether the GDS is reliable for depression screening in individuals with mild or moderate **dementia**. Several studies have shown good agreement with observer ratings of depression, whether or not the patient had dementia. However, persons with dementia may deny symptoms of depression. It also appears that less educated people are more likely to score in the depressed range on the GDS 15-item short form. These caveats notwithstanding, the GDS can be usefully applied in general medical settings in combination with other clinical assessments, observation, and interviews with elder patient and their families.

Both symptom pattern and symptom severity must be considered when trying to identify depression. These dimensions are taken into account in the development of symptom scales and, while clinical judgment takes priority, a scale such as the GDS can help in identifying persons with depression, whether they are making satisfactory progress with treatment, or when they may need further assessment or referral.

Description

Yesavitch and his coworkers chose 100 statements that they determined were related to seven common characteristics of depression in later life. These included:

- somatic concern
- lowered **affect** (affect is the outward expression of emotion)
- cognitive impairment
- feelings of discrimination
- impaired motivation
- lack of future orientation
- lack of self-esteem

The best 30 items were selected after administration of the 100 items to 46 depressed and normal elders. Those items were then administered to 20 elders without depression and 51 who were in treatment for depression. The test was 84% sensitive and 95% specific for a depression diagnosis. Repeated studies have demonstrated the value of GDS.

Examples of the questions in the GDS include:

- Are you basically satisfied with your life?
- Have you dropped many of your activities and interests?
- Are you hopeful about the future?
- Do you often get restless and fidgety?
- Do you frequently get upset over little things?
- Do you enjoy getting up in the morning?

A time frame should be specified for administration of the test, for example, "Answer these questions by thinking of how you've felt the past two weeks."

Results

A scoring grid accompanies the GDS. One point is given for each respondent's answer that matches those on the grid. For example, the grid response to "Are you basically satisfied with your life?" is "no." If the elderly person responds in the negative one point is scored; if the response is "yes," then no point is scored. For the 30-item assessment, a score of 0–9 is considered normal; 10–19 indicates mild depression, and a score over 20 is suggestive of severe depression. The maximum number of points that can be scored is 30.

Gestalt therapy

Definition

Gestalt therapy is a complex psychological system that stresses the development of client self-awareness and personal responsibility.

Purpose

The goal of Gestalt therapy is to raise clients' awareness regarding how they function in their environment (with family, at work, school, friends). The focus of therapy is more on what is happening (the moment-to-moment process) than what is being discussed (the content). Awareness is being alert to what are the most important events in clients' lives and their environment with full sensorimotor, emotional, cognitive, and energy support. Support is defined as anything that makes contact with or withdrawal from with the environment possible, including energy, body support, breathing, information, concern for others, and language, for example.

In therapy, clients become aware of what they are doing, how they are doing it, and how they change themselves, and at the same time, learn to accept and value themselves. Individuals, according to this approach, define, develop, and learn about themselves in relationship to others, and that they are constantly changing.

Gestalt therapy is "unpredictable" in that the therapist and client follow moment-to-moment experience and neither knows exactly where this will take them. Gestalt therapy is complex and intuitive, but it is based on the following principles:

- Holism. Gestalt therapy takes into account the whole person including thoughts, feelings, behavior, body sensations, and dreams. The focus is on integration, that is, how the many parts of the person fit together, and how the client makes contact (interacts) with the environment.
- Field theory. According to this theory, everything is related, in flux, interrelated, and in process. The therapist focuses on how the client makes contact with the environment (family, work, school, friends, authority figures).
- The figure-formation process describes how individuals organize or manipulate their environment from moment to moment.
- Organismic self-regulation is the creative adjustment that the organism (person) makes in relation to the environment. The person's equilibrium with his or her environment is "disturbed" by the emergence of a client need, sensation, or interest and is related to the figure-formation process in that the need of the person organizes the field. For example, if an individual wants coffee, this coffee need is what comes out of the defused background and becomes "figural" (comes to the forefront of the client's environment or field) and when the individual enters a room, the "figural" will be related to the coffee need. The therapist is interested in what is "figural" for a person because it may provide insight into the person's need(s).
- The Now. The concept of the here and now is what is being done, thought, and felt at the moment, and not in the past or the future.
- Unfinished business is defined as the unexpressed feelings that are associated with distinct memories and fantasies. These feelings may be resentment, rage, hatred, pain, anxiety, **grief**, guilt, and abandonment that are not fully experienced in awareness, linger in the background, and are carried into the present life and cause preoccupations, compulsive behaviors, wariness, and other self- defeating behaviors. Unfinished business will persist until the person faces and deals with these denied or alienated feelings.

The current practice of Gestalt therapy includes treatment of a wide range of problems and has been successfully employed in the treatment of a wide range of "psychosomatic" disorders including migraine, ulcerative colitis, and spastic neck and back. Therapists work with couples and families, and with individuals who have difficulties coping with authority figures. In addition, Gestalt therapy has been used for brief **crisis intervention**, to help persons with **post-traumatic stress disorders**, alcohol and drug abuse, depression, or anxiety disorders; with adults in a poverty program; with seriously mentally ill individuals with psychotic disorders; and those with borderline **personality disorders**.

Description

The relationship between the therapist and the client is the most important aspect of **psychotherapy** in Gestalt therapy. In Gestalt therapy, the interaction between therapist and client is an ever changing dialogue marked by straightforward caring, warmth, acceptance, and self-responsibility. There are four characteristics of dialogue:

- Inclusion, in which the therapist puts him- or herself, as much as is possible, into the experience of the client. The therapist does not judge, analyze, or interpret what he or she observes.
- Presence refers to the therapist expressing his or her observations, preferences, feelings, personal experience, and thoughts to the client.
- Commitment to dialogue allows a feeling of connection (contact) between the therapist and the client.
- Dialogue is active and can be nonverbal as well as verbal. It can be dancing, song, words, or any modality that expresses and moves the energy between the therapist and the client.

Gestalt therapy holds the view that people are endlessly remaking or discovering themselves; therefore, individuals are always in constant transformation. The therapist's approach is to help clients: to increase or deepen their awareness of themselves and with aspects of themselves and their relationship with others, by attending and engaging with the client; to explore the client's experience; and to describe what is. All techniques used within the therapeutic relationship help clients to work through and move beyond painful emotional blocks and is an ongoing process. This allows the client to explore new behavior, first, in the context of the therapeutic relationship and then, as appropriate, in the outside world.

The therapeutic process begins at the first contact between client and therapist. The assessment method for the Gestalt therapist has been unique to Gestalt therapy theory, as well as some psychodynamic treatments, and other humanistic treatments. Assessment and screening are usually done as part of the ongoing relationship with the client and not as a separate period of diagnostic testing and history taking. Assessment information is obtained by beginning the therapeutic work and includes: the client's willingness and support for work in the Gestalt therapy framework, the match between the client and the therapist, diagnostic and personality information, the decision regarding the frequency of sessions, the need for adjunctive treatment (such as day treatment, **biofeedback** training), and the need for medication and medical consultation.

Gestalt therapists now make use of the traditional diagnostic categories to obtain necessary information to help patients with serious mental illnesses (such as psychotic disorders and borderline disorders) and because of administrative and insurance reimbursement procedures. Despite these changes, it is believed that Gestalt therapy assessment techniques will continue to be varied since Gestalt therapists draw on other therapeutic systems.

In therapy, the Gestalt therapist is active and sessions are lively and characterized by warmth, acceptance, caring, and self-responsibility and promote direct experiencing of a situation or event rather than passively talking about the event. Events recalled from the past are explored and felt in the here and now of the therapy session. Clients can see, hear, and be told how they are seen, what is seen, how the therapist feels, what the therapist is like as a person, and how client awareness is limited by how they and the therapist interact with or engage each other— that is, make contact.

The Gestalt therapist has a wide range of active interventions (cognitive and behavioral) at his or her disposal and may use any technique or method as long as it is (a) aimed toward increasing awareness, (b) arises out of the dialogue and the therapist's perception of what is going on with the client (sensing, feeling, thinking) in the immediate therapy session), and (c) within the parameters of ethical practice.

Exercises and experiments

Many therapeutic interventions called exercises and experiments have been developed to enhance awareness and bring about client change. Exercises are defined as ready-made techniques that are sometimes used to evoke certain emotions (such as the expression of anger) in clients. Experiments, on the other hand, grow out of the immediate interaction (dialogue) between client and therapist. They are spontaneous, one-of-a-kind, and relevant to a particular moment and the particular development of an emerging issue such as the client's reports of a need, dream, fantasy, and body awareness. Experiments are

done with full participation and collaboration with clients and are designed to expand clients' awareness and to help them to try out new ways of behaving rather than to achieve a particular result. These experiments may take many forms. According to Gerald Corey, some are: "imagining a threatening future event; setting up a dialogue between a client and some significant person in his and her life; dramatizing the memory of a painful event; reliving a particularly profound early experience in the present; assuming the identity of one's mother or father through role-playing; focusing on gestures, posture, and other nonverbal signs of inner expression; carrying on a dialogue between two conflicting aspects within the person."

While participating in experiments, clients actually experience the feelings associated with their conflicts or issues in the here and now. Experiments are tailored to each individual client and used in a timely manner; they are to be carried out in a context that offers safety and support while encouraging the client to risk trying out new behavior. The Gestalt therapy focus is on the entire person and all parts—verbal and nonverbal behaviors, emotional feelings— all are attended to.

Gestalt therapists are said to rely on spontaneity, inventiveness, and "present-centeredness" and a range of possible therapeutic encounters, interactions that leads to exercises and experiments that are potentially infinite but can be categorized as follows.

THE USE OF STATEMENTS AND QUESTIONS TO FOCUS AWARENESS. Many interventions have to do with simply asking "what the client is aware of experiencing;" or asking simple and direct questions as, "What are you feeling?" "What are you thinking?" The client may be instructed to start a sentence with "Now, I am aware..." or is asked to repeat a behavior, as in, "Please wring your hands together again." A frequent technique is to follow the client's awareness report with the instruction, "Stay with it!" or "Feel it out!"
