Psychotherapists, and mental health professionals in general, have long worked closely with medical practitioners. Usually the physician has a psychologist or two who are highly regarded and are the recipients of a stream of referrals. Occasionally this informal arrangement results in a physician/psychologist consultation on a difficult or unusual patient, or other forms of informal collaboration. The characteristic of the traditional model, however, is that two independent practitioners come together in a laissez-faire arrangement in the interest of better patient care.

This informal, independent relationship has at times been expanded in some arrangements to include innovative or unusual services. For example, a surgeon may ask that a stressed or fearful patient receive preoperative counseling in the hospital. Some dentists rely on psychotherapists to work with patients who manifest a severe fear of going to the dentist, and many psychologists are cultivating relationships with dentists with the same intensity that they do with physicians. Some psychologists specializing in the diagnosis of attention deficit and attention deficit hyperactivity disorders (ADD/ADHD) actually have regularly scheduled times in which they administer psychological tests in the neurologist's office. In all these arrangements the traditional characteristic prevails in which independent practitioners are collaborating.

Interestingly, some current arrangements between independent medical and psychological practitioners closely approach the integrated models to be discussed below. In one example a group practice of psychologists assigns its members to be on co-location in hospitals, working side by side with physicians on a regular schedule. In others psychologists are similarly assigned to be on co-location in outpatient settings, mimicking full integration except that being from two different entities the behavioral care practitioners lack decision-making authority and equity in the system being serviced.

III. THE TWO INTEGRATION MODELS OF COLLABORATION

The most far-reaching conceptualization of collaboration is that of the *integration* of behavioral health into primary care in a seamless, indistinguishable system. Actually this model encompasses two different models, both of which are compatible within the same setting,

and will be described separately below. These integration models are seen by many authorities to be the health delivery systems of the future, and they are currently being implemented in a number of large health systems in several states. The largest and most aggressive implementation is at Kaiser Permanente with its 2.4 million enrollees in Northern California. Others in varying stages of implementation include the Group Health Cooperative of Puget Sound (Washington), HealthPartners and Allina (both Minnesota), and HealthCare Partners (Southern California). These systems anticipate decreased costs, especially from medical cost offset through integrated behavioral care, as well as increased access, more appropriate care, and greater patient and provider satisfaction, all as value added. If these organizations (or even just one with a winning formula) attain these goals, the health system will move rapidly toward integration.

As previously mentioned, the integration model is really two compatible models. The first is horizontal integration, which seeks to provide a general response to the diverse needs of primary care. It, in itself, is a series of models, beginning with minimal integration and proceeding in intensity. At its simplest form horizontal integration may provide a toll free number where a PCP can obtain consultation on difficult patients on a 24-hour-a-day basis. For health systems that are not prepared for anything comprehensive, this telephone on-call can be plugged in quickly and with a minimum of disruption. Horizontal integration can proceed upward where the PCP can request specific behavioral health consultations to address medication and psychological treatment strategies, triage, treatment compliance, relapse prevention, lifestyle changes, and a multitude of other kinds of consultative services.

The midpoint in the increase of horizontal integration is co-location, where behavioral care providers are in primary care settings working side by side with PCPs. Extensive research has demonstrated the superiority of this model in patient acceptance of the referral for therapy. In the traditional referral model only 40% of those needing behavioral interventions are identified and referred for therapy. Of these, only 10% follow through and seek psychotherapy. Thus, in the usual primary care setting, only 4% of those needing behavioral care receive it. In the co-location model, where the physician walks with the patient a few steps down the hall to the psychologist's office and participates in a three-way 15-minute session (patient, PCP, and psychologist), 85 to 90% of these patients go into psychotherapy. Patient satisfaction is high, and patients

seemingly see the referral as within the medical system rather to an outside mental health system with its unfortunate stigma attached.

Physician satisfaction is equally high inasmuch as access to behavioral intervention is immediate, readily accepted by the patient, and effective in its outcome. This and the opportunity to catch a behavioral care provider for consultation in the setting at any time is called the hallway hand-off.

Proceeding upward through the scale of horizontal integration is the formation of teams consisting of PCPs, behavioral care providers, nurse practitioners, and health educators who are given the responsibility for all the health care (direct as well as referral to specialists) for a specified population cohort. In its ultimate form, there is an obliteration of departments of medicine, psychiatry, and nursing, and the team is a semiautonomous unit with its own budget and support staff.

Perhaps the most far-reaching example of this team approach is found in the retooling of the Kaiser Permanente system in Northern California. Its 2.4 million enrollees are being divided into cohorts of 20,000 enrollees, each having its own primary care team of physicians, psychologists, nurse practitioners, and a health educator. Kaiser anticipates achieving the advantages of "small group practice" while retaining the leverage and clout of a huge total enrollment.

The second type of integration, called vertical integration, focuses its programs on specific segments of the primary care population. These are usually segments that account for disproportionate medical costs, often because of psychological problems that accompany them, or because of noncompliance to medical regimen. The most frequent are group programs for arthritis, asthma, diabetes, hypertension, ischemic heart disease, and emphysema, which together account for 40 cents of the health care dollar in the age group of 18 to 55. Other programs focus on psychological problems that also result in high medical utilization. The most important of these is depression, from which at one time or another 40% of primary care patients will suffer. Other psychological group programs are panic and anxiety disorders, including agoraphobia, and pain management. The programs are conducted by the team and will be described in a later section.

The usual vertically integrated programs employ one or two, and at most three programs. A notable exception is found at Kaiser Permanente in San Jose, where over a dozen such program have been used successfully for almost a decade. There the psychologist who heads the Department of Behavioral Medicine works closely with the

head of the Department of Medicine in a joint endeavor that has often been regarded as a model to be emulated.

In a well-integrated primary care system, horizontal and vertical integration are not only compatible, but they are both indispensable. Most programs beginning the path to integration adopt one vertical program, such as depression, and make very hesitant moves toward expanding to additional vertical programs. Horizontal integration seems to proceed even slower, with the infusion of beginning consultation programs between PCPs and behavioral health providers, and a reluctance to proceed to the next step. Two factors are required to proceed on a well-scheduled integration program. The first is the ability to electronically track the financial and other benefits, a capacity most health systems lack. The second is the buy-in of both the medical and administrative leaders to the need for integration. In even the most determined systems, a satisfactory level of buy-in required to proceed appropriately from early to more advanced steps involves a minimum of 1 year.

IV. BARRIERS TO COLLABORATIVE CARE

There are a number of formidable barriers to collaboration, especially as these pertain to the more extensive concept of integration. Some are historic, whereas others are current, and they all involve economic, turf, or training issues. Social policy moves slowly; health care policy moves even more slowly. We are confronted by centuries of tradition, attitudes, beliefs, and biases, and at least one century of modern medicine in which allopathics and the biomedical model have contributed enormously, along with public health, to our longevity, well-being, and quality of life. This very success can mitigate against change. The following are the more apparent barriers to collaboration and integration.

A. Mind–Body Dualism

Descartes, the 16th century philosopher and physician, is regarded as the one who first admonished medicine that the mind and the body are separate. This dualism exists in various forms to this day. The lines of demarcation between separate departments of medicine and psychiatry have spawned a necessary profession known as liaison psychiatry that attempts to bridge the gap between the two specialties. The existence of liaison psychiatry underscores the dualism, and in providing a stop-gap response it perpetuates it.

Reductionism, which posits that disease can best be understood at the molecular level of biology and physiology is, along with the mind-body dualism, at the very heart of the medical culture and the basis for much of its past scientific progress. It disregards research in medical psychology that demonstrates the interplay between the body's tissues and their environment, and that along with genetics, lifestyles are integral to most modern diseases. Long before Descartes, Hippocrates argued that it is more important to know what kind of person has a disease, than what disease a person has.

B. Entrenched Behaviorism

Psychology in the United States has never completely overcome the heritage given it by John B. Watson, who maintained that at birth a child is a blank slate and that the environment can make of a child a genius or a criminal. Biology has not received appropriate attention by American psychology, which has self-opted out of what is now known as the genetic revolution. The ultimate psychosocial model is no more prepared to deal with DNA than the strict biomedical model can explain disease-producing behavior. Integration involves the sharing of turf on both sides of the mind–body dualism.

C. Financial Barriers

1. *Not Out of My Budget*

Little progress has been made in integrating behavioral and medical health care through arrangements in which money is pooled from either or both of the departmental budgets of medicine and psychiatry. In a few settings where PCPs are having difficulty managing “troublesome” patients who manifest a variety of behavioral problems, medical budgets have been used to cover a limited collaboration. This is usually done to relieve PCPs from being overburdened with these patients. More often, however, collaboration costs are expected to come from the psychiatric budget. Consequently, most collaborative efforts never get beyond the discussion stage because each department is guarding its own strained budget, not recognizing that integrated care yields a medical cost offset that can be shared. (For more information on health care financing, as well as medical cost offset, see “Economic/Policy Issues” in this *Encyclopedia*.)

2. *Resistance from the Carve-outs*

The delivery of behavioral care through separate companies known as carve-outs has grown to encom-

pass over 150 to 175 million Americans, depending on how populations are counted. Collaboration is problematic, and integration is next to impossible when the primary care system has a different ownership than the behavioral care system. Separate behavioral care delivery is currently a huge industry that pays lip service to “carving-in,” because serious consideration to do so lacks financial incentive and may actually reduce profits. This equity separation is the most formidable barrier, as integration (or the carve-in) can only be accomplished by dissolving the ownership of large for-profit companies, something that does not seem probable in the immediate future.

3. Resistance by Specialists

In the usual health care arrangement, the primary care system refers to specialists for care beyond the primary level. With the increases in capitation and risk pools, this means the primary care system can lose money if it overly refers to specialists, since these specialists are usually practitioners outside the primary care system that must still be reimbursed from the primary care system. The trend, therefore, is to do the front-end specialty work (such as minor surgery, as well as less severe gastroenterology, cardiology, pulmonology, and even oncology) right in the primary care setting. Consequently, PCPs are doing more of what previously was referred to specialists, nurse practitioners and physician assistants are doing more of the PCP’s work, lesser trained nurses are doing what previously required registered nurses, and so forth. The more primary care includes specialty practice, the fewer are the referrals to specialists. This trend increases with degrees of integration, and with the subsequent loss of turf, specialists understandably oppose integration arrangements and models. Among the most resistant of the specialists are practicing psychotherapists who prefer solo (separate) practice, and whose referrals would decrease in an integrated system.

D. What, More Training?

More than half of all behavioral care is delivered by PCPs who still miss as much as 80% of the patients who could benefit from such services. Clearly, PCPs need much more than the few hours of the lectures in psychiatry that are included in the 4-year medical school curriculum, and psychologists and social workers must be grounded in the biological sciences with further courses in neuroanatomy, neurology, and clinical medicine. Because of the overloaded curriculum in

both medical schools and graduate psychology and social work programs, there is strong opposition from academia, necessitating postgraduate training.

E. Primary Care Time Constraints

The average patient appointment with a primary care physician in the United States is 7 minutes. This is the result of the pressure to see more and more patients within the course of a day, leaving the physician no time to listen to the patient’s problems beyond the initial complaint. Research has shown that lifestyle problems that may be at the root of the patient’s physical disease do not emerge until well after the 7-minute limit. Every clinician fears opening the Pandora’s box and seeing the patient dissolve into tears and emotional turmoil while the waiting room is filled with patients with and without appointments. Under current managed care arrangements, there is an even greater pressure on the PCP to see more and more patients.

F. The One-on-One Complex

Traditional health care delivery, whether this be medical or behavioral, is based on a one-on-one relationship and responsibility between doctor and patient. When referral is made it is to a specialist who replicates the one-on-one arrangement. The resistance to changing this to the more team-oriented innovative and integrated therapies is enormous on both the parts of medicine and behavioral health. Arguments for the preservation of the system are couched in terms of the doctor–patient relationship and in confidentiality, regardless of the fact that integrated services have demonstrated that patients readily extend the doctor–patient relationship to the treating team, and are comfortable in trusting the matter of confidentiality to the same team.

V. EXAMPLES OF POPULATION-BASED AND DISEASE-BASED INTEGRATED THERAPIES

Integrated therapies are almost always group programs conducted by primary care teams and serve three functions with varying degrees among the various programs as to which is the primary in a specific model: treatment, management, and prevention. These programs are based on empirically derived protocols and are often called psychoeducational. These can be further described as disease-based programs that will be discussed

first, and population-based programs to be described later. The disease-based programs can be further delineated into those that address physical diseases (e.g., arthritis, asthma, diabetes, emphysema, hypertension, ischemic heart disease) and those that address psychological conditions (e.g., depression, panic/anxiety states, borderline personality disorder, agoraphobia, and multiple phobias).

A. Treatment

The surprising feature of psychoeducational group models is that they can be therapeutic, and for some conditions, more effective than traditional modes. Research indicates that the greatest therapeutic effect is most likely to be with lifestyles that reflect the patient's overscrupulousness: perfectionists, agoraphobics, adult children of alcoholics, and other conditions in which the patient suffers from overbearing neurotic guilt. Lesser therapeutic effect is seen in personality disorders, addicts, and other patients who are rebellious and challenge authority. These patients also manifest chaotic lifestyles and are noncompliant with medical or psychological regimens. Because these patients can also develop depressions, panic attacks, and other psychological conditions, it is important to separate them into their own psychoeducational groups where their chaotic lifestyles and rebelliousness can not only be addressed, but also will be prevented from disrupting the treatment of the nonchaotic patients.

B. Management

In chronic medical conditions such as arthritis, asthma, diabetes, hypertension, and other diseases, the goal is not to cure that which cannot be cured. This does not mean that reduction in pain and morbidity are not in themselves therapeutic; the emphasis, however, is in disease management. It is with these intractable conditions, medical and psychological, that management is important. Patients with physical diseases are taught how to comply with medical regimens; monitor their own condition; reduce stress through relaxation, imagery, and other stress management techniques; and provide a support system for each other. Most so-called Axis II patients can learn impulse control so that they become more manageable and less vulnerable to the consequences of their own emotional lability. Schizophrenics are also incurable, but they can learn independent living as well as techniques to prevent the

"crises" that provoke acute exacerbation requiring hospitalization. All management programs have in common the increased coping skills of the various patients represented in the widely differing conditions.

C. Prevention

The remarkable finding is that for appropriate patients assigned to appropriate psychoeducational programs, the demand for more intrusive services is significantly, if not dramatically, diminished. This is true prevention: Services are no longer needed (i.e., the "demand" side in health economics), as contrasted with reducing services as found in most cost containment (i.e., the "supply" side in health economics). Reducing costs by reducing demand is certainly more desirable than rationing care, and is the very essence of both prevention and cost containment. Hospitalization, the costliest health care, can be reduced for patients suffering from chronic medical conditions, schizophrenia, and borderline personalities. The latter characteristically threaten suicide, necessitating hospitalization as a precaution. Further more, patients in these programs learn skills instead of taking pills, thus reducing the skyrocketing cost of pharmacology. The support system replaces the patient's need for frequent emergency room visits, and it has been found that these programs significantly reduce the need and demand for costly, protracted individual psychotherapy.

D. Elements of Psychoeducational Programs

There are a number of elements that psychoeducational programs have in common, although not every protocol will contain each and every one of the following:

An educational component from which the patient learns a great deal about the medical or psychological condition, as well as the interplay between one's body and emotions.

Pain management for those populations suffering from chronic pain. This includes help in reducing undue reliance on medication and addressing any problems of iatrogenic addiction.

Relaxation techniques, which include meditation and guided imagery.

Stress management, adjusted to meet the needs of specific conditions and populations.

A support system, which includes not only the group milieu, but also the presence of "veterans" who have been through the program. A useful modification of

this element is the pairing of patients into a “buddy system” that allows them to call each other in time of need.

A *self-evaluation component*, which not only enables the patient to assess how well he or she is doing psychologically, but also teaches the patient to monitor such critical features as blood pressure, diet, insulin, and other signs important in chronic illness.

Homework is assigned after every session. The homework is carefully designed to move the patient to the next step of self-mastery, and may include desensitization, behavioral exercises, planned encounters with one’s relationships or environment, readings, and other assignments that are critical to the well-being of the patient. The homework is never perfunctory. It is always relevant to the condition being treated and well timed to enhance development.

Timing, length, and number of sessions vary from protocol to protocol, reflecting the needs of each population or condition, and in accordance with research and experience.

Treatment of depression for those patients whose severely altered mood is interfering with their ability to participate in the program.

Self-efficacy (after Albert Bandura), refers to the belief that one can perform a specific action or complete a task. Although this involves self-confidence in general, it is the confidence to perform a specific task. Positive changes can be traced to an increase in self-efficacy brought about by a carefully designed protocol that will advance the sense of self-efficacy.

Learned helplessness (after Martin Seligman) is a concept that holds that helplessness is learned and can be unlearned. Some patients with chronic illnesses fall into a state of feeling helpless in the face of their disease. A well-designed protocol will enable a patient to confront and unlearn helplessness.

A *sense of coherence* (after Anton Antonovsky) is required for a person to make sense out of adversity. Patients with chronic physical or mental illness feel not only that their circumstances do not make sense, but neither does their life. The ability to cope often depends on the presence or absence of this sense of coherence, and the protocol should be designed to enhance it.

Exercise is an essential component of every protocol, and is the feature that is most often neglected by patients. Exercise helps ameliorate depression, raises the sense of self-efficacy, and promotes coping behavior. The patient should be encouraged to

plan and implement his or her own exercise regimen and then to stick to it.

Modular formatting enables a protocol to serve different but similar populations and conditions by inserting or substituting condition-specific modules. Well-designed protocols permit and even augment a practice called “mixing and matching.”

E. Population-Based Programs

Programs that utilize all or most of the medical and psychological protocols within a specific population do so because that population is often best addressed as a cohort or entity. One of the most successful such programs is the Teenage Clinic at Kaiser Permanente in San Francisco which for several decades has treated adolescents by their parents’ consent without the parental presence or control usually found in pediatrics. Teams of pediatricians, behavioral health practitioners, and nurse practitioners have demonstrated that this population-based arrangement significantly reduces teenage pregnancy, drug abuse, and sexually transmitted diseases. These successes are attributed to the opportunity accorded teenagers to discuss issues they fear mentioning to their parents and to a team that includes providers highly trained and experienced in the integration of adolescent psychology and primary care.

Integrated substance abuse programs meld addiction treatment with most or all of the protocols previously described, addressing the nearly universal comorbidity that is characteristic of addicted patients. Integrated substance abuse programs have protocols in food and gambling addictions along with the usual chemical addiction approaches. In this way psychological and medical conditions are treated in an appropriate manner in which the treatment of the substance abuse remains paramount, whereas in the usual primary care setting the primacy of the addiction treatment might well be subordinated.

Because the needs of older adults tend to be so different from those of the general populations, separate Medicare programs are growing in popularity. These patients face higher rates of chronic illness, and even terminal illness for themselves or their spouse than are found in the general population. Marital, occupational, parenting, and other issues common to younger adults are of little importance, while bereavement, loneliness, alienation, and physical/psychological limitations are at the forefront.

VI. THE FUTURE OF PSYCHOTHERAPY AS INTEGRATED PRIMARY BEHAVIORAL CARE

The next frontier in organized health care delivery is the integrated program where behavioral health is an integral part of primary care. As these integrated programs increase in numbers, traditional psychotherapy practice (whether solo or in small groups) will continue to decline while opportunities in health psychology will abound. Several large-scale health care systems are in the process of integrating. The nation's largest HMO has launched a major retooling after which 2.4 million covered lives will be divided into 20,000 person cohorts, each served by integrated teams of primary care physicians, behavioral health providers, nurse practitioners, and health educators. As these programs continue to report medical cost offset savings, more effective care, financial enhancement, and high patient and provider satisfaction, there will be a national acceleration in the integration of health care. Co-location will be the typical arrangement, with behavioral health providers practicing in close collaboration with primary care physicians.

The behavioral health provider of the future will need training quite different from that offered now in most graduate programs. The curriculum of the future will be heavily weighted with courses in medical psychology, behavioral medicine, outcomes research and program planning, finances, and administration. Proficiency in group psychoeducational protocols that are both disease- and population-based will replace the current emphasis on individual psychotherapy. Although psychoeducation will never fully replace individual psychotherapy, experience in currently integrated large-scale programs would predict that the following proportions of the psychotherapist's time will prevail in the not too distant future: 25% individual psychotherapy, 25% time-limited group therapy, and 50% psychoeducational programs. Several health care settings are already reflecting this configuration. Extrapolating this time allocation, taking into account that eight or more patients are seen in groups during the time required to see just one individual patient, 90% or more of patients will be treated in models reflecting group protocols.

VII. SUMMARY

Collaboration refers to a range of concepts, but it always involves cooperation in diagnosis and treatment of an individual patient by two or more practi-

tioners from different fields of health care. For the psychotherapist, its simplest form is an informal arrangement for referral and consultation between a behavioral specialist and a primary care physician or other medical specialist. Each is otherwise independent of the other and each bills the patient or the third party payer separately for the services provided. This traditional concept of collaboration is sometimes expanded to include innovative or unusual services provided by the behavioral care specialist on a regular basis. For example, a surgeon may wish preoperative counseling in the hospital for each patient. Or a neurologist may wish the regular scheduled presence of a psychologist to conduct testing with cases suspected of ADD/ADHD.

There are two integration models of collaboration, known as horizontal and vertical integration, which differ but can be compatible in the same health care delivery system. With true integration, however, the health care system requires successive degrees of intensity as it becomes more comprehensive and complex. Horizontal integration may proceed from a simple 24-hour consultation telephone number available to all physicians, through co-location where the behavioral practitioner works side by side with primary care physicians, to complete integration in which health care is provided by teams of practitioners that include behavioral care practitioners.

Vertical integration focuses its programs on specific segments of the primary care population, and especially for those in which psychological problems are accompanied with high medical costs. These are termed population-based, or disease-based programs. The most frequent group programs are for chronic medical conditions, such as arthritis, asthma, diabetes, hypertension, ischemic heart disease, and emphysema, all of which manifest a strong psychological component often expressed by noncompliance with their medical regimen. Other group programs address essentially psychological programs that complicate the medical system. These include borderline personality disorder, agoraphobia and multiple phobias, panic and anxiety disorder, and pain management. Health care systems utilizing both horizontal and vertical integration are relatively recent, but may be the forerunner of the future in collaborative care.

Barriers to collaborative care are centuries of mind-body dualism reflected in separate departments of medicine and psychiatry (or psychology). From the psychological standpoint, American behaviorism lags behind in the integration of the physical into its psy-

chological theories. It can be said that all specialties, medical as well as psychological, inadvertently preserve the separation by zealously guarding their individual turf. The most formidable barriers, however, are financial. These range in the usual health setting from the not-out-of-my-budget mentality to the prevalence today of behavioral care carve-outs that perpetuate organizational separation.

Population and disease-based integration has developed a number of group programs that have both a psychotherapeutic and a psychoeducational component, and consistently share a number of characteristics in their protocols. These characteristics have all three essential elements: treatment, management and prevention.

peal. For example, recent modifications of CST for persons with developmental disabilities have proven valuable in the treatment of challenging behavior associated with limitations in communicative ability and useful in promoting choice.

GLOSSARY

feedback Information provided to an individual following a response that is intended to promote the acquisition of behavior.

modeling Action performed by a therapist or coach to illustrate important elements of a response requiring imitation by clients or patients. Feedback and instructions are also used to shape the behavioral repertoire to approximate more closely the actions of the model.

Communication skills training (CST) promotes problem-solving skills by teaching patients to resolve disputes through restructuring their attitudes, adopting and adhering to new rules of social interaction, and clearly expressing and receiving meaning. In CST, therapists frequently combine elements of behavioral, family systems, humanistic, and other approaches to reduce interpersonal problems. Although initially developed in the context of family interaction (e.g., spouse to spouse, or parent to adolescent), in recent years the approach has been found to have broad ap-

I. DESCRIPTION OF TREATMENT

Communication skills are vital for achieving goals through social interaction. CST emphasizes pragmatics, communication in a social context, and can be useful in a wide range of treatment programs for many types of individuals and situations because of a diverse, yet sound conceptual and empirical base.

As it is most commonly known, CST is used to teach problem-solving skills, most frequently to help resolve parent-adolescent and marital conflict. Because of the diversity of programs, it is useful to identify specific operations common to all CST. First, most CST seeks to promote the clear expression and reception of meaning. Effective problem-solving requires minimizing negative communication habits and speeds the process of arriving at mutually favorable solutions. By contrast, emotionally charged accusations, frequent changes of topic, and interruptions frequently impede the promotion of clear communication. CST also attempts to teach the individual how to restructure attitudes (e.g., zero-sum or all or nothing thinking) that may inhibit or derail effective problem-solving. Second, CST trains

families in reflective listening (i.e., relating perceived meaning back to the speaker) in an attempt to enhance the behavioral component of problem-solving. Moreover, ensuring that clients take an active role in trying to understand one another minimizes the likelihood that a “nonparticipant” will seek to undermine solutions. A third dimension of CST focuses attention on the quality of family relations. In general, CST emphasizes a democratic approach to family relations. Issues are raised and clarified through mutual agreement and the rights of all parties are respected in arriving at a solution (i.e., equalization of decision-making power).

An early example of the CST approach is the four-step model introduced by Arthur L. Robin, Sharon L. Foster, and colleagues as a component of their problem-solving communication training (PSCT) for parents and adolescents. During the first of a course of four to six sessions, families are introduced to the model. Specifically, families are told to (1) define the problem concisely without accusations, (2) brainstorm alternative solutions, (3) evaluate solutions by listing their positive and negative consequences and deciding on a mutually satisfactory agreement, and, finally (4) specify the actions required to implement the solution. This training also involves the therapist’s provision of feedback, modeling, and behavioral rehearsal (i.e., role-play) to correct negative habits. Families are also taught to self-monitor negative communication patterns such as interruptions, lack of eye contact, and sarcasm, and to replace them with more effective behaviors such as maintaining eye contact, active listening, verification of meaning, appropriate voice tone, and appropriate nonverbal posturing (e.g., leaning slightly forward to indicate interest).

At each session, a specific problem, such as chore completion, curfew obedience, or homework compliance, is discussed. Therapists then help guide families through a structured discussion and intervene when family members stray from the four-step guidelines. Therapist prompts may be in the form of a discussion of the inappropriate behavior, demonstration of more appropriate behavior, or direct feedback about the error. Often, family members are uneven in their mastery of the communications skills and will receive additional feedback and instruction during the sessions. Cognitive restructuring (i.e., challenging or reframing maladaptive thoughts) and planning for the generalization of treatment gains through homework assignments are also common features of PSCT.

Applications of CST to marital and relationship problems have been theoretically diverse and include systems-oriented and social-learning approaches. One

of the best known interventions for relationship problems, behavioral marital therapy (BMT), represents an application of reinforcement principles to problems encountered in romantic relationships. Over the years, BMT has been broadened by Neil Jacobson and colleagues to include other features; however, the core of BMT appears to be the promotion of “support-understanding techniques” and problem-solving training. Support-understanding techniques encourage collaboration and positive affect. For example, each partner might first generate a list of behaviors that they would like their partner to perform. Subsequently, each partner agrees to perform three of the actions from their partner’s list. Problem-solving techniques are very similar to those described by Robin and Foster.

Couple Communication is a recent example of a systems-oriented program designed by Sherod Miller and Peter A.D. Sherrard to teach important communication skills to couples in conflict. Its three main goals are to help couples communicate more effectively about day-to-day issues, manage and resolve conflicts more effectively, and to help build a more satisfying relationship. The intervention model aims to increase awareness of the relationship, teach skills for communicating more effectively, expand options for enriching the relationship, and increase satisfaction with the relationship itself. Although incorporating many features of more experiential and family-systems therapies (i.e., employing the use of skill mats to promote kinesthetic learning), the program is notable for its systematic incorporation of feedback, coaching, and contracting and shares these features with the model promoted by Robin, Jacobson, and others.

CST can be useful in helping patients with disabilities such as mental retardation or autism to communicate effectively in social settings. Although significant modifications are required to adapt CSTs for the communication impaired and developmentally disabled, Fred P. Orelove and Dick Sobsey have outlined a program to teach basic functional communication to children with severe or multiple disabilities. Before implementing such a program, four decisions must be made: (1) which communication functions would be most useful to the individual, (2) what specific content or messages should be communicated, (3) which form (mode) of communication should be selected—vocal, gestural, or graphic, (4) how each item should be taught. After these decisions have been made, a program of assessing and teaching specific patterns of communication can be implemented based on five fundamental principles: maximization (striving for the greatest increase in appropriate communication), functionality (focusing on social outcomes), individualization (uniquely assessing

each child and what he or she requires), mutuality (aiming at both communication partners and their context assessment and intervention), and normalization (teaching common communication unless there is an undeniable benefit to the individual in teaching different skills). Another program, designed by Laura G. Klinger and Geraldine Dawson, is intended to facilitate social interaction, specifically for children with autism. It comprises two strategy levels and is based on the five general principles outlined by Orelove and Sobsey. Level One involves facilitating attention to people, social contingency, and turn-taking. Level Two targets imitation, early communication, and joint attention skills. These strategies may be implemented by parents, teachers, psychologists, and other developmental specialists.

Interventions have also been designed based on the premise of teaching communication skills as an alternative to challenging behavior. In their review of functional communication interventions, David P. Wacker and Joe Reichle describe a number of simple and effective programs that involve two common steps. First, factors maintaining problem target behaviors must be identified. Second, the maintaining factors (e.g., rewards) must be made available only when the specified appropriate communicative response is made. These interventions are performed in three general phases: assessment, initial intervention, and expanded intervention aimed at generalizing and maintaining outcomes. V. Mark Durand and colleagues have explored several factors that increase the success of functional communication training in reducing challenging behavior. The four main factors are response match, response mastery, response milieu, and the consequences of the challenging behavior. "Response match" means that the newly trained response should produce the same consequence as the targeted challenging behavior. For example, raising a hand should garner attention in the same way that striking a peer would have prior to training. Other concepts such as "response mastery" and "response milieu" speak to the importance of ensuring that the newly trained functional communication response becomes more efficient in producing changes in individual's environment than the formerly high-frequency problem behavior. Taken together, the diverse applications of CST are impressive in scope.

II. THEORETICAL BASES

Communication skills training has gradually evolved from a treatment approach focused on reducing family

conflict to a much broader array of therapies concerned with the resolution of human conflict in areas ranging from the home to business and institutional settings. The initial conceptual underpinnings of CST, however, spring from a humanistic, social-learning perspective suggesting that conflict is often produced by perceived differences in power. As originally conceptualized by Robin and colleagues, PSCT suggests that adolescents initially argue with their parents in a developmentally appropriate quest for independence. Unfortunately, overly "authoritarian" responses from parents sometimes lead to increased conflict. Reacting in a more "democratic" manner, that is, emphasizing mutual solutions and the equalization of decision-making power, replaces negative communication with a social environment more likely to yield solutions to problems arising in parent-child relations. This early form of CST was based on the principles of behavior modification, experimental problem solving, and effective communication.

Behavioral marital therapy emerged most directly from reinforcement and social learning theory. The early BMT notion of behavioral exchange was modeled on behavioral formulations of the marital relationship in terms of contingency contracting and seeking to foster changes in partner behavior. In more recent years, BMT has expanded to incorporate a theoretically diverse number of treatment techniques, including a greater focus on communication and problem-solving skills, and more acceptance-based procedures. The Couple Communication program is based on systems-theory concepts and principles. Viewing a relationship as a "system," and more specifically as a "self-managing-adaptive system," implies that relationships are not static and that the behavior of the partners constitutes the dynamic of their relationship. The Couple Communication program and the concepts and skills taught in the program are designed to enhance the couple's ability to communicate effectively and become their own best problem solvers.

The theoretical justification for employing CST for persons with developmental disabilities is that the difficulties of these individuals are due largely to deficits in social communication, rather than simply speech production. Research in this field has only recently begun to focus on the social-emotional domain rather than on cognitive or linguistic deficits. Functional communication training is derived from learning theory and behavior analysis. Adherents of this perspective argue for the functionality or adaptiveness of the existing problem behavior (for example, self-injury may communicate physical discomfort) and note that when taught an appropriate communicative alternative, such as a gesture to obtain medical care, individuals with developmental

disabilities will often show substantial reductions in self-injury and other forms of problem behavior.

III. EMPIRICAL STUDIES

A large body of research on CST has pointed to its effectiveness in a variety of applications. Robin has conducted a host of studies that demonstrate the versatility of his CST approach with the most recent applications in the context of eating disorders. The effectiveness of his problem-solving communication training program has been established in both hypothetical (analogue) and actual therapy settings during structured treatment programs. Improvements in problem-solving have also been noted outside of training settings. For example, in one study, reductions in parent-adolescent conflict in the home were still evident up to 10 months following therapy. A lack of generalization is sometimes cited as a treatment limitation in other studies and reviews. Evidence of both parent and adolescent satisfaction with the improvements in family interaction has also been noted.

BMT is among the most heavily researched treatment programs of any kind. Findings have suggested that it is superior to no-treatment controls and placebo and equivalent to or more effective than other forms of marital therapy. Although generalization and maintenance of treatment effects and the clinical significance of results have sometimes been a concern, researchers continue to work to improve outcomes. Empirical support for the Couple Communication program is less robust than for BMT, but some evidence of increases in constructive communication skill use, relationship satisfaction, and maintenance of treatment effects have been reported.

V. M. Durand, David Wacker, Brian Iwata, and a host of others have found solid support for the use of functional communication and other behaviorally oriented skills training as a treatment modality for challenging behavior among persons diagnosed with developmental disabilities. The data have been encouraging in the assessment and treatment of problems such as aggression, self-injurious behavior, and stereotyped behavior, as well as other problems associated with autism. Moreover, these studies have been conducted in a variety of settings (e.g., schools, group homes, and vocational settings) and implemented by professionals, paraprofessionals, and family members alike.

IV. SUMMARY

The main elements that unite all the CST programs are the clear expression and reception of meaning, re-

structuring of inappropriate attitudes (on the part of each member of the interaction unit), and equalization of decision-making power. CST programs typically utilize the above model to reframe disagreements and to generate solutions to recurrent problems that plague the family or relationship partners. There are now a large number of empirical studies that support the efficacy and wide applicability of CST in the family context, including specific applications for problems that intersect the interpersonal sphere such as alcoholism, sexual dysfunction, and depression.

In recent years, CSTs have also been developed for patients with developmental disabilities. Indications are that persons with disabilities and their caretakers also benefit from structured programs that teach persons in the caretaker-patient relationship how to communicate more effectively in the social milieu. Once the strategies for each individual have been developed based on an ideographic assessment, they may be implemented by parents, teachers, and other specialists involved in the individual's care. Communication skills programs may also be used to design more effective interventions for challenging behavior. When implemented, their goal is to replace problem behavior, such as self-injury, with socially appropriate communication. These programs, too, appear to have a high success rate. Although technically difficult to implement and sometimes effortful or unpleasant for participants, it is expected that further development of CST programs will be undertaken with increasingly diverse populations.

GLOSSARY

comorbidity The co-occurrence of more than one disorder in the same individual.

endocrinopathy A disorder caused by or affecting the endocrine system of the body.

epidemiologic Relating to the study of epidemiology or to the characteristics of a disease or physiologic phenomenon in a population as a whole rather than in individuals.

I. DEFINITION AND HISTORY OF CONCEPT

Comorbidity is defined as the co-occurrence of more than one disorder in the same individual. In its broadest sense, comorbidity can include the co-occurrence of medical and psychiatric disorders, such as the dementia associated with organic conditions or the affective changes resulting from endocrinopathies. In psychiatry, comorbidity is generally taken to mean the association of diagnosable psychiatric disorders. Comorbidity is an epidemiologic phenomenon, relating to the character-

istics of a population, and the reported comorbidity of certain disorders in a population does not necessarily imply that they will be comorbid in any given individual. However, observations of comorbidity among populations may be extremely useful in informing the therapist's understanding of an individual patient.

The observation of comorbidity between disorders does not in and of itself demonstrate any particular type of relationship between them, least of all causality. Comorbidity can result from many factors. One disorder may represent an early manifestation of another. There may be problems of classification, in which the use of same or similar symptoms define different disorders. Detection artifacts can occur. For example, the presence of one disorder in a patient may make another condition more visible, even though it may be no more common than in a general population. Similarly, the presence of one disorder may influence the observations of clinicians and make them more likely to report the presence of another disorder.

Nonetheless, rates of co-occurrence of psychiatric disorders that are far in excess of what could be expected from chance have repeatedly been reported among many different populations. The recognition of this fact by mental health professionals has been long in coming but represents a major advance in the basic assumption of mental health care. Documentation of comorbidities have likewise led to important advances in our knowledge of mental illness and thereby our ability to provide effective, comprehensive care.

One may speculate as to why the recognition of comorbidity came later to mental health than to some other areas of medicine. Often therapists have found a unitary explanation for their patients' problems to be both of heuristic value and a source of comfort. The psychodynamic concepts of nuclear conflict and infantile neurosis, although valuable in many respects, may have engendered a notion that individuals have one great problem alone. The tendency in some psychotherapeutic schools to value contemporaneous observations of process over a more "medical" model of diagnosis, especially prior to *DSM-III* may have rendered irrelevant the concept of comorbidity, based as it is on diagnosis. The ascendance of the empiric model of *DSM-III* and *-IV* can create an epistemological problem for some therapists, in that many of the plethora of diagnoses contained in the *DSMs* have numerous features in common. This level of detail enhances the utility of *DSM* criteria as discriminators among diagnoses. However, these commonalities can also obscure the differences among conditions and thereby lead clinicians to gloss over comorbidities. In any case therapists today are much more likely than in the past to recognize that their patients frequently most confront a variety of illnesses and problems. These may often aggravate each other and must be addressed in their multiplicity if the patient is to find meaningful symptomatic relief and functional improvement.

Therapists approach patients with a certain mindset, reflective of particular schools of therapy but also of generally accepted values, such as empathy, professional responsibility, and the importance of a conceptual framework for diagnosis and treatment. Part of this framework for any therapist today must be the possibility of comorbid disorders in any patient. This point of view, like any other assumption, should be used to enrich and amplify one's view of the patient rather than to unnecessarily codify or stereotype that view. Most data on comorbidity is epidemiologic, although each patient has an individual course of life. In addition, the recognition of an additional problem or disorder does not necessarily require that it be treated, especially in today's climate of focused and time-limited psychotherapies. Still, most therapists have a desire to know as much as they can about their patients' life so as to serve both the patients' needs and enhance their own satisfaction.

II. COMORBIDITY AND SUBSTANCE ABUSE

Therapists should be aware of many particular comorbidities that have been documented in psychiatric re-

search. The most extensive documentation of comorbidity involves substance abuse and psychiatric disorders. Alcoholism and other addictions affect 20% of the population at some time in their lives, and this number is greatly increased if one also considers tobacco consumption a form of substance abuse. It is reckoned that at least one third of persons with addictions have some other comorbid Axis I disorder. In the national comorbidity survey reported in 1988, 47% of alcoholics had a comorbid psychiatric diagnosis. This number rises even higher in psychiatric inpatient settings and among the homeless.

Anxiety and affective disorders are the most common mental illnesses other than substance disorders in the general population. Thus, it is not surprising to find a high rate of comorbidity between these conditions and substance abuse. Some authors report a particular association between the primary onset of an anxiety disorder and the subsequent development of alcoholism, but the opposite temporal relationship is also quite possible. Persons with affective disorders often are attracted to substance use and abuse in an attempt to self-medicate. The Epidemiological Catchment Area (ECA) study showed that 30% to 50% of their alcoholic patients had comorbid major depression, although this rate of occurrence decreased substantially with abstinence.

Persons with schizophrenia, especially men, are also more likely than nonill controls to have a comorbid substance abuse problem. Lifetime concurrence in this group of around 50% is frequently reported for alcohol use disorders. In 1990, a report from the Eastern Psychiatric Institute showed that, among schizophrenic patients, 47% abused alcohol, 42% abused cannabis, 25% abused stimulants, and 18% abused hallucinogens. In this population, drug dependence was associated with more hospitalizations and with more psychosocial symptoms.

Other reports have suggested an increased level of comorbidity for substance abuse among adolescents and young adults with attention deficit hyperactivity disorder. This may be particularly marked among patients with associated learning problems, family dysfunction, or social economic distress. Researchers have speculated as to whether this might result from an underlying biobehavioral predisposition, the consequence of an impulsive lifestyle and social and educational failures, or various other combinations of factors.

III. COMORBIDITY IN CHILDHOOD DISORDERS

Comorbidity of psychiatric disorders in children occurs far in excess of chance. In the studies of this

phenomenon that have been conducted in the last 15 years, rates of co-occurrent disorders in participants studied from 40% to 70% are commonly reported. Child adolescent psychiatry disorders are commonly described as externalizing, such as conduct disorder and hyperactivity, and internalizing, such as anxiety and depressive disorders. Researchers have demonstrated an especially high comorbidity within each of these categories but also a very significant comorbidity between these two areas. As early as 1982 Puig–Antich reported a significant association between conduct disorder and depression, and a frequent association between hyperactivity and depression has also been reported. At times this degree of overlap has led observers to question whether or not some of these conditions are actually separate disorders.

The most commonly diagnosed psychiatric disorder in children in the United States is attention deficit hyperactivity disorder (ADHD). Various rates of prevalence from 3% to 10% have been reported. The recognition of this disorder is influenced by many external factors, such as particular family, social, and educational expectations and the availability of mental health services. It is said that this condition is both heavily underdiagnosed and overdiagnosed. It is also frequently misdiagnosed; for example, many children described as having ADHD actually have a primary depression. Nonetheless rigorous studies of children with this condition have repeatedly disclosed the frequent occurrence of comorbid conditions. As many as two thirds of elementary school age children with ADHD have at least one other diagnosable psychiatric disorder. In the Ontario Child Health Study investigators noted that 42% of such children had comorbid conduct disorder, 17.3% had somatization disorder, and 19.3% had the broad category of emotional disorder. Another study conducted by Cohen and his coworkers reported similar findings including 23% of children with overanxious disorder, 24% with separation anxiety, and 13% with major depressive disorder.

Not surprisingly a converse comorbidity is seen among children with disruptive behavior disorders such as conduct disorder and oppositional defiant disorder. Some 50% of these children have mood disorders, and perhaps 20% or more have learning problems or learning disabilities.

Anxiety disorders in children have been traditionally underrecognized. This may be a result of early theoretical notions that regarded anxiety as mainly a symptom of neurosis that could be expected to abate incidentally in the course of psychotherapy. We have learned in recent years that, regardless of its origin, anxiety persists

in children as with a life of its own, regardless of its origin. The *DSM-IV* notes the existence of separation anxiety disorder and generalized anxiety disorder in children. Children may also experience social phobia and panic disorder. Obsessive–compulsive disorder (OCD) is one of the anxiety disorders as is posttraumatic stress disorder (PTSD).

All of these disorders, including PTSD, can be comorbid with each other. Clinicians who follow patients over the years meet children who may first present with a separation anxiety disorder, then go on to develop a social phobia and later in life manifest OCD. Many other sequences also occur, and any and all of these conditions can occur simultaneously. It is reported that the majority of children with the specific phobia also have a second anxiety disorder diagnosis. Two thirds of children with anxiety disorders also have depressive disorders, at least at some time in their lives. Seventeen to twenty-two percent of children with a primary anxiety disorder may have ADHD, and a comorbidity with conduct disorder and oppositional defiant disorder has also been observed. Posttraumatic stress disorder in children as well as in adults requires special consideration. This disorder in and of itself has a protean range of symptoms, which may lead the clinician to misattribute symptoms that might be reflective of a concurrent or preexistent second psychiatric disorder. Depression and anxiety disorders are most especially observed in the company of PTSD and may require psychiatric treatment in addition to that being already offered for trauma.

Eating disorders are regrettably common in our appearance-oriented society. It is reported that 75% of female teenagers describe themselves as fat. One to four percent of adolescent and young adult women go on to develop anorexia nervosa or bulimia and perhaps one tenth as many young males. People with anorexia have increased rates of major depressive disorder, dysthymia and OCD. Persons with bulimia also have high rates of anxiety and addictive disorders. In the experience of many clinicians, it is impossible for many patients to recover from their eating disorders without adequate treatment for these comorbid conditions.

IV. OTHER COMORBIDITIES

Any of the comorbidities reported in child and adolescent psychiatric patients may also be seen in adulthood. In addition, the clinician must be mindful of other frequently reported co-current conditions. Patients with schizophrenia often have concurrent

cognitive deficits and affective disorders. Suicidality is common in young males with schizophrenia especially early in their illness.

There is extensive comorbidity among the affective disorders. Many researchers believe this is a manifestation of early appearance of disorders. For example, a patient who has recurrent depressive episodes may go on in time to develop full bipolar illness. More than 40% of patients with major depression can expect to have one or more "nonmood" psychiatric disorders during their lifetimes. These include alcoholism and substance abuse, anxiety disorders, eating disorders, and certain personality disorders such as borderline personality disorder. Affective disorders are often seen in association with somatoform and conversion disorders, although firm numbers for comorbidity are difficult to come by.

Persons with panic disorder have an extremely high rate of comorbidity with other anxiety disorders such as social phobia, generalized anxiety disorder and OCD. They also have a very high rate of substance abuse. Virtually all of these people, who represent 2% to 5% of the general population, have some other associated psychiatric disorder. Social and specific phobias are also reported to be comorbid with other disorders, though this comorbidity seems less than that of panic disorder. The comorbidity of PTSD with many other conditions as reported among children, is also seen in adults.

Sixty-seven percent of persons with primary OCD can expect to have a major depression during their lifetimes, and typically 31% of them at any given time. OCD also has a demonstrated concurrence with Tourette syndrome that probably results from shared neurobiological factors. OCD patients may have a delusional component to their condition, which at times may be so intense as to resemble psychosis and even require antipsychotic medication. It is not certain however as to whether there is any increased occurrence of true psychosis among these patients. Patients with OCD do have a high rate of concurrent anxiety disorders such as social phobia, specific phobia, and panic disorder.

The comorbidity of psychiatric and medical illnesses constitutes a major *raison d'être* for psychiatry as a specialty and is the basis for an entire subspecialty, consult-liaison psychiatry. A comprehensive treatment of this area is beyond the scope of this article. The *DSM-IV* notes that general medical conditions can be responsible for psychotic disorders, anxiety disorders, mood disorders, sexual dysfunction, sleep

disorders, catatonia, and personality changes. Medical conditions such as endocrine disorders, infectious diseases, metabolic disorders, malignancies, and neurological injuries and diseases have all been associated with mental illness. Any patient entering psychotherapy should be receiving ongoing primary medical care. A patient with a known medical illness, or whose condition suggests the possibility of medical illness, deserves thorough medical assessment. The reader should consult a comprehensive textbook for further consideration of this area.

V. APPLICATIONS OF CONCEPT

It should be apparent that in many areas of psychiatry comorbidity is the rule rather than the exception. What is the psychotherapist to do with this information? Obviously one must be aware that a patient describing a single unitary problem may have a larger range of problems or disorders. It may be necessary for the therapist to address problems beyond those originally proposed to help the patient. Even if the patient does not wish to pursue treatment for these other areas, the ethical therapist has a responsibility to share his or her observations and to advise the patient of any difficulties the patient might be facing.

Therapists may be inclined at times to omit or minimize their discussion of comorbid factors of patients. This may be out of a desire to avoid discouraging the patient or aggravating a condition. However, in the longer term, the goals of any psychotherapy are better served by honesty accompanied by tact and sensitivity. While some patients may be daunted by an enumeration of comorbid problems, many others will be reassured by a delineation of what exactly they are facing, and may even be encouraged by what progress they have already made in the face of multiple problems.

GLOSSARY

awareness training A component of competing response training in which the therapist teaches the client to identify each occurrence of the habit behavior or antecedents to the habit behavior.

competing response An incompatible behavior that the client engages in contingent on the occurrence of the habit behavior as part of competing response training.

habit disorder A repetitive behavior that does not typically serve any social function but occurs with sufficient frequency or intensity to cause distress to the client or significant others. Habit disorders include nervous habits such as thumbsucking, nail biting, and hair pulling, tics such as head jerking or facial grimacing, and stuttering which involves word or syllable repetition, prolongation of word sounds, and blocking.

I. DESCRIPTION OF TREATMENT

Competing response training is a treatment procedure used with habit disorders including nervous

habits (fingernail biting, thumbsucking, hair pulling, etc.), tics (head jerking, facial grimacing, shoulder jerking, etc.), and stuttering. The essence of competing response training is to teach the client to become aware of each instance of the habit behavior and to engage in an incompatible behavior contingent on the occurrence of the habit or the antecedents to the habit. Competing response training involves two components, awareness training and competing response practice. Awareness training is critical to the use of competing response training because the client must be aware of each occurrence of the habit to effectively use the competing response contingent on the habit.

Competing response training was originally developed as a component of the habit-reversal procedure outlined by Nathan Azrin and Greg Nunn in 1973. The habit-reversal procedure involves a number of treatment components including awareness training, competing response practice, habit control motivation, and generalization training. Azrin and Nunn and other researchers evaluated the effectiveness of habit reversal for a variety of nervous habits, tics, and stuttering. Researchers also demonstrated that competing response training (involving awareness training and competing response practice) was an effective procedure as well. For example, in 1985 Ray Miltenberger, Wayne Fuqua, and Tim McKinley showed that both habit reversal and competing response training were effective in the treatment of motor tics exhibited by children and adults. Other research by Miltenberger and Fuqua in 1985

showed that competing response training was effective for the treatment of nervous habits such as nail biting and hair pulling exhibited by adults. Miltenberger and his colleagues have referred to competing response training as simplified habit reversal because it consists of a subset of the original habit-reversal components.

Competing response training is typically implemented in one or a small number of outpatient treatment sessions. Following an assessment interview, the therapist implements the awareness training procedure and then the competing response practice procedure with the client.

A. Awareness Training

The goal of awareness training is to teach the client to identify each occurrence of the habit and to identify the antecedents or warning signs that the habit behavior is about to occur. A number of procedures are used to achieve this goal.

First, in the response description procedure, the client is asked to describe the habit behavior. The client describes all the behavioral movements involved in the habit behavior and all of the different ways in which the habit behavior may occur. Next, in the response detection procedure, the client is taught to detect each occurrence of the habit behavior in session. The therapist starts by simulating the habit behavior and having the client identify the occurrence of the behavior when exhibited by the therapist. The client then practices identifying each occurrence of the habit that he or she exhibits in the session. Some habit behaviors such as motor and vocal tics or stuttering may naturally occur in session. Other behaviors such as nervous habits (e.g., hair pulling, nail biting) typically do not occur in session. For tics or habits that occur in session, the client is instructed to indicate each time the habit naturally occurs. The client might say “there’s one” to identify the occurrence of a motor tic or raise a finger to indicate the occurrence of a vocal tic or stutter. The therapist praises the client for correctly identifying the habit behavior when it occurs. If a habit behavior occurs and the client does not identify it, the therapist points out to the client that the behavior just occurred. This process continues until the client reliably identifies (without prompts) each instance of the habit as it occurs.

For habit behaviors such as nervous habits that do not typically occur in the treatment session, the therapist implements response detection by having the client simulate occurrences of the habit. The client will

simulate the movements involved in the habit behavior and then identify the occurrence of the behavior.

After the client has practiced response detection a number of times, the therapist then focuses on detecting the antecedents or warning signs that precede the occurrence of the habit behavior. The therapist first has the client identify the situations or behaviors that precede the occurrence of the habit behavior. For example, a client might touch her hair before hair pulling or inspect his finger nails for rough edges before nail biting. The therapist also has the client identify any thoughts, feelings, or physical sensations that precede the occurrence of the habit. For example, the client might experience a sensation such as tension in a muscle before engaging in a motor tic. If the antecedent is an overt behavior, the therapist has the client simulate the behavior and identify its occurrence. If the antecedent is covert, the therapist has the client imagine its occurrence. Any time the antecedent naturally occurs in the session, the client is instructed to identify its occurrence. The therapist provides praise for correct identification of antecedents in session and prompts the client if the client fails to identify an antecedent that just occurred.

B. Competing Response Practice

The goal of competing response practice is to teach the client to engage in a competing response each time the habit behavior occurs or when an antecedent to the habit behavior occurs. The therapist implements competing response practice after awareness training is completed, and the client can identify each occurrence of the habit or antecedents to the habit.

To begin competing response practice, the client (with the aid of the therapist) chooses one or more competing responses that can be used in situations in which the habit behavior typically occurs. The therapist instructs the client that the competing response should be a behavior that is, (a) physically incompatible with the habit behavior, (b) easy for the client to engage in, and (c) inconspicuous so that the competing response does not draw attention to the client when the client is around others. An example of a competing response for hair pulling or thumbsucking might be to make a fist while holding the hands down at the side. An example of a competing response for a motor tic such as head jerking might be to tense the neck muscles while pulling the chin down slightly toward the chest. The therapist instructs the client to engage in the competing response for about one minute each time the habit behavior occurs or when an antecedent to the habit behavior occurs. After choosing the competing

response(s), the therapist has the client practice use of the competing response contingent on the habit or antecedents to the habit in the session.

If the habit behavior occurs naturally in session (e.g., tics or stuttering), the client practices use of the competing response each time the habit occurs. The therapist praises the client for using the competing response at the appropriate time and prompts the client to use the competing response if the habit occurs but the client fails to use the competing response. This practice continues until the client reliably uses the competing response immediately contingent on the habit. The therapist also has the client practice use of the competing response contingent on the antecedents to the habit. After reviewing the antecedents with the client, the therapist instructs the client to use the competing response each time one of the antecedents occurs. If the antecedents are overt, the therapist will provide praise for correct use of the competing response or prompts to use the competing response if the client did not use it at the correct time. If the antecedents are covert, the therapist cannot provide such feedback but rather praises the client for reports of successful use of the competing response contingent on the covert antecedents.

If the client's habit behavior does not naturally occur in session (e.g., nail biting, hair pulling), the therapist will implement competing response practice as described above as the client simulates the habit behavior and the antecedents to the habit behavior. For example, the client will reach up to her scalp to simulate a hair pulling behavior, stop the behavior, and immediately engage in the competing response. During competing response practice, the client will simulate a variety of ways that the behavior may occur or a variety of situations in which the behavior occurs and implement the competing response. The therapist will have the client practice the competing response in about 10 to 12 simulations of the behavior or antecedents to the behavior. After the competing response practice is completed in the session, the therapist instructs the client to use the competing response outside of the therapy session every time the habit behavior or an antecedent to the habit behavior occurs.

After implementing the awareness training and competing response practice procedures with the client in the initial treatment session, the therapist then conducts a number of followup or booster sessions to evaluate the client's progress using the procedures to control the habit behavior outside of the treatment session. In followup sessions, the therapist will review the procedures and have the client practice the procedures. The therapist will review difficult situations and help

the client identify ways to consistently use the competing response in those situations.

II. THEORETICAL BASES

The success of the competing response training procedure depends on consistent use of the competing response contingent on the occurrence of the habit or the antecedents to the habit. The competing response produces reductions in the habit behavior through one or two behavioral processes. Use of the competing response may function as an activity punisher. Thus, the contingent use of the competing response would punish the habit behavior. The other possible explanation for the effectiveness of the competing response in reducing habit behaviors is that the competing response is an alternative behavior that occurs in place of the habit behavior and supplants the habit behavior. The occurrence of the habit or an antecedent to the habit serves as a cue for the client to engage in the competing response as an alternative behavior. The therapist and significant others reinforce the correct use of the behavior. Whether the competing response supplants the habit behavior or punishes the habit behavior is not clear. It is possible that one or both processes are operating to decrease the habit behavior in any particular case.

III. APPLICATIONS AND EXCLUSIONS

Research has shown that competing response training is effective in reducing motor tics such as head shaking, eye blinking, facial tics, shoulder jerking, and head jerking; nervous habits such as nail biting, hair pulling, thumbsucking, chewing on clothes, scratching, and eye rubbing; and stuttering in children and adults. Competing response training has also been used to reduce outbursts of anger during athletic competition and to decrease rumination (regurgitation and rechewing of food) following meals.

Research has also shown that competing response training may not be effective with young children and with individuals with mental retardation. The ineffectiveness of competing response training may be due to the fact that children or individuals with disabilities are less motivated to change their behavior. They may not be distressed by the behavior and, therefore, may not express a desire to stop the habit and may not comply with the treatment procedures.

IV. EMPIRICAL STUDIES

Research by Miltenberger and colleagues has shown that competing response training is effective for a variety of habit disorders. For example, in 1985, Miltenberger, Fuqua, and McKinley showed that both habit reversal and competing response training were effective in decreasing motor tics. In 1985, Miltenberger and Fuqua also showed that competing response training was effective for nervous habits. In 1993, Joel Wagaman, Miltenberger, and Rich Arndorfer showed that competing response training was an effective treatment for stuttering in children. In addition to these studies, other research has demonstrated the effectiveness of competing response training for habits, tics, and stuttering.

Research also suggests that, in some cases, social support procedures or other operant contingencies may be necessary to ensure the effectiveness of competing response training, especially with children. For example, in 1999, Ethan Long and colleagues used differential reinforcement and response cost procedures with children and individuals with mental retardation after competing response training by itself was ineffective in the treatment of thumbsucking, nail biting, and hair pulling. Social support or other reinforcement contingencies may help promote the consistent use of the competing response by the client with the habit disorder. When the competing response is used consistently each time the habit behavior occurs, competing response training is more likely to be effective.

V. CASE ILLUSTRATION

Keith was a 12-year-old male who exhibited two motor tics: a mouth tic in which he pulled back the corners of his mouth, stretched his mouth open, and stuck out his tongue; and an eye-blinking tic involving hard eye blinking. Keith was diagnosed with Tourette's disorder and attention deficit hyperactivity disorder and was receiving sertraline (25 mg) daily. He received competing response training as part of a research project completed by Doug Woods, Ray Miltenberger, and Vicki Lumley in 1996.

The therapist first established a recording plan in which Keith was videotaped for 20 minutes in his home two times a week to evaluate the occurrence of tics before and after treatment. The occurrence or nonoccurrence of both tics was recorded in continuous 10-second intervals, and a percentage of intervals with tic occurrences was calculated for each tic. Competing response training was implemented with Keith for his mouth tic

in a one-hour treatment session and two 20-minute booster sessions scheduled one week apart. After improvements were seen in the mouth tic, the same treatment regimen was administered for the eye-blink tic.

The therapist began with awareness training to teach Keith to become aware of each occurrence of the tic. Keith described the movements involved in the tic and demonstrated the tic for the therapist as part of the response description procedure. Keith was not able to identify any antecedents to his tics. As part of the response detection procedure, he then observed himself on videotape and pointed out each occurrence of the tic that he saw on the tape. After identifying occurrences of his tic on tape, Keith practiced identifying each instance of the tic that occurred in the session as he talked with the therapist. The therapist praised him for correctly identifying the occurrence of the tic and pointed out any time a tic occurred that Keith failed to recognize.

After Keith was reliably identifying each occurrence of his tic, the therapist initiated competing response practice. The competing response for Keith's mouth tic involved pursing his lips for one minute. This behavior was chosen because it was incompatible with the tic and was an inconspicuous behavior that Keith could engage in whenever the tic occurred. Keith was instructed to engage in this competing response any time the tic occurred or when he was about to engage in the tic. After describing the competing response and delivering instructions to use it contingent on the tic, the therapist had Keith practice the competing response in the session. Each time that Keith engaged in the tic and then immediately engaged in the competing response, the therapist provided praise. Each time Keith engaged in the tic and failed to use the competing response, the therapist provided a reminder to use the competing response. Competing response practice continued until Keith had correctly identified 10 to 12 instances of the tic in the session with praise from the therapist.

The therapist also instructed Keith's parents to praise him for using his competing response and prompt him to use the competing response if he engaged in a tic and failed to do so. The initial session ended with the therapist instructing Keith to use his competing response contingent on the tic in all situations outside of the session and instructing the parents to provide praise and prompts at appropriate times outside of the session.

In each of the two booster sessions, the therapist reviewed the treatment components with Keith and his parents and had Keith practice the competing response contingent on instances of the tic in session. Keith was encouraged to use the competing response consistently outside of the session and was reminded that consistent

use of the competing response would produce the best results in reducing the frequency of his tic.

After Keith's mouth tic decreased from a baseline mean of 26% of observation intervals to less than 3% following the use of competing response training, the same procedures were implemented with the eye-blink tic. The competing response for the eye-blink tic involved a controlled blink every 3 seconds for a total of 15 seconds. The eye-blink tic occurred in 21% of observation intervals before treatment and was reduced to less than 3% of intervals after treatment.

VI. SUMMARY

Competing response training involves two components of the habit-reversal procedure: awareness training and competing response practice. In one or a small number of outpatient treatment sessions, the client learns to become aware of each occurrence of the habit behavior and to use a competing response contingent on the habit behavior. Competing response training, similar to habit reversal, has been shown to be a successful treatment for a variety of tics, nervous habits, and stuttering in children and adults.

I. DESCRIPTION OF COMPLAINTS MANAGEMENT TRAINING

The basic aim of the treatment protocol is to provide a range of techniques that allow patients to manage their specific anxiety-provoking symptoms and thereby promote perceived control over them. The selection of management techniques is tailored to the individual complaints and needs of the patient. Accordingly, one core element of CMT is the continuous self-monitoring and recording of complaints in a diary to serve as a basis for selecting individual treatment techniques. In the following, examples will be cited from panic disorder and benzodiazepine withdrawal, for the treatment has been applied in these two conditions. CMT consists of three steps: (A) assessment of complaints; (B) training phase; and (C) generalization and relapse prevention.

GLOSSARY

- benzodiazepines** Tranquilizers (e.g., diazepam and alprazolam,) with wide-ranging effect on the nervous system. The main sites of action are the limbic system and the cerebellum; they have a calming and muscle relaxant effect.
- dyspnea** Difficulty in breathing or in catching the breath.
- GABA** Gamma-amino-butyric-acid, the major inhibitory neurotransmitter system of the brain.
- tachycardia** Abnormally rapid beating of the heart.
- vagal innervation** Increasing the vagal (parasympathetic) tone which leads to a decrease in heart rate.
- valsalva** An eighteenth-century physiologist after whom the vagal innervation technique of exerting pressure on the chest is named.

Complaints management training (CMT) is a cognitive-behavioral intervention for anxiety disorders in which somatic symptoms or complaints are a major source of distress. This entry contains a description of the treatment together with its hypothesized mode of action. Outcome data are presented for panic disorder and withdrawal from long-term tranquilizer use.

A. Assessment of Complaints

A detailed assessment is carried out into the range of somatic and bodily complaints, their antecedents, and consequences, in addition to the usual diagnostic procedures investigating the nature of the patients' disorder. Scales with lists of symptoms, such as the list of panic symptoms of the DSM-IV edited by the American Psychiatric Association (APA) in 2000 or the Body Sensation Questionnaire from Diane Chambless and co-workers published in 1984 may also be employed. Alternatively, an idiosyncratic list of the patient's

Nausea														
Tension, sleep disruption														
Other symptoms:														
<i>restlessness</i>	6	5												

Please indicate intensity (I) of each symptom and anxiety/stress (A) evoked by the symptom from 0 = not at all to 10 = extreme

FIGURE 1 Daily record of complaints: intensity and anxiety.

symptoms can be compiled (as an example, see Figure 1). The list is handed over to patients in the form of a diary. An anxiety rating should be added to the identified symptoms. Before the treatment techniques are selected, patients complete the diary for two weeks to indicate which symptoms are currently occurring and are the most distressing. The patients continue to complete the diary throughout treatment to provide feedback about the relief of symptoms and about changes in the extant symptoms, and thereby the need to change the treatment strategy. During the assessment phase, patients are usually given either relaxation or breathing exercises to be carried out daily in preparation of the following treatment.

B. Training Phase

Before being given training in specific techniques, patients are fully briefed about the impending treatment starting with psychoeducation.

1. Psychoeducation

At first, patients receive extensive psychoeducation as to the nature of their disorder. Depending on their relevance, models of anxiety are presented such as the three components model, the threshold model, and the vicious circle of panic model. If applicable, information about benzodiazepines and their effects, the danger of addiction with long-term use, and a full account of withdrawal symptoms are given. Explanations are supported by graphs, and patients are given a written account of this information because many of them tend to be too anxious to process the information during the session. Within this information explanations are reported for the identified symptoms. It is suggested that the symptoms are normal, harmless, and transient, and eased or counteracted by specific management techniques.

2. Training in Specific Techniques

During the assessment phase, patients carry out exercises in progressive muscle relaxation and breathing

retraining (slow, abdominal breathing with short pauses at the beginning and end of each respiratory cycle). Specific techniques are then chosen on the basis of the complaints indicated in the diary. Frequently employed management skills are shown in Table 1. Techniques are practiced within sessions until patients master them. Practice is first carried out in a relaxed state and afterward, whenever possible, under challenge to produce the symptom. Alternatively, stressful situations, symptoms, or states are imagined and counteracted with the newly learned technique. In some cases, instantaneous feedback of the not otherwise observable physiological changes may support the acquisition of skills. This feedback has been shown to be useful when teaching vagal innervation techniques that aim to control tachycardias.

Vagal innervation techniques offer a direct way to lower heart rate, which can be achieved by massaging the carotid, pressing on one eye during expiration, and using the Valsalva maneuver. The Valsalva technique is preferred by patients and consists of increasing pressure in the chest by tensing abdominal and intracostal muscles after a deep inhalation. It is assumed that these techniques stimulate baroreceptors and thereby lower heart

rate. Training of the Valsalva maneuver benefits from being supported by a beat-by-beat heart-rate monitor. Whenever instruments are used to aid the acquisition of skills, patients need to be made familiar with the apparatus and its functioning.

C. Generalization and Relapse Prevention

Patients are instructed to practice the newly learned management techniques between sessions and to record successes and failures for discussion in the following session. Having acquired a management technique, patients are asked to apply it at the first sign of an emerging symptom. Training is then extended to everyday life situations that have previously given rise to complaints. To be able to cope with setbacks, patients are instructed as to the incremental nature of the improvement and are told that minor lapses are not indicative of a relapse. Depending on the nature and severity of the disorder, treatment typically takes six to twelve sessions.

II. THEORETICAL BASES

The aim of complaints management training is to convey control over bodily reactions that are anxiety-eliciting. Assuming that elevated anxiety states between attacks are engendered by their unpredictability and uncontrollability, a technique that is perceived as bringing them under control will also reduce fears about the occurrence of further attacks and thereby reduce generalized anxiety states. Together with the ability to change intentionally a physiological function, the fear of its signaled consequences—be they health concerns or the next panic attack—will also attenuate. Two lines of evidence are cited in support of the validity of the complaints management approach. First, acquiring perceived control over feared objects and events often leads to a reduction of anxiety. Second, some anxiety disorders appear to be uniquely sensitive to bodily symptoms.

A. Controllability

Aversive stimuli are considered more unpleasant if they are also uncontrollable. Electric shocks are rated to be more unpleasant if they cannot be changed compared with shocks of equal intensity that could be regulated—although participants did not actually reduce their intensity. Having to listen to a radio program is

TABLE 1
Frequently Reported Complaints
and Employed Management Techniques

<i>Complaints</i>	<i>Management techniques</i>
Dyspnea	Slow abdominal breathing
Tachycardia	Valsalva
Perspiration	Cooling of wrists
Tightness in chest and throat	Slow breathing, relaxation, Valsalva
Dizziness, imbalance	Seeking support, e.g., wall or furniture, slow breathing, focusing on visual and acoustic stimuli
Muscle ache, muscle tension	Hot baths, relaxation
Trembling/shaking	Relaxation
Depersonalization (changed bodily perception)	Reality testing: e.g., stamp on the ground, strong grip
Derealization	Focusing on objects at different distances, touching of objects
Headache	Relaxation, massage
Nausea	Fresh air/smelling substances
Tension, sleep disruption	Relaxation

more irritating when there is no control over the volume. Finally, monotonous work routines are considered less stressful if rest periods are presumed to be under one's own control. In turn, phobic stimuli or objects are seen to be uncontrollable by phobics, who tend to have no coping reactions at their disposal with which to contain the stimulus or render it harmless.

Conveying control over a fear-inducing stimulus has an anxiety-reducing effect. Giving specific phobics control over the duration of exposure to slides of the phobic object resulted in them being less fearful of the slides than controls who were exposed for the same duration but could not switch off the slides themselves. Being instructed that they can leave the fear-inducing situation made agoraphobics less anxious during exposure, although they did not make use of their privilege.

B. Sensitivity to Bodily Symptoms

Anxiety disorders differ with regard to the target of the fear reaction. Although the focus of the phobic attention and reaction is directed towards objects or situations in the environment, general anxiety states tend to be preoccupied with somatic and social concerns. Panic disorder is uniquely sensitive to bodily changes. Given the massive distress created by a panic attack, bodily symptoms experienced during the attack—and thereby associated with them—are thereafter able to elicit panic attacks. Individuals who suffer from intense anxiety attacks direct their attention to bodily changes that might signal the advent of the next panic attack in an effort to be able to predict, and prepare for, the next attack. This, in turn, also makes them more sensitive to bodily changes.

A similar sensitivity to somatic symptoms is also reported by long-term users of benzodiazepines, particularly during withdrawal from the drug. It is as yet unclear whether the somatic sensitivity is part of panic disorder—a frequent comorbid disorder of benzodiazepine dependence—or whether long-term use of tranquilizers by itself results in heightened somatic sensitivity. Benzodiazepines support the activity of GABA, a neurotransmitter with an ubiquitous inhibitory effect in the nervous system. Assuming that prolonged use of the medication leads to a reduction of the brain's own production of inhibitory ligands, tolerance to and withdrawal from the drug can be expected to result in heightened activity of the brain systems that have hitherto been inhibited, thereby inducing somatic complaints. Over time, these have

been found to subside with renewed use of the drug, which is probably also the reason why withdrawal is difficult for the majority of patients. As with panic disorder, a technique that is perceived as bringing under control a somatic symptom that is associated with anxiety states can be expected to be anxiety-reducing during drug withdrawal. It is thought that the coping strategies will thus become behavioral alternatives to drug taking.

C. Hypothesized Mechanism of Complaints Management Training

Acquiring perceived control over anxiety-inducing bodily sensations reduces their threatening impact; it relinquishes fears about their meaning and consequences and the occurrence of further attacks, and thereby also reduces generalized anxiety states. Two considerations are important in the choice of techniques:

1. *Specificity*: Unlike anxiety management training in which a generalized anxiety state is counteracted by a similarly generalized relaxation response, complaints management training has been developed to deal with specific somatic responses. Given the specificity of some of the physiological reactions that assume a signaling function in panic disorder, it is necessary to create specific techniques with which to bring physiological reactions under control.
2. *Rapidity of action*: The more rapid the relief from the somatic symptom, the more fear reducing will the employed technique be as it conveys a greater extent of relevant feedback of its success.

III. EMPIRICAL STUDIES

There are two areas in which the principles of complaints management training have so far been applied in treatment: (A) panic disorder and (B) withdrawal from tranquilizer use. Complaints management training is successful in giving rapid relief of panic disorder. Within a few sessions it was more efficacious than breathing retraining. It was also as successful as cognitive restructuring, resulting in some 50% reduction in panic attacks within three sessions. Complaints management training also promotes discontinuation of long-term use of benzodiazepines. It eases withdrawal symptoms and improves depressive mood compared to anxiety management training.

A. Panic Disorder

A number of different techniques have been employed to bring under control somatic responses that are related to panic. The most frequently used technique is respiratory training. David H. Barlow and his associates have termed this approach panic control training. Eleven sessions of a combination of cognitive restructuring with breathing retraining and interoceptive exposure constitute a highly effective treatment in panic disorder. This treatment worked equally well with and without imipramine, a tricyclic antidepressant, and appeared more durable than imipramine alone six months after treatment cessation. Psychological treatments of panic disorder have previously been shown to be more effective than alprazolam, a benzodiazepine.

In 1988, Gudrun Sartory and Deli Olajide compared breathing retraining with Valsalva, a vagal innervation technique, and found a slight advantage of the latter. Both groups received progressive relaxation and the instruction that panic could be brought under control with their respective technique—slow breathing or vagal innervation. The number of weekly panics and somatic symptoms decreased equally in both groups, but the group receiving vagal innervation techniques evidenced less cognitive anxiety and considered panics to be less disruptive than the breathing retraining group. It was thought that vagal innervation techniques conveyed more rapid control over panic and therefore more relevant feedback regarding its efficacy than the breathing technique.

Comparing complaints management training with cognitive restructuring showed that they worked equally well. Initially, both groups received extensive psychoeducation as to the nature of panics, after which one group was trained in control techniques and the other spent the sessions discussing dysfunctional thoughts and attributions. As improvements set in fairly rapidly, it is thought that the initial psychoeducation had in itself a major effect. Explanations as to how panics come about constitute a form of reattribution that is known to be effective.

B. Tranquilizer Withdrawal

Elsesser et al. compared the effect of complaints management training with that of anxiety management training, the treatment that had previously been shown to be effective in facilitating benzodiazepine withdrawal. Immediately after treatment, the abstinence rate was higher in the complaints than in the anxiety management group

(Fig. 2a), and patients in the former were also less anxious and depressed (Fig. 2b). At followup, there was no longer a significant difference between groups in terms of abstinence rate (65%). Complaints management training appears, however, to ease withdrawal and to lower anxiety and depression more rapidly than anxiety management training.

The evaluation of the efficacy of a single-treatment mode presents some difficulty, for treatment trials usually combine a number of approaches in any condition and group. Caution must therefore be exercised when attempting to interpret the outcome of trials in terms of the effect of any single component of treatment. Some of the components are necessary to introduce or convey the techniques and have been found to be in themselves effective. Teaching the technique of slow abdominal breathing is usually embedded in progressive relaxation training, as tense abdominal muscles are likely to prevent slow and easy breathing. A further component is an extensive rationale as to why a particular technique will be helpful for a symptom. This necessitates discussion of the symptoms, including—to a certain extent—their reattribution. This strategy is the mainstay of cognitive restructuring, which is by itself highly effective in the treatment of panic disorder. Furthermore, in order to learn to control a certain physiological response, it has to be elicited in the first place. Exposure to fear-eliciting stimuli also has an anxiety-reducing effect. Studies dismantling the respective effects of the different components have so far not been carried out.

While taking into account these constraints on evaluation, complaints management training can be said to be of use in anxiety disorders with a prominent focus on bodily sensations. This is the case in panic disorder, tranquilizer withdrawal, and conceivably also in somatoform disorders, although there are as yet no formal treatment data available.

IV. SUMMARY

Complaints management training is a cognitive-behavioral intervention for anxiety disorders in which somatic symptoms are a major source of distress. It contains a range of techniques that enable patients to ease bodily symptoms and thereby promote perceived control over them. A detailed assessment is carried out on somatic and bodily complaints with the help of a diary. Patients are given extensive psychoeducation as to the nature of their disorder and are trained in techniques that are chosen on the basis of their spe-

FIGURE 2 Two groups of long-term users of benzodiazepines (BZ) who had previously been unsuccessful in their attempt to withdraw were treated either with anxiety management training (AMT) or complaints management training (CMT). Both groups received nine weekly sessions; measurements took place at two weekly intervals. (A) shows the decrease in BZ consumption and (B) the course of depression ratings in the two groups. [Reprinted from Elsesser et al. (1996) with permission from Elsevier Science].

cific complaints. Frequently used techniques are Valsalva, a vagal innervation method to control tachycardias, breathing retraining for hyperventilation, and relaxation for feelings of tightness and muscle tension. Complaints management training has so far

proved successful in panic disorder and as psychological support of benzodiazepine withdrawal. It is thought that perceived control over the anxiety-provoking bodily symptom constitutes the main therapeutic mechanism.

activity. But it is also possible to create reinforcers from stimuli that have no initial biological significance by creating a learned association between those stimuli and biological reinforcers. Such reinforcers are labeled conditioned reinforcers (or “secondary reinforcers” in the early experimental literature) to reflect the fact that a learning procedure is necessary for the development of their reinforcement value.

GLOSSARY

higher-order conditioning A form of Pavlovian conditioning in which the unconditioned stimulus (US) is the conditioned stimulus (CS) from previous conditioning.

Pavlovian conditioning Learning that occurs when a stimulus that naturally elicits an unconditioned response (UR) is preceded by an initially neutral stimulus (CS). Because of the association established by the CS–US pairing, the CS elicits a response (CR) related to the UR.

reinforcement The psychological principle that a response followed by a reward will increase in strength; the more immediate the reward, the greater the strength.

A significant number of psychotherapies utilize the principle of reinforcement as the conceptual foundation of their treatments. Reinforcement theory originated in the laboratory with animal subjects, where the rewards used to reinforce the desired behavior have obvious biological value, such as food, water, and sexual

I. PAVLOVIAN CONDITIONING AS THE BASIS OF CONDITIONED REINFORCEMENT

The great majority of reinforcers that control human behavior have little immediate impact on satisfying the biological motives that underlie the reinforcement contingencies commonly studied in the laboratory. People are not born with a tendency to work for money, to like the taste of alcohol or coffee, or to value Porsches over Chevrolets. Such values are learned, according to the current consensus, by the process of *Pavlovian conditioning*. A stimulus paired with a stimulus that has unlearned *reinforcement* value (which Pavlov designated the unconditioned stimulus or US) acquires not only the ability to elicit the responses appropriate to the Pavlovian US but its reinforcing value as well. Thus; a conditioned reinforcer is a Pavlovian conditioned stimulus (CS) that has been paired with a US of positive value. The implication is that variables that govern

Pavlovian conditioning also determine when initially neutral stimuli become conditioned reinforcers.

It is important to recognize that Pavlovian conditioning is not the simple process that it was once supposed. Simple pairing between the CS and US is inadequate for conditioning to occur because the CS must also provide information about the US occurrence that is not available from other sources. Associations between the CS and US may also occur even when they are not directly paired, due to shared associations with a third stimulus. In Pavlov's studies of "second-order conditioning," for example, a bell was first paired with food in the dog's mouth, so that the bell elicited salivation. Then a light was paired with the bell, and the light also elicited salivation without itself being paired with the food. Pavlov also studied higher-order mediated associations but found that the conditioned response was not maintained beyond the third-order level. Pavlov nevertheless believed that mediated associations were of major importance for Pavlovian conditioning of human behavior because language could serve as a "second signaling system" that provided a basis for such mediated associations readily to occur.

Although the present discussion will consider only events that assume positive value because of their conditioning history, it is important to recognize that stimulus events may assume negative value as well, thus serving as conditioned aversive stimuli that may motivate various types of avoidance and escape behavior. Conditioning of aversive properties to initially neutral stimuli, and the behavioral dynamics that result from such conditioning, have played a major role in theories of various forms of neurotic behavior, for example, phobias, and compulsive behavior such as incessant hand-washing. We will confine ourselves to positive conditioned reinforcement, both because of the need to limit the range of discussion and because the scientific investigation of positive conditioned reinforcers and conditioned aversive stimuli has evolved into essentially separate enterprises, as has their application to clinical situations. Nevertheless, it is important to appreciate that similar conceptual issues occur in both arenas.

II. LABORATORY EXAMPLES OF CONDITIONED REINFORCEMENT

A simple example of how conditioned reinforcement has been studied is provided by the report by B. F. Skinner in his first major book, *Behavior of Organisms*, published in 1938. Rats were first trained to approach a food

cup at the sound of the pellet dispenser, and then food was removed from the situation when a lever was introduced into the experimental chamber. Lever presses produced the sound of the pellet dispenser but no food. The rate of lever pressing increased over the first 5 to 10 minutes, then decreased, and finally was reduced to near-zero levels after 30 to 45 minutes of training. Approximately 40 to 80 total bar presses occurred over that period of time. Skinner's results are typical of many subsequent studies. The response-contingent presentation of a stimulus previously paired with the primary reward produces some initial level of acquisition, but then loses its ability to maintain the behavior as training continues. Presumably this loss of control over responding reflects the extinction of the conditioned value of the conditioned reinforcer in that its presentation in the absence of the primary reinforcer removes the conditioned value that was originally established by the pairings of the initially neutral stimulus and the primary reward. The rate at which this extinction process occurs thus determines the duration of time over which a conditioned reinforcer will be effective after it is no longer paired with the primary reward.

A more durable method for using conditioned reinforcement is to maintain separately the correlation between the stimulus and primary reward while at the same time making the conditioned reinforcer contingent on a designated response that otherwise is never followed by the unconditioned reward. An example of such a procedure was developed by Dr. J. W. Zimmerman and his colleagues in the 1960s. Pigeons received food delivery randomly distributed in time, but any scheduled food presentation was delayed until 6 seconds had elapsed without a peck to a small illuminated disc, in order to ensure that pecking behavior was not adventitiously followed by food. While the pecking behavior was never followed by food, it did produce conditioned reinforcers, consisting of brief presentations (0.5 sec) of the stimulus complex that ordinarily accompanied food presentation. Because this stimulus complex (a light onset and distinct sound) was paired with the food deliveries that occurred in the absence of pecking, it continued to be paired with the food reward. Consequently, pecking was maintained by the conditioned reinforcer presented in the absence of food, despite the pecking behavior delaying food presentations that otherwise would have occurred. Despite its maladaptive character, pecking behavior was sustained for months of training, as long as the pairings of the stimulus complex and the food were maintained.

III. PRACTICAL ADVANTAGES OF CONDITIONED REINFORCEMENT

Conditioned reinforcers have substantial advantages over primary reinforcers in a significant number of training situations. One problem with using a primary reinforcer is that its consumption may interrupt the stream of behavior that is being trained. For example, in animal acts such as “Shamu the Killer Whale” at Sea World, the primary reward is a quantity of fish presented at the side of the tank. Thus, if only the food reward were used when Shamu executed the various parts of his performance, the continuous stream of behavior would be disrupted by trips to the side of the pool to obtain the food. So instead the training procedure involves presenting auditory signals (usually audible only to the whale) as feedback for the various segments of the performance, which allows the behavior segments to be reinforced without the requirement that the subject procure the reward by approaching the food site.

A similar advantage for conditioned reinforcement contingencies may be seen in even the simplest animal training. When using a food reward to train your dog to roll over, for example, a typical problem is that the dog will quickly discriminate that you are the source of the food and will attend closely to you, often approaching and begging for the food at the expense of the behavior that you are attempting to shape. Although it is possible to extinguish this competing behavior, a more expeditious procedure is first to establish a discriminative contingency such that the food is delivered only after the sound of a clicker, and then to use the clicker as a conditioned reinforcer contingent on the behavior being shaped. The underlying principle is that Pavlovian contingencies may often compete with the operant contingencies, so that a judicious choice of the stimulus signaling reward availability is often necessary to minimize competition from the sign tracking that so often occurs when signals for food are physically localized in the environment.

A further example of the utility of using conditioned reinforcers is when the consumption of the primary reinforcer may be debilitating and therefore can occur only infrequently. One representative experiment is the study of various pharmacological manipulations on the lever-pressing behavior of a male rat that is maintained by access to a receptive female rat. Whenever the female rat has been obtained, the lever pressing that produced her access is typically disrupted for substantial periods of time, so that at most one to three primary reinforcers per day can be presented (because of the inherent difficulties

of delivering only small portions of the reward). Thus, the primary reinforcer is presented only after extended periods of bar pressing (e.g., the first bar press after 30 minutes has elapsed). The result is that the amount of maintained behavior is very low, making it difficult to study how the pharmacological variables affect the male rat's performance. However, when presentation of the female is preceded by a 30-second signal, and that signal is presented on its own more frequent schedule, the lever pressing greatly increases in frequency, allowing the drug effects to be assessed more easily.

The most common laboratory usage of conditioned reinforcement involves situations in which the primary contingencies of reinforcement are delayed in their presentation. Delayed reinforcement is much less effective in controlling behavior than is immediate reinforcement, and if the delay is sufficiently long, the animal may be incapable of learning even simple behaviors. For example, if a pigeon is presented a choice between a horizontal and vertical line, with the outcome of the choice presented one minute later (food or no food depending on whether the choice was to the stimulus the experimenter designated as correct), the pigeon will almost always fail to learn the discrimination. However, if differential stimuli are presented during the 60-second delay (e.g., a red light leading to food at the end of the delay versus a green light leading to no food at the end of the delay), the pigeon will learn the line-tilt discrimination almost as rapidly as if food/no food had been presented immediately after the pigeon's choice response. Thus, a major function of conditioned reinforcement is to facilitate control by delayed primary reinforcement.

A third important usage of conditioned reinforcement is in the training of behavioral chains. A common laboratory exercise for beginning psychology students is to train a rat to perform an apparently complex sequence of behavior, including, for example, running through a hoop, pulling a string through a hole, pressing a lever, and then pushing a marble, with the entire sequence required before the rat earns its food reward. The key concept for successfully training such behavior is “backward chaining.” The last element of the chain, in this case the marble pushing, is first trained with the food reinforcer; then the presentation of the marble serves as a conditioned reinforcer for training the preceding chain element (the lever press). The presentation of the lever then serves as a conditioned reinforcer for training the string pulling, and the presentation of the string can then be used as a conditioned reinforcer for training the running through the hoop.

Using this procedure, one can establish quite elaborate sequences of behavior, which appear extremely impressive until the observer learns the very simple principles that are involved. Backward chaining is often used in applied settings, especially for severely retarded children learning complex tasks such as feeding themselves or learning to tie a necktie.

After a chain sequence has been established, the pattern by which it extinguishes when food is removed from the situation also reveals an important principle. The element closest to the food extinguishes first, then the penultimate element, and so on. Extinction of a chain thus occurs in the reverse order of how it was learned. This is important because the initial elements of a chain may persist for prolonged periods of time after removal of the primary reinforcer. For example, a rat that has learned a complex maze may quickly run through the initial portions of the maze even after it has learned that no food is now in the goal box, but then gradually slow down its behavior the closer it gets to the goal box, ultimately not even entering it. The persistence of the early links of the chain occurs because the value of the conditioned reinforcer that maintains it must be extinguished before the behavior ceases. In the preceding example, after the rat learns that marble pushing is no longer followed by food, the presentation of the marble loses its conditioned value, which causes the lever pressing to decrease, which in turn causes the presentation of the lever to lose its value, and thus allows extinction of the string-pulling behavior. Each type of extinction takes some amount of time, so that prolonged training after the food has been removed is often necessary before the initial elements of the chain gradually wane. A commonplace example is when a coke machine that someone uses regularly no longer functions, keeping one's money while not delivering a coke. Often the behavior of going to the coke machine will persist even when the act of putting money into the machine does not occur. Thus, the terminal element of the chain has been extinguished due to the experience of losing one's money, but the early elements of the chain will persist until they, too, are extinguished by the arrival at the coke machine losing its value as a conditioned reinforcer.

IV. THEORETICAL ISSUES AND INTERPRETATIONS

The major issue concerning conditioned reinforcement as a theoretical concept is the basis of the facilitation by conditioned reinforcers of delayed primary

reinforcement. Professional animal trainers such as those who work at Sea World often describe the stimuli appearing in the delay between the response and the primary reward as "bridging stimuli," which suggests that the function of conditioned reinforcers is to facilitate the association between the animal's response and the delayed reward. That is to say, the intervening stimulus serves as a cognitive mediator that may have no value in itself except as it cues the subsequent delivery of the primary reinforcer. In contrast, the traditional conception of conditioned reinforcement is that conditioned reinforcers do indeed have value because of their Pavlovian association with the primary reinforcer.

For most practical purposes, it makes little difference which of these two interpretations is correct; it is possible that either may be correct depending on the specific training situation. Nevertheless, considerable research has been devoted to developing experimental tests that critically distinguish between then bridging versus conditioned value conceptions of conditioned reinforcement. An illustrative experiment that distinguishes between the two theoretical interpretations of conditioned reinforcement involves the line-tilt discrimination described above. Pigeons chose between vertical and horizontal lines, with the outcome of their choice (food or no food) occurring 60 seconds later. When different colored lights correlated with the outcome were present throughout that 60-second delay (e.g., red after a correct choice and green after an incorrect choice), the discrimination was rapidly learned. Moreover, when the differential colors occurred only for the first few seconds after the choice, and then the last few seconds prior to the outcome, the discrimination was learned as rapidly as if the colors had been present throughout the delay. The critical condition in the experiment, which distinguishes between the bridging versus conditioned value interpretations of conditioned reinforcement, was that which reversed the colors occurring at the beginning versus the end of the delay-of-reinforcement interval. Thus, red occurred immediately after the correct choice for a few seconds, and then green was presented a few seconds prior to the food reward contingent on that correct choice; also, green occurred immediately after the incorrect choice for a few seconds, and then red occurred during the last few seconds of the delay interval but here was not paired with food. The design of the experiment thus pitted the delayed primary reinforcement contingencies against the immediate conditioned reinforcement contingencies. The result was that after a brief period

of random responding all subjects began predominantly choosing the incorrect choice alternative because it was followed immediately by the color that preceded the food at the end of the delay.

Eventually, however, the choice behavior ceased to occur because continuous choice of the incorrect alternative meant that the red color no longer was paired with food and thus lost its conditioned value. But at no time did the animals learn to choose the correct line orientation because the color never paired with food was always immediately contingent on that behavior. The experiment thus demonstrates that the conditioned value of the conditioned reinforcer, not its ability to bridge the delay interval to food, determined its ability to control behavior.

The concept that a conditioned reinforcer has value in its own right provides insight into numerous experimental outcomes that otherwise seem odd or inexplicable. As one example, consider the phenomenon of “contrafree-loading,” the finding that animals will engage in operant behavior even when the food reinforcer contingent on the behavior is also freely available in the conditioning chamber itself. Moreover, animals will learn to emit the response even when the free food is available from the outset of training. Such behavior has been observed with several different species, with several different types of reinforcers. The behavior appears paradoxical because it violates the law of least effort, which otherwise has been upheld in many different settings. This paradox disappears, however, when the role of conditioned reinforcement is appreciated. The critical ingredient is the stimulus change contingent on the operant behavior that does not occur during procurement of the free food. Thus, the operant response is followed by the stimulus change plus the food, while the approach to the free food container is followed only by the food. Because the stimulus change is paired with the food, it apparently gains value in its own right, thus making the stimulus plus food combination more valuable than food alone. This interpretation is supported by the finding that when the stimulus change is equated for the two sources of food, preference for free food quickly develops.

A more general psychological phenomenon for which conditioned reinforcement serves as an explanatory framework is imitation learning. Consider first how talking birds acquire comprehensible vocal behavior. An apparent prerequisite for such vocal behavior is that the bird develop an attachment to its caretaker, so that attributes of the caretaker acquire positive value via their pairings with the primary rewards provided by the caretaker. One of these attributes is the sound of the caretaker's

voice, including specific verbal utterances. The bird then increasingly approximates these sounds because the similarity between the bird's own sounds and those of the caretaker cause the bird's own sounds to have positive value as well. Thus, the closer the bird approximates its caretaker's verbal utterances, the greater the degree of conditioned reinforcement contingent on vocalizing. Close matches will eventually occur because that is when conditioned reinforcement is at its maximum.

The foregoing analysis can be extended easily to a considerable amount of human behavior. The most obvious is the development of the phonetic structure of infant babbling, which evolves from including the entire spectrum of sound to being restricted to only those phonemes in the immediate linguistic community. An increasingly pervasive example is provided by the ubiquitous changes in the language patterns of teenagers. To the chagrin of many parents, an epidemic of speech insertions that serve no semantic function has developed: “you know, “like,” and so forth. These patterns of verbal behavior have spread to a remarkable degree among teenagers, with the result that they often seem to be speaking in their own idiosyncratic dialect. Informal observations suggest that most are unaware that their speech patterns elicit disdain from the adult linguistic community, and they often are unaware that their speech is in fact deviant from cultural norms. The concept of conditioned reinforcement offers a ready explanation for why such behavior is maintained. Teenagers are reinforced by assuming the characteristics of their peers, characteristics that include speech patterns as well as clothes and social customs such as piercing one's body with various metal adornments. The robustness of the behavior in face of adult censure provides striking confirmation of the power of the conditioned reinforcement value of peer-modeled behavior.

The most pervasive of all applications of conditioned reinforcement is the industry of advertising. John B. Watson, who founded Behaviorism as a distinct school of psychology in 1913, was the first to recognize the enormous power of Pavlovian conditioning as a means of establishing value to commodities that were otherwise neutral. After a very successful academic career, in 1920 he was fired from Johns Hopkins University for his sexual misconduct (an affair with a graduate student, whom he later married). After no other universities would hire him, he assumed a job with a major advertising company in New York. His initial marketing research determined that most consumers were unable to distinguish between different brands of the same product when tested

without knowledge of the product brand being tested. He then speculated that it was primarily the associations that were attached to a product name that gave that product its commercial appeal, and he proceeded to demonstrate experimentally that this was in fact the case. Much of the modern industry of advertising continues to be based on that simple idea.

Numerous laboratory experiments, involving many kinds of animals including humans, have demonstrated that the value of many different commodities, objects, and the like, can be systemically changed by their pairing with primary reinforcers. A significant number of these experiments involved gustatory stimuli (tastes), where initially neutral stimuli were paired either with something pleasant (e.g., milkshake) or aversive (quinine). Later when the same tastes were presented in a neutral medium such as water, tastes previously paired with the pleasant substance were rated as much more desirable or pleasant than tastes initially of the same value but not involved in the training procedure. Conversely, tastes that had been paired with the unpleasant substance were rated as much less desirable than tastes that had not been trained. It should be apparent that conditioning taste preferences plays an important role in much of human appetitive behavior. For example, most people do not initially like the taste of beer but quickly develop a positive value for that taste after only a few pairings of the taste with the alcohol in the beer.

Such "Revaluation" experiments have also been conducted with aesthetic judgments. In a typical experiment, pictures (e.g., travel slides) are divided into the categories of pleasant value, negative value, or neutral, and then different sets of the neutral slides are followed in their presentation by either the positive or the negative stimuli. The result has been that the value of the initially neutral slides is changed in the direction of the stimuli that follow them, as assessed by ratings by the subject after the different types of pairings. These changes have been independent of whether the subject had been aware of the different types of sequences. The fact that the subject is unaware of the change in his or her evaluation of the stimuli is of special importance to the advertising industry in that it allows manipulation of the consumer's attitudes and values without the consumer being aware of that manipulation.

The conditioned value of commercial products due to their pairing with primary reinforcers can also be made durable by using several different kinds of primary reinforcers. Conditioned reinforcers that are associated with

several different kinds of primary reinforcer have been labeled "generalized reinforcers" by B. F. Skinner, who assumes that their associations with multiple reinforcers makes them extremely resistant to extinguishing their value. Money is the most obvious example of a generalized conditioned reinforcer.

V. CLINICAL APPLICATIONS OF CONDITIONED REINFORCEMENT

Explicit manipulation of the value of Pavlovian conditioned stimuli, whether positive conditioned reinforcers or conditioned aversive stimuli, plays an important role in various clinical applications. Aversion therapy is the most obvious type of application. Stimuli associated with maladaptive behavior such as smoking or alcoholism have become positive conditioned reinforcers through their pairing with the pharmacological effects of nicotine or alcohol, and thus help maintain the behaviors of smoking or drinking. The goal of aversion therapy is thus to reverse the value of these Pavlovian conditioned stimuli from being positive conditioned reinforcers to being conditioned aversive stimuli. For smoking-related stimuli, the method most commonly used has been the rapid-smoking procedure, whereby the client is encouraged to smoke at a very high rate, thus creating an aversive bodily state that is paired with all of the stimulus properties of smoking. For the aversion therapy treatment of alcoholism, the smell and taste of various alcoholic beverages have been paired with emetic agents that cause nausea and vomiting, in order that these unpleasant bodily states become associated with those alcohol-related stimuli. Such procedures are generally regarded as among the more effective procedures for treating these common addictions.

The role of conditioned reinforcers in maintaining maladaptive behavior is often not fully appreciated. As an example of the practical importance of understanding the dynamics of conditioned reinforcement in clinical settings, consider a recent analysis of the maintenance of smoking behavior and the consequent implications for smoking-cessation treatments. It is now generally acknowledged that the pharmacological reward properties of nicotine are crucial for maintaining smoking behavior, with the result that nicotine replacement, either by nicotine chewing gum or the nicotine skin patch, has become a major therapeutic approach. While a significant improvement in smoking cessation rates, relative to placebo controls, usually

does occur with this approach, the effect is typically small, primarily it seems because nicotine replacement has little impact on the degree of craving for cigarettes, even though it greatly reduces the number of physiological symptoms associated with smoking withdrawal (e.g., nervousness, weight gain). The apparent basis of the persistence of craving in spite of the continued presence of nicotine is that the sensory properties of smoking have acquired hedonic value in their own right, and it is they, not nicotine itself, that are the object of craving. Support for this hypothesis comes from several studies in which various methods of mimicking the sensations of smoking (e.g., inhalation of aerosols of dilute citric acid) have substantially reduced the level of craving, sometimes to a degree comparable to smoking a commercial cigarette. The interpretation of this effect is that the sensory properties of smoking have become conditioned reinforcers that retain their hedonic value even when the subject is in the state of nicotine satiation at the physiological level. The implication is that smoking-cessation treatments must consider the conditioned-reinforcement properties of smoking-related cues as being as important, if not more so, as the primary reward properties of nicotine itself.

The most explicit use of conditioned reinforcement in clinical settings involves token economies in which many different aspects of behavior are monitored and reinforced when appropriate with some type of token that later can be traded for desired commodities. The experimental research on which some applications are based dates to experiments in the 1930s in which chimpanzees were trained to work for poker chips that could be traded for food only after the work session was completed. In the 1960s Teodoro Ayllon and Nathan Azrin, two of the early pioneers in adapting the principles of behavioral psychology to applied settings, administered a token economy in a state psychiatric hospital. Patients received tokens for behaviors such as attending activities on the ward, group meetings, and therapy sessions, and for grooming, making one's bed, showering, engaging in appropriate meal-time behavior, and socially interacting. Tokens could be exchanged for a variety of reinforcers such as cosmetics, candy, cigarettes, and clothing; renting chairs for one's room; ordering items from a mail-order catalog; using a piano or radio; spending time in a lounge; watching television; and having a private room.

Token economies in many other psychiatric settings were developed during the ensuing two decades, and their effects have been systematically compared to the

traditional psychiatric treatments under controlled conditions. Such comparisons have shown token economies to be more successful than traditional treatments in reducing bizarre behavior, improving social interaction and communication skills, and developing participation in activities. Perhaps most importantly, these gains have been reflected in the increased number of patients discharged and in their adjustment in the outside community after termination from the program.

Token economies have been used with a variety of populations in numerous types of settings. Among them are the mentally retarded, nursing-home residents, alcoholics, and drug addicts. Perhaps their most common venue has been educational settings, but they have also been used in day-care centers, prisons, and business and industry.

It is important to keep in mind the two important advantages that token economies have over forms of reinforcement contingencies. First, they allow the immediate delivery of a reinforcer in a nonintrusive way that does not disrupt the stream of behavior. For example, if a retarded child is studying diligently at his desk, presenting a token to the child is much less likely to disrupt his behavior than if the reward were a cookie. Second, because many different types of rewards can be paired with tokens, the idiosyncratic variation among peoples' preferences will not be problematic in determining what type of reward will be an effective reinforcer. For example, some children may be insensitive to the reward of social praise, but they are unlikely to be insensitive to all of the various kinds of things that tokens will purchase.

The major issue in using token economies is how to fade out the tokens and replace them with the more usual social contingencies of praise, the value of a job well done, and the like. The specific techniques used in fading out the token contingencies vary widely with the setting in which the token economy has been implemented, and there is a large professional literature about the procedures necessary to prevent the gains established under the token economy from being lost.

VI. SUMMARY

The present brief review has touched on only the major applications of the concept of conditioned reinforcement. Other interesting aspects of human behavior that potentially could be enlightened by the concept are fetishes, daydreaming, and changing tastes in fashion. Such diversity of applications reflects the basic fact of

human nature that the great majority of the events, activities, and commodities that motivate and reinforce human behavior are creations of our learning histories. The basis of that learning is often obscure because the underlying associations with biologically based rewards are mediated by multiple second-order associations, so that no one individual linkage between a conditioned and primary reinforcers seems essential. Nevertheless, when conditioned reinforcement contingencies are explicitly manipulated, they have been shown to be tremendously powerful determinants of human behavior.

GLOSSARY

confidentiality Characterizes an understanding between parties in a defined relationship; the necessary ingredient is trust that one party (e.g., a professional or a spouse) will not divulge information about the private life of the other party (e.g., a person using professional services or the other spouse).

privacy An individual person's right to control one's own body, mental life, possessions, and business affairs, with freedom from intrusion, interference, or knowledge on the part of others.

privileged Communication that has special safeguards (e.g., from divulgence or legal action) in a judicial arena or other investigation at law, such as a legislative proceeding. The legal basis of the protection is called a *privilege*.

I. INTRODUCTION

The doctor–patient relationship is the cornerstone of psychotherapy. Fundamental to that relationship is

strict adherence to a code of professional ethics. At the heart of these ethical principles is confidentiality. Skills are also vital to psychotherapy, although effective psychotherapy by a beginner can take place in a well-supervised learning situation. However, ethical behavior, including preservation of privacy and confidentiality, is essential from the very outset of all psychotherapy. Confidential communications are protected by law in certain relationships with an attorney, member of the clergy, physician or mental health professional, and husband or wife. In addition, formal ethical codes of the professions govern physicians, attorneys, and the clergy. Rapidly evolving information systems create many new challenges to confidentiality.

II. WHY CONFIDENTIALITY IS FUNDAMENTAL TO PSYCHOTHERAPY

Effective psychotherapy depends on the patient's feeling safe to be completely frank and candid. Such openness does not develop quickly. The patient has to gain trust in the therapist's ethical reliability not to break confidence or to demean or exploit the patient. Frequently the patient is not aware of deeper motives or feelings, except perhaps through a vague sense of anxiety, and only the work of treatment will bring these to light. Patients also may be aware of motives, feelings, thoughts, fantasies, dream material, or actions that cause painful shame and/or guilt. Only in an atmosphere

of trust and confidence can the patient open the door to these intimate mental contents to another person. Frequently patients explicitly ask for reassurance about confidentiality before embarking on a sensitive topic. The material that emerges is often a surprise to the therapist and even the patient.

Psychotherapy modalities vary considerably in how much they facilitate the patient's divulging sensitive material. Psychoanalytically based treatments (psychoanalysis, psychodynamic psychotherapy) employ methods that encourage free association, the patient's freedom to speak whatever comes to mind. Therapists using these treatments anticipate that part of a patient's mental life is hidden even from the patient. Improvement in symptoms, function, and overall quality of life result from emerging self-knowledge and conscious mastery of hitherto unconscious elements from past experiences or current inner conflicts. Psychodynamic treatments are open to exploring unexpected twists and turns in mental life. Structured, short-term psychodynamic treatments may narrow the scope of what will be addressed, but they nonetheless must be prepared for surprises and have a strategy for dealing with them.

Interpersonal psychotherapy focuses more exclusively on the patient's roles and relationships with other people that frequently generate powerful emotions. Disclosure is essential for the patient and the therapist to know what these really are, so that the patient can understand and manage them better. Cognitive-behavioral therapy requires openness on the part of the patient to observe, identify, and work to control or modify automatic thoughts, dominant patterns of thinking, and repetitive, maladaptive behaviors. Strict behavioral therapies, being focused on the patient's actions rather than inner mental life, may involve less disclosure, but behaviors must be known to be treated, including those that induce shame or guilt in the patient. Regardless of the form of treatment, patients expect a confidential atmosphere, which must be maintained. Being unschooled in the fine distinctions between therapeutic methods, patients may expect or wish to talk about sensitive issues regardless of the chosen format. Sometimes the technique and focus of the treatment will have to change as a result of new revelations by the patient.

Patients commonly talk about their relationships in psychotherapy, which means that extensive knowledge of other people's private lives enters into the therapy. The patient must also feel secure that these people and these relationships will not be harmed as a result of disclosures in psychotherapy. It must be in the patient's

domain alone, not the therapist's, to take actions that affect others or change the nature of relationships.

Even more, the patient must feel secure that disclosures to a therapist will not damage the patient's life situation in any way. This entails protection from prosecution, investigation, harm in civil proceedings, public shame or humiliation, disruption of personal relationships—let alone any kind of exploitation on the part of the therapist. Only when the patient feels that no harm will come from telling the truth can that person take on the task of facing the unknown, understanding mental processes, dealing with consequences, resolving anger, anxiety, shame or guilt, establishing self-control, and realigning one's inner and outer life. This benefit to the patient, and the consequent benefit to society of access to this valuable treatment method, is the basis of legal and ethical protections of confidentiality in psychotherapy.

III. ETHICAL FOUNDATIONS OF CONFIDENTIALITY

The bedrock of ethics in Western medicine lies in the ancient Hippocratic Oath, written around 400 B.C.E. and recited to this day by physicians as they graduate from medical school. From it come these words about confidentiality:

Whatsoever I see and hear concerning the life of men, in my attendance on the sick or even apart therefrom, which ought not to be noised abroad, I will keep silence thereon, counting such things to be as holy secrets.

Another fundamental tenet of Western medicine is *Primum non nocere*—first, do no harm. Confidential information revealed to others can, of course, do enormous personal and financial harm.

Confidentiality remains central to the ethical principles of the healing professions today. The American Medical Association's (AMA's) Principles of Medical Ethics, presented in the Preamble as "standards of conduct which define the essentials of honorable behavior for the physician," state that "A physician . . . shall safeguard patient confidences within the constraints of the law" (Section IV). The American Psychiatric Association (APA) adds to the AMA principles "Annotations Especially Applicable to Psychiatry." The annotation for this section begins,

Psychiatric records, including even the identification of a person as a patient, must be protected with

extreme care. Confidentiality is essential to psychiatric treatment. This is based in part on the special nature of psychiatric therapy as well as on the traditional ethical relationship between physician and patient.

Detailed elaboration deals with the many situations in which confidentiality comes into conflict with other societal needs or interests. Among these is the setting itself in which the treatment takes place: A hospital or multidisciplinary clinic where several professionals may work with a patient poses a different challenge than the private office of a solo practitioner. Other professions that practice psychotherapy have similar ethical positions.

IV. LEGAL PROTECTIONS OF CONFIDENTIALITY IN PSYCHOTHERAPY

The laws of every state of the United States protect medical confidentiality, and, as cited by the U.S. Supreme Court in the 1996 decision in *Jaffee v. Redmond*, all states also have statutes establishing some form of psychotherapist–patient privilege in court proceedings. Laws in various jurisdictions safeguard the confidentiality of patient information, but some also specify situations in which it may or must be superceded by other priorities, such as reporting child abuse or imminent threats of violence. In addition, state professional licensing boards have the right to sanction or remove the license of a practitioner who breaches ethical codes, including confidentiality. Psychotherapy of couples, families, or groups pose special issues in regard to legal protections of confidentiality, because other people are in the room with the therapist and the individual identified as a patient in a legal proceeding. Special measures are usually taken to pledge participants to preserve confidentiality in these situations, but there is little case law to establish whether it could be challenged in court.

Ironically in comparison with the states, a privilege protecting confidential psychotherapy information in federal courts was nonexistent until recently. This changed radically in 1996 when the U.S. Supreme Court handed down a decision regarding the admissibility of psychotherapy data as evidence in federal courts in *Jaffee v. Redmond*. Although this decision technically applies only to rules of evidence in the district in which the case arose, it has been highly influential in subsequent decisions in the states as well as federal courts. Its rationale and authority have also been used to advocate for legislation and/or regulation

to protect the confidentiality of information obtained during psychotherapy.

Jaffee v. Redmond arose from an incident in which a female police officer shot and killed a man who appeared about to stab another person. The officer subsequently was so distressed that she sought psychotherapy with a social worker. The family of the deceased suspect sued the officer and the city for damages. The psychotherapist refused to testify or divulge the records of her patient, and the case was ultimately appealed to the U.S. Supreme Court. Many professional organizations submitted *amicus curiae* briefs in this case, including the American Psychiatric Association, the American Psychological Association, and a consortium of psychoanalytic organizations.

In a strongly worded decision with only one dissent, the Court ruled in favor of protecting confidentiality of psychotherapy as an absolute privilege on a par with the attorney–client privilege. (Although general exceptions may exist for an absolute privilege, e.g., breach of confidence to prevent imminent bodily harm, the privilege may not be subjected in individual cases to a balancing test against other compelling needs, such as the full disclosure of evidence.) The rationale for the *Jaffee* decision rested on the fact that effective psychotherapy, an important social good, could not take place without the patient's being able to place complete trust in the confidentiality of communications in treatment. In the Supreme Court's words:

Effective psychotherapy ... depends upon an atmosphere of confidence and trust in which the patient is willing to make a frank and complete disclosure of facts, emotions, memories, and fears. Because of the sensitive nature of the problems for which individuals consult psychotherapists, disclosure of confidential communications made during counseling sessions may cause embarrassment or disgrace. For this reason, the mere possibility of disclosure may impede development of the confidential relationship necessary for successful treatment.

The decision clearly affects psychotherapy regardless of the profession of the psychotherapist, specifically in this case a social worker.

Because the *Jaffee* decision of the Supreme Court applies specifically and only to psychotherapy and establishes an absolute privilege, it can be convincingly argued that the decision protects information revealed in psychotherapy more than ordinary health data or even information about especially sensitive conditions,

such as mental illness, addictions, HIV–AIDS or genetic abnormalities.

V. EXCEPTIONS TO THE PRIVILEGE OF CONFIDENTIALITY

In all exceptions to psychotherapist–patient confidentiality the prevailing concern of the psychotherapist must be to limit disclosure as stringently as possible, consistent with the purpose that necessitates disclosure. At times the psychotherapist may be more vigorous than the patient in defense of confidentiality because of potential damage not only to this patient but also to the trust of other people who contemplate entering psychotherapy.

A. Prevention of Harm to the Patient or Others

The most compelling exceptions to the confidentiality of psychotherapy have to do with preventing physical harm to the patient or other people. For example, a psychotherapist could act to hospitalize a patient to prevent imminent suicide or to treat a psychosis in which the patient could do irreparable damage. In most instances this breach of confidentiality would be considered defensible. Some but not all jurisdictions have specific requirements that health professionals warn potential victims of imminent homicidal behavior, and some require reporting of abuse of children and/or elderly people. Judicial precedent also exists in the landmark *Tarasoff* case in California state courts, in which a “duty to protect” potential victims of violence was stated.

The requirement to report child or elder abuse raises dilemmas for psychotherapists in situations where the long-term achievement of understanding and ending the abuse may be derailed by breach of trust and confidence resulting from mandatory reporting to the authorities. Some therapists warn the patient in advance that legal statutes require them to report abuse revealed to them by the patient. The disadvantage of this approach is that the patient may fail to reveal a central, serious problem so that it can be addressed in psychotherapy. Such warnings would be antithetical to the basic rule of psychoanalysis and render it impossible to establish a treatment process. On the other hand, confronting an ongoing, seriously damaging behavior pattern and invoking external restraint to stop guilt-provoking, out-of-control activities may facilitate treatment by challenging denial, limiting discharge

through action, and bringing the issues under clearer scrutiny in the treatment situation.

Ethical codes also acknowledge the fact that clinical or legal requirements may force a breach of confidentiality. The AMA Principles of Medical Ethics cited earlier qualified its confidentiality statement by adding the phrase “within the constraints of the law.” The APA annotation states that “Psychiatrists at times may find it necessary, in order to protect the patient or the community from imminent danger, to reveal confidential information disclosed by the patient.”

B. Disclosure Authorized by the Patient

Patients frequently sign consent forms permitting blanket disclosure of clinical information to process claims for insurance benefits. Such perfunctory consent forms at the outset of a treatment relationship cannot be considered to be informed consent, because the patient does not know the nature of the information to be disclosed, when or to whom disclosure will take place, and what use of it will be made by the recipient of the information. It is essential that the therapist discuss with the patient the full implications and risks of waiving confidentiality for a specific disclosure. One should document the informed consent with the patient’s signature, the date, a defined recipient, and often details about what may or may not be divulged and a finite time period during which the authorization is valid.

Authorization is also required for disclosure to another health care professional because of transition to another therapist or concurrent treatment by another clinician, such as a patient in psychotherapy by a social worker who is working with a psychiatrist to manage medications. Therapists may obtain supervision or consultation without the patient’s authorization, in which case the supervisor or consultant is fully bound by the constraints of confidentiality.

The rise of managed care, which now covers over 175 million Americans, has raised many issues about confidentiality. Patients and therapists are reluctant to reveal information from psychotherapy to managed care reviewers whose identities and professional qualifications are unknown, and to accept unwanted interference in the therapeutic approach, to obtain approval for payment for therapy. As a result many skilled and experienced psychotherapists refuse to contract with managed care organizations. New government regulations to be discussed later will limit communications

with third-party payers to the minimum necessary to accomplish the essential purpose.

C. Does Limited Disclosure Invalidate Confidentiality?

An important unresolved issue is whether the fact of having made a disclosure for any reason totally invalidates the psychotherapy privilege in subsequent legal proceedings. A New York state court opinion in 2000 took the position that limited disclosure to warn a potential victim of violence did not waive the psychotherapy privilege. Revelation of limited information such as a diagnosis for insurance claim purposes does not invalidate the psychotherapy privilege. To minimize the risk to the privilege it is important to separate a therapist's notations about the specific contents of psychotherapy from administrative information about the broader clinical care of the patient.

D. Disclosure Required Because of Legal Action Initiated by the Patient

When a patient initiates a legal matter in which her medical condition is at issue, she generally waives the privilege of confidentiality of general medical records. The records from all relevant health care providers are likely to be open to the court and to attorneys for both plaintiff and defendant. Common examples are claims for damages for physical or mental harm due to accidents and claims against employers for work-related disability determinations. However, it may still be possible to maintain the privilege of confidentiality of psychotherapy records. Psychotherapists tend to oppose the release of information regarding the contents of psychotherapy, using the arguments associated with *Jaffee v. Redmond*. The resolution of such difficult situations commonly involves review of the records by the presiding judge *in camera* to select for disclosure only information relevant to the case at hand. Strong opposition to exposing the details of psychotherapy is essential to minimize the misuse of records by attorneys for "fishing expeditions" or to harass or embarrass opposing litigants and their relatives or associates.

If the patient initiates malpractice litigation or a complaint to a licensing board against her psychotherapist, the patient's psychotherapy records may be used without authorization in the investigation and adjudication of the matter. Full and fair investigation of an ethics complaint to a professional organization against

a psychotherapist necessitates the patient's authorization of access to psychotherapy records and information. Professional colleagues conduct the investigation within the ambit of confidentiality.

E. Law Enforcement

Criminal investigators sometimes seek access to mental health care records to identify potential suspects. Therapists are ethically obligated to resist such unauthorized intrusions into patients' psychotherapy notes by every available legal means. Investigations of health care professionals for possible insurance fraud and abuse or violations of state professional codes may also bring law enforcement officers to a therapist's office demanding to see records. Although legal or ethical violations by a therapist cannot be condoned, establishing due legal process and procedural safeguards to protect patients' private information is an indispensable obligation of all parties to such an investigation.

F. Research

Participation in research studies requires the patient's full and informed, written consent. If the patient is not available to give consent for retrospective studies, the optimal condition is that only information completely devoid of all identifying information may be used, with suitable safeguards to prevent the cross-linking of deidentified data with other identifying databases. Psychotherapy advocates take the position that the preservation of the full confidentiality of psychotherapy must take precedence over potential benefits of research investigation. Institutional review boards commonly scrutinize proposed research for protection of confidentiality but may not be fully cognizant of the special requirements for confidentiality in psychotherapy.

VI. CASE ILLUSTRATIONS

A. Mr. A.

A man in his late 40s in his seventh psychotherapy session, Mr. A. paused and then asked his psychiatrist if everything he said was truly confidential. The psychiatrist replied that within the limits of the law, and with the exception of any emergency involving threat to life and limb, confidentiality would be maintained. The psychiatrist added that she would actively use all legal means to resist any efforts to intrude in any case. Mr. A. then haltingly revealed, with great shame, that

he had disturbing sexual thoughts about his teenaged daughter. They went on to work with the origins of these thoughts in his own early sexual experiences in family life. Both the intensity of the thoughts and the shame about them diminished, and the patient felt comfortable that he could control any such impulses in the future.

If the therapist had responded to this revelation as potential abuse and reported it to the authorities, the patient and his family would have been harmed, and he would not have had the opportunity to master the conflict within himself. The case also highlights the fact that psychotherapy may open doors to discussion of fantasies, dreams, and impulses on which the patient would be highly unlikely to act. An important tenet of psychotherapy, not always understood in everyday life, is that thought is not the same as action. In mental life people may have extreme thoughts and feelings or consider seriously problematic behaviors before deciding on a more reasonable course of action.

B. Mr. B.

A managing partner of a major law firm, Mr. B., brought to psychotherapy complicated, sensitive difficulties involving a number of prominent people in business and politics in his community. He was in the initial stages of his own candidacy for the state legislature. For him to work effectively in psychotherapy to understand his feelings and judiciously manage his delicate role in the situation, he had to be absolutely sure that all information regarding situations, himself, and other persons would remain totally confidential.

C. Mrs. C.

Mrs. C. was involved in an extramarital affair that was not going well. She wanted to preserve and rehabilitate her marriage, but divorce was a possibility. She felt she could only work out her conflicting issues if the affair would remain a secret that would be divulged only by her if at all, after due consideration and not by intrusion into her therapy records.

D. Joe D.

Joe D. is a 19-year-old boy devastated by the loss of his girlfriend to another man. In psychotherapy he ventilated his rage and expressed the wish to use his old truck to push the other man's car off a cliff. By verbalizing fury in this way, he gradually settled down and

avoided impulsive, dangerous action. The case illustrates the fact that patients sometimes reveal drastic impulses on which it would be very uncharacteristic for them to act, and that expressing them both relieves pressure and provides opportunities to reinforce self-control. In a psychotherapy record in court such statements could be misinterpreted without consideration of the treatment context in which the therapist evaluated them and concluded that they presented no significant risk of harmful action.

E. Officer Mary Lu Redmond

Mary Lu Redmond, the policewoman defendant in the U.S. Supreme Court case, *Jaffee v. Redmond*, would have been unable to enter psychotherapy to deal with her distress about having killed a man in the course of duty, had she known that what she said could be used in a civil action against her. The U.S. Supreme Court stated that neither the public interest nor equity would be served by denying police officers access to psychotherapeutic care that was available to the rest of the community.

VII. ELECTRONIC COMMUNICATIONS AND CONFIDENTIALITY

Health care records have traditionally been maintained on paper. Electronic communications by fax, e-mail or the Internet now present a much broader risk of instant disclosure to unauthorized entities. Medical records maintained in a computer database may be useful in coordinating care by many different health care providers, but they can potentially be used by insurance companies to deny health, disability, life, or even auto insurance. Insurance carriers maintain a central medical information bureau that underwriters can access. This facilitates discrimination against people with mental illness. Health insurance claims to self-insured employers have sometimes been used to make employment decisions. With growing consolidation of the banking, investment, and insurance industries, records of payments by check to psychotherapists could be revealed to an insurance carrier that is part of the financial organization and be used to deny insurance coverage. Recent revelations regarding FBI access to e-mail communications, without the knowledge of individuals using an Internet service provider, raise serious questions about the use of e-mail for communications with a physician or for long-distance psychotherapy. Studies of methods to deidentify

health care information have demonstrated that the possibilities for cross-linking with widely available databases make it perhaps impossible to remove potentially identifying data without totally corrupting the data and making it unreliable. Privacy advocates in the psychotherapy community caution against the use of electronic means for storing or communicating information regarding psychotherapy without very high standards of protection through encryption, audit trails, and thoroughly erasing records that are no longer active.

VIII. LEGISLATIVE AND REGULATORY DEVELOPMENTS AFFECTING CONFIDENTIALITY

These issues have prompted efforts to establish privacy regulations for electronic communications and databases, both in health care and in the business world. Privacy advocates are staunchly opposed by powerful forces in the insurance industry, financial institutions, public health agencies, medical and demographic research, and electronic communications industries. In 1996 the U.S. Congress appointed the National Committee on Vital and Health Statistics, representing the broad spectrum of interested parties, to investigate the problem and recommend solutions. The committee's report thoroughly discussed the issues and proposed actions that remain controversial. The Congress also set a deadline of 1999 for itself to develop health care privacy legislation, and if it failed to do so, tasked the Department of Health and Human Services (HHS) to develop privacy regulations in the Health Insurance Portability and Accountability Act (HIPAA). Many bills failed to reach enactment in Congress, and in August, 1999, HHS proposed a set of regulations for health care information transmitted by electronic communications. The proposed regulations also devoted attention to preventing unauthorized secondary disclosure to other entities by entities that had received authorized data. After analyzing a record-setting 52,000 comments on the draft regulations, HHS in the Clinton administration promulgated the final HIPAA regulations in December, 2000, to take effect in April, 2003.

The final regulations extend to all medical records, electronic or otherwise, and set national standards without invalidating stricter state statutes. In contrast to the draft regulations, they retain the customary requirement of initial patient consent for the release of medical information for treatment operations and claims processing purposes. They also establish a higher level of authorization required for disclosure of

specific information for certain purposes. Patients will be allowed to inspect their general medical record and require corrections or insert comments if they take issue with the information it contains. Employers may not have access to health care records without patient authorization. The lengthy and complex regulations are undergoing extensive analysis by all stakeholders at the time of this writing, so that any interpretations are provisional. Companion regulations of security procedures, such as encryption and audit trails, essential to the successful application of the privacy regulations, remain to be promulgated. Although already published in the Federal Register, the privacy regulations may be subject to modification by Congress or the Bush administration.

Citing *Jaffee v. Redmond*, the HIPAA regulations propose a high level of specific protection for psychotherapy notes. Psychotherapy notes—the psychotherapy part of the identifiable medical record—are singled out from medical records in general for protection from unauthorized disclosure. The regulations apply to individual, group, marital, and family therapy. Authorization for disclosure must not be a required precondition for treatment or insurance eligibility, enrollment, or payment for treatment. However, psychotherapy records may be disclosed without patient authorization for health care oversight (e.g., investigation for fraud or violation of professional licensing codes) or defense of litigation against the therapist. There is also an exception “when needed to avert a serious and imminent threat to health and safety.” Notes may be disclosed to coroners or medical examiners to determine the cause of death. “Consent” is required to use notes to “carry out treatment” or for supervision in training. Many other details and ramifications remain unclear.

IX. SUMMARY

Confidentiality is essential to the work of psychotherapy. It is protected both by professional ethical standards and state law. The U.S. Supreme Court decision in *Jaffee v. Redmond* in 1996 established an absolute privilege protecting information from psychotherapy from use as evidence in federal courts. This decision has been influential in the state courts as well as in comprehensive HIPAA privacy regulations that will take effect in 2003. Numerous threats to the privacy of psychotherapy information nonetheless exist in a rapidly expanding environment of information gathering and exchange. They must be addressed by the individual practitioner,

professional organizations, and the public at large through vigorous advocacy efforts.

GLOSSARY

configuration An association of meanings whereby each set of meanings is given a position relative to the other sets.

motives A term that refers to the intrapsychic reasons for explaining why a mental process occurs. A given subsystem of mental processes may contain intrinsic properties that function as motives when that subsystem is activated. There may be motives to do or not to do an act or to perform or not perform a mental function.

person schemas High-order, well-organized views of self and others. Person schemas are psychological meanings that reflect identity, relationships, and potential social activities.

psychodynamic configuration A constellation of motives and person schemas that organize information processing, intentions, and expectations. These configurations include beliefs, wishes, fears, and defensive strategies. A conflictual configuration often involves a *wish*, a *threat* of a dreaded state, and a *defensive posture*. The defense is a way of compromising the wish to avoid its feared consequences.

role-relationship models Inner schemas and scripts that function as cognitive maps for interpersonal emotions and transactions. They can be activated unconsciously as well as consciously. Roles for self in such models contribute to a sense of identity, and the roles of self and other can define a sense of affiliation and attachment.

schemas Usually, unconscious cognitive maps that can serve as organizers in the formation of thought. Schemas influence how motives reach conscious awareness as well as how external stimuli are interpreted. Schemas tend to endure and to change slowly with integration of new information. Small-order schemas can be nested into hierarchies such as configurations of role-relationship models for a particular attachment.

I. DESCRIPTION OF TREATMENT

Configurational analysis is a method of psychological formulation that focuses on cognitive-emotional conflicts and the dynamics of identity and relationship roles. It combines concepts derived from psychodynamic, interpersonal, cognitive-behavioral, and family systems theories. It also integrates ego-psychology, object relations, and self-psychology methods of formulation. Configurational analysis is a simplified, practical, and teachable system based on agreements reached in clinical research.

Configurational analysis is a system that can be used for initial case formulation, case reformulation during treatment, and analysis of what changed after treatment. The steps most repeated in all three operations involve state analysis, control of emotional topics analysis, and person schematic analysis, which clarifies the deeper organization of emotional and conflicted themes by varied views of and beliefs about self and others. These steps can explain recurrent and maladaptive

interpersonal patterns as well as some psychiatric symptoms and syndromes.

The system is an integrated one that combines concepts from various schools of thought. It uses definitions that were developed in a clinical research effort and that combine concepts from psychodynamics (with its varied schools), social systems theory (with its attention to roles and social schemas), and cognitive science (with its connection to neurobiological systems).

By repeating the steps of configurational analysis successively from the perspectives of initial formulation, formulation of therapy process, and formulation of therapy outcome, clinicians can increase specifications of what changed and how that change came about. The result empowers clinicians as their own researchers and can improve their clinical effectiveness, their ability as teachers, and their sense of personal growth.

Configurational analysis begins with an emphasis on what can be observed and reported. The objective phenomena then to be explained may be symptoms or patterns of maladaptive interpersonal behavior. Next, the states of mind in which these phenomena occur are described, including those states with variants. This method of formulation includes paying attention to defensive controls of emotional and relationship expressions. At the level of states, this means attention to degrees of regulation of action and feeling as in undermodulated states (impulsive behavior, intrusive ideas, and floods of emotion), well-modulated states (deliberate expression of emotional intensity), and overmodulated states (rigidity, pretense, or stifling of unwanted experiences).

These states of mind can be examined in terms of wishes, fears, and defenses against expressions in thought and action. That is, a person may desire certain states, dread others, and enter a particular state (such as aloof indifference) as a defensive compromise. An initial *configuration* emerges from such an analysis. This configuration is the relative association of desired, dreaded, and compromise states that occur in a recurrent maladaptive cycle.

This cycle of states may then be further examined for important topics of concern and the defensive control processes that are used to control intense and alarming levels of emotion. In this third of the four steps of configurational analysis (phenomena, states, topics-and-controls, self-other views), the reasons for the repeated maladaptive cycle are partly clarified. This effort at lucidity is continued in the fourth step, which infers self and other views that organize different states of mind. This leads to a configuration of *role-relationship models* and the states in which they

do or do not occur. In this approach to formulation, one then integrates the inferences and plans a treatment strategy. These steps of configurational analysis are summarized in Table 1.

The four principal steps of configurational analysis function as a formulation of the initial or current condition of a patient to be treated by psychotherapy. The following paragraphs provide condensed instructions for clinicians who use this method.

Step 1. Phenomena to Be Explained

List symptoms, signs, problems, or specific sets of maladaptive traits. Separate the initial complaints made

TABLE 1
Steps of Configurational Analysis

(Each step can also include social and biological levels as well as past developmental contributors to the current situation.)

1. PROBLEMS
Select and describe the symptoms, life problems, and/or maladaptive character traits that need to be explained.
 2. STATES OF MIND
Describe states in which the selected phenomena do and do not occur as well as recurrent maladaptive cycles of states. Organize these when possible into configurations of desired states, dreaded states, and compromise states.
 3. TOPICS OF CONCERN
AND DEFENSIVE CONTROL PROCESSES
Describe topics of concern during problematic states. Describe how expressions of ideas and emotions are obscured. Infer how avoidant states may function to ward off dreaded, undermodulated states. Describe differences in emotional styles in desired, dreaded, and compromise states. Describe how control shifts lead to a shift in state.
 4. IDENTITY AND RELATIONSHIPS
Describe organizing roles, beliefs, and scripts of expression in each state. Describe wish-fear dilemmas in relation to desired and dreaded role-relationship models. Infer how defensive control processes and compromise role-relationship models ward off dangers. Identify dysfunctional attitudes and how these are involved in maladaptive state cycles.
 5. INTEGRATION
Consider the interactions of problems, states, controls, and role-relationship modes. Plan how to stabilize working states by support, how to counteract defensive avoidances by direction of attention, and how to alter dysfunctional attitudes by interpretation, trials of new behavior, and repetitions.
-

Source: Horowitz (1997).

by the patient from those reported subsequently. List difficulties the observer recognizes but the patient does not complain of directly. Include both intrusions and omissions from rational consciousness and behavior. Intrusions are episodes of consciousness or action that are unwanted, unbidden, or hard to dispel, such as an impending sense of doom, an unwelcome repetition in memory, images of a traumatic event, or a temper outburst. Omissions include the absence of desired and adaptive experiences or actions, such as inability to become sexually aroused, inability to recollect a loved one, and failure to confront the implications of important situations. Indicate how these symptoms and signs occur in current life outside the session, how they developed in the past, and if and when they were observed directly in the clinical setting.

Step 2. States of Mind

List recurrent states and define them by patterns and discords of verbal and nonverbal behavior, as well as by reports of subjective experiences. Indicate common shifts between states and triggers for entry into undermodulated states. Begin with states that contain the major distressing phenomena described in Step 1. These are often undermodulated states. Next list states that seem more controlled and complete the list with overcontrolled states of mind. The term shimmering state can be used to define states in which mixed and contradictory signs occur (e.g., tearing and stifling sadness). Discuss which states are desired, which are dreaded, and which are defensive compromises that reduce pleasure but prevent the risk of unpleasurable states.

Step 3. Topics of Concern and Defensive Control Processes

Describe unresolved and conflictual topics. These are often the themes associated with repetitive intrusions into and omissions from adaptive trains of thought. Model these themes as constellations of ideas, emotions, and cognitive maneuvers to control emotion such as inhibition of ideas, shifts in topic, and distortions of appraisals.

State why it has been hard for the person to reach a point of resolution, decision, or acceptance on a problematic topic. Relate constellations of memory and fantasy to recent life events, psychosomatic reactions, and social situations. State the degree to which objective reality accords with the subject's subjective beliefs. Identify dysfunctional beliefs. Indicate the subject's stress-induced versus habitual use of defensive operations. Relate different defenses, resistances, or obstacles to the different states of mind noted in Step 2.

Step 4. Identity and Relationships

Extend inferences about dysfunctional beliefs to cover erroneous views of self and others. Develop a role-relationship model for each important state of mind in the state cycle. From these, infer configurations of desired, dreaded, problematic compromise, and quasi-adaptive compromise role-relationship models. When there is sufficient information, reconstruct the development of the dysfunctional beliefs contained in these person schemas. Describe the degree of integration and harmonization of schemas or the lack thereof, as in extreme, irrational, contradictory, or dissociated views of self or others.

Configurations of desired, dreaded, and defensive compromise role-relationship models are the deepest level of inference in this method of formulation. They explain recurrent states. Compromise role-relationship models organize states that avoid the feared consequences embedded in wish-fear dilemmas. These compromise role-relationship models avoid the dilemma of linked desired and dreaded intentions and expectations. Defensive controls can activate such compromise role relationships.

Formulating the patient's defensive styles (Step 3) before formulating their role-relationship models (Step 4) helps the clinician find person schematic beliefs in two ways. First, when heightened defenses are observed, the topics that come up provide a focus for discovering unexpressed beliefs that are conflictual, unresolved, antithetical, or contradictory. Second, by asking how and why increased defensiveness has occurred at this moment, the therapist and patient can learn to counteract otherwise automatic avoidances and distortions. As a result, the patient will be able to express usually warded off ideas and feelings.

For example, consider a patient in psychotherapy for the maladaptive effects on his life from his Narcissistic Personality Disorder. He defensively used externalization of blame by sliding meanings to exaggerate the faults of others and to minimize his own role in disputes. He did this to prevent entry into a dreaded sense of identity inferiority and shame.

Analysis of episodes of blaming others excessively clarified his surface role as a superior righteous person and as a critic who said whether self or other was at fault or was inferior or superior. It also clarified his deeper role as an inferior shamed person.

During psychotherapy, the importance of the critic role in the patient's preconscious thinking was emphasized, and this then heightened his level of self-observation. He was later able to use such heightened self-observation to examine his vulnerability to shame, modify his irrational expectations of devastation from

shame, and so curb his automatic tendency to expressively blame others. This in turn modified his maladaptive interpersonal pattern.

This patient desired to experience a state organized by self as good and strong and others as approving, leading to pride. But he dreaded an opposite state of devastated shame organized by a dreaded role as bad and inferior. In a compromise self-righteous rage state, this patient had a role-relationship model in which he was strong and good, facing a bad adversary, with the sense of a critic allied with himself. He was the admired, heroic avenger doing virtuous battle. When a transition into a problematic mixed state of shame, rage, and anxiety occurred, he shifted to a role-relationship model in which his harm to others was excessive, the adversary was wronged, and he sensed a critic allied with his opponent. Expectations of accusation from the critic role led to a role-relationship model of an inferior and bad self being degraded by a strong and good other, leading into his state of devastated shame.

His mixed state of shame, rage, and anxiety occurred before, sometimes instead of devastated shame. In the mixed state he was anxious as to who was to blame, ashamed at his part, but also angry at the bond established between the sensed critic and his opponent. Clarification required conscious examination of beliefs in each of these recurrent states. Then the source of his vulnerability to share and his defensive externalization of all blame by irrational projections were examined. For example, shifts in blaming characterized his family. Each person in the mother–father–son triad was alternately admired and blamed for problems by the other two. He was periodically allied in distortions and abandoned by extrusions.

II. RESEARCH ISSUES

Following the publication of *States of Mind: Configurational Analysis of Individual Personality*, the method was systematized in empirical research. These investigations evolved definitions of states of mind, defensive control processes, and person schemas that could be agreed upon with the reliability of independent judges. With reliable measures of these constructs, validity was evaluated by seeing how well patterns cohered and associated with other variables. The key elements in configurational analysis—states of mind, defensive control processes, and person schemas—that were found to have reliability and predictive validity were then put together into an updated system presented in *Formulation As a Basis for Planning Psychotherapy Treatment*.

III. USE OF CONFIGURATIONAL ANALYSIS

The psychiatric diagnosis system is based on categories of description rather than categories of etiology. For that reason, it is hard to relate diagnosis to rational psychotherapy plans. An intervening case formulation is needed. Configurational analysis provides a system for such formulations. The steps are few, and the clinician can keep them in mind.

As has already been discussed, the steps start at the surface of observation: signs and symptoms. The next step organizes these and other phenomena into states of mind, maladaptive but recurrent cycles of state shifts, and it stipulates the emotional topics that lead to such shifts. When emotional conflicts are partially identified, it is possible to infer deeper levels of state organization in terms of models (person schematizations), configurations of desired, dreaded, and defensive self-concepts, and role relationships. In each role-relationship model, characteristics, traits, emotions, values, intentions, and expectations of self in relation to an important other are considered. Such configurations help us to understand how people may have multiple and contradictory views.

Aspects of formulation using the configurational analysis method can be discussed with a patient. State analysis is especially close to experience and can enhance self-observation. Change can occur during the process of enhanced awareness, new decisions, and trials of new expressive behaviors in psychotherapy.

In addition to initial case formulation, change can be described using configurational analysis: What phenomena are new and what phenomena have gone? What states of mind have been modified? What new and less defensive modes of awareness and expression have altered a habitual style? What new insights and plans counteract irrational beliefs? Such analyses can answer the question, “what can change” in psychotherapy.

IV. DEFINING WHAT CHANGES IN PSYCHOTHERAPY

The steps of configurational analysis, once learned as a systematic approach to early case formulation, can be applied to the study of process and outcome of therapy. A pathway is indicated as a sequence of 10 steps outlined in this entry. These steps can answer the question, “What changes in psychotherapy, and how does it come about?” The steps repeat the steps of configurational analysis from three perspectives: initial evaluation, therapy process, and treatment outcome.

A. Formulating the Initial Condition

The initial condition is formulated using the four steps already described. The following steps (5–10) are repetitions of steps 1–4 as related to analyzing the therapeutic process and formulating treatment outcomes.

B. Analysis of Therapeutic Process

Step 5. Problems and States of Mind

Review symptom changes that occurred during treatment. Focus on entry into and exit from the states listed in Step 2 as they (a) occur in therapy or are reported for (b) current outside-of-session relationships, and (c) past relationships. Describe the states of the therapist and the therapist and patient as a pair or group. Describe the effect of therapist interventions on states. Include the effects of medication and social situational changes.

Step 6. Topics of Concern and Defensive Control Processes

Describe the effects of the therapist's interventions on key themes and defenses.

Step 7. Identity and Relationships

Discuss the effects of transference, countertransference, therapeutic alliance, separations, and new attachments. Indicate the dilemmas of the therapist. Describe new relationship experiences and reschematization of identity and role-relationship models.

C. Formulation of Treatment Outcome

Step 8. Problems and States of Mind

Describe outcome in terms of changes from pre- to post-therapy (or termination) periods. Include discussion of the effects of external changes, including shifts in family, social, and environmental contexts. Discuss new states and modifications of state cycles.

Step 9. Topics of Concern and Defensive Control Processes

Describe outcome in terms of changes in the topics of concern. Indicate resolutions of conflicts as well as residual problematic themes and continued dysfunctional avoidances or distortions.

Step 10. Identity and Relationships

Describe changes (or persistence) in maladaptive interpersonal behavioral patterns. Infer the changes and developments in person schemas. Include modifications in enduring attitudes, value hierarchies, and personal agendas.

By repeating the steps of configurational analysis successively from the perspectives of initial formulation, formulation of therapy process, and formulation of therapy outcome, clinicians can increase specifications of what changed and how that change came about. The result empowers clinicians as their own researchers and can improve their clinical effectiveness, their ability as teachers, and their sense of personal growth.

GLOSSARY

clarification Technique for gaining clearer understanding of the meaning of a patient's conscious (manifest) behavior and experience.

confrontation Technique of directing a patient's attention to inner experiences or perceptions of outer reality of which he or she is conscious or is about to be made conscious.

countertransference The therapist's unconscious feelings and attitudes toward the patient reflecting his or her earlier experiences with important others.

interpretation Verbalized understanding of meaning, conscious or unconscious, of patient behavior or experience.

introjection Form of internalization that acts as part of self-structure (i.e., self-as-object) and is reflected either consciously or unconsciously in self-representations. They form the basis for projections and are invested in varying degrees with infantile motivations. Aggressive patterns are expressed as either aggressive (hostile, sadistic) or victim (vulnerable, masochistic) introjects, narcissistic patterns as either superior (grandiose) or inferior (devalued) introjects.

I. MEANING OF CONFRONTATION

To begin, we should be clear about exactly what we mean by "confrontation," namely a technique designed to draw the patient's attention to certain inner experiences or perceptions of outer reality. Confrontation comes into play typically in an effort to overcome the patient's resistance to acknowledging or recognizing a particular content or connection, and is not meant to force any change in the patient's conduct, attitudes, or decisions. It is therefore intended to change the patient's thinking and not his or her behavior. The distinction from clarification, another useful form of intervention, is often difficult, since they are frequently used in conjunction. Although clarification has the function of making clear or of bringing about recognition, it does so in a more neutral and dispassionate fashion; confrontation adds the note of activity on the part of the therapist, emphasis, even forcefulness. The confrontative element is often carried in subtle ways by the therapist's tone of voice, unusual use of language,

humor, the element of surprise, affective tone, and so on. The therapist can even convey his or her emphasis by way of facial expressions: raising an eyebrow, assuming a quizzical or doubtful look, shaking the head, and so on. Even a shrug can convey to a patient a sufficient connotation to make an effective confrontation. Confrontations are not always or necessarily forceful; they may be subtle, gentle, and inviting as well.

II. CONFRONTATION VERSUS INTERPRETATION

It is customary to distinguish confrontation from interpretation. From one point of view, interpretation involves sharing a hypothesis with the patient along with an invitation to engage in its exploration and understanding; confrontation, however, involves presenting a more unilateral view of what the therapist regards as reality. Confrontation can be regarded as a starting point for bringing to light new problems, associations, or understandings, which become the object for further exploration, whereas interpretation implies more of a closure or resolving of some connection or understanding that had been hitherto obscure or in doubt. Thus, interpretation has the purpose of resolving internal conflicts by bringing unconscious elements to the surface and drawing them within the patient's awareness, whereas confrontation is designed to create conflict where there had previously been none.

Confrontation, as a therapeutic technique, seems to imply that the therapist knows or sees something that the patient does not. Recent debates among analysts have centered around the question of whether and to what degree the analyst can have any privileged knowledge of or access to reality or any better or deeper understanding of motives and their implications than the patient. Some have argued that the therapist can have no special knowledge, or can have no better knowledge of the real than the patient, especially when it comes to knowing or understanding what is going on in the patient's mind. The argument has a certain validity, but would only have convincing effect if it were applied to a caricature of confrontation. When the therapist confronts the patient, his or her assertion does not imply that the therapist is right and the patient is wrong, but the confrontation offers the patient another perspective or directs the patient's attention to something he or she is ignoring or overlooking and thereby opens the way to an alternate consideration and a rethinking or reconsideration of his or her position. One of the benefits of ther-

apy is that the patient's problems are engaged by two heads rather than one.

Even more subtle differences may come into play. There is a difference between accusing the patient of wasting time and observing that the patient is still reacting as if the work with the therapist were doomed to be unproductive. The former renders a judgment and an accusation, and has more the flavor of a confrontation, whereas the latter offers more of a translation. The latter statement is more in the order of a clarification or even an interpretation. The difference has to do with the presence of the therapist in the intervention. The patient's assent to the first intervention necessarily involves accepting both the fact and the confrontative, even authoritative, role of the therapist. Assent to the latter requires only acceptance of the fact, whereas the therapist's role is more in the line of suggesting or clarifying. In a sense, then, confrontation involves a certain forcing of the therapist on the patient, or even an intrusiveness of the therapist, however gentle, calling for or creating a pressure toward internalization of the therapist by the patient. The interaction is not simply the product of the patient's projective imagination, but involves real activity on the part of the therapist, in one or other degree amalgamated with transference elements, but setting the stage for a defensively toned introjection rather than a more selective and secondary process identification.

III. CLINICAL APPLICATION

Confrontation as a therapeutic technique has a more prominent position in the treatment of more primitive or highly resistant patients. Along with clarification, it is the primary channel for dealing with manifest content in the patient's ongoing behavior. Confrontation is a part of the therapy in some degree with all patients, but particularly in regressed patients or in regressive crises with some borderline patients, confrontation is often essential.

Confrontation carries with it the connotations of activity, energy, forcefulness, challenge, and the overcoming of opposition, all of which reflect in some degree the aggressive derivation of confrontation in overcoming an obstacle to therapeutic progress and its degree of deviation from what many would regard as more neutral therapeutic techniques. In the ordinary run of therapy, confrontation is usually employed as a means of overcoming resistances, promoting further therapeutic progress, and as leading to interpretation of the patient's defenses and their underlying motivations. In

the treatment of character disorders, the confrontations with the patient's patterns of characterologic behavior are frequently a necessary step in arriving at the underlying conflicts and their unconscious motivation.

Confrontations are not always benign or merely conflictual, but may also turn out to be dramatic or heroic. We can regard a confrontation as heroic when it becomes an emotionally charged, parametric, manipulative, technical tool demanded by development of an actual or potential situation of impasse and utilized to remobilize a workable therapeutic alliance. An example might include telling a patient that it was no wonder that no one liked him if he behaved in such an unpleasant manner whenever anyone tried to help him. Another example might be confrontation of a somewhat paranoid patient, in which the therapist tells the patient that his premises were wrong and that, if he so wished, he could become paranoid, but another possibility was that he could also accept the therapist's effort to be helpful and that they could choose either to work together or not, but if the patient chose to continue with his paranoid attitudes, he would run the risk of further sickness and hospitalization. Similarly, a therapist may decide to confront a patient enmeshed in a prolonged resistance and therapeutic misalliance that the therapist found necessary to interrupt by telling the patient that he was getting nowhere in the treatment and that he ought to consider some other alternatives besides continuing therapy with him. Only the threat of the loss of the transference object was able to shake the patient's resistance to development of the transference neurosis and lead to further analytic progress. Such confrontations have as their purpose the reconstitution of a disrupted or distorted therapeutic alliance.

Heroic confrontations are called for when the therapy has reached an impasse, when the therapeutic alliance has been or is in danger or disruption, or has reached a point of chronic distortion so that the therapeutic misalliance has frustrated and subverted the work of the therapy. The success of such heroic confrontations depends in large manner on the capacity of both patient and therapist to regain the ground of some workable therapeutic alliance without which therapy is doomed to disruption, stalemate, and failure. An additional note is that confrontation is usually oriented toward reestablishing the patient's sense of the therapeutic role of the therapist and the therapeutic situation, or of some other external reality in the patient's life situation.

Many patients have a remarkable capacity to see the world on their own terms, taking their own psychic reality as the reality. This propensity is particularly marked

in borderline patients, who experience the therapist more or less exclusively in transference terms resulting in various forms of therapeutic misalliances. The work of tactful clarification and confrontation with the actuality of the therapeutic situation is often a central and persistent aspect of the therapeutic work with borderline patients, although it is by no means rare in other forms of personality disorder. In general, these patients do not have a stable sense of self based on introjections and identifications derived from experiences with real, responsive, caring, and responsible people in their developmental past. For these patients, actual characteristics of the therapist, whether mediated through the alliance or as aspects of their real personality, may be critical elements in the restructuring of the internal objects necessary for adequate ego functioning. Confrontation of these characteristics in the therapist-patient interaction may be a major aspect of the treatment process.

In therapy with such patients, the use of confrontation implies a shift to a more active, involved, and real interaction with the patient. It also implies a shift to a more supportive orientation, even within the context of a longer-term uncovering and exploratory effort. Particularly in the context of a regressive crisis or of a more chronic regressive stance, when the patient's capacity for therapeutic alliance is tenuous, or when the alliance is disrupted or severely distorted and failures of reality testing become apparent, confrontation may be essential to preserve and continue the therapeutic work.

IV. COUNTERTRANSFERENCE AND CONFRONTATION

Confrontation also involves inherent risks of becoming a vehicle for expression of countertransference. Therapeutic confrontation must not become a vehicle of irritation, frustration, or sadism, but must be offered from a therapeutic perspective and with the therapeutic intention of benefit to the patient as an objective. Confrontation is never far from slipping over into a more controlling, determining, advising, or authoritative, even authoritarian, stance, which easily yields to the influence of countertransference reactions and transference-countertransference interactions. As a cautionary note, therefore, it is important to keep in mind that confrontation always serves a subsidiary function to the overriding focus on exploring, uncovering, and understanding the patient's dynamics and underlying motivations.

It is generally agreed that therapists must exercise caution in the expression of their own feelings, since they

can readily become the vehicle for countertransference influences and will inevitably have a powerful effect on the patient. Any expression of feelings must be carefully monitored, expressed only in terms that are beneficial to the patient, and with thoughtful consideration of the countertransference implications. As some analysts have argued, countertransference enactments are unavoidable, so that when they occur the therapist should try to put them to good use in the therapeutic work. But I would suggest that such enactments cannot be effectively processed to the benefit of the therapy except within the context of the alliance—there is no basis within a transference-countertransference interaction for such a therapeutic perspective. Only when it can be experienced and understood from the perspective of the alliance can such an enactment be turned to therapeutic advantage. Confrontation is therefore primarily a device for directing the patient's attention in a more effective manner to some aspect of his or her mental content or behaviors or to aspects of the patient's interpersonal or environmental involvements, especially those occurring in the therapy in relation to the therapist, that otherwise would remain hidden or repressed. Confrontation is useful insofar as it leads toward interpretation or makes the material for interpretation more available. Confrontation can be regarded, therefore, as a routine part of psychoanalytical or psychotherapeutic technique and as necessary for the analysis of resistance.

V. REGRESSION

Although at points of regressive crisis confrontation may be essential, it is also at such points in the therapeutic course that patients are most vulnerable to the misuse of confrontation and the contamination by countertransference. In the treatment of more primitive personality disorder patients, I would emphasize the tenuousness of the therapeutic alliance and the need to utilize confrontation with caution with an eye to building the patient's trust in the therapist's good judgment and constructive intentions. Observing certain restrictions can help to achieve this objective:

1. Assess the reality and related stress in the patient's current life situation. In situations of external stress, particularly when they provoke a regressive reaction in the patient, it does not help to increase the level of stress within the therapy. The therapist's empathy and thoughtful evaluation guides the advisability of confrontation and the need for support at any given point.

2. Avoid breaking down needed defenses: Here again the titration of activity versus passivity, support versus

challenge, call for a balancing act that is at times delicate. In regressive states, patients may need to maintain even primitive levels of defense and it becomes therapeutically inadvisable to confront such defenses when there is danger of precipitating a more severe regression. However, there are also times when confrontation is required to pull a patient out of his or her regressive slump, reconstitute the therapeutic alliance, and get the therapy back on course.

3. Avoid overstimulating the patient's wish for closeness. Greater levels of activity and attempts to be supportive can have a secondary effect of creating a closer and more personal contact between therapist and patient, or, in other words, drawing the patient into a more real relation with the therapist and correspondingly diminishing the effectiveness of the alliance. This can be both overstimulating and seductive, and, while it runs the risk of precipitating further defensive retreat or regression, can also have the long-term effect of creating expectations that will make the continued effectiveness of the therapeutic effort down the line more precarious. The patient may have to take flight in defensive panic or rage or act out from the intensity of the feelings that may be precipitated. This can plunge the patient into intense fears of abandonment, loneliness, and fear of his or her own self-destructive impulses and destructiveness.

4. Avoid overstimulating the patient's rage. Confrontation, particularly when it is connected with limit-setting, often has the effect of reestablishing the boundaries between patient and therapist and cause the patient to feel deprived and frustrated. The rage brings with it fears of abandonment and annihilation, which only increase the regressive risks.

5. Avoid confrontation of narcissistic entitlement. We can distinguish between narcissistic entitlement and the more profound and regressive entitlement to survive. Confrontation of the patient's entitlement may have the intention of calling attention to the patient's narcissistic entitlement, but it can easily miss the mark and only threaten the patient on the level of his or her entitlement to survive. Certainly, the periods of regression are hardly the time to challenge any patient's narcissism at whatever level. Narcissism is better dealt with only at points at which the therapeutic alliance is more stable and positive, and then preferably through gradual and progressive techniques of clarification and interpretation. Confrontations of the patient's narcissism are at best risky, even under optimal conditions. There is always risk in such confrontations of precipitating a regressive crisis.

Confrontation may also be called for when some dangerous or self-defeating consequence is involved in

the regressive episode. One young man, who presented with a variety of hysterical and phobic anxieties, began his analysis with a fair amount of precipitant anxiety. Within a short order, he was seized with panic and a terror-stricken fear that the analyst would attack him from behind and stab him in the chest. This created an immediate threat that the analysis would be prematurely and disruptively terminated by this paranoid terror. Without having any idea of what was involved in the patient's panic, the analyst took a relatively strong confrontative position and pointed out that the patient was experiencing terror for reasons that neither he nor the patient were at that point aware, but that, if the patient allowed his fears to dominate, that they were in danger of disrupting the analysis. He insisted that the patient be able to control his fear so that it did not result in self-defeating acting out and that he and the patient try to work together to understand what was happening. The patient quieted down at least to the degree that he was able to remain on the analytic couch, and the ensuing exploration revealed the multiple layers of implication that determined the patient's panic.

The risks of regression are obviously more at issue in patients in the lower-order borderline spectrum, and are correspondingly less of a problem in higher-order patients, and even less so in narcissistic and neurotic levels. In higher-order patients the same issues are alive, but the patient's capacity to enter and maintain an effective therapeutic alliance serves as a buffer both to the underlying regressive potential and the patient's vulnerability to countertransference influences. Nonetheless, the rules of thumb for utilizing confrontation are relevant even for these patients, and are reflective of general norms of tact and consideration in dealing with any patients.

VI. CONFRONTATION AND THE THERAPEUTIC ALLIANCE

An important issue in considering the therapeutic role of confrontation is the relationship between confrontation and the therapeutic alliance. Confrontation can be brought into play in the service of building a therapeutic alliance, but also of salvaging a disrupted alliance or more persistent misalliance. When the therapeutic alliance is intact and operating meaningfully, confrontation usually has little if any place. When the alliance is failing or has been disrupted, however, confrontation may become essential. The alliance includes a degree of meaningful empathic attunement, which guides the therapist's decision whether to confront or not, and also sets the stage for the patient's receptivity and responsiveness to the con-

fronting initiative. In a sense, then, confrontation can be used in the absence of a therapeutic alliance for purposes of establishing or retrieving the alliance. This is possible only if the confrontation on the part of the therapist is brought to bear from the perspective of his or her part in the alliance in an effort to engage the patient and reestablish the interpersonal context of collaborative effort.

Confrontation offered from a position of consistent caring and respect for the patient's autonomy, and generated from a basic concern for maintenance and reinforcement of the therapeutic alliance can have a powerful therapeutic effect. It must be remembered, however, that the confrontation is intended to lead in the direction of further therapeutic work and understanding. Confrontation for confrontation's sake inevitably runs the risk of countertransference contamination. It is more advantageous to try to understand where the patients are, and why they are where they are, than to confront them where they are not. Consequently, confrontations that lead in the direction of further exploring the basis for resistances or of examining the roots of transference distortions are therapeutically helpful. Where they do not, they run the risk of simply reinforcing the transference-countertransference dynamics and may simply lead in the direction of further patient compliance and counterproductive submissiveness.

Nonetheless, confrontation along with clarification may have an important role to play in any therapy, especially early in the course of the therapy. Interpretation is not possible or useful until the patient has developed some degree of at least a working alliance. To the extent that the therapist's interpretations are offered while the patient is caught up in the vicissitudes of projective distortions and negative transference reactions, they will be heard as either threatening or accusatory, or in an idealizing transference situation as unempathic reinforcements of the patient's views. Consequently, a relative focus on the patient's daily life experience and persistent gentle and gradual confrontation and clarification can lead not only to establishing a better alliance but can also gradually clarify and delineate the pathological patterns of interaction that the patient generates both within the therapeutic interaction with the therapist and with important objects outside of the therapy. Success with many patients, even difficult patients, is a function of the accuracy, empathy, and timeliness of the therapist's gentle and thoughtful confrontations, which both open the way for later interpretations and to a degree help to draw out the transference. Gentle confrontation and clarification of the patient's feelings about the therapist can open the way to dealing with therapeutic alliance issues and further catalyzing transference reactions.

VII. DEALING WITH DENIAL

One of the specific contexts in which confrontation is often required is when denial becomes a prominent factor in the patient's resistance. Denial, as with other defensive mechanisms, can operate at all levels of intensity, but can function at a relatively massive level even to the point where the patient becomes unaware of any inner feelings or impulses. When such denial affects the assessment of potentially threatening or dangerous consequences of a course of action, or has become sufficiently embedded so that therapeutic progress is stalemated, confrontation may be the only resource in the therapist's armamentarium that will enable him or her to break through the patient's denial. The element of unmasking denial is inherent in all forms of true confrontation, not as an attack on the patient's vulnerability, but that in whatever fashion confrontation is implemented, it is directed against the defense with the aim of unmasking and coming to grips with the patient's protected vulnerability.

The confrontation of denial may be spread over a considerable period of time, rather than being focused at a single point of time. One young man experienced occasional episodes of total immobilization, as if he were in a trancelike state in which he had great difficulty in following what has happened in his immediate environment and was unable to respond or react in any comfortable manner. Gentle questioning on my part, a subtle insistence that his experience must be connected with a mental process reflecting something significant in his life experience, gradually began to shift the ground and enabled him to slowly come in contact with the underlying affect. Sometimes days after the event, he would begin to experience some feeling of anger or irritation, or on rare occasions he would be suddenly overwhelmed with a burst of intense rage that he was completely at a loss to connect with any stimulus or context in the immediate situation.

The rage underlying these experiences was nearly psychotic in proportion and terrified him, presumably because of a previous psychotic breakdown, in which the intensity of his rage had welled up with overwhelming and traumatic effect. Gradually, the patient began to experience rage attacks that he found overwhelming at the time of their occurrence, but in therapy was able to reflect on and explore what he had been experiencing and gradually to connect his intense feelings with the traumatic experiences of his difficult and traumatic relationship with his parents. When it became clear to me that rage was at the root of his disturbing experiences, and that the level of his protective

denial prevented any easy access to these feelings, I continued to use a confrontational approach so that whenever any of these episodes came into focus I was not slow to suggest that what underlay the patient's experience was his anger and rage, and that our therapeutic task was to find out what his anger was about. The effort I am describing took place over a period of years of intensive psychotherapy. Consequently, confrontation is not always limited to a specific here-and-now intervention, but may involve a process that extends over continual periods of time.

VIII. NARCISSISM

Another difficult area in which confrontation can at times play a significant role is in dealing with the patient's narcissism. One context occurs when patient and analyst are caught up in a narcissistic alliance based on the patient's narcissistic expectations, gratifications, and fantasies, which impedes progress toward a more meaningful and effective therapeutic alliance. Gentle confrontation with the patient's narcissistic expectations and fantasies within the limits of his or her narcissistic vulnerability is a possible vehicle for addressing the distortions in the alliance and helping the patient to gain a better foothold for the therapeutic work. As previously noted, the decision whether to confront or not, rests in part on an assessment of the degree to which the patient is using the narcissistic alliance for defensive or resistive purposes, as opposed to the extent to which the narcissistic alliance may be the best the patient can do at that point in time and must be tolerated as necessary for maintaining any therapeutic relationship whatever. In the latter instance, confrontation may not be the best tactic, and the therapist might better wait until some degree of therapeutic alliance has evolved, or until enough of the components of the narcissistic transference are available for interpretation.

Other aspects of the patient's narcissism have to do with narcissistic entitlements and the need for engaging with and ultimately working through the underlying components of shame and inferiority. These dynamics and the underlying structural components can be described in terms of narcissistic superior and inferior introjective configurations. Keeping in mind the distinction between narcissistic entitlement and the entitlement to survive, it is nonetheless at times essential to confront the patient's entitlements. When these are expressed in the form of provocative behavior, it is useful to point out the patient's entitled attitudes, and even to focus on their impact on the therapist. The patient

may be outraged at this challenge to his or her self-proclaimed “rights,” but such confrontation may be the only path toward further exploration and understanding. The patient may respond by foregoing any provocative behavior and adopting a more compliant facade out of fear of abandonment and loss of the therapist, but these maneuvers and the misalliances they reflect can also be confronted, leading to further exploration and analysis. Whether such confrontations are made with essentially neutral affect or with a tinge of irritation is a matter of clinical judgment, and involves questions related to the amount of self-disclosure that will be therapeutically useful on one hand and the degree of countertransference contamination on the other. If the therapist’s irritation is not completely suppressed, it may bear fruit in letting the patient know that his or her infantile entitlement can evoke hostility from the important others in the patient’s life.

Although excessive entitlements reflect the dynamics of the superior narcissistic introject, the inferior narcissistic introject may also play out its brand of entitlement in a form of restricted entitlement in which patients play out their inferiority, fail to stand up for themselves, or allow others to take advantage of them. This behavior also requires confrontation, but this can run the risk of inflicting a narcissistic injury in that it calls attention to the patient’s inadequacy and failings. This too, however, can open the way to further exploration and meaningful resolution of the underlying fears and impediments. The art of confrontation of a patient’s narcissism lies in dosing and timing, and maintaining a positive and respectful view of the patient. Confrontations tend to inflict narcissistic injuries on patients, and the therapist must keep in mind that these toxic effects must be administered in tolerable doses, so that untoward side effects are not created. The process is a form of gradual desensitization, which slowly increases the titration of confrontation and its immediacy and directness within the limits of the patient’s tolerance and the mitigation of his or her narcissistic vulnerability.

The therapeutic task in the treatment of narcissism lies in making contact with, articulating, and gradually analyzing the inferior side of the patient’s narcissism, particularly the sense of inferiority and shame, which pervades the inner world of all narcissistic patients, whether the inferior aspect of the patient’s narcissistic introjects is relatively conscious or not. In narcissistic patients, the underlying sense of shame often gives rise to projections, which take the form of expecting humiliation or criticism, experiencing the otherwise benign reaction of others as forms of humiliation or criticism, and other forms of ridicule, scorn, contempt and rejection from important

others including the therapist. Analysis of these components of the patient’s inner world cannot proceed unless these elements have been drawn into conscious awareness to some degree. Confrontation can often usefully accomplish this objective. Only when the patient is aware of this dimension of his or her inner life is it possible to seek further for explanation and understanding.

IX. SUMMARY

This discussion of confrontation can be summarized in the following guidelines for the use of confrontation:

1. Confrontation draws upon empathy, but empathy does not mean that we share an identity or an ideology with the patient.

2. Countertransference distortions are likely when we find ourselves angry, disappointed, exasperated, gratified, especially frustrated, jealous, or in some other way imposing our individual imperatives upon confrontations.

3. Confrontations can be contaminated by fantasies of being the magic healer, rescuer, shaman, sage, or parent, because this may not be the level of need and communication on which the patient is operating.

4. Confrontation consists of mutually self-corrective activities. It is not intended to be a directive or a prohibition for the patient. We seek forbearance, not compliance, firmness, not coercion from the patient. We cannot offer options; we can only help someone to use the options he or she has.

5. Efforts to understand too much are suspicious indications of countertransference ambition. We cannot respond to every demand and confront every defense. Denial cannot be eliminated completely, because strategic denial may be a requirement for the patient is keep on living.

6. A tendency to overemphasize technique or, conversely, to discourage thoughtful reflection as “cerebral” are signs of countertransference distortions.

7. Confrontations are more effective in a context of trust. Trust means only that we have a common field of acceptance. Although it is feasible to have a mutual alliance at the outset, trust is always conditional.

8. Words are not magic, nor must confrontations be followed by signs of conspicuous change. Confrontations are only special vehicles of communication that seek an opening at a point of contact with protected vulnerability.

9. On the whole, confrontations are only statements about the other person’s existence, not hypotheses about

his or her status as a scientific object. We respond to his or her separate reality and cannot, therefore, be too punctilious about the longitudinal truth of what we say.

10. We can generalize; we can be precise. But it is essential that we also be contemporaneous.

- punishment* Application of a negative stimulus that decreases the frequency of a behavior.
- shaping* Reinforcing successive approximations of a desired response until that behavior is fully achieved.
- time-out* Extinction of undesirable behavior by removing attention-based reinforcers for that behavior.
- token economy with response cost* Establishment of primary and secondary reinforcers contingent upon the presence of a desired behavior or absence of an undesired behavior.

GLOSSARY

- contingency contracting* Distribution of rewards and punishments for a behavior via a written contract constructed between two or more parties.
- contingency management* A therapeutic procedure involving the modification of behavior via the control or manipulation of consequences (contingencies) to the behavior.
- differential reinforcement of other or incompatible behavior* Rewarding general behavior other than an undesirable behavior or rewarding specific behavior that is antagonistic to an undesirable behavior.
- extinction* Removal of a positive stimulus that decreases the frequency of a behavior.
- negative reinforcement* Removal of a negative stimulus that increases the frequency of a behavior.
- positive reinforcement* Application of a positive stimulus that increases the frequency of a behavior.
- Premack's principle* Reinforcing a target behavior by awarding some privilege to engage in a more desired behavior afterward.

I. DEFINITION

Contingency management refers generally to the modification of behavior via the control or manipulation of consequences (contingencies) to the behavior. In essence, some control is sought over what follows a certain behavior to increase or decrease the frequency or other characteristics (e.g., intensity) of that behavior. Contingency management involves a collection of therapeutic techniques derived from Skinnerian principles of reinforcement. In addition, practitioners of contingency management often enlist those who surround a particular client to distribute consequences, but contingency management may involve the client himself or herself as well.

II. TYPES OF CONSEQUENCES

Consequences that follow a particular behavior can often be categorized as positive or negative. In addition,

such consequences may be given or taken away. A positive consequence that is given refers to positive reinforcement and generally serves to increase the frequency of a behavior. Examples include providing bonus incentives for workers or rewarding a child for extra chores via a new privilege. A positive consequence that is taken away is a form of extinction and generally serves to decrease the frequency of a behavior. Examples include hanging up the telephone on an obscene caller or depriving a child of attention as he or she throws a temper tantrum. In each case, the perpetrator is denied access to reward (e.g., arousal, attention), which should lessen the frequency of the behavior in the future. Extinction may involve the absence of negative consequences as well, according to Tryon in 1996.

A negative consequence that is given refers to punishment and generally serves to decrease the frequency of a behavior. A common example is spanking a child for recklessly running into the street. Finally, a negative consequence that is taken away refers to negative reinforcement and generally serves to increase the frequency of a behavior. Examples include wearing deodorant to ward off complaints from others and avoiding an anxiety-provoking situation (e.g., driving across a bridge) to lessen anxiety as one leaves the situation. Contingency management generally involves manipulating these consequences, both positive and negative, to modify a particular behavior.

Specific types of consequences used in contingency management include tangible and intangible stimuli. Positive tangible consequences include such things as food, money, toys, and privileges, whereas negative tangible consequences include such things as pain or physical discomfort. Positive intangible consequences include such things as attention, sympathy, and social support, whereas negative intangible consequences include such things as emotional deprivation, lack of conversation, or failure to help.

III. INITIAL STEPS TO CONTINGENCY MANAGEMENT

A contingency management approach to therapy begins with selecting and carefully defining the behaviors to be changed as well as rewards, penalties, and punishments. In doing so, input should be sought from the person who is displaying the behavior of interest as well as those who often surround the person and/or who have significant influence on him or her. Input may be solicited directly via interview or more indi-

rectly via questionnaire, videotaping, or analogue observation in an office setting. In the case of a child, for example, input may be derived from the child, parents, teachers, siblings, peers, dating partners, grandparents, group leaders, or relevant others. For adults, relevant others generally include a spouse, children, friends, relatives, and business associates, among others.

Targeted behaviors should also be clearly defined. In the case of a child who throws temper tantrums, for example, specific targeted misbehaviors might include crying, throwing an object, hitting someone, screaming, or refusing to move. In the case of an adult with alcoholism, specific targeted misbehaviors might include missing work days, showing up unannounced at a friend's house, or driving while drunk. Each of these behaviors can be easily observed and recorded. Vague descriptions of targeted behaviors, such as aggression or lack of respect for others, should be avoided. Other criteria for targeted behaviors include feasibility and desirability. Targeted behaviors should be practical, make sense to those involved, and be within a client's value system.

IV. TYPES OF CONTINGENCY MANAGEMENT

Several treatment techniques come under the general rubric of contingency management, including token economy with response cost, contingency contracting, shaping, differential reinforcement of other or incompatible behavior, time-out, and procedures based on Premack's principle. Each is discussed briefly next.

A. Token Economy with Response Cost

A token economy involves the establishment of primary and secondary reinforcers contingent upon the presence of a desired behavior and/or the absence of an undesired behavior. Specifically, a system is set up such that a behavior is linked to the receipt of tokens, points, or some other stimulus to compensate a person for engaging in or not engaging in a behavior. In doing so, some form of compensation is given immediately following the desired behavior. Accumulation of these stimuli (i.e., tokens, points) is later exchanged for primary and usually tangible reinforcers that the person enjoys (e.g., food, access to toys, privileges, release from chores). Failure to accumulate a specified number of points usually means a failure to receive the reward, or the token economy can be structured so that different

accumulations of tokens or points lead to different levels of reinforcement. For example, a large amount of accrued tokens could be rewarded with 10 hours of release time from an inpatient unit, whereas a smaller amount of accrued tokens could be rewarded with 5 hours of release time.

Token economies are often supplemented with a response cost procedure whereby a person loses tokens or points for some specified misbehavior (e.g., noncompliance, stealing, screaming). In this scenario, the person is fined for the misbehavior by losing some, but not necessarily all, of their accumulated tokens or points. This procedure thus penalizes misbehavior and provides immediate feedback to the person about the inappropriateness of his or her behavior. For example, running down the hallway at school could be penalized by asking the offending child to hand over three tokens. Response cost is typically used to curb behavioral excesses.

Token economies have been used successfully in many areas, but are most common to classrooms and institutional settings. Classroom token economies are often used to address academic behaviors such as handing in assignments or completing projects, disruptive behaviors such as getting out of one's seat or inappropriate talking, and organizational behaviors such as studying and keeping one's desk neat. Institutional token economies are common to inpatient units and residential facilities for persons with disabilities. These token economies are often used to improve daily living and social skills, attendance at therapy sessions, and self-destructive and other behaviors.

B. Contingency Contracting

Contingency contracting involves the distribution of rewards, penalties, and punishments via a written contract constructed between two or more parties. Contracting is often used in family therapy as a vehicle for problem-solving, but is also an excellent way of providing rewards, penalties, and punishments in a structured and agreed-on format. After a specific behavior (e.g., curfew) is defined as the presenting problem, each party (e.g., parent and adolescent) develops parameters to indicate how they would like the behavior defined and what consequences may follow its presence or absence. In the case of curfew, each party may eventually decide that 9:30 p.m. curfew on weeknights and 11:00 p.m. curfew on weekends is desirable. Both parties may then agree that adherence to this curfew time will be rewarded via continued allowance, whereas broken curfew will be met with grounding and suspension of allowance.

Contracting usually requires that each party negotiate behaviors of interest as well as acceptable consequences. Contracting typically begins with a mildly problematic behavior that is easily defined and amenable to placement in a contract. This is done to give the conflicting parties practice at the contracting process and to experience success in problem-solving. Subsequent contracts gradually become more detailed and complex, and may involve multiple behaviors and consequences. For example, a teenager may agree to attend school, adhere to curfew, and complete homework in exchange for visits with friends, money, and special privileges. Failure to complete these tasks may result in loss of these reinforcers or assignment of other punishers such as chores. Many contracts are also designed so that basic behaviors are not directly reinforced. For example, many parents object to paying their children to go to school, a task they should be doing anyway. To address this, a contract may specify that a child must attend school to earn the opportunity to complete chores at home for which he or she is paid (i.e., a two-part reinforcement contingency). Of course, each contract should reflect that family's value system.

Contracts are often used with parents and children but can also be used for other clinical populations. For example, a person with substance abuse can contract with co-workers to attend work sober, a person with schizophrenia can contract with a therapist to maintain medication use, and a person with depression can contract with friends to increase attendance at social events. Contracting is also preferable in chaotic situations where increased structure for problem-solving and consequence administration is desired.

C. Shaping

Shaping refers to reinforcing successive approximations of a desired behavior until that behavior is gradually achieved. General examples include learning to play a musical instrument or playing a sport such as golf. In these activities, small, gradual steps must be taken toward the final goal. In many clinical populations, asking a client to reach a certain goal is untenable because of some interfering behavior such as fear, withdrawal, noncompliance, or lack of skill. Therefore, smaller steps toward the overall goal are designed to facilitate progress. A common example is approach toward a feared stimulus such as a dog. A person phobic of dogs will not simply walk up to a canine and pet it; instead, gradual steps toward the dog must be taken without fear. Shaping also involves the distribution of

rewards, penalties, and punishments for completing or failing to complete each step.

Gradual approach without fear is a common example of shaping, but many other examples are available. For children with school refusal behavior, for example, shaping often involves requiring a child to attend one class/hour per day and gradually increasing the number of classes/hours attended over time. For persons with depression, shaping could involve asking a client to make two calls a week to friends, and subsequently increasing his or her number of social contacts. For couples with sexual dysfunction, shaping could involve reconstructing the sexual repertoire so that only certain areas of the body are initially touched; as therapy progresses, more intimate contact is allowed and reinforced. Shaping generally involves only those steps that resemble the final overall goal (e.g., active social interactions).

D. Differential Reinforcement of Other or Incompatible Behavior

Differential reinforcement of other behavior (DRO) refers to rewarding behavior other than a specified undesirable behavior. A child with autism, for example, may be given a reward during any 5-minute interval during which he or she plays with no aggressive behavior. In related fashion, an adult may be rewarded for interacting with others and not avoiding an anxiety-provoking situation. Differential reinforcement of incompatible behavior is similar to DRO, but involves rewarding a behavior that is specifically antagonistic to, or not able to be done physically at the same time as, an undesirable behavior. For example, a child may be rewarded for folding his or her hands on a desk, a behavior incompatible with hair pulling. Or, an adult in a group home for persons with schizophrenia may be rewarded for doing a chore in the home, a behavior incompatible with running away.

E. Time-Out

Time-out involves the extinction of undesirable behavior by removing positive reinforcers for that behavior. Time-out is most commonly used for children, and often involves isolating a child for misbehavior to deprive that child of attention from others. A child who is disruptive in class, for example, can be sent to another room alone so that reinforcing peer attention is denied. In-school suspension is sometimes used in this regard. Or, a parent may choose to ignore a child for having a temper tantrum to deny the child the benefit of parental attention. Time-

out is also used as a punishment in that the isolating setting should be a boring one devoid of fun.

Several caveats to time-out are often ignored and can lead to problems with the technique. First, time-out will only work for those whose misbehavior is attention-seeking in nature. If a child is disruptive in class to escape an aversive assignment, for example, then time-out serves more as a reward. Similarly, for children with autism, time-out is often more a negatively reinforcing event than a punishing one. Second, time-out is generally more effective if the person knows why he or she is being placed in time-out. Children, for example, should be informed before and after time-out as to why time-out occurred. Finally, time-out should not be linked with a stoppage of the required task before time-out. If a child was picking up toys prior to a tantrum and subsequent time-out, then he or she should return to the task following time-out.

Time-out may be used for other populations as well. For example, a person with schizophrenia on an inpatient unit may be placed in his or her room for aggressive behavior, an adolescent in a group home may be placed in time-out for yelling at another resident, and a couple who engages in heated arguments can agree to place themselves in temporary time-out to ease passions and prevent an abusive situation from taking place. As such, time-out can serve as a preventative measure as well as a mechanism for depriving reinforcement for a misbehavior.

F. Premack's Principle

Premack's principle (or the differential probability hypothesis) refers to reinforcing a target behavior by awarding some privilege to engage in a more desired behavior afterward. For example, a child may be told that he or she can have dessert after eating his or her vegetables, or be told that he or she can play baseball after completing a certain chore. The more highly desirable behavior is used to entice a person to engage in a usually productive, albeit less enjoyable, activity. Typically, Premack's principle is used by parents in addressing their children, and therapists often build this principle into their parent-training regimens. Premack's principle is used loosely in other clinical settings as well. For example, a person who successfully loses weight may then be allowed to shop for new clothes.

Premack's principle is often extended in parent-training programs to encourage appropriate child behavior and discourage inappropriate behavior. For example, parents may establish a set of house rules that

carry rewards if followed and punishments if not. The establishment of this consequence system is often linked to other areas of parent training such as modifying parental commands, setting up daily routines, and increasing supervision of the child.

V. PARAMETERS OF CONTINGENCY MANAGEMENT

No matter what contingency management procedure is used in a therapeutic setting, one must still decide on certain parameters for its use. One parameter is who actually distributes the rewards, penalties, and punishments. Generally speaking, those closest to a person and/or those who have the most influence over the person's behavior should be considered. For children, this almost always involves parents, but also teachers, older siblings, grandparents, dating partners, and peers. For adults, this almost always involves a spouse, but also friends, children, co-workers, and other relatives. In addition, rewards, penalties, and punishments may be given by the client himself or herself. For example, a person with depression who successfully modifies an irrational thought can be taught or encouraged to praise oneself for doing so.

Another parameter to be considered is where contingencies should be distributed. Generally speaking, the contingencies should apply closely to the setting in which the misbehavior occurs. For example, if a child is disruptive at school, some consequences should be given there. Likewise, for an adult with depression who is moping at home, consequences may be given there. This allows for more immediacy of rewards, penalties, and punishments, which is crucial to the success of contingency management. This does not preclude, however, the use of consequences in other settings. A child disruptive at school, for example, should also face consequences from his or her parents at home that night.

Another parameter to be considered in contingency management is whether consequences should be given in an individual or group format. In an individual format, the identified person solely receives rewards or punishments. A person who successfully attends a shopping mall and withstands a panic attack without fleeing, for example, could be praised by a spouse at that time. However, a group format may be used to increase help or peer pressure to change behavior. For example, a classroom of children could be told that if everyone turns in five math homework assignments that week, the class will have a party on Friday. How-

ever, if even one person fails to do so, no party will take place. The idea here is to increase peer support, tutoring, and other factors that will increase the likelihood that all children, with a particular focus on one or two, will complete their work. The potential downside, of course, is coercion or negative feelings toward one who does not reach the goal. Therefore, it is best to use this approach in a more cooperative environment. Another example is to penalize a group of people for the misbehavior of one person. In this situation, the same goal and caveats apply.

Group contingencies can be modified so that rewards, penalties, and/or punishments are applied to individuals who successfully or unsuccessfully attain a certain goal. In this situation, the group may know that an individual is up for a reward and assist him or her to get it, or may know that the entire group is up for a reward if the individual is successful. Here, the group is not necessarily penalized for an individual's failure to reach a certain goal. To enhance the cost-effectiveness of group contingencies, a lottery system may be established. In this system, group members are told that they are eligible for a prize drawing if they reach a certain goal (e.g., treatment completion). Eligible members then participate in a lottery that rewards one or more persons but not necessarily everyone who is eligible.

VI. POTENTIAL PROBLEMS OF CONTINGENCY MANAGEMENT

Aside from the caveats to group contingency management just presented, other potential problems should be noted by therapists. One of the biggest threats to the success of contingency management procedures is inconsistent application of the rewards, penalties, and punishments. Several scenarios for this apply to parents and children. First, it is often difficult for parents, who may have had a long history of reflexively attending to their child's misbehavior, to break free from that pattern and respond only to appropriate behavior. Second, parents who have little history of rewarding their children, who emphasize punishment instead, may require time to correctly implement a positive reinforcement system. Third, a mother and father may inconsistently apply contingencies or some third party (e.g., grandparent) may sabotage the process. Fourth, parents may implement contingency management procedures at first but then relapse to old patterns of behavior or for some reason delay the administration of consequences. In these cases, it is best

for the therapist to explore the reasons for treatment noncompliance or failure and perhaps simplify the procedures or target fewer behaviors.

Another threat to contingency management is poor preparation for generalization of treatment effects. The positive effects of contingency management tend to fade over time and especially once the procedures are discontinued. Continued use of the procedures or, if not feasible, some type of intermittent reinforcement or booster session, is recommended. In addition, it should be reemphasized that contingency management is not usually conducted as a sole treatment technique, but combined with other behavioral methods to enhance therapeutic outcome.

Other potential problems to contingency management are more generic. For example, a common problem is that the consequences are not salient enough for an identified client. In this case, rewards, penalties, and/or punishments may need to be intensified or modified to better fit the preferences of the person. Another problem is delay in the immediacy of the consequences. Preferably, consequences should be delivered very soon after appropriate or inappropriate behavior. Finally, contingency management procedures will work best if cooperation from all relevant parties is present. This is most crucial to children with behavior problems, as parents, teachers, and others should be in frequent contact so that different types of behavior can be well-defined and addressed consistently.

VII. TARGET GROUPS FOR CONTINGENCY MANAGEMENT

Contingency management procedures have been used successfully for a number of clinical populations, most notably for children and persons with pain, substance abuse, or pervasive developmental disability. With respect to children, the most common use of contingency management has been with youth with disruptive behavior, especially attention deficit hyperactivity and conduct/oppositional defiant disorder. In this population, contingency management procedures have been shown to produce short-term improvements in academic productivity and accuracy as well as disruptive behavior. In most cases, home-based and school-based contingency management are utilized simultaneously. Contingency management has also been used for children with internalizing problems such as fear, anxiety disorders, and selective mutism. In this population, children are rewarded for successfully engaging in exposure-based tasks. In addition, contingency manage-

ment is often used to address problems of physical functioning such as enuresis and encopresis. Most often, children with these disorders are rewarded for instances of dryness and required to engage in cleanliness practices as a deterrent to soiling.

With respect to persons with pain, contingency management is often combined with other behavioral procedures to address those whose overt pain behavior persists beyond the normal healing process. Contingency management is typically targeted toward behaviors such as verbal pain behavior (e.g., complaints, crying), nonverbal pain behavior (e.g., limping, grimacing), level of activity (e.g., excessive resting), and inappropriate use of medication. In this situation, significant others are encouraged to lessen sympathy, attention, and support whenever the targeted person engages in these maladaptive behaviors. In addition, positive reinforcement should be given whenever the person is active, using medication appropriately, and focusing on life events other than pain.

Various researchers have also used contingency management procedures to address persons with substance abuse. In this population, contingency management has been used to help improve treatment session attendance, abstinence, appropriate medication use, accurate predictions of drug screens, and relapse prevention. Common reinforcers include take-home doses of medication, money, clinic privileges, vouchers for services, employment, housing, and reimbursement of fees. However, the effectiveness of contingency management for this population is subject to factors such as type of drug abused, type and immediacy of reinforcement, frequency of drug screens, patient diversity, and acceptance of the program.

For persons with pervasive developmental disabilities, contingency management is used to reduce maladaptive behaviors and increase adaptive behaviors. Common maladaptive behaviors of focus include self-injury, aggression, inappropriate vocalizations and verbalizations, improper sexual activity, and excessive self-stimulation. Common adaptive behaviors of focus include daily living skills (e.g., eating, dressing, toileting, washing), social interactions, and treatment compliance.

Contingency management procedures have been used for other clinical groups as well. For example, they have been used successfully to address persons with polydipsia, irritable bowel syndrome, vomiting, depression, marital problems, delusional verbalization, bedtime disruptions, pacifier use, and violent behavior. In addition, contingency management has been used to increase adaptive behaviors such as oral hygiene, appropriate eating, cooperation, productivity, homework, writing, and exercise.

VIII. SAMPLE CASE

Following is a sample case of a child with school refusal behavior whose treatment plan included parent training in contingency management. Derek was a 10-year-old boy referred to an outpatient clinic for recent difficulties attending school. Since the beginning of the academic year, Derek had displayed intermittent problems going to school, sometimes throwing temper tantrums in the morning in an effort to stay home with his mother and younger sister during the day. These problems were manageable to some extent in the beginning, but had escalated in the past 3 weeks to the point where Derek's parents could no longer get him to school. Attempts on their part to get him to go to school were met with screaming, crying, refusal to move, clinging, and locking himself in the bedroom or car. In addition, on two recent occasions when Derek did attend school, he left during the day to return home.

A thorough assessment indicated that Derek was not anxious about school and did not have any academic or social problems there. Indeed, Derek's teachers indicated that he was a good student when in class. The assessment also ruled out any medical conditions that might explain Derek's behavior. Instead, the assessment revealed that Derek had a long history of attention-seeking misbehavior, beginning with temper tantrums when he was a young child. These misbehaviors had grown in intensity over the years and had now extended to school refusal behavior. The problem was exacerbated by the fact that Derek's father had to go to work early in the morning, leaving Derek's mother to contend with her son. During the day when not at home, Derek enjoyed several amenities, including running errands with his mother, playing video games, and riding his bicycle. The situation was further problematic in that the school had recently threatened to charge Derek's parents with educational neglect.

To address these misbehaviors, Derek's parents were trained in various aspects of contingency management in addition to adjusting parental commands and setting routines during the morning, day, and evening. Parental commands were modified to be more succinct, straightforward, and devoid of lecturing or asking questions. Three target behaviors were then chosen to be the focus of contingency management. These behaviors included, in order of severity, screaming, refusal to move, and locking himself in a room or car. Consequences were first set up to target screaming: If Derek engaged in any screaming in the morning, he would lose privileges during the

day and be required to sit on the edge of his bed during school hours. His nighttime routine would also be restricted to the house (i.e., no play time with friends). If he did not scream in the morning, especially following commands to go to school, then he would complete chores and schoolwork during the day and be allowed to see his friends for an hour at night.

In addition to this consequence system, Derek's parents were instructed not to pay any physical or verbal attention to their son when he engaged in inappropriate behavior (unless severe injury was being risked). Instead, they were encouraged to smile and speak to him only when he was preparing for school (e.g., getting dressed without complaint), completing schoolwork, or otherwise acting appropriately. This took some practice, as both parents had been used to interacting with Derek primarily when he misbehaved. However, following several days of intervention, Derek's screaming did subside.

The next misbehavior was more severe: refusal to move in the morning. A consequence system was established such that, if Derek refused to move in the morning (e.g., would not get out of bed, dress, eat breakfast, or go to the car), he would be completely grounded for the day, be required to complete schoolwork, and lose allowance. However, if he successfully prepared for school, got in the car, and allowed his mother to drive him to school before returning home, he would be allowed to see his friends 2 hours per day at night. Although school attendance was not yet required at this point, it was made clear to Derek that that would be the next step. Following some tantrums the next day and implementation of the contingencies, Derek's behavior in this regard gradually improved.

Finally, Derek was required to do all of the above in addition to entering the school building and attending class. All parties had reported that Derek would go to class without any problem once there, so getting him there was the primary goal at this point. Similar consequences applied to his refusal and willingness to attend school, and procedures were designed so that both of Derek's parents would be available to take him to school. On the first 2 days of the intervention, Derek refused to attend school and even ran out of the house once to be with friends. However, he was found and restricted to his room for the rest of the day. During the next 2 days, Derek made it to school but refused to enter the school building. Again, consequences were issued. On the following day, Derek did attend school for the entire day, and school personnel increased their supervision of him to prevent any escape. Derek was subsequently rewarded for his attendance via play time

with friends at night, choice of an activity with the family, and praise from his parents. Although intermittent success going to school was seen during the next few days, Derek eventually returned to full-time school attendance within 2 weeks. Derek's parents reported that the consequence system would be continued and extended into other areas of noncompliance.

IX. SUMMARY

Contingency management is a commonly used therapeutic technique that has been administered successfully to treat various clinical problems. The technique is based on Skinnerian laws of reinforcement, or that consequences to a behavior serve to shape the frequency and other characteristics of that behavior. Examples include token economy with response cost, contracting, shaping, differential reinforcement of other or incompatible behavior, time-out, and use of Premack's principle. Although commonly used with parents and children, contingency management has also been applied to various adult populations. Advantages of contingency management include its portability, easy-to-understand nature, wide applicability, and naturalness. Threats to contingency management include inconsistent application and lack of salience of consequences, factors that should be monitored closely by therapists.

problem drinker General term used to refer to persons who abuse alcohol or are physiologically dependent on alcohol; also sometimes used to mean nondependent alcohol abusers.

standard drink Serving of an alcoholic beverage containing approximately 0.5 ounce of ethanol (e.g., 12 ounces of 4% beer, 4 to 5 ounces of 10 to 12% table wine, 1 to 1.5 ounces of 40 to 50% distilled spirits).

GLOSSARY

behavioral self-control training Clients are taught to set drink limits, self-monitor their drinking, and employ coping skills to exercise control over when, where, why, and how much they drink.

controlled drinking Nonabstinent outcome by persons who have had drinking problems, often defined in terms of limited quantity and frequency of drinking, lack of negative drinking-related consequences, and subjective sense of mastery or control over drinking.

cue exposure Therapy procedure in which client is repeatedly exposed to stimuli that elicit craving to drink so that person learns to resist urges to continue drinking in the presence of alcohol and other drinking cues.

harm reduction Broadly defined, refers to policies and interventions designed to reduce, minimize, or eliminate unhealthy outcomes that might result from continuing to engage in high-risk drinking and drug-taking.

I. DEFINITION, PREVALENCE, AND STABILITY OF CONTROLLED DRINKING

The term *controlled drinking* is used to describe non-abstinence outcomes—that is, moderate or non-problem drinking—by persons who have abused or have been dependent on alcohol. Definitions of controlled drinking typically include some limit on the quantity of alcohol consumed per day; for example, consumption of no more than 3 to 5 “standard drinks” per day (1 standard drink = 0.5 ounce of ethanol). Similarly, the British Department of Health recommends that men limit their consumption to no more than 4 “units” per day and that women limit their consumption to no more than 3 “units” per day (1 unit = 8 grams of ethanol). In addition to limits on quantity consumed per day, some definitions of controlled drinking prescribe limits on the number of drinking days per week and limits on the speed with which one

consumes each drink (e.g., no more than one unit or standard drink per hour).

Controlled drinking is also typically defined by the reduction or absence of harmful drinking-related consequences. These include drinking-related health problems (e.g., significantly elevated liver enzymes, pancreatitis), legal problems (e.g., arrests for public intoxication, driving under the influence), occupational problems (e.g., missed work, poor performance, lost jobs due to drinking), and social and familial problems (e.g., drinking-related loss of friends, separation or divorce).

Controlled drinking also may be defined in terms of the drinker's subjective sense of control, but this is more difficult to assess than quantity consumed and consequences experienced. Although people without drinking problems occasionally experience urges or cravings for a drink, and persons without drinking problems occasionally drink more than they intend, the non-problem drinker typically experiences a sense that he or she is choosing when and how much to drink. Adapting Bandura's concept of self-efficacy, the definition of controlled drinking by problem drinkers could include the realistic belief that one can engage in self-control behaviors to create a moderate drinking outcome.

These three components of controlled drinking provide researchers, clinicians, and clients specific guidelines to evaluate the degree to which a problem drinker is moderating his or her drinking; however, problem drinkers need not fulfill all three components to reduce their drinking problem and improve their psychosocial functioning. As is the case with anxiety, mood, and other behavior disorders, improvement of drinking problems is not an all-or-none outcome.

Some clients and clinicians find the term "controlled drinking" an ambiguous and provocative one. It is ambiguous in the sense that all problem drinkers could be said to be "controlling" their drinking in the sense that they almost always exercise some choice regarding where, when, what, how much, and with whom they drink, even when their drinking is excessive and results in harmful consequences. It is provocative in the sense that some models of "alcoholism" assert that controlled, moderate, harm-free drinking is impossible once problem drinkers have manifested abuse or dependence.

Both treatment outcome studies and investigations of spontaneous remission or natural recovery have demonstrated that controlled drinking occurs in a meaningful subset of persons diagnosed with alcohol abuse and dependence. The likelihood of controlled drinking appears to differ depending on the severity of the population studied, but even in studies of chronic, dependent

drinkers, 10 to 15% have met study criteria for controlled drinking at follow-up. What is perhaps especially discouraging is the finding that abstinence by dependent drinkers appears to be no more frequent than is controlled or moderate drinking. The majority of alcohol-dependent patients experience relapse episodes or return to continuous problem drinking, and it is difficult to be optimistic about long-term, continuous abstinence or moderate drinking by dependent drinkers.

Is moderate drinking more or less stable an outcome than abstinence? The empirical evidence on this question is mixed, with some studies showing relapse more often following controlled drinking, some showing relapse more often following abstinence, and some showing no difference. Stability of any drinking pattern should not be taken for granted and many problem drinkers alternate among periods of abstinence, moderation, and excessive drinking. The stability of *both* moderate drinking and abstinence are probably influenced by multiple factors, including clients' psychological characteristics (e.g., psychological adjustment, impulsivity), drinking history, beliefs or expectations about drinking and abstinence, social support for abstinence versus moderate drinking, participation in abstinence-oriented or controlled drinking training, and the frequency of and ability to cope with transient intrapersonal and environmental stress.

II. SPECIFIC INTERVENTIONS TO TEACH MODERATE DRINKING

A. Basic Alcohol Education

To help set the foundation for later interventions—such as building motivation to restrain drinking, setting drink limits, and self-monitoring—clients are taught how alcohol is absorbed and metabolized, its effect on the central nervous system, beverage equivalencies, and the correlation between blood alcohol level and behavioral impairment. Basic alcohol education can be provided using pamphlets and book chapters on the topic or the therapist can provide basic alcohol education during an early session in the course of therapy.

B. Assessing and Building Readiness to Change

Despite cultural and clinical lore to the contrary, many problem drinkers are well aware of their excessive drinking and its consequences. To label as "denial"

the ambivalence that many problem drinkers (and people with other problems) feel about changing a cardinal feature of their behavior is simplistic and often inaccurate. Awareness alone, however, does not resolve ambivalence. Cultural mores that devalue expressions of personal “weakness,” and clinical interviewers who adopt an insensitive, disrespectful, and confrontational style, make it difficult for clients to verbalize—to family, friends and therapist—the disappointment, guilt, or shame they feel about their failed attempts to alter their problem drinking.

History-taking during assessment often reveals that a client’s excessive drinking serves one or more psychological functions, while concurrently impairing the client’s functioning in other life areas. Although the reinforcing properties of heavy drinking may appear intermittent and unclear to the therapist, they are powerful to the client and may overshadow the short- and long-term punishing effects of such drinking. Furthermore, as much as clients may recognize the disadvantages of their drinking, they are also afraid of the physiological and psychological consequences of quitting or reducing their alcohol consumption, many of which they have experienced during previous voluntary or unintentional periods of abstinence.

Therefore, to assess the client’s readiness to change, and to help build the client’s motivation for what may be a difficult process of initiating and maintaining a change in one’s drinking, the therapist can use empathy and reflective listening to explore the client’s ambivalence and to uncover and reinforce commitment to change. Motivation may also be assessed and strengthened by having the client list the advantages and disadvantages of both continuing to drink and of reducing or quitting drinking. Paper-and-pencil measures of readiness to change and useful guides to motivational interviewing are available to help the clinician undertake this intervention.

C. Goal Setting

The therapist provides guidance as the client sets (and periodically reviews) explicit, healthy limits on the maximum number of standard drinks or alcohol units he or she will consume per day and the maximum number of drinking days per week. In addition to setting this regular daily limit (for example, no more than 3 standard drinks per day and no more than 5 days of drinking per week), clients may be encouraged to consider limiting the number of drinks per hour and allowing themselves “special days” on which they may

exceed the regular limit (for example, up to 4 or 5 standard drinks once per month at a party).

Some therapists recommend that clients set themselves an initial 4-week period of abstinence—to reduce their tolerance, recover from any minor impairment in liver function, and demonstrate self-control—before they undertake moderate drinking. Alternatively, some therapists have clients reduce their daily limits over several weeks, “stepping-down” the daily limits over time to reach the client’s ultimate drinking limit, without an intervening period of abstinence. Further research may determine whether an initial period of abstinence is generally more or less productive of successful controlled drinking than stair-step decreases to moderation. In the absence of an unequivocal answer, and in light of individual differences in clients’ drinking histories, health statuses, and goal preferences, therapists may prefer to negotiate this issue with clients on a case-by-case basis.

D. Self-Monitoring

The drinker records, usually on a preprinted paper form, relevant aspects of his or her drinking, including, for example, urges to drink, number of drinks consumed, type of beverage consumed, and where and with whom the drinking occurred. Some therapists design the self-monitoring form in collaboration with the client; others present the client with copies of a preprinted form. In either case, the value of self-monitoring should be described to or elicited from the client, and the client should be encouraged to monitor every drink (and/or urge to drink), as soon as it is consumed (or experienced).

In addition to paper-and-pencil recording, self-monitoring could also employ other technologies, such as audio-recording and miniature personal computers, to record the selected drinking information. Similarly to its use with a wide variety of behavior problems, self-monitoring serves both as an assessment tool, because it provides the client and clinician with data about the target behavior, and as an intervention, because some clients will reactively decrease their consumption as a function of self-monitoring reactivity.

E. Change Drinking Pattern

The client is encouraged to change the manner and situations in which he or she drinks, in part to interrupt long-standing drinking habits that have led to excess. For example, the client could switch from undiluted

spirits to diluted drinks or beer; the client could wait at least 30 minutes between each drink and/or substitute nonalcoholic beverages between each alcoholic drink; and the client could delay the onset of drinking until the middle or late evening. The manner in which the client consumes each drink can also be modified, for example, by sipping rather than gulping drinks and by setting down one's glass between sips.

Using the self-monitoring data and client recollection of past drinking situations, the therapist can also help the client brainstorm ways to avoid high-probability situations for excessive drinking (or plan to exercise vigilance in those situations). Other ways to change the manner and situations in which one drinks include engaging in nondrinking activities (games, sports) while drinking, avoiding participation in round-buying (or skipping rounds to stay within one's limit), and restricting drinking to meals. The client can also be encouraged to appreciate the effects and benefits of moderate drinking. For example, the client can be encouraged to drink to enjoy the taste and initial feeling of intoxication, rather than to fit in with a group of heavy drinkers, to cope with depression or anger, or to postpone dealing with problems.

F. Social Skills Training

Research on self-reported reasons for relapse indicates that many clients drink excessively to cope with social pressure, negative emotions, stress resulting from daily hassles, and major life events. Therefore, specific skill training has been employed to help clients cope with challenges to their drinking goals, whether abstinence or moderate drinking. These skills include assertive drink refusal, progressive muscle relaxation, and problem-solving.

G. Contingency Contracting

Contingency contracts, which specify the relationship between performance of a target behavior and its consequences, have been used with problem drinkers to reinforce both abstinence and moderate drinking. Although behavioral contracts can take a variety of forms, there are several basic elements of most behavior contracts. These include a clear and detailed description of a client's drinking limits (including, for example, the inter-drink interval, number of abstinent days per week, definition and frequency of special drink days); a time limit for attaining the drinking goal (or approximations to the final goal); specific and immediate positive reinforcements for main-

tenance of the drinking limits; and self-monitoring or some other method of observation, measurement, and recording of the target behavior.

Contracts may also include punishments (e.g., loss of money or valued object) for failure to meet contractual obligations. The contract should also include an explicit date for renegotiation and all relevant parties should sign the contract, assuming it is written. It is not uncommon for the therapist to have a role in the monitoring of contract compliance and delivery of reinforcements. As therapy proceeds, it is best to find ways to transfer these tasks to others in the client's natural environment. Empirical evidence does not consistently favor the effectiveness of mutually authored contracts over therapist-authored contracts, but some clients will prefer the former and coauthored contracts probably engage the client more fully in the contracting process.

H. Making Use of Found Time

The client may have some difficulty filling the time once taken up with heavy, prolonged drinking and its aftermath. To avoid boredom, and to help support a moderate drinking habit, the client can be encouraged to take up new (and increase existing) recreational activities to take the place of drinking. The therapist can guide the client as he or she considers a wide range of athletic, intellectual, social, political, religious, musical, and other activities he or she might want to sample. The client can also be encouraged to consider what functions heavy drinking had served, and what nondrinking activities might also accomplish those goals (e.g., other ways of mixing with people without spending long periods of time in bars).

I. Challenging Unrealistic Alcohol Outcome Expectancies

Alcohol expectancies are the beliefs one holds about the positive/desirable and negative/undesirable outcomes of drinking. For example, some people believe that drinking alcohol will make it easier for them to meet new people; that drinking helps them perform better sexually; that drinking will result in difficulty thinking clearly or speaking clearly. Such beliefs result from observing the outcomes of drinking by others (both *in vivo* and portrayed in popular culture) and by recalling (and anticipating) effects from one's own past drinking. Beliefs about the outcomes of drinking also appear to be contextual, depending on, for example, how much one anticipates drinking and what type of alcohol one will drink.

Using interview and any one of several paper-and-pencil self-report inventories, therapists and clients can learn the content and strength of the client's alcohol outcome expectancies. Clients are guided to examine which of their expectancies are realistic, and which exaggerate the benefits or minimize the harms of excessive drinking. Unrealistically positive outcomes that the client associates with excessive drinking can be challenged; alternate ways to achieve positive outcomes can be explored; and undesirable outcomes expected as a result of immoderate drinking can be reinforced.

J. Cue Exposure Therapy (CET)

Another cognitive-behavioral intervention—cue exposure with response prevention—has been used to help clients who want to control their drinking, as well as those who want to abstain. The assumption underlying CET is that a variety of cues have been associated over time with craving for and excessive consumption of alcohol. As a result, cues paired with withdrawal and relief drinking can come to elicit a conditioned desire or craving when the experienced drinker is in the presence of those cues. These cues include, for example, seeing or imagining one's favorite alcohol beverage, experiencing certain emotional states, being in the presence of other problem drinkers, and attending social events such as parties. Locations where one buys or consumes alcohol, illicit drug use and cigarette smoking, and, of course, consumption of an alcoholic beverage, may also trigger craving and excessive drinking.

CET is based on the idea that repeated exposure to these cues—without engaging in the conditioned response of perseverative drinking—can break the connection between experience of these cues, the strong desire or craving to drink, and relapse drinking. For clients with a moderate drinking goal, CET helps the client learn to resist urges to continue drinking in the presence of alcohol and other drinking cues *after* having consumed one or more alcoholic drinks.

CET with a moderate drinking goal (CET-MDG) involves repeated sessions during which the client is exposed to cues designed to elicit desire for additional alcohol after the client has consumed a priming dose of one or more drinks. In addition to the sight and smell of one's favorite beverage, cues can include photos or videos portraying other people drinking, verbal descriptions of likely drinking situations, and role-plays designed to provoke emotions that elicit craving. Each CET-MDG session typically involves two or three "cue exposure episodes," with repeated assessment of craving,

intoxication or self-efficacy, often combined with practice of coping skills to deal with one's desire to continue drinking. CET continues until the client reports that exposure to cues no longer provokes meaningful cravings. Throughout the therapy, clients are encouraged to engage and work through their cravings, instead of fearing, avoiding, or giving in to cravings.

Although the therapy takes place initially in the clinical setting, the client can be instructed to engage in self-guided cue exposure sessions in between sessions to build self-efficacy and promote generalization to the natural environment. Another way to facilitate generalization is to follow successful clinic-based sessions with therapist-guided cue exposure sessions in real-life settings. For example, clients could be escorted to a bar or restaurant where they typically drink excessively. Similarly to the clinic-based sessions, after consuming the priming dose of alcohol, the client would be asked to imagine experiencing emotions or interacting with persons who might provoke craving. As in the clinic, craving and self-efficacy would be measured periodically during the *in vivo* cue exposure session and the therapist and client would review how the client responded to cue exposure.

During the course of CET-MDG, the client learns that the desire to continue drinking, even after one has had a priming dose (that is, a moderate amount of alcohol), will dissipate with the passage of time (habituation) and the employment of various coping skills. Although cue exposure is based on classical conditioning, and presumably works by gradual extinction or deconditioning of craving, cue exposure may also work by increasing a client's self-efficacy. That is, CET-MDG may also increase a client's belief that he or she can successfully and repeatedly resist the temptation or craving to continue drinking past one's limits, even after consuming one or more drinks. For some clients, this realization is a powerful therapeutic experience.

III. MODES OF CONTROLLED DRINKING TRAINING

Behavioral self-control training and cue exposure therapy may be delivered using both individual therapy and group therapy. In addition, there are self-help pamphlets and books that have been written for clients (and therapists) to employ as guides to moderate drinking. For those clients who are comfortable with personal computers, there is software that teaches clients behavioral self-control techniques to modify their drinking.

IV. SOCIAL SUPPORT FOR MODERATE DRINKING

It seems reasonable to assume that family and friends serve as models for both controlled and uncontrolled drinking, and the therapist should assess whether their drinking habits will serve as a model for moderate drinking by the client. Also, because friends, family members, employers, probation officers, and others may believe that abstinence is the only achievable outcome for the client, clinicians should assess how supportive significant others will be of a controlled drinking goal by the client. These persons may benefit from education by the therapist regarding the prevalence of controlled drinking and the advantages of a trial of behavioral self-control training and cue exposure therapy for clients who want to moderate their drinking.

Social support may also be provided by other former problem-drinkers who are moderating their drinking. For example, mutual help groups for problem drinkers who want to moderate their drinking have been formed in the United States (Moderation Management; website address: <http://www.moderation.org>). Therapists might also consider facilitating postdischarge support groups for clients who have participated in controlled drinking training programs.

V. THEORETICAL BASES

Most controlled drinking interventions described above are based on teaching and reinforcing behavioral self-control. That is, the client is taught new skills and encouraged to employ existing skills to exercise control over when, where, why, and how much he or she drinks alcohol. The vast majority of outcome studies assessing the effectiveness of controlled drinking training have evaluated interventions based on principles of operant, associative, and observational learning. It is important to note, however, that cognitive-behavioral therapies are frequently used to help clients achieve abstinence, and that psychodynamic, humanistic, and other therapeutic approaches may be employed to help clients who want to moderate their drinking.

VI. APPLICATIONS AND EXCLUSIONS

Although some problem drinkers want to and will be able to drink moderately, many clinicians wonder if it is

worth offering controlled drinking training. Shouldn't clients always be told to abstain, both for their mental and physical health? Although abstinence might seem the easier and safer goal choice for those who abuse or are dependent on alcohol, there are several advantages of offering moderation as an outcome goal and moderation training as an intervention for persons with drinking problems.

A. Advantages of Offering Controlled Drinking in Treatment

First, moderation training may be viewed as one form of harm reduction. Harm reduction, broadly defined, refers to interventions designed to reduce, minimize, or eliminate unhealthy outcomes that might result from continuing to engage in high-risk behaviors. For example, controlled drinking by high-risk and incipient problem drinkers may arrest or reduce a pattern of drinking that would result in negative consequences later in life. It may also benefit heavy drinkers who might not otherwise go on to develop drinking problems, but who would still benefit from reducing their consumption.

Second, there is a growing body of evidence indicating potential health benefits of moderate drinking. Controlled drinking may also facilitate client participation in social, familial, and occupational situations and activities in which alcohol is consumed in moderation, both for its taste and its effects on conviviality. Even if only a subset of those with drinking problems are able to moderate their drinking, a history of alcohol abuse or dependence need not automatically preclude every problem drinker from enjoying the benefits of moderate consumption of alcohol.

Third, some outcome studies suggest that younger, male patients may be less likely to relapse, or more likely to experience healthy psychological and social functioning, if they are moderating their drinking rather than abstaining. Just as abstinence is a more stable and functional outcome for some problem drinkers, controlled drinking appears to be a more stable or functional outcome for others. Excessive drinking often leads to poor health and poor psychosocial adjustment, but that does not mean abstinence is the exclusive or automatic route to good health and adjustment.

Fourth, an abstinence-only requirement may reduce the attractiveness of psychotherapy for many alcohol-dependent and alcohol-abusing persons. A therapist who is open to discussion of nonabstinence outcome goals may be more likely to motivate change by problem drinkers who are ambivalent about the prospect of

life-long abstinence and who would otherwise not seek or stay in therapy. In addition, controlled drinking has advantages as an intermediate step on the way to abstinence for clients who might decide to abstain after successfully (or unsuccessfully) attempting to moderate their drinking.

A related advantage is that open discussion of controlled drinking, as either an intermediate or final outcome goal, acknowledges the reality that the ultimate decision to aim for abstinence or moderate drinking rests with the client. A clinician can provide helpful guidance as the client wrestles with this decision, but it is unrealistic to think that clients automatically accept treatment goals imposed on them by psychotherapists, probation officers, physicians, AA sponsors, or family members. Contrary to clinical lore about the necessity of accepting abstinence as the first step in recovery, some researchers have found that patients' acceptance or rejection of abstinence-only beliefs is not related to drinking outcome. The insistence by some service providers that clients accept abstinence as a condition of treatment may not be necessary for treatment success.

Finally, the client who selects his or her drinking outcome goal may be more likely to engage in therapy than the client who believes that an abstinence or moderate drinking goal has been imposed by someone else. For those health care professionals who have limited experience negotiating outcome goals with clients, William Miller and Stephen Rollnick published a book in 1991 on motivational interviewing techniques that are designed to promote change without countertherapeutic confrontation.

As any clinician who conducts controlled drinking therapy will readily acknowledge, some problem drinkers—based on their drinking history, previous treatment experience, health status, and so on—are best counseled to consider abstinence rather than controlled drinking. However, encouraging abstinence based on a client's individual situation seems likely to foster a different working relationship than demanding abstinence as a condition of therapy. Even for those clients for whom abstinence seems a healthier short-term or final outcome goal, moderate drinking is an improvement over the excessive, unhealthy drinking that led to treatment.

B. Who Is an Appropriate Candidate for Moderate Drinking?

It appears that a subset of problem drinkers control their drinking, either through their own efforts or with

training in behavioral self-control skills. Furthermore, controlled drinking does not inevitably result in relapse, and perhaps no more so than does abstinence. Therefore, the important question faced by both clinicians and problem drinkers is not, "Does controlled drinking occur?," but rather, "For which problem drinkers is controlled drinking an appropriate goal?" Reviews of patient characteristics associated with controlled drinking, abstinence, and relapse have concluded that several variables hold promise as predictors of moderate drinking, including severity of dependence, "alcoholic" self-concept or identity, and psychological and social functioning.

1. Severity of Dependence

This characteristic has received considerable attention as a factor that differentiates good candidates for controlled drinking from poor candidates. Specifically, some investigations have found moderate drinking more likely if the problem drinker has a history of relatively few signs and symptoms of dependence. However, other studies have reported that severity of dependence was not associated with outcome or found outcome associated with certain aspects of severity (e.g., presence of liver disease), but not others (e.g., duration of problem drinking).

The inconsistency with which severity of dependence predicts outcome across studies may be a function of how severity is measured. Future research may reveal that some measures of dependence (e.g., number of withdrawal symptoms, duration of drinking, negative consequences) predict controlled drinking better than do others. Also, even though the likelihood of moderate drinking may decline as severity of dependence increases, there may be a range of severity within which the likelihood of controlled drinking remains relatively constant. A subset of even the most severely dependent drinkers may be able to moderate their drinking as a function of other personal and environmental factors.

2. Alcoholic Identity

This characteristic, which has also been summarized using the term "persuasion," reflects the self-conceptualization of the problem drinker. Specifically, patients' selection of controlled drinking as their outcome goal, their beliefs and expectations of control, and their rejection of the label "alcoholic" appear to be associated with moderate drinking. Nonetheless, the number of problem drinkers who want to moderate their drinking (and the number who want to abstain) is larger than the number who will achieve their desired outcome. In addition, we

are faced with the challenge of distinguishing problem drinkers whose selection of controlled drinking (or abstinence) as an outcome goal is reasonably attainable from those whose choice is unrealistic. Furthermore, severity of dependence and self-conceptualization may be correlated in a substantial subset of problem drinkers. Subjective expectancy of being able to control one's drinking, and one's willingness to adopt an identity as "alcoholic," are probably correlated with one's history of tolerance and withdrawal and the experience of negative alcohol-related consequences that are considered indications of dependence.

3. Psychological and Social Functioning

In light of research showing that premorbid functioning predicts outcome in a variety of psychological disorders, it is not surprising that pretreatment psychological and social functioning also predict outcome in persons with alcohol problems. Specifically, psychological adjustment and better social functioning (e.g., intact family, social support, employment) are correlated with moderate drinking after discharge from alcoholism treatment. Social and psychological stability may contribute to outcome independently of severity of dependence and alcoholic identity, but we should consider the possibility that psychosocial functioning probably influences, and is influenced by, a problem drinker's drinking history, goal choice, and identity.

4. Demographic Variables and Family History Variables

Based on the current evidence, education and race are not consistently correlated with outcome, although there is some support for the prospect that younger drinkers (and perhaps older drinkers who have "burned out") may be appropriate candidates for controlled drinking. Also, some investigations that have included both genders found a larger proportion of those controlling their drinking during follow-up were women, and more research may reveal the biological, psychological, and social aspects of gender that influence drinking outcome. Although there has been considerable attention to the hypothesis that a predisposition to alcoholism is inherited, family history of drinking problems does not appear to be a consistently reliable predictor of which clients will moderate their drinking and which will abstain.

5. Integrating Multiple Predictors

An integrative model to predict treatment outcome published by G. Elal-Lawrence and colleagues in 1986 may serve as a useful guide to assessing a client's candi-

dacy for controlled drinking therapy. This model posits that it is the congruent or incongruent interrelationship among cognitive, behavioral, and physiological characteristics that predicts controlled drinking, abstinence, or relapse. Specifically, controlled drinking would be more likely if a problem drinker does not hold an abstinence-only ideology, believes he or she can control his or her drinking, and is in good physiological health. Abstinence would be more likely if the problem drinker holds an abstinence ideology, believes he or she can abstain from drinking, and is physiologically healthy. The model predicts relapse will result when the problem drinker has a poor physiological history (i.e., greater severity of dependence) and does not expect to be able to abstain, but believes that abstinence is the only appropriate outcome goal.

The model is a useful addition to the literature on predictors of outcome because it integrates multiple variables into meaningful dimensions, rather than simply counting the number of characteristics associated with controlled drinking or abstinence. It also explains why relapsers, abstainers, and moderate drinkers appear similar on some variables while differing on others: it is not any one client characteristic that is predictive, but the congruence–incongruence of one's drinking identity, one's outcome expectancies, and one's severity of dependence that is predictive. In addition to assessing these client characteristics, the clinician and client should also consider posttreatment environment and skills for coping with stressful life events as predictors of drinking outcome over time.

Although moderate drinking has been associated with lower severity of dependence, rejection of an alcoholic identity, selection and expectation of controlled drinking as an outcome goal, psychosocial stability, and a supportive posttreatment environment (and perhaps youth and female gender), these results should not be interpreted as indicating that every problem drinker who possesses these characteristics will be able to control his or her drinking. Nor should one assume that a problem drinker must possess all of the predictive characteristics to moderate one's drinking successfully. There is still considerable need for research on how to best match clients to specific therapies and specific environments to help them achieve specific drinking outcomes.

C. Acceptance of Controlled Drinking

As noted earlier, controlled drinking training is controversial in some countries and its application may be

limited by institutional treatment philosophy and setting. For example, abstinence is the predominant outcome goal prescribed for alcoholics and problem drinkers in American alcoholism treatment programs. A survey of American alcohol treatment agencies found that controlled drinking was considered unacceptable for clients in almost every responding residential program (including inpatient detoxification and rehabilitation services as well as halfway houses). However, almost one-half of the responding outpatient programs reported moderate drinking as appropriate for a minority of their clientele (e.g., drunk driving offenders).

Canadian alcohol treatment programs typically report somewhat more acceptance of controlled drinking than their geographic neighbor. A nationwide survey employing a random sample of Canadian alcohol treatment services found that about 40% of responding agencies endorsed controlled drinking as an acceptable goal for their clientele. Furthermore, one-third of the respondents working in agencies that did not offer controlled drinking reported moderate drinking as acceptable for clients in other services or for their own clients after they left the agency. Acceptance rates vary by type of service, with those programs treating more severely dependent clients (e.g., inpatient programs, community residential services, and halfway houses) rejecting controlled drinking as an outcome goal more frequently than outpatient services.

Unlike the United States, national surveys of Western European and Australian services have found widespread acceptance and application of controlled drinking as an outcome goal for problem drinkers. For example, two surveys of British alcohol treatment agencies revealed that about three-fourths of services found controlled drinking acceptable. Norwegian alcohol treatment centers are even more accepting of controlled drinking; 90% of respondents reported allowing outpatient clients to choose between abstinence and moderate drinking and 59% reported allowing inpatients a choice between outcome goals. Controlled drinking is also widely acceptable in Australia, with almost three-fourths of surveyed agencies in New South Wales accepting controlled drinking as an appropriate goal for some proportion of clients. Similarly to the results of surveys in the United States, United Kingdom, and Canada, acceptance varied by type of service in the Australian study. The vast majority of community-based services and alcohol treatment units endorsed controlled drinking, but none of the private services and only about one-fourth of residential services reported controlled drinking as acceptable.

VII. EMPIRICAL STUDIES

Empirical evaluations of controlled drinking training began to be published in the early 1970s. Over the past three decades, investigators have conducted studies using single case experimental designs and group designs to assess the effect of different components of behavioral self-control training and, to a lesser extent, cue exposure therapy, in a variety of outpatient and inpatient settings with both alcohol abusing and more severely dependent drinkers. Although the results of any one study may be discounted based on concerns about the quality of treatment, definition of the subject population, and validity of dependent measures and follow-up procedures, the effectiveness of cognitive-behavior therapy to help clients moderate their drinking has been demonstrated repeatedly.

Although not without their own disadvantages, meta-analytic reviews offer an alternative to critiques of individual investigations and narrative reviews because meta-analysis averages effect sizes across outcome studies that have employed different dependent measures. Furthermore, meta-analysis can be used to assess the association of outcome with client and study characteristics. In 2000, Glenn Walters conducted just such a meta-analysis to evaluate the efficacy of behavioral self-control training (BSCT) for problem drinkers.

Following a literature search to gather potentially relevant studies for review, Walters selected 17 studies published between 1973 and 1997 in which the investigators had compared BSCT to either a no-treatment control or otherwise treated comparison group. The combined effect size across all studies, dependent measures, follow-up periods, and types of drinking problem was .33, indicating a statistically significant and clinically meaningful relationship between this form of therapy and improved functioning.

Analyses of effect sizes by type of comparison group revealed that BSCT was superior to no-treatment controls and to other non-BSCT interventions for controlled drinking; BSCT was equally effective in achieving improvements in drinking and functioning as were abstinence-oriented interventions. Effect sizes did not differ significantly by type of outcome variable (that is, alcohol consumption versus drinking-related problems), by severity of client drinking (that is, alcohol abuse versus alcohol dependence), or by length of follow-up (that is, less than 1 year versus 1 year or longer). On this basis, Walters concluded that behavioral self-control training has been, on average, as effective as abstinence-oriented interventions and more

effective than non-BSCT interventions to reduce alcohol consumption and drinking-related problems over meaningful follow-up periods in a wide range of problem drinkers.

Cue exposure therapy with a moderation goal has been subjected to considerably less extensive evaluation, but initial research is very promising. For example, a recent study compared BSCT to CET-MDG using a short-term (6 sessions), outpatient, group therapy format (three or four clients with one therapist) with non-dependent, but seriously abusive, drinkers. Clients in the CET-MDG condition consumed a priming dose of 2 or 3 standard drinks (depending on gender), followed by in-session cue exposure and intersession homework of self-directed cue exposure in progressively more challenging situations. Both treatments showed improvements in perceived control, dependence symptoms, and quantity/frequency consumed, but the CET participants reported more improvement on the quantity and frequency measures than the BSCT participants.

VIII. CASE ILLUSTRATION

J.T. was a 21-year-old, male, never-married university student who was referred to an outpatient psychology clinic for assessment of his drinking following a conviction for DUI. By his report, J. typically drank at a student-oriented tavern near campus (although occasionally also in his dorm room) and his average consumption was two or three 15-ounce mugs of beer on Wednesdays, and six 15-ounce mugs of beer on Thursday, Friday, and Saturday nights. Self-monitoring during the initial weeks of therapy were consistent with this report, and also revealed that he occasionally drank as many as 15 standard drinks (beer and distilled spirits) on some evenings. Although the DUI conviction led to his referral, he readily acknowledged concern about his occasional inability to stop drinking once he had begun and he expressed a fear that he was on his way toward becoming a "serious alcoholic."

J.'s responses on the Michigan Alcoholism Screening Test (MAST) indicated he had experienced meaningful negative consequences from drinking, even though his total MAST score (14) was considerably lower than most problem drinkers seen in residential settings. His motivations for drinking were social companionship and enjoyment of the "buzz" of intoxication, but he was more likely to drink if he was feeling frustrated after an argument with his ex-girlfriend, a hectic week, or conflicts with family or friends. His parents were

currently occasional social drinkers, but one of J.'s siblings had had a drinking problem while attending college, and he considered two of his grandparents and several aunts and uncles to be "alcoholics."

During the assessment, J. stated that he desired a goal of controlled drinking rather than abstinence. His age (young adult), abusive (but not dependent) drinking history, lack of commitment to abstinence, and social stability suggested that he was a good candidate for a controlled drinking goal. Discussing with his therapist the advantages of explicit limit-setting, J. decided to moderate his drinking to not more than two or three drinks per night, and not more than three drinking episodes per week. Other therapy goals included increased self-confidence and self-esteem, increased assertiveness, and decreased reliance on alcohol as a coping skill to deal with interpersonal problems.

As both an outcome evaluation and therapeutic intervention, J.T. was asked to self-monitor his drinking, which continued throughout treatment. The self-monitoring initially included type and amount of alcohol consumed per day, drinking context (e.g., time of day, drinking location, companions), and consequences of drinking (both desirable and undesirable). Later in therapy, the self-monitoring form was revised to include recording of his drinking urges and accompanying thoughts and feelings, in addition to amount and type of alcohol consumed.

Initially, several additional components of BSCT (basic alcohol education, goal setting, functional analysis of drinking behavior, generation of coping strategies to be employed in high-risk drinking situations) were employed to help him moderate his drinking. Although the quantity consumed per drinking day decreased compared to baseline, neither J. nor his therapist was satisfied with the impact of these techniques on his drinking. Following an explanation of the rationale and procedure of CET with a moderation goal, J. agreed to a trial of CET. Sessions increased to twice per week for the next 5 weeks: One session each week was devoted to cue exposure and the other session was devoted to working on J.'s non-drinking-related difficulties. (During and following CET, self-esteem, relationship issues, and assertiveness were addressed using a supportive, rational-emotive therapy-based, problem-solving approach. Specifically, the therapist and client engaged in role-play, therapist-guided imagery, and discussion to dispute his unrealistic beliefs.)

The first two CET sessions were conducted in the psychology clinic. The sessions began by having J. drink a priming dose of alcohol (12-ounce can of his favorite

beer consumed in a glass mug), followed by formalized blocks of exposure to visual, tactile, and olfactory cues for drinking (i.e., he opened another 12-ounce can of his favorite beer, poured it into the glass mug, and followed instructions to hold the glass, look at the beer, smell the beer, and imagine how tasty it would be to drink it). The therapist also prompted him to rate his degree of intoxication and craving on a periodic basis.

The next three cue exposure sessions were conducted *in vivo* at J.T.'s favorite tavern. The client and therapist met at the clinic, walked to the tavern, and J. purchased the priming dose (15-ounce mug of his preferred beer). He then made a baseline rating of his desire for a drink and drank the priming dose over a period of approximately 15 minutes. Fifteen minutes after he finished the priming dose, a second mug of beer was purchased and placed in front of the client. He was asked to make the three standard ratings (desire, intoxication, and ability to resist a drink), but formalized blocks of visual, tactile, and olfactory cues were not used in the *in vivo* sessions. Instead, the client and the therapist discussed how delightful it would be to consume the second beer and how wasteful it would be to leave the beer unconsumed. Every several minutes, J. was asked to rate his desire for the beer, his degree of intoxication and his perceived ability to resist consuming the beer. In between ratings, J. and the therapist discussed ways he could cope with cravings.

Self-monitoring data during the CET phase and post-CET counseling phase of therapy revealed that the number of days each week on which he exceeded his drinking goal decreased meaningfully compared to both pretreatment and the initial, pre-CET period of therapy. However, there were occasional days on which he exceeded his goal, sometimes by two or three beers and sometimes by twice that many standard drinks. Qualitative data mirrored the self-monitoring record and revealed a notable change in J.T.'s identity: "[I've] realized I'm not the alcoholic I thought I was turning into, and I've been good about controlling it. There has been more than a couple of times that it has gotten out of hand, but for the most part there are other times that it could have gotten out of hand ... but didn't." When asked what components of therapy he found most helpful, he noted, "[Most useful for me was] probably the self-monitoring, you know, writing stuff down. And the cue exposure stuff we [did] ... especially going to [the *in vivo* bar] a couple of times. I think that's helped a lot ... just realizing I can go there and control it. You know, I had this mindset that once I got in there I wouldn't be able to stop once I started, you know, if I

had one ... I'd have 10." Ten months following termination, a follow-up interview revealed continued maintenance of moderate drinking, absence of negative consequences from drinking, and a psychological sense of mastery over his drinking.

IX. SUMMARY

The definition of controlled drinking may comprise three components: limits on the quantity, frequency, and rate of consumption; lack of negative drinking-related consequences; and a sense of self-efficacy about controlling one's drinking. Although controlled drinking—and abstinence—are relatively infrequent outcomes by more severely dependent drinkers, controlled drinking is apparently common by problem drinkers at the lower end of the severity continuum. Moderate drinking also has been associated with rejection of an alcoholic identity, selection and expectation of controlled drinking as an outcome goal, psychosocial stability, and a supportive posttreatment environment. However, given the instability of drinking patterns in many problem drinkers, and conflicting indicators in some clients, models that propose an interaction among drinking history, health, and cognitive and environmental factors may prove more useful in conceptualizing and predicting drinking over time. Despite the clinical advantages of offering controlled drinking to problem drinkers, and the empirical support for behavioral self-control training and cue exposure therapy to help some problem drinkers moderate their consumption, many alcohol treatment services in the United States and Canada do not offer controlled drinking training or accept controlled drinking as an outcome goal. The acceptance of controlled drinking as an outcome goal is considerably more widespread in Norway, Australia, and the United Kingdom.

GLOSSARY

anti-plan intervention An anti-plan intervention (including an interpretation), is an intervention that may impede patients in their efforts to carry out their unconscious plans. For example, a person who is working to become more independent may be set back by the interpretation that he or she is afraid of his or her dependency (see unconscious plan).

pathogenic belief A belief that is in varying degrees unconscious and that underlies the patients' problems. It warns persons suffering from it that if they attempt to solve their problems, they will endanger themselves or others. For example, persons may be impeded in their quest for success by the pathogenic belief that if they are successful they may hurt others.

pro-plan intervention An intervention (including an interpretation) that patients may use in their efforts to carry out their unconscious plan. For example, patients who want to be successful but believe that their success will hurt others may be helped by the interpretation that they are holding themselves back lest they hurt others.

survivor guilt The kind of guilt felt by persons who believe they have surpassed others by obtaining more of the good

things of life than others. Pathogenic beliefs are often concerned with survivor guilt toward parents and siblings.

unconscious plan The patients' unconscious plan (which in some cases may be partially conscious) specifies where patients want to go in their therapy. The unconscious plan is usually broad, loosely organized, and opportunistic. It is not a blueprint. It takes account of the therapist's personality and of changing life circumstances. An example is a person's planning to overcome his or her fear of rejection so that he or she may develop closer ties to others.

unconscious test An experimental action, ordinarily verbal, that the patient produces in relation to the therapist. The patient's purpose is to disprove his or her pathogenic beliefs. Patients hope that the therapist will pass their tests and so help them to disprove these beliefs. For example, patients who believe that they will be rejected may threaten to stop treatment, hoping unconsciously that the therapist will indicate or imply that the patient should continue.

I. INTRODUCTION TO THE THEORY

Control-mastery theory is a theory of the mind, psychopathology, and psychotherapy. It was introduced by Joseph Weiss, and was investigated empirically and developed by Weiss, Harold Sampson, and the San Francisco Psychotherapy Research Group (formerly the Mount Zion Psychotherapy Research Group).

Control-mastery theory assumes that patients are highly motivated, both consciously and unconsciously, to solve their problems, to rid themselves of symptoms, and to seek highly adaptive and important goals, such

as a sense of well-being, a satisfying relationship, or a meaningful career. Patients are in conflict about wanting to accomplish these things. This is because they suffer from pathogenic beliefs that tell them that by moving toward their goals they will endanger themselves or others. Throughout therapy, patients work with the therapist to change these beliefs and to reach their forbidden goals. They work to disprove their pathogenic beliefs by testing them in relation to the therapist, hoping that the therapist will pass their tests. In addition, patients use therapist interventions and interpretations to realize that their pathogenic beliefs are false, and a poor guide to behavior. The therapist's task is to help patients in their efforts to disprove their pathogenic beliefs and to move toward their goals.

II. THEORETICAL BASES

As our research and the research of academic psychologists have demonstrated, people perform many of the same functions unconsciously that they perform consciously. They unconsciously assess reality, think, and make and carry out decisions and plans. They unconsciously ward off mental contents, such as memories, motives, affects, and ideas, as long as they consider them dangerous. They unconsciously permit such contents to become conscious when they unconsciously decide that they may safely experience them.

Patients develop the pathogenic beliefs, which underlie their psychopathology, usually in early childhood, through traumatic experiences with parents and siblings. These beliefs, which are about reality and morality, may be extremely powerful. This is because for the infant and young child, parents are absolute authorities whom the infant or the young children needs in order to survive. Young children are highly motivated to maintain their all-important attachments to their parents. In order to do this they must believe their parents' teachings are valid, and that the ways their parents treat them are appropriate. For example, a young boy, who experienced himself as neglected by his parents, developed the pathogenic belief that he would and should be neglected, not only by his parents, but also by others.

The strength of children's attachments to their parents, and of the pathogenic beliefs acquired in their relations to their parents, is shown by the observation that adults, who in therapy are attempting to give up their pathogenic beliefs, often feel disloyal to their parents. If adult patients believe they have surpassed their parents by giving up the maladaptive beliefs and behav-

iors that they learned from their parents, and by acquiring more of the good things of life than their parents, they are likely to experience survivor guilt (surpassing guilt) to their parents.

III. THE THERAPEUTIC PROCESS

The therapeutic process is the process by which patients work with their therapists to change their pathogenic beliefs and to pursue the goals forbidden by these beliefs. Patients test their pathogenic beliefs by trial actions (usually verbal) that according to their beliefs should affect the therapist in a particular way. They hope that the therapist will not react as the beliefs predict. If the therapist does not, they may take a small step toward disproving the beliefs. If patients experience the therapist as passing their tests, they will feel safer with the therapist, and they will immediately change in the following ways:

1. They will become less anxious.
2. They will become bolder.
3. They will become more insightful.

Patients in therapy work in accordance with a simple unconscious plan that tells them which problems to tackle and which ones to defer. In making their plans, patients are concerned with many things, especially with avoiding danger. For example, a female patient who unconsciously believed that she had to comply with male authorities lest she hurt them, felt endangered by her therapy with a male therapist. She feared that she would have to accept poor interpretations or follow bad advice. Her plan for the opening days of therapy was to reassure herself against this danger. She tested her belief that she would hurt the therapist if she disagreed with him. First she tested indirectly, then progressively more directly. The therapist passed her tests; he was not upset, and after about 6 months' time the patient had largely overcome her fear of complying with the therapist, and so became relatively comfortable and cooperative.

IV. THE THERAPIST'S APPROACH

The therapist's task is to help patients disprove their pathogenic beliefs and move toward their goals. The therapist's attempts to accomplish this are case-specific. They depend on the therapist's assessments of the

patient's particular beliefs and goals, and the patient's ways of testing his or her pathogenic beliefs. For example, if a patient's primary pathogenic belief is that he or she will be rejected, the therapist might be helpful if he or she is friendly and accepting. If the patient's primary pathogenic belief is that he or she will be intruded upon, or possessed by the therapist, the therapist may be helpful by being unintrusive.

V. EMPIRICAL STUDIES (INCLUDING STUDIES OF THE PATIENT'S PLAN FORMULATION)

The San Francisco Psychotherapy Research Group (formerly the Mount Zion Psychotherapy Research Group) was founded in 1972 by Harold Sampson and Joseph Weiss to investigate and develop the control-mastery theory by formal empirical research methods. A number of our studies were carried out on the transcripts of the analysis of Mrs. C, which had been recorded and transcribed for research purposes. Several of these studies were designed to test our assumption that patients unconsciously control the coming forth of unconscious mental contents, bringing them to consciousness when they unconsciously decide that they may safely do so.

In one such study, Suzanne Gassner, using as data the transcripts of the first hundred sessions of Mrs. C's analysis, tested our hypothesis against two alternative hypotheses. According to one alternative, the patient brings forth repressed unconscious contents when the contents (in this case impulses) are frustrated, and so intensified to the point that they push through the patients' defenses to consciousness. According to the other alternative, the patient brings forth repressed contents when they are disguised to the point that they escape the forces of repression. The three hypotheses may be tested against one another because they make different predictions about what patients feel, while previously repressed contents that have not been interpreted are becoming conscious.

According to our hypothesis, patients have overcome their anxiety about the repressed contents before they come forth and so will not feel particularly anxious while they are emerging. Moreover, because they have overcome their anxiety about the contents, they will not need to defend themselves against experiencing them as they are coming forth, and so will experience them fully. According to the hypothesis that the contents come forth by pushing through the defenses, the

patient will come in conflict with them, and so feel increased anxiety while they are coming forth. According to the hypothesis that they come forth because they are disguised (or isolated) the person will not feel anxious about them as they are emerging, and because they are disguised, will not experience them fully.

Gassner located a number of mental contents that had been repressed in the first 10 sessions of Mrs. C's analysis, but which came forth spontaneously (without being interpreted) after session 40. She then had judges, by use of rating scales, measure the patient's degree of anxiety, and her level of experiencing, in the segments in which the contents were emerging. Her findings strongly support our hypothesis. The patient was not anxious in these segments (by one measure, she was significantly less anxious than in random segments). Moreover, her level of experiencing in these segments was significantly higher than in random segments.

Another research study was designed to test our hypotheses about the patient's unconscious testing of the therapist, and was carried out by George Silberschatz, using the transcripts of the first 100 sessions of Mrs. C's analysis. From our study of Mrs. C, we had assumed that Mrs. C unconsciously made demands on the analyst so as to assure herself that she could not push him around. We assumed that she would be relieved when the analyst did not yield to her demands. Another group of investigators assumed that Mrs. C unconsciously made demands on the therapist in order to satisfy certain unconscious impulses. They assumed that Mrs. C would become more tense and anxious when the analyst did not yield to her demands. Silberschatz, whose research design was considered satisfactory to both groups of investigators, demonstrated that when the analyst responded to Mrs. C's demands by not yielding to them, Mrs. C became less tense and anxious than before the analyst's response. Silberschatz' findings were statistically significant. These findings strongly support our assumption that the patient is unconsciously testing the analyst by her demands, rather than unconsciously seeking the gratification of unconscious impulses.

Another series of investigations was carried out by our group to test the hypothesis that patients benefit from any intervention, including any interpretation that they can use in their efforts to disprove their pathogenic beliefs and to pursue the goals forbidden by them. We assumed that after a pro-plan intervention, the patients' pathogenic beliefs are temporarily weakened. Therefore, we hypothesized that since patients maintain their repressions in obedience to their pathogenic beliefs, that after a pro-plan intervention, patients

would become a little more insightful, and a little less inhibited. We assumed, too, that anti-plan interventions would not help the patient, or might even set the patient back.

The first step we took in preparation for studying the effects of pro-plan and anti-plan interventions was carried out by Joseph Caston, in 1986. It was to demonstrate that independent judges could agree reliably on a formulation of the patient's plan. Caston broke down the patient's plan formulation into four components: (1) the patient's goals, (2) the obstructions (pathogenic beliefs) that impede patients in the pursuit of their goals, (3) the tests the patient might perform in their efforts to disprove their pathogenic beliefs, and (4) the insights patients could use in their efforts to disprove their pathogenic beliefs.

Caston gave independent judges extensive lists of goals, pathogenic beliefs, tests, and insights, along with the condensed transcripts of the first 10 sessions of Mrs. C's analysis. The judges were asked to read the transcripts, and then to rate the items in each category for their pertinence to the patient's plan. Caston found that the judges did agree on a plan formulation, and that their agreement was statistically significant.

Caston used his plan formulation to evaluate Mrs. C's responses to pro-plan and anti-plan interventions. Caston tested the hypothesis that the patient would respond immediately to pro-plan interventions by becoming bolder and more insightful, and that she would respond negatively to anti-plan interpretations by becoming less insightful, and less bold. Caston found strong confirmation of this hypothesis in his pilot study; however in the replication study he found that the hypothesis held for pro-plan interventions, but not for anti-plan interventions. Apparently Mrs. C responded favorably to pro-plan interventions but was not set back by anti-plan interventions.

In a study of the last 100 sessions of Mrs. C's analysis, Marshall Bush and Suzanne Gassner in 1986 tested the hypothesis that Mrs. C would demonstrate an immediate beneficial effect when offered pro-plan interventions, but that she would be set back by anti-plan interventions. They found strong statistical support for this hypothesis.

Our research group also studied the immediate effects of pro-plan and anti-plan interpretations in brief psychotherapies. Polly Fretter, Jessica Broitman, and Lynn Davilla studied three 16-session psychotherapies to determine whether pro-plan interpretations had a beneficial effect. They used a new version of Caston's method of obtaining a plan formulation that had been

developed by John Curtis and George Silberschatz. In addition, unlike Caston, they did not study the effect of all interventions, but only of interpretations (that is, interventions designed to provide insight).

Fretter showed that following a pro-plan interpretation, the patient was less defensive, and so developed a statistically higher level of experiencing. Broitman demonstrated that after a pro-plan interpretation, the patient became more insightful, as measured by a generic insight scale. Her finding was statistically significant. Davilla, whose findings were statistically significant, demonstrated that the patient, following a pro-plan interpretation, moved toward his or her goals as defined in the patient's plan formulation.

Our group also studied the long-term (as opposed to the immediate) effect of pro-plan interventions. In the three cases investigated by Fretter, Broitman, and Davilla, it was demonstrated that the patient who was offered the highest percentage of pro-plan interpretations did the best, as measured by a series of outcome measures, administered 6 months after the termination of treatment. The patient who received the second highest proportion did the second best, and the patient who received the lowest percentage did the worst.

We also investigated the immediate effect of pro-plan interpretations on the patient's pulse rate, skin conductance, and body movement, in three brief psychotherapies (these are not the same therapies studied by Fretter, Broitman, and Davilla). Nnamdi Pole demonstrated that pro-plan interpretations had an immediate effect on the patient's pulse rate: the pulse rate decreased. His research also showed that the patient sometimes responded very rapidly to pro-plan interpretations: The patient's pulse rate would sometimes fall before the therapist finished an interpretation, and before the patient consciously acknowledged the validity of the interpretation.

Our research group has also studied brief psychotherapies to test the hypothesis that a patient shows an immediate favorable reaction when the therapist passes her tests. Curtis and Silberschatz, in the study of two brief psychotherapies, demonstrated that immediately after a passed test, the patient showed a higher level of experiencing than before the passed test. In another study, Tom Kelly demonstrated that the patient responded to a passed test by an immediate decrease in tension, as measured by a voice stress measure. In a study of one patient, Jerry Linsner showed that after a passed test the patient demonstrated an increase in pro-plan insight as defined in the patient's plan formulation. In a study of three patients, Jack Bugas demonstrated that after a passed test

the patient demonstrated a greater capacity to exert control over regressive behavior.

In our clinical work we observed that pathogenic beliefs are often concerned with survivor guilt. Lynn O'Connor and Jack Berry conducted a series of investigations concerning the role of survivor guilt in psychopathology. These studies were conducted by means of a new pencil-and-paper questionnaire, the Interpersonal Guilt Questionnaire (IGQ), developed by O'Connor and others to measure survivor guilt and several other forms of guilt. The investigations, which were statistically significant, demonstrated that survivor guilt is highly correlated with feelings of shame, and also with feelings of fraudulence and pessimism. It correlates with a tendency to be submissive, and it is high in persons suffering from depression. It is high in recovering addicts and children of alcoholics. It predicted recidivism in a group of women on probation in Massachusetts.

VI. SUMMARY

The control-mastery theory assumes that patients' problems stem from grim, frightening, unconscious, maladaptive beliefs. These beliefs, here called "pathogenic," impede the patient's functioning, and prevent the patient from pursuing highly adaptive goals. Patients suffer from these beliefs, and are highly motivated both to disprove them and to pursue the goals forbidden by them. The patient works throughout therapy in accordance with an unconscious plan to accomplish these things. The thera-

pist's basic task, which follows from the above, is to help patients to disprove their pathogenic beliefs and to pursue their goals. The theory has been supported by numerous formal quantitative research studies.

GLOSSARY

defenses A person's habitual ways of protecting herself or himself against uncomfortable thoughts and feelings.

expressive therapy Therapy aiming to uncover unconscious thoughts, beliefs, and feelings; often stirring up anxiety as new mental content is discovered.

intrapsychic Within one person's mind, not between people.

psychoanalytic Pertaining to the school of thought that values understanding the unconscious mind (e.g., via expressive therapy and psychoanalysis).

supportive therapy Therapy geared at lowering anxiety, helping a patient feel better without necessarily understanding new things about himself or herself.

transference The patient's thoughts, feelings, and beliefs about the therapist that are derived from the relationships the patient had with earlier important relationships such as parents.

I. INTRODUCTION

In 1946, Franz Alexander wrote of the "corrective emotional experience" as the essential helping factor in

psychotherapy. The corrective emotional experience (CEE) refers to the "reexposure of the patient, under more favorable circumstances, to the emotional situations which he could not handle in the past." The reexposure is undertaken in psychotherapy via a reparative relationship with the therapist. Although considered by some to be a mainstay of psychotherapy, the CEE has had a very negative reputation in some circles, notably psychoanalytic ones. This has been perhaps because of some of Alexander's specific practices with the CEE, such as active role-playing in the analytic session. Contemporary studies of the elements of change and cure in psychotherapy suggest that a fresh look at the notion of the CEE reveals an important tool for the therapist. In this article, I will further define the term and put it in historical and contemporary contexts. I will describe the relationship between the CEE and the therapeutic alliance, which is the most robust predictor of good outcomes in psychotherapy.

II. DEFINITION, HISTORY, AND CONTEMPORARY USES OF THE CORRECTIVE EMOTIONAL EXPERIENCE

A. Franz Alexander's Definition

Alexander considered the basic principle of psychotherapy to be the patients' reexperiencing of formerly traumatic situations in the context of a

therapeutic relationship with a new partner, the therapist, who generates an atmosphere of tolerance and equanimity. Given the new relationship, the patient relives problematic events from the past and develops new ways to respond. The prototype for this reexperiencing was Jean Valjean, the hardened criminal in Victor Hugo's "Les Misérables." Alexander uses "reexperiencing" loosely, in that the therapeutic factor was the difference between the initial experiences and those with the therapist, in this case, a bishop.

1. Jean Valjean as the Patient

Jean Valjean was described as an ex-convict who experienced only cruelty in the world until he was startled by the kindness of a bishop he had been robbing. He discovers the effect of this encounter when he meets a little boy who dropped a coin. The ex-convict stepped on the coin, refusing to let the boy retrieve it. The boy ran off, and overcome with remorse, Valjean frantically attempted to find him, return the money, and thereby redeem himself. He did not find the boy but was, as Alexander quoted Hugo, able to start "a colossal and final struggle ... between his wickedness and that man's [the bishop's] goodness."

Alexander noted that the commonplace kindness of the bishop to a nasty ex-convict would not normally deserve our attention, but that the episode with the boy and Hugo's ensuing psychological explanation of Valjean's conversion were a prescient observation about the effects of psychotherapy. The catalyst to the criminal's change was the overwhelming nature of the bishop's generosity. Such generosity threw the criminal's expectations of people's responses into total disarray. Alexander noted that the emotional balance established by the criminal was based on his cruelty in response to his repeated experiences of the cruelty of the world he lived in. When the bishop broke that rule, Valjean experienced "the most formidable assault by which he had yet been shaken." In this state, he mistreated the little boy as if to reestablish the familiar patterns of cruelty by which he had organized his world. But the experience with the bishop so challenged that pattern that he no longer saw the world this way.

Alexander clarifies that a single experience of this sort could not "undo the cumulative effects of lifelong maltreatment" unless the criminal originally had a decent conscience in the first place, one that was later severely tarnished by years of hardship. The originally intact conscience rendered the criminal a good candidate for the very brief "psychotherapy," this experience with the bishop and the little boy.

2. The Role of the Therapist

Alexander specifies that the main job of the therapist is to offer a response to the patient that is utterly unlike the response expected from an authoritative person. Thus, the patient has a repeated opportunity to face, under more favorable circumstances, emotional experiences that were previously intolerable but can now be dealt with in a different manner. He noted that a patient's intellectual understanding of his problems would be insufficient to their cure, that the feelings stirred up in the therapeutic relationship were a mainstay that enables a patient to change.

Alexander described several steps to the process of treating emotional conflict. First, the future patient experiences a number of problematic events, emotionally distressing to the point of being traumatic. The patient comes to expect trouble, especially from significant others around him. The therapist now steps in with a different attitude than the patient expected, and the patient is surprised. The bishop was kind to the man who was robbing him. In being treated better than he deserved, the criminal's armour was chinked—he could no longer perceive people as deserving his meanness, and so began a transformation of his character, an apocryphal tale used by Alexander to describe this new concept, the corrective emotional experience.

Alexander emphasized that the therapist is not neutral, but always maintains a helpful attitude. He also noted that the reactions of the therapist should often not be spontaneous, lest they repeat the parents' problematic reactions to the budding patient, for example, "with impatience or solicitude which caused the neurosis" in the first place. Alexander was referring to patients' tendency to elicit from those around them characteristic responses. The job of the therapist is to know when to respond unspontaneously, to disconfirm the patient's expectations, no matter how tenaciously the patient pulls for them.

B. Reactions to the CEE

Several problems with the CEE concept have discouraged its use over the decades. Four specific problems will be discussed: Alexander's use of medications in the sessions, the lack of applicability of the CEE to all kinds of patients, the use of role-playing to create the CEE in the therapy, and the history of a disdainful attitude toward supportive techniques, as the CEE has generally although erroneously been described.

1. “Narcosynthesis”

Alexander suggested that drug-induced states of mind could be ideal for the CEE to unfold in therapy. Under narcotic treatment, patients could relive in fantasy the past dangers that they had been unable to master. With the therapist present, the patient’s anxiety would be reduced and the patient could become better able to face the previously intolerable situation. Today, in session, use of medications in this way, “narcosynthesis,” is rare, although “reliving” the past with the therapist is a viable strategy for some clinicians, as discussed below.

Writing in the 1940s, Alexander had far less available to him in the way of a pharmacopoeia. Currently, disorders of mood and thought, with symptoms such as mood instability, psychosis, anxiety, and depression are usually addressed with medications. Any current discussion of the CEE makes most sense with the proper use of medications in mind, because no relationship between therapist and patient can begin until the symptoms are manageable. Ironically, although Alexander’s use of in-session medications has little following, the general use of medicines is ubiquitous and psychotherapy can often progress only because of their effects.

2. The Problem of Applying the CEE

Detailed review of past experiences is often a way psychotherapy begins. How such review is used subsequently in the treatment varies with patient and clinician. There is controversy about the efficacy of this method for the treatment of some disorders, given the potential risks that an attempted CEE could bring. For some patients with posttraumatic stress disorder, symptoms can worsen after reexposure to past traumas. In contrast, some recent research by Edna Foa and others shows that it can be very helpful when a patient therapeutically reexperiences past trauma. The astute clinician carefully follows the patient’s state of mind in sessions and knows when reviewing certain material would be likely to help the patient.

3. The Problem of Role-Playing

Alexander was in line with some current psychoanalytic thinking in his emphasis on the patient’s relationship with the therapist as the curative factor in the therapy. He ran afoul of psychoanalytic communities with his approach to the patient via role-playing in psychotherapy. Alexander (and his followers) would attempt to revisit traumatic interpersonal events in a patient’s life by taking the role of the previously trau-

matizing other (e.g., parent, teacher, boss) and enacting scenarios designed to counter these early pathogenic experiences. In the therapeutic setting, the therapist would facilitate reality testing and so enable the patient to feel and respond differently than in the past. The goal was to allow the patient to have the new experience in the safety of the therapist’s office and apply the learning outside the office in his daily life. These psychotherapies were brief in duration, a number of months, and part of the mission was to use role-playing in order to shorten therapies that were growing increasingly unwieldy in their multiyear duration.

Psychoanalysts continue to criticize role-playing as a manipulation of the transference, forcing the patient to notice the “goodness” of the therapist contrasted with the “badness” of previously hurtful others. Howard Levine, writing an annotated list of essential reading in psychoanalytic psychotherapy in 1995, called this play acting the *bete noire* of psychoanalysis, and noted that role-playing contrasted with standard psychoanalytic thoughts of how therapy produces change. Role-playing can be seen as putting the patient in an artificial position, having to respond to the therapist’s theatrics rather than reaching greater awareness about his or her own mental life in the context of the relationship with the therapist.

4. The Problem of CEE as a Supportive Technique

Different kinds of psychotherapies have different aims, which can be described on a supportive–expressive continuum. Supportive techniques shore up a patient’s defenses; expressive techniques analyze defenses and uncover unconscious material. Support in psychotherapy serves to decrease a patient’s anxiety, helps patients feel better about past actions and events, and enables patients to appreciate their skills in adapting to events around them. In psychoanalytic terms, what is supported is the patient’s ego function. The patient is not necessarily helped to understand more about his or her unconscious mind via supportive techniques (but is only able to do so when adequately supported). An example of a supportive comment is: “You seemed to have worked very hard to finish that project and yet the professor crushed you with his comments about it” rather than the relatively unsupportive but more exploratory “How do you understand the professor’s response to your work?” This is relatively unsupportive, but not absolutely; while there is support in the therapist’s attention to and wondering about the story the patient tells, this is an example of expressive technique,

aimed to uncover more than what the patient already knows, thinks and feels.

The generally supportive experience of being accepted is a main feature of the corrective emotional experience, but the emphasis on support was another strike against the CEE. Historically, although not universally, support has been considered a risky if not poor psychoanalytic technique, undermining the possibility for patients to further their understanding of what had been previously unconscious. Anxiety can be a motivator for further self-exploration. When patients are feeling supported, they can relinquish the anxious mood but perhaps also any interest in understanding what they feel and why and how they create trouble in their life. When the goal of treatment is to allay a symptom such as anxiety rather than foster deeper understanding, support is a predominant tool. In psychoanalytic endeavors, anxiety is considered an ally to the therapeutic mission when it motivates the patient to think in new ways and uncover new mental material. As Alexander's use of Jean Valjean as a case example demonstrates, the CEE is both supportive and expressive. In this case, a seemingly supportive move by the bishop was actually experienced as quite anxiety producing for the thief. The thief's capacity for remorse, introspection, and reparative attempts evolved only after his perceptions of the world were shaken, after the bishop startled him with persistent kindness. The thief and the bishop exemplify naturally corrective experiences of life with other people, consistent with Alexander's note that the CEE need not take place only in the relationship with the therapist; there are opportunities for corrective experiences within the relationships of the daily life of the patient.

Given these problems with and misunderstandings about the CEE, it is little wonder that it has not always been considered a useful construct. Thoughtful appraisal of how Alexander defined and used the CEE brings us to the next consideration: how the CEE can be used within the context of the therapeutic alliance.

III. THERAPEUTIC ALLIANCE, CORRECTIVE EMOTIONAL EXPERIENCE, AND THE OUTCOME OF PSYCHOTHERAPY

A. The Therapeutic Alliance

1. Definition of the Therapeutic Alliance

The therapeutic alliance is the connection between patient and therapist, the mutual agreement to work

together on tasks related to the patient's well-being. The alliance is a joint sense of mission, collaboration, trust in the other, and hope. With such an alliance, the patient expects the therapist will understand him, tolerate him, and help him understand himself better and then feel better, now and in the future.

The feeling of being understood, cared about, and cared for is an important emotional state in which to embark on psychotherapy, a *sine qua non* for most patients to even begin considering candid revelation to an utter stranger, the therapist. To feel allied with another person can itself be corrective. When the match between therapist and patient is successful, a surprising, impressive amount of work can be accomplished. It is no surprise then that the single factor in psychotherapy that explains the outcome of the psychotherapy has been repeatedly demonstrated to be the therapeutic alliance.

2. The Therapeutic Alliance and Psychotherapy Outcome Studies

Psychotherapy is difficult to study. Psychotherapy outcome studies show that psychotherapy does work: patients, family members, therapists, and neutral research judges agree, based on a generous variety of measures such as symptom checklists, mental health rating scales, and measures of ability to function at home and at work. The one element common to the successful psychotherapies is the therapeutic alliance. The repeated showing of the alliance as the main predictor of good outcome leads scholars and clinicians to consider the alliance the "quintessential" aspect of all psychotherapies.

B. The CEE as a Tool for the Therapist Who Has a Therapeutic Alliance with the Patient

Psychotherapy takes place only in the context of an adequate therapeutic alliance. In this circumstance, the therapist has access to various tools such as supporting the patient's better efforts at self-understanding, questioning the wisdom of others, medicating the more severe symptoms, and using the CEE to alert the patient to a new perspective on interpersonal relationships. In this context, the surprises of the corrective emotional experience can unfold as the therapist disconfirms the expected responses that the patient has long come to elicit from others.

Much that is inherent in psychotherapy would be an example of the CEE tool: the therapist being timely, in speech and presence; having reasonably pleasant facial

expressions when greeting the patient; looking at and listening the patient; remembering the content of the last session and the dreams and stories of previous discussions; knowing the important anniversary dates in the patient's life, and so on. These techniques tell the patient he or she is valued, worthy of listening to, and being helped. The CEE as a tool differs from the narrower specificity of other tools, such as interpretive comments about material previously out of the patient's conscious awareness. Once thought by psychoanalysts and analytically oriented clinicians to be the most crucial technique for therapeutic success, interpretations are now considered by some to be another valid tool but not the most valuable one. Hanna Levenson, in her 1995 review of time-limited therapies, considers the CEE to be the "modernist" way of construing the historically important accurate and precise interpretation of unconscious material, emphasizing the relational rather than the intrapsychic in psychotherapy. The importance attributed to relational over interpretive tools of the therapist has increased in recent years, concordant with the repeated findings of good therapeutic outcome based on the relationship rather than on the accuracy of interpretation.

C. The Therapist's Judgment

The importance of the therapeutic alliance, the therapist's most basic tool, and the use of the CEE as a specialized tool are not to suggest that the therapist is without judgmental capacity. Therapy would not be worth much were that so. Rather, the therapist offers a reasonably balanced ear and may certainly disagree with and disapprove of some of the patient's behaviors and plans. For example, a patient prone to feeling entitled to more than her due, who treats others with contempt, has her CEE when the therapist enables her to hear her disdain and consider how this stance puts people off and has probably contributed to the patient's need for the therapy.

IV. SUMMARY

The CEE as an explicit concept has been with therapists since the 1940s. It has elements of both supportive and expressive psychotherapeutic technique. The corrective emotional experience is felt by the patient who expects certain responses from people but is instead surprised by the therapist's disconfirmation of the

expected response. It is a tool available to the therapist who has formed a good therapeutic alliance with the patient. In its more dramatic incarnations, such as when induced by medications in a therapy session, it has been eschewed by psychoanalysts. More gently introduced, it is part of every psychotherapy that has helped a patient and merits a place in future psychotherapy research studies that can further the understanding of how and why psychotherapy works.

Acknowledgments

I want to express my appreciation to Jonathan Fried for editorial assistance, and to colleagues Susan Bers, Lisa Marcus, Nancy Olson, and Joan Wexler for insightful comments about the CEE.

Correspondence Training

Karen T. Carey

California State University, Fresno

- I. Description of Treatment
 - II. Theoretical Bases
 - III. Empirical Studies
 - IV. Summary
- Further Reading

Correspondence training involves developing the relationship between children's verbal accounts of behavior and their actual behavior, between saying and doing. According to Ruth Baer, J. Williams, Patricia Osnes, and Trevor Stokes in 1983, correspondence training is training in "promise keeping."

GLOSSARY

- delayed reinforcement** Reinforcement occurs after some period of delay following a correct response to a target behavior.
- generalization** The result of behavior change occurring under different conditions, settings, and behaviors from the original targeted conditions, settings, and behaviors.
- maintenance** The maintaining of behaviors over time following an intervention.
- natural communities of reinforcement** Reinforcement that is available in the normal, day-to-day environment.
- prompt** Verbal directions, modeling, or physical guidance that help an individual initiate a response.
- self-regulation** Involves observation or monitoring of one's own behavior, judgmental processes concerning one's own performance, and reactions of the individual to his or her behavior and performance.
- social reinforcement** Reinforcement that can include physical contact such as hugs or verbal statements such as approval when an individual engages in an appropriate response.
- tangible reinforcement** Objects, such as toys or stickers for young children, given when an individual engages in an appropriate response.
- target behavior** The behavior selected for change.

I. DESCRIPTION OF TREATMENT

The focus of correspondence training is on verbalizations used to mediate behaviors. According to Ruth Baer, J. Williams, Patricia Osnes, and Trevor Stokes in 1983, "reinforcement is made contingent on both promising to engage in a target response and then actually doing so, or on truthfully reporting past actions" (p. 479).

In general, the treatment involves asking the child what he or she plans to do in a certain situation (e.g., "Are you going to talk to your teacher today?"). If the child responds positively to the question asked, the adult restates the behavior or tells the child to engage in the behavior (e.g., "Ok, you will talk to your teacher today"). If the child does not spontaneously respond to the initial question, the adult prompts the child until the child responds.

After the child has had an opportunity to engage in the behavior the child is provided with feedback regarding his or her behavior. If the child engaged in the behavior (i.e., talked to the teacher), the child is verbally,

socially, or tangibly reinforced. If the criterion was not met (i.e., the child did not talk to the teacher), the adult tells the child the criterion was not met and does not provide a reinforcer (e.g., "You said you were going to talk to your teacher today, but you didn't, so you can't have a sticker"). By repeatedly reinforcing correspondence between a child's verbal and nonverbal behavior it is expected that the child's verbal behavior will serve as a powerful discriminant stimulus for appropriate responding.

II. THEORETICAL BASES

Correspondence training is a self-mediated intervention technique. Such techniques are based on the concept of self-regulation, which involves one's ability to monitor one's own behavior. According to Frederick Kanfer and Paul Karoly in 1982, self-regulation or self-management "signifies the gradual assumption of control by the individual over cueing, directing, rewarding, and correcting his or her own behavior" (p. 576). Methods of external control by parents, teachers, or peers can be used to teach self-management skills.

Furthermore, language has been a target for many self-regulation intervention efforts for several reasons. First, language is often a well-developed skill with a pattern that results in some control over one's behavior. Second, language can be readily used across different environments and with different individuals. Lastly, language can be used conveniently and with little effort. Thus, language may facilitate behavioral changes across inconvenient settings and difficult circumstances.

Correspondence training is a type of self-regulation whereby the individual verbally agrees to engage in some targeted behavior and then after doing so is reinforced. Results of a number of studies indicate that it is a successful intervention for changing behavior.

III. EMPIRICAL STUDIES

In 1985, Ruth Baer, J. A. Williams, Patricia Osnes, and Trevor Stokes studied the effects of correspondence training with a 3-year-old boy described as having normal intelligence and no major behavior problems. Three behaviors were selected for training: picking up his pajamas after dressing, picking up his clothes after a bath, and choosing fruit for dessert. His mother observed both occurrences and nonoccurrences of the targeted behaviors.

The procedure was examined across two conditions. In the first condition, the child was questioned about specific home behaviors in the late afternoon prior to going home. During this private questioning period the child was asked by the teacher what he was going to do at home. When the child responded correctly he was praised. Prompts were provided to the child when needed in order for him to respond. However, prompts were required for only several sessions in order to elicit complete sentences (e.g., "I'm going to choose fruit for dessert"), and then were withdrawn.

On the next day, reinforcement was given only if the correct promise had been made the preceding day. Even if the behavior was not performed, the correct promise was reinforced. The consequences were described as follows by Ruth Baer, Patricia Osnes, and Trevor Stokes: "a grab bag containing slips of paper, each with one of the following written on it: 1 Big Hug; 2 Big Hugs; 2 Tosses in the Air; 3 Tosses in the Air; 3 Swings; 4 Swings; 5 Swings; 2 Tickles; 3 Tickles; 4 Tickles; Piggy Back Ride; Pick a Toy. If (the child) drew Pick a Toy, he was allowed to choose from a selection of inexpensive trinkets."

In the second condition, the teacher gave social praise and tangible reinforcers for actual correspondence between the promise and behavior: "Yesterday you said you would ... and you did! That's very good! You get to draw from the surprise bag today." Or "Yesterday you said you would ..., but you didn't. That means that you can't pick a surprise today."

The results showed that the second condition involving reinforcement of correspondence immediately changed target behaviors. The delay of reinforcement was successful without the correspondence training only when followed by the successful application of correspondence training to two prior targeted behaviors. Thus it was first necessary to establish a history of correspondence.

Correspondence training may be used for generalization and maintenance of responses. According to Patricia Osnes and Trevor Stokes, correspondence training may help with generalization to facilitate entry into natural communities of reinforcement by increasing the likelihood of reinforcement and positive attention from adults and peers. Through correspondence training children achieve a successful history between verbalizations and actions: what they say they will do and how they actually behave.

Correspondence training has also been used to enhance dinnertime conversation for preschool children. In 1979, Jacque Jewett and Hewitt Clark described the

intervention in the following way: "If the teacher could obtain reasonably accurate information on the children's dinnertime conversation, they could reinforce their corresponding verbal behavior on a delayed basis in the preschool group setting."

The subjects were four children ages 4 and 5 described as middle class, having intelligible speech, and with at least one sibling over the age of 4. Families were paid a nominal amount for participation. The evening meal was tape-recorded and was returned each morning to the school.

Outcome measures of conversations were (1) children's statements of appreciation, (2) conversational questions, and (3) comments "to prompt or to coach the target children" (p. 591). Conversational comments included initiating a topic, continuing a topic, or restating a comment. The central features of the study were (1) taped dinnertime conversations between family members, (2) the simulated family meal held by the preschool teacher, (3) the training sessions, and (4) the feedback sessions.

The training sessions were held in the preschool classroom prior to lunchtime. Based on the teacher's judgment the sessions lasted anywhere from 1 to 10 minutes. The teacher selected topics for the conversations and on the first day of a new topic the teacher modeled examples of comments for that topic. The comments were then taught, using prompting, modeling, practice, and social reinforcement. When the child was able to verbalize the comments independently or within 30 seconds of a modeled comment, the criterion was considered to have been met. The child then had to verbalize the appropriate set of comments for the next meal. Practice was directed toward any difficulties the child had. Correct sentence structure and variation of comments were also prompted.

The teacher then held simulated family style lunches. During this time, the children and teacher role-played a dinnertime meal with the teacher acting as different members of the child's family. Within the context of the teacher's role, she provided the child with social reinforcement. During the first day of each training session the teacher gave prompts freely. Predinner practice occurred in the afternoon and was the same as the prelunch practice.

Each day, at 10:30 a.m. the teacher held a feedback session to check correspondence between what the children reported and what comments were actually made at dinner the previous night. The teacher gave a prompt and the child was asked to repeat the comments: "Did you say all of the right things at dinner?"

"Who did you ask questions to and what did you ask them?"

Further prompts and modeling of the correct responses were allowed for "eligible" children. If the teacher had to assist a child, a brief delay was given. ("Now you're saying it right, but I had to help you. I'll come back in a minute to see if you can remember all by yourself".)

Assistance was given to those children who had not met the criterion. The prompts were continued until the child met the criterion without assistance and earned the reward. The criterion was one comment to each specified family member in each planned category.

A social and snack reinforcement was provided contingent on the correspondence between verbal report and the use of the comments during the family dinner. Lunch feedback, in the afternoon, was identical, except that it focused on the simulated family meal.

Results indicated the effectiveness of the intervention for all four subjects. After the teacher discontinued the intervention, a 2-week follow-up revealed that each child's dinnertime conversation was being maintained by the natural community of reinforcement within each family through parent-child attention, family interaction, and new topics.

Correspondence training has also been used to enhance sharing in young children. Ann Rogers-Warren and Donald Baer, in 1976, developed and implemented such an intervention for use with 33 preschool children. The children were taught to share and praise one another for sharing. The teacher modeled the behaviors for the children and the children practiced sharing and praising one another. Following appropriate sharing and praising, the teacher reinforced the children.

In the first condition, children modeled the behavior and then were asked to report whether or not they engaged in sharing and praising. In this phase, both true and untrue reports of sharing and praising were reinforced. The second condition consisted of reinforcement for true reports of actual sharing and praising, following modeling. Both conditions were effective in increasing sharing behaviors and generalized to other settings. By training children in correspondence between saying and doing, the researchers effectively increased these children's prosocial behaviors.

IV. SUMMARY

Correspondence training is a type of self-regulation with demonstrated usefulness in getting individuals to

do what they say they will do. Particularly useful with young children, correspondence training allows children to achieve success between verbalizations and actions. Learning rules governed by language and then followed by reinforcement can be beneficial in altering children's behavioral trajectories.

GLOSSARY

charges A manager's efforts to recoup costs based on considerations of cost, market, and regulatory compliance—what the market will bear and not necessarily a function of the resources that must be consumed to bring about an intervention.

effectiveness The effect of an intervention in terms of bringing about desired outcomes in real-world conditions.

efficacy The ability of a treatment to bring about desired outcome under ideal conditions (i.e., homogeneous patient population, high fidelity of treatment to an ideal, delivery of defined care, etc.) that usually only pertain in highly controlled research or academic settings.

efficiency The ratio of the cost to benefits, for instance in a cost-benefit analysis, an efficiency ratio of less than one means that the intervention actually makes money.

elasticity The medical service utilization feature that is a measure of the sensitivity of the utilization of benefit to the generosity of the insurance benefit. A particular intervention or service is said to be elastic to the extent that its use is influenced by how much the patient must pay out of pocket as opposed to how much the patient wants/needs the benefit.

CEA ratio The expression of the relative costs per unit of outcome of an intervention designed to improve care in comparison to another intervention or no care.

cost-benefit analysis A method used to evaluate the outcomes and costs of interventions designed to improve health in which all the variables are expressed in economic units.

cost-effective analysis A method used to evaluate the outcomes and costs of interventions designed to improve health in comparison to one another.

cost offset The idea that expenditures in one realm (i.e., psychotherapy benefit) may be accompanied by reduction in expenditures in another (i.e., hospitalization).

opportunity costs The maximal value of a resource if the resource has some alternative use. An example might be the lost wages for the time spent in a doctor's waiting room.

parity The equalization of medical benefit coverage across illness domain categories. For instance, it has been common practice to provide more generous insurance coverage for the expenses associated with medical or physical illnesses in comparison to psychiatric or mental illnesses.

QALY (quality adjusted life years) The preferred outcome measure for societal CEAs in which disability and changes in life expectancy are components of outcome. The quality adjusted dimension refers to a weighting that is based on the premise that some people would rather be dead than live a certain way or alternatively would be ready to trade fewer years of a higher quality of life for more years at a lesser quality of life.

I. INTRODUCTION

Costs have preoccupied the purchasers of care in the last quarter century as health care costs have steadily

outpaced the inflation indices or other measures of costs. With this focus on costs has come also a deep interest in the effectiveness of health care expenditures. Managed care has been one effort to contain costs and direct resources to fund effective care.

The practice of psychotherapy has changed (many would say "suffered") greatly from the policies of managed care that have emphasized reducing costs and utilization in order to save money. This process is documented elsewhere in this Encyclopedia. The efforts to show that psychotherapy is cost-effective for a variety of conditions has been largely successful, if not exhaustive. This article reviews some of the basic ideas of cost-effectiveness generally, as well as specifically for psychotherapy, and indicates some of the questions that the future must address. Formal features of the structure of the field of psychotherapy, such as its large number of potential practitioners and its application to illnesses that are imprecise in their definition and sometimes difficult to distinguish from variants of normal behavior, have created a great deal of wariness on the part of those who manage benefits and pay the bills. Psychotherapy has posed a great challenge to public policymakers who attempt to rationalize the U.S. medical system. Psychotherapy has been denied and limited more than most medical interventions, perhaps in part as a function of the stigma associated with mental illness.

II. INSURANCE COVERAGE FOR PSYCHOTHERAPY

Even before the current era of managed mental health care benefits in which few patients are provided the psychotherapy benefits they actually need, it was common practice for insurance companies to limit coverage for psychotherapy with higher co-payments, stricter yearly limits, and lower lifetime limits than for other medical care. Parity for psychotherapy has not existed. These discriminatory practices were considered justified by insurers because of the widespread assumption that psychotherapy benefits are vulnerable to abuse by those not in need and will, therefore, unnecessarily inflate health care expenditures in a way not shared by other medical benefits. Psychotherapy benefits were said to have "elasticity" in which the use of the benefit is particularly sensitive to what the patient must pay.

The idea of parity of insurance coverage for mental health benefits (i.e., at the same level as for other medical benefits) has been hotly debated with opponents arguing that parity for mental health coverage is far too

expensive to provide. A RAND study by Sturm examined assumptions about the high price of mental health parity expressed in the policy debates surrounding the Mental Health Parity Act of 1996. This study demonstrated that while access to mental health specialty care under conditions of parity increased to 7% of enrollees (compared to 5% of enrollees found in the free care condition in the earlier RAND Health Insurance Experiment), there was a relative shift to outpatient care, reduced hospitalization rates, and reduced payments per service. Children were the main beneficiaries of the expanded availability of benefits that were estimated to cost only an additional \$1.00 per enrollee per year. The assumptions underlying concerns about the high costs of parity for mental health benefits were shown to be incorrect, based on outdated data, and dramatically overstated by a factor of 4 to 8.

III. DIFFICULTIES IN PROVIDING A PSYCHOTHERAPY MEDICAL BENEFIT

The psychotherapy coverage in health care insurance systems in the United States has a long, complex history. The clearest current inadequacy is the lack of parity with medical services for mental as well as physical illness. Physical illnesses are viewed by the public as inevitable, occurring as a person ages, or as a tragic event striking a person down in early life. Except perhaps for those illnesses caused by an individual's behavior that can be seen as self-destructive, such as the role of obesity in heart disease or poor diabetes control, patients who are stricken have the benefit of societal sympathy. Parson's explication of the sick role points to an institutionalized "forgiveness" of a patient's usual social role obligations, as well as the expectation that the patient has not been able to control the condition and will seek competent medical help.

In contrast, mental illness in a family often arouses intense shame and guilt in connection to the anticipated perception of weakness in the ill person as well as in family members. Contributing to these feelings is an ethic in the industrialized Western world that values self-sufficiency and self-control. Mental illness can readily be viewed as a failure to function in the self-contained manner expected.

The social stigma attached to people with mental illness can also spread to those who treat them. The treatment of a person with mental illness is usually highly confidential, commonly resulting in misconceptions

within the lay public about the nature of that treatment, the patients who suffer mental illness, and those who treat them. It is not unusual for patients and their therapists to be regarded with denigration.

Defining and measuring psychotherapy is an important challenge, particularly for those who would manage such care. The delivery of psychotherapy has also only recently become somewhat standardized with the development of a few relatively specific and behaviorally oriented "manualized" approaches. Psychotherapy manuals offer a way to specify indications, goals, and specific techniques of psychotherapy to give a standardized approach. For research ends, standardization has been essential to develop reliable means of evaluating psychotherapy. Furthermore, these approaches have assisted in the clinical training of psychotherapy. However, among clinicians the manualized approach has been criticized for its rigidity and that it can never truly substitute for the expertise of an experienced, dedicated clinician.

IV. COST EFFECTIVENESS

Increasingly policymakers and payers are insisting on a consideration of the economic dimensions of care before an intervention will be provided as a benefit covered by insurance or provided as part of a public sector program for un- or minimally insured patients. Cost-effectiveness (CEA) and cost-benefit analyses (CBA) have emerged as tools that allow an estimation of the cost of providing a particular form of care in relation to other interventions or no care. Cost-benefit and CEAs are similar ways to express the value of an intervention in relation to the effort to bring it about. Cost benefit analyses seek to represent all dimensions of the cost-benefit equation in monetary values whereas CEAs do not require the expression of outcomes in monetary terms. Cost effective analyses are preferred in most health service approaches because of the difficulty in expressing the outcome variables of symptoms, quality of life, and mortality experience in monetary terms. The principles of CEA for medical and mental health programs in general apply to psychotherapy efforts in particular.

A. Perspective

One major issue in the assessment of costs and effectiveness is the perspective of the study that determines the breadth of what is being examined. Different perspectives include: (a) only the resources

furnished by the provider (the "management" perspective), (b) all the explicit resource costs associated with production of the services (the "accountant" perspective), or (c) all explicit and implicit resource costs that would address opportunity costs such as those for resources that are both donated or already owned (the "economist" perspective or "societal" perspective). For example, the management perspective of costs of developing a psychotherapy service in a public sector outpatient clinic would include the number, type, and hours of the psychotherapists assigned to or hired for such a service, the amount of electricity and other utilities they consumed, the costs of their malpractice insurance, and so on. The accountant would add the cost of the management of those services, and various other overhead expenses allocated to this function indirectly but directly incurred by the institution for doing business as an institution, such as the need to provide parking for all the workers, a security force, and so on. The economist would add the "opportunity" costs of using the resources (such as real estate, equipment, personnel) differently (even if they were "donated" without direct cost to the institution), as well as other hidden costs such as the supervision of the staff that was provided free to the institution and in exchange for a faculty appointment by another institution. The societal perspective allows studies to be more easily compared and to understand more clearly the full implications of choices about what to support and not to support.

B. Dimensions of Benefit

A comprehensive cost-effective analysis must take careful account of the economic benefits of an intervention in assessing net economic costs. Just as costs have multiple dimensions, so do benefits. As Weisbrod noted in 1983, these benefits for psychiatric patients might include increased earnings of those treated, changes in labor market behavior that address the ability and willingness of the patient to seek employment, improvement in decision making about the use of expensive services, improved role functioning in terms of family and economic behavior, and improved physical and mental health. It is enormously difficult to measure these benefits economically and to express them accurately in monetary terms. Increasingly, to standardize studies allowing for comparisons and clarity of interpretation of results, one consensus outcome of CEAs is the cost-effectiveness ratio, an expression of the cost per unit of effect or the difference in the cost between the

two compared treatments divided by the difference in effectiveness of the two compared treatments. The cost-effectiveness ratio is the incremental cost of obtaining a particular effect from one intervention in comparison to another. Such a comparison also calls for a universal measure of outcome, the quality adjusted life year (QALY). This measure is the increase in life years (when that is an appropriate measure of effect), weighted for quality, brought about by the intervention.

One difficulty in establishing a broad and coherent policy addressing the support of psychotherapy has been the measurement of the various effects or outcomes of psychotherapy. For instance, it is only recently that there is a growing consensus that outcomes should include not only symptomatic relief, but also the capacity for greater social and vocational performance, utilization of nonpsychiatric as well as psychiatric health services, as well as other quality-of-life measures.

C. Dimensions of Costs

Cost is a complex idea. Cost is the value of the resources being withdrawn from society to bring about a specific intervention. Costs are to be distinguished from charges which are simply a manager's efforts to recoup costs based on considerations of cost, market, and regulatory compliance. Domains of costs that must be considered in a CEA are the following: (a) changes in the use of health care resources, (b) changes in the use of non-health resources, (c) changes in the use of informal care giver time, and (d) changes in the use of the patient time.

Health care costs include the direct costs of the intervention itself (drugs, personnel, supplies, etc.). The methodology for estimating total direct costs (of an intervention, program, etc.) is generally based on determining the unit cost of services and multiplying it by the amount of such services consumed. Different programs within an agency may use different production strategies to produce similar treatments. For instance, long-term psychotherapy provided by social workers may have a different cost structure from long-term psychotherapy provided by psychiatrists.

Another issue concerning the measurement of unit costs concerns the precise definition of the service unit. Service units can be defined as outputs that measure the services received by clients or as input or production inputs that measure the number of hours of staff effort. For example, if a therapist sees five patients during an hour-long group session, the group session can be counted as five client visits and five group hours in terms of output or as one group hour from the perspective of input.

An important concept and a consideration of the cost and benefit of any delivered medical service is the impact on other medical service-seeking behaviors. For instance, it has been shown in some instances that the provision of consultation or psychiatric services reduces the length of stay of hospitalized patients, particularly those suffering from orthopedic injuries. In this case, the difference between the cost of care with and without the second procedure, in this case psychotherapy, is called the "cost offset factor," in which the provision of a relatively inexpensive treatment can substantially influence the utilization of an expensive (usually inpatient) treatment by patients with various illnesses.

Non-health care resources used in the production of an intervention must also be considered. When an agency produces many different services, there are costs not directly attributable to the service in question but which are necessary to the agency's capacity to provide service. These include explicit as well as implicit, off-budget agency costs such as, for example, the time and effort of management to lobby the legislature for increased mental health services.

Furthermore, there are multiple types of costs in addition to production costs. In mental health studies it is customary to address maintenance costs for food, shelter, and other necessities for patients involved because some of the interventions (inpatient settings, some partial hospital programs) provide these services. Law enforcement costs are another type of cost that are relevant in considering the possible cost shifting when the criminal justice system is used as a de facto substitute for the psychiatric treatment system. Other well-known costs are the considerable cost shifting between psychiatric and other health care costs.

The time of the informal care giver(s) must also be considered. The concept of "family burden" addresses the resources consumed by a patient's family to provide care. If a particular service achieves cost reduction by shifting the burden to family members, then this service may end up not being cost-effective from a societal view, but very cost-effective from a provider's view.

The time the patient spends in seeking and receiving treatment is a cost that must also be considered. It should be included in the numerator if it is conceptualized as an opportunity cost and expressed in monetary terms. It can be included in the denominator of the cost-effectiveness ratio if it is conceptualized and measured as a dimension of QALY. If the experience of the treatment is included as part of the effect of care, then it will be difficult to monetize the dimension of time, and it probably should be considered a dimension of QALY.

Another class of costs that can be considered either in the cost numerator or the effectiveness denominator is a class of costs sometimes referred to as indirect costs or productivity costs.

V. STUDIES OF COST EFFECTIVENESS

There have been many studies of the cost-effectiveness for specific disorders or illnesses. A few selected topics are addressed here. These are anxiety disorders, affective disorders, physical illnesses, borderline personality disorder, substance abuse, schizophrenia, and general considerations.

A. Anxiety Disorders

Anxiety disorders are the most common mental health problems and the most expensive, costing 31% of all mental health costs (both direct and indirect) and totaling over \$46.6 billion in 1990. Salvador-Carulla and colleagues measured cost offset in panic disorder that is treated by psychotropic medication and supportive psychotherapy. Patients followed for 1 year experienced a reduction in use of medical treatments in the year following treatment, compared to the year prior, but had an increase in direct costs because of the expense of psychiatric visits and medication. Nonetheless, the indirect costs from sick days decreased by 79%, leading overall to a 30% reduction in total costs for those patients with the treatments.

B. Affective Disorders

Affective disorders are a common illness with 11% of the adult population in the United States suffering each year with an affective disorder. Of these patients, one half have major depression, one third dysthymia, and one sixth bipolar disorder. One fifth of Americans will have an affective illness during their lifetime. Greenberg and colleagues estimated the cost of depression in the United States in 1990, including both the direct costs of medical treatment and the indirect costs from mortality and reduced productivity, at 43 billion dollars. Several investigators have documented the greater disability and medical costs from depression than for other common medical conditions and other mental health disorders. In addition, depressed patients seek general medical care and have higher general medical costs than non-depressed patients.

There are a handful of studies that document directly the cost impact and cost savings of psychotherapy for depressed patients. For patients with major depression, several studies demonstrate cost-effectiveness, particularly when psychotherapy contributes to reduced hospital duration and hospital costs or to decreased costs of successful treatment compared to more usual care. Psychotherapy also leads to decreased costs from reduction in length of hospital stay for depressed medical inpatients. Depression is an extremely costly illness in lost productivity, in pain and suffering, in increased general medical costs, and in loss of life through suicide. If all societal costs are considered, any psychotherapy that has been demonstrated to be effective can almost presumptively be considered cost-effective. In addition, a small number of studies demonstrate directly the cost-effectiveness of a variety of psychotherapeutic approaches for this enormous public health problem.

C. Physical Disorders

Concomitant mental illness complicates medical illness and emotional reactions short of mental illness can profoundly affect the course of physical conditions. Psychotherapeutic interventions have been shown to be profoundly helpful in decreasing pain and suffering in a host of medical conditions and in some they can lead to improved physical health and cost savings in medical care.

A number of studies document the fact that depressed, anxious, and emotionally distressed medical patients utilize more medical services and have more medical expenses and longer hospital stays. Furthermore, patients who are medically ill with psychiatric illness do not respond as well to medical treatment if their psychiatric illness is left untreated. Druss and colleagues have demonstrated that the cost of medical care for depressed patients is higher than for those without mental illness. Rosenheck and colleagues have shown that if the depression is not treated, the medical costs may be increased along with the disability days.

Other results of investigations concerning physical illnesses have included the finding that psychotherapy for families of patients with Alzheimer's disease lowers the health care costs of these patients; that psychiatric consultation lowers health care costs for patients with somatization disorder, and that group therapy in addition further lowers medical costs for these patients. Linden and colleagues undertook a meta-analysis of psychological therapies for patients with heart disease and found significant clinical improvement and improved survival

for those treated with the addition of a psychological approach. Johannesson and colleagues found clinical improvement of coronary artery disease in cardiac patients for programs with multifaceted interventions that include psychotherapy and demonstrated cost-effectiveness in terms of life years gained. Psychotherapeutic services for orthopedic patients have been documented to be cost-effective in the care of some orthopedic patients as well as pain patients by reducing the utilization of other medical services.

While a number of studies of psychotherapy for cancer patients illustrates its beneficial effects in improving adjustment and ameliorating emotional distress, three groups in particular document improved survival when psychotherapy is added to the treatment plan. These cancers are as follows: breast cancer, malignant melanoma, and leukemia and lymphoma.

D. Borderline Personality Disorder

Borderline Personality Disorder is a psychiatric diagnosis that carries a high degree of disease burden in morbidity, mortality, as well as general medical, psychiatric and social costs. Borderline patients have a high rate of suicide attempts and use of emergency medical services. Borderline personality disorder is a potentially devastating mental illness with high costs in pain, suffering, disability, suicide attempts, completed suicides, and high medical, hospital and psychiatric costs. Several different approaches to psychotherapy have proven to be highly cost effective for this disorder by demonstrating that effective care substantially reduces the need for hospital level care. The work of Linehan is the closest to a cost effectiveness study in demonstrating this point.

E. Substance Abuse

Substance abuse is also an enormously expensive public health problem. Tobacco use is associated with 400,000 deaths per year. The costs of alcohol abuse to society have been estimated conservatively to be 99 billion dollars. Patients who abuse alcohol have higher rates of absenteeism, lowered productivity, and disability.

Psychotherapy is a potentially useful and cost-effective treatment for all substance abusers. It more than doubles the number of smokers who quit. Hester and colleagues performed an extensive review of treatments for alcohol abuse and found that brief interventions, social skills training, motivational enhancement, and a community reinforcement approach are all effective. Fals-Stewart found that behavioral couples therapy

provides a highly cost-effective treatment for substance abusers living with a partner, compared to individual treatment. Although both approaches provided cost savings in the social costs of substance abuse, the couples approach was three times as cost savings.

F. Schizophrenia

Schizophrenia is another costly illness for which psychotherapy can be cost-effective. The cost of schizophrenia in the United States in 1991 was 65 billion dollars, including treatment costs (19 billion dollars) and productivity lost due to illness (46 billion dollars). Psychotherapy, especially family therapy, given in combination with medication, has been shown to be cost-effective in the treatment of schizophrenia by decreasing the rate of relapse and the number of days spent in the hospital. Family therapy has been shown to be most effective for the families of patients with schizophrenia who are characterized as showing high "expressed emotion," meaning that there is a tendency for family members to express critical and overinvolved attitudes toward the schizophrenic patient and his or her illness. A number of studies have demonstrated the superiority and cost-effectiveness of family therapy compared to other treatments for schizophrenia.

Lieberman and colleagues as well as others have documented that a form of psychotherapy, social skills training, is also effective in schizophrenia. Patients treated with social skill training show improved social functioning, lowered relapse rates, and decreased time in the hospital compared to controls given other treatments, demonstrating a cost savings effect.

G. General Studies

There are also a number of general studies that have shed light on the question of cost-effectiveness of psychotherapy. Gabbard and colleagues carried out a survey of the literature on the economic impact of psychotherapy published between 1984 and 1994. This review of 18 studies, 10 with random assignment and 8 without random assignment, found that 80% of the former and 100% of the latter suggested that psychotherapy reduces total costs. This review found that psychotherapy appears to be cost-effective, especially for patients with severe disorders, including schizophrenia, bipolar affective disorder, and borderline personality disorder.

One study demonstrating substantial cost offset is a Bell South pilot project from 1991 to 1993 by Saeman, which hints at the complex relationship between medical

services utilization and costs and psychiatric services utilization and costs. Three thousand Bell South workers and their families were given psychiatric benefits including two psychotherapy visits per week or a total of 52 visits a year, a lowered co-payment for psychotherapy visits, partial psychiatric hospitalization services, and an employee assistance program (EAP). There were significant subsequent decreases in psychiatric inpatient stays (by 30%) as well as in both outpatient and inpatient medical and surgical services (by 78% and 87%, respectively). Total health care expenses per company member declined from \$17 to \$8 per month even though outpatient psychiatric services increased by 33% and partial psychiatric hospitalization increased by 45%.

Two other studies demonstrate cost-effectiveness by virtue of a reduction in lost workdays. Klarreich and colleagues found that providing rational-emotive psychotherapy through an EAP of one large company led to a decrease in absenteeism from 10 to 3 days per year per employee equal to a decrease of \$1,054 in the annual cost of absenteeism per employee. For each dollar spent on psychotherapy, the corporation saved \$2.74. In a British study by Mynors-Wallis and colleagues randomly assigned 70 primary care patients with concomitant psychiatric illness to a problem-solving therapy by a trained nurse. The outcome compared with the usual treatment delivered by a general practitioner. There was no difference in clinical outcome as measured by four structured clinical assessment measures. However, the patients who received the psychotherapy had fewer subsequent lost workdays that more than offset the cost of providing the therapy.

VI. CONCLUSION

Although there are too few large-scale studies addressing the cost-effectiveness of psychotherapy for specific diagnostic groups of patients, we can arrive at some important impressions from the studies that we do have. Those that exist do confirm that, for many conditions psychotherapy works, is cost-effective, can often provide a significant cost offset in other medical and hospital expenses, and is not overused or "abused" by those not truly in need. However, there is much work to be done to add explicit detail to these findings.

terial that has been extruded from the projecting person. The target of the projection may or may not become unconsciously responsive to this process and may or may not actually experience elements of it and act accordingly.

transference The emotional reactions of the patient toward the therapist, in which thoughts or feelings related to an early stage of development are “transferred” from the objects (usually parents) of that earlier period to the therapist.

GLOSSARY

countertransference Broadly speaking, any emotional reaction of the therapist toward the patient. There are two definitional traditions: classical and totalistic.

1. The classical definition defines countertransference as the emotional “transference” reactions that the therapist has toward the patient.
2. Totalistic countertransference refers to all the therapist’s emotional reactions toward a patient, which are composed of (a) the therapist’s irrational transference feelings toward the patient, (b) the “realistic” emotional reactions of the therapist toward the patient, and (c) the emotional psychological reactions of the therapist toward the patient that are in response to the patient’s transference reactions toward the therapist.

parallel process Refers to the replication in the relationship between the supervisor and the supervisee of some of the dynamic transference and countertransference elements in the relationship between the patient and the supervisee.

projective identification The process whereby primarily unconscious fantasy is “projected” or imagined to exist in another person with the result that the person projected into will return in some modified version the psychological ma-

I. DEFINITION

Countertransference is a complex concept. Basically, the broad conceptualization is intended to include all the psychological and emotional reactions of the therapist toward the patient. More recently, it has come to signify not only the irrational or transference reactions of the therapist toward the patient, but also the therapist’s emotional reactions to the transference of the patient. Finally, some authors define an aspect of countertransference as the “objective” elements of the therapist’s reaction toward the patient. This includes the idea that the therapist is responding to the realistic dimensions of the qualities of the patient.

II. HISTORY

Freud had coined the term countertransference (*gegenübertragung*) and referenced it only on several occasions during his writing, and never treated it

systematically. Freud seemed to conceptualize countertransference as the analyst's transference toward the patient. Consequently, for Freud the notion of countertransference was a part of therapy that needed to be managed and "kept in check."

Several early analysts conceptualized the relationship between analyst and patient differently from Freud and were interested in modifying the strict rule of neutrality and abstinence. Ferenczi was clearly in this school, as was Michael Balint. Helene Deutsch was among the first to emphasize a different dimension of countertransference, in which she put forward the "complementary attitude" of the identification with the transference objects. She indicated that although these reactions could be an interference with therapy, they also could be a constructive influence and could serve as the underlying elements of empathic responsiveness.

These ideas of the possible usefulness of the countertransference were developed more systematically by Racker and Little, both of whom, coming from an object-relations perspective, developed the idea of the usefulness of countertransference in elucidating the unconscious mental life of the patient. By the time that Racker was writing, the notion of projective identification had been established through the Kleinian approaches.

As the concept of countertransference broadened, and included realistic and predictable dimensions of the analyst's response to the patient and dimensions of the analyst's own conflicts, there grew, along with the admonishment of the dangers of countertransference, the increasing belief that countertransference reactions on the therapist's part could provide important and valuable information about the patient.

With the effort to apply psychoanalytic principles to the treatment of people with severe psychotic disorders, the role of the therapist's response became increasingly more important as a therapeutic tool in the treatment of such patients. Harold Searles was instrumental in developing the idea of the centrality of the therapist's emotional reactions to the patient for a genuine therapeutic process. His work was based on that of many who had gone before, including Freida Fromm-Reichmann, Margaret Little, Phyllis B. Cohen, and Sandor Ferenczi, as well as Harry Stack Sullivan.

III. TYPES OF COUNTERTRANSFERENCE

Countertransference types can be conceptualized on the basis of the content (love, hate, turning away) as a

function of the psychopathology of the patient (psychotic, depressive, borderline, etc), as elements in the analyst's life (the sick, pregnant, or recently traumatized analyst), and specific content as a function of a stage of therapy (beginning, termination, etc.). Enumerating all these possible countertransference reactions is, of course, beyond the scope of this article. However, an account of problematic countertransferences might prove useful.

Victor Altshul and I identified three kinds of problematic countertransferences. These are the turning away countertransference, activated countertransference, and unconscious enactment. Each poses a different kind of problem.

The turning away countertransference includes those kinds of reactions that represent some kind of reduction in interest or investment in the patient. Such states as boredom, apathy, sleepiness, repugnance and forgetfulness are all the manifestations of such a reaction. They all share the property of an inability to feel engaged by the patient. There are, of course, many reasons why the therapist may experience a "turning away" reaction. Such a difficulty in engaging the patient might be due to a psychological effort on the part of the patient to make him- or herself uninteresting or unattractive, and this kind of psychological effort, albeit unconscious, might also reflect a hostile set of motivations toward the analyst.

Whatever the motivations for the genesis of a turning away reaction, it is important for the therapist to recognize that he or she is having such a reaction and to relate it to what is going on with the therapist and the therapy. One of the most important steps in this process is the accurate diagnosis of the emotional responsiveness of the therapist to the patient.

Another form of countertransference that we identified is the activated countertransference. In this instance, empathy is hampered by an intensely positive or negative feeling toward the patient. Positive countertransference might be characterized by intense liking/loving of the patient, desire to be with the patient, and the idealization of the patient's efforts in psychotherapy. Erotic countertransference is a common manifestation, as is an intense maternal countertransference. An intensely negative countertransference is also a form of activated countertransference. Intense hatred or strong negative feelings allude to a special importance in the therapist's mental life filled by the patient.

Activated countertransference carries the burden and seduction of a compulsion to take action. Intense admiration, idealization, erotic feelings, and rescue fantasies for the patient seem so compelling that the impulse to

action is irresistible for some. These reactions become problematic when the therapist loses his or her sense of control of the therapeutic relationship and begins to feel that he or she is there for a different reason, such as to rectify a wrong in the patient's life or to provide comfort when insight is more appropriate.

Another form of problematic countertransference are unconscious enactments. These problematic reactions entail the acting out of a technical failure without the experience of a conscious reaction in the form of a judgment of the failure. For example, as we noted in our previous work, one of us worked with a therapist who forgot the second appointment with the new patient. Initially, he was at a loss to understand why and did not feel particularly troubled or uncomfortable. As the therapy progressed, it became clear that the patient had been severely neglected by parental figures in her past, frequently acting as if the patient did not exist. It soon became clear that the patient had succeeded in evoking in the therapist the feeling of rage and reproach that had to be dealt with by the forgetting enactment.

IV. TECHNICAL IMPLICATIONS

By far the major challenge is for the therapist to be prepared educationally and personally to be aware of and capable of examination of such feelings toward the patient. The therapist must seek to understand the realistic elements of his or her own transference reactions and his or her response to the projective identification processes entailed in the patient's own transference.

Recognizing the problem is a major step in solving it. The key that there is a problem is the presence of any strong feeling about the patient, whether positive or negative. Other clues are attitudes that are unusual for the therapist, slips, momentary forgetting, and other parapraxia may also allude to the fact that there is an unconscious and unacknowledged process between the patient and the therapist that needs to be examined.

It is important for the therapist to be able to recognize his or her own unmet needs that are aroused by the therapy and to identify clearly the patient's contribution to his or her countertransference. There has been a substantial debate in psychotherapeutic circles as to whether elements of countertransference should be disclosed to patients. There are rare occasions when it is useful for there to be substantial disclosure of countertransference feelings toward the patient. Such disclosure is more likely to be burdensome, intensive, and confusing to most patients than it is to be therapeutic. There may be occasions in which it is sensible

for a limited disclosure, but for the most part, disclosure of the therapist's emotional reactions to the patient becomes a burden, particularly early on in the therapy. The therapist should stay away from tactless, intrusive confessions to the patient. However, when the therapist enacts an error and obvious lapse in technique, then it is sensible to acknowledge the lapse and explore this with the patient.

One specialized aspect in which countertransference can play out is in the supervisory process. Sometimes, through the mechanism of unconscious communication and projective identification, the therapist and the supervisor can unwittingly begin to enact by replicating dimensions of the transference-countertransference relationship between the patient and the therapist. This can lead to the therapist coming to act more like the patient in relationship to the supervisor. Again, these kinds of enactments and processes can be used to great benefit to help clarify the kinds of emotional and unconscious themes in the relationship between the patient and the therapist. This process is referred to as a parallel process.

V. CONCLUSION

Countertransference, like resistance, is a concept describing a phenomenon that in the early days of psychoanalysis was viewed as a problematic component of the work. However, the term countertransference has come to be redefined so that it is viewed as an inevitable aspect of the work with patients in an intensive psychotherapeutic manner. Furthermore, this new use of countertransference can be a rich source of information of what is going on within the patient.

GLOSSARY

insight-oriented couples therapy A therapy that emphasizes the interpretation of recurrent maladaptive patterns from a developmental perspective.

Insight-oriented couples therapy emphasizes the interpretation of recurrent maladaptive relationship patterns from a developmental perspective. This article describes the sequence of interventions comprising insight-oriented couples therapy, theoretical explications of the presumed processes by which partners gain a new understanding of dysfunctional relationship themes and modify maladaptive interpersonal exchanges, and empirical findings regarding this treatment approach.

I. DESCRIPTION OF TREATMENT

Insight-oriented approaches to couples therapy emphasize recurrent maladaptive relationship patterns that develop from early interpersonal experiences either in

the family of origin or within other significant emotional relationships. These approaches vary in the extent to which they emphasize the unconscious nature of these relational patterns, the developmental period during which these maladaptive patterns are acquired, and the extent to which interpersonal anxieties derive from frustration of innate drives. However, a shared focus of insight-oriented strategies are previous relationship injuries resulting in sustained interpersonal vulnerabilities and related defensive strategies interfering with emotional intimacy, many of which operate beyond partners' conscious awareness. Consequently, insight-oriented approaches to couples therapy emphasize that partners' maladaptive relationship patterns are likely to continue until they are understood in a developmental context. This exploration and new understanding serve to reduce the couple's attendant anxiety in current relationships and permit them to develop alternative, healthier relationship patterns.

The general sequence of intervention components comprising insight-oriented couples therapy is presented in Table 1. Understanding of maladaptive relationship patterns begins with identifying exaggerated emotional responses to current situations—for example, intense hurt or anger in response to modest disapproval from one's partner. Both partners are encouraged to explore early relationship experiences that evoked similar feelings and to consider how these emotional responses may have originally developed as protective coping strategies or as tactics for satisfying interpersonal needs.

TABLE 1
Sequential Components of Insight-Oriented
Couples Therapy

-
1. Identifying exaggerated emotional responses to current situations.
 2. Framing these responses as acquired affective dispositions in a developmental context.
 3. Identifying affective coping strategies that interfere with higher relationship values.
 4. Promoting resolution of these developmental conflicts through interpretive and related cathartic techniques.
 5. Promoting alternative coping strategies that enhance relationship intimacy.
-

An essential prerequisite to interpretation of relational themes is a thorough knowledge of each partner's relational history. Critical information includes not only the pattern of relationships within the family of origin, but also relational themes in the family extending to prior generations. Beyond the family, intimate relationships with significant others of both genders provide insight regarding prior struggles with such issues as perceived acceptance and valuation by others, trust and disappointment, stability and resilience of relationships to interpersonal injury, levels of attachment and respect for autonomy, and similar relational themes.

Initially, previous relationships are explored without explicit linkage to current relational difficulties, in order to reduce anxiety and resistance during this exploration phase. Both partners are encouraged to remain "intently curious" about their own relational history but to refrain from premature interpretations that may be either incorrect, incomplete, or excessively self-critical. Just as important is for the individual's partner to adopt an accepting, empathic tone during the other's developmental exploration, encouraging self-disclosure in a supportive but noninterpretive manner.

Gradually, as the couple continues to explore tensions and unsatisfying patterns in their own relationship, both partners can be encouraged to examine ways in which exaggerated emotional responses to current situations have at least partial basis in affective dispositions and related coping styles acquired in the developmental context. Developing a shared formulation of core relationship themes is a critical antecedent to subsequent linkage of these themes to current relationship exchanges. Both individuals can be helped to understand that, whereas certain relational coping

strategies may have been adaptive or even essential in previous relationships, the same interpersonal strategies interfere with emotional intimacy and satisfaction in the present relationship.

In insight-oriented couples therapy, the therapist's direct access to exchanges between partners affords a unique opportunity for linking enduring relationship themes to current relationship events. Rather than interpreting exaggerated responses that distort exchanges between either partner and the therapist, the focus is on partners' own exchanges in the immediate moment. Interpretations emphasize linkage of each partner's exaggerated affect and maladaptive responses to his or her own relationship history, emphasizing the repetition of relationship patterns and their maintaining factors in the present context. In linking the couple's current struggles to enduring relationship patterns the therapist encourages attention to the following: How does the immediate conflict between partners relate to core relationship themes explored earlier in the therapy? What are each person's feelings toward the other and their desired response? What impact do they wish to have on the other in this moment? How do their perceptions regarding their partner's inner experience relate to their attitudes toward themselves? What fantasies do they have regarding their partner's possible responses? What kinds of responses from their partner would they anticipate being helpful in modifying their core beliefs about their partner, themselves, and this relationship?

In insight-oriented couples therapy, cognitive linkage of relational themes from early development to the current context is frequently insufficient for reconstructing or modifying these interpersonal patterns. The affective component of interpretation is seen in the reconstruction of these critical emotional experiences in the immediate context; new understanding by both partners often promotes more empathic responses toward both themselves and the other, facilitating more satisfactory resolutions to conflict. Often the individuals must be encouraged to work through previous relationship injuries, grieving losses and unmet needs, expressing ambivalence or anger toward previous critical others in the safety of the conjoint therapy, and acquiring increased differentiation of prior relationships from the present one.

Partners' insight into enduring maladaptive relationship themes makes possible but does not inevitably lead to changes in their own relationship. In addition to interpretive strategies, insight-oriented couples therapy promotes interactions that counteract early maladaptive schemas. Thus, the couple therapist

allows partners' maladaptive patterns to be enacted within limits, but then assists both partners in examining exaggerated affective components of their present exchange. Partners' exaggerated responses are framed as acquired coping strategies that interfere with higher relationship values such as intimacy, trust, altruism, and compassion. Interpretations of the developmental context underlying the current unsatisfactory exchange help both partners to depersonalize the noxious effects of the other's behavior, to feel less wounded, and consequently to be less reactive in a reciprocally negative manner.

Both individuals are encouraged to be less anxious and less condemning of both their own and their partner's affect, and are helped to explore and then express their own affect in less aggressive or antagonistic fashion. Throughout this process, each individual plays a critical therapeutic role by learning to offer a secure context in facilitating their partner's affective self-disclosures in a softened, more vulnerable manner. The couple therapist models empathic understanding for both partners and encourages new patterns of responding that enhance relationship intimacy. That is, by facilitating the nonoccurrence of expected traumatic experiences in the couple's relationship, both individuals are able to challenge assumptions and expectations comprising underlying maladaptive schemas. Thus, therapeutic change results from the experiential learning in which both partners encounter relationship outcomes different from those expected or feared. In response, partners' interactions become more adaptive and flexible in matching the objective reality of current conflicts and realizing opportunities for satisfying more of each other's needs.

II. THEORETICAL BASES

Couple interventions emphasizing the interpretation of maladaptive relationship themes derive from diverse theoretical approaches that can be placed on a continuum from traditional psychoanalytic techniques rooted primarily in object relations theory to schema-based interventions derived from more traditional cognitive theory (see Figure 1).

In its most orthodox formulation, insight-oriented couples therapy derives from object relations theory and its central tenet that the primary drive in infants is to secure attachment to the mother. From interactions primarily with the mother, infants develop internalized images of the self, images of significant others, and sets of trans-

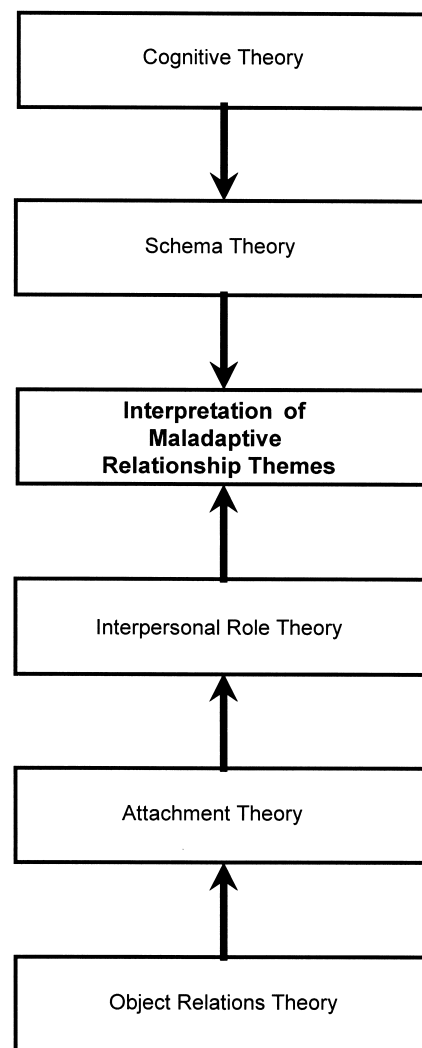

FIGURE 1 Theoretical approaches emphasizing affective and developmental components of couples' distress.

actions connecting these images or objects. From an object relations perspective, maladaptive relationship patterns of adults reflect enduring pathogenic introjects that give rise to inevitable frustration when these are projected onto relationships with significant others. In a distressed marriage, partners' pathogenic introjects interact in an unconscious, complementary manner resulting in repeated disappointments culminating in persistent conflict. Consequently, the goal of psychoanalytically oriented couples therapy is helping partners to modify each other's projections, to distinguish these from objective aspects of their own self, and to assume ownership of their own projections.

Evolving from object relations theory, attachment theory emphasizes the importance of emotional closeness to others as an innate survival function from which infants develop information-processing capabilities and emotional responses intended to foster secure emotional bonds. From an attachment perspective, difficulties in intimate adult relationships may be viewed as stemming from underlying insecure or anxious models of attachment. Partners' dominant emotional experiences drive reciprocal feedback loops maintaining such behaviors as excessive clinging or avoidance. Susan Johnson and Leslie Greenberg developed "emotionally focused couples therapy" (EFT) from an attachment theory perspective.

Interpersonal role theory regards the persistence of maladaptive interpersonal patterns as resulting from their reinforcement by the responses of significant others. Rather than stressing constructs of projective and introjective identification, interpersonal theory emphasizes the unconscious assignment of specific roles to oneself and others in which feared relational events are elicited and enacted by the individual in his or her interactions with others.

Schema theory emphasizes relationship schemas extending beyond attachment to the mother (object relations theory) or significant others (attachment theory) to consider more generally how early relationship experiences influence adult intimate relationships. Although schema theory is linked more closely to traditional cognitive theory than to psychodynamic theory, schema-based approaches to couples therapy overlap considerably with more traditional insight-oriented strategies in their emphasis on interpretation of interpersonal exchanges within the therapy session as a vehicle for change, attention to affect during the processing of schema-related events, and their emphasis on the childhood origins of maladaptive schemas and the emotional reworking of these early experiences.

Drawing on earlier psychodynamic formulations, Douglas Snyder and colleagues described an insight-oriented approach to couples therapy emphasizing affective reconstruction of previous relationship injuries. In affective reconstruction, developmental origins of interpersonal themes and their manifestation in a couple's relationship are explored using techniques roughly akin to traditional interpretive strategies promoting insight, but emphasizing interpersonal schemas and relationship dispositions rather than instinctual impulses or drive derivatives. Previous relationships, their affective components, and strategies for emotional gratification and anxiety containment are reconstructed with a focus on

identifying for each partner consistencies in their interpersonal conflicts and coping styles across relationships. In addition, ways in which previous coping strategies vital to prior relationships represent distortions or inappropriate solutions for emotional intimacy and satisfaction in the current relationship are articulated.

III. EMPIRICAL STUDIES

Among insight-oriented approaches to couples therapy, both the emotionally focused therapy developed by Susan Johnson and Leslie Greenberg and the affective reconstructive therapy described by Douglas Snyder and colleagues have been shown to be effective in reducing couples' distress and improving relationship satisfaction.

Several controlled trials of EFT have been conducted by Johnson, Greenberg, and colleagues—yielding an average effect size of 1.3, indicating that the average couple receiving EFT was better off at the end of treatment than 90% of couples in no-treatment control conditions. Findings have indicated that roughly 70% of couples receiving EFT experience significant reductions in distress in 8 to 12 sessions, and that treatment effects remain stable or improve over time. Research on the process of EFT suggests that engagement with emotional experience and interactional shifts are the active ingredients of change in this approach.

Douglas Snyder and Robert Wills compared their insight-oriented approach emphasizing affective reconstruction with a traditional behavioral couples therapy emphasizing communication skills training and behavior exchange techniques. Thirty couples were randomly assigned to each of these two treatment conditions, and 20 couples were assigned to a wait-list control group. At termination after approximately 20 sessions, couples in both treatment modalities showed significant gains in relationship satisfaction compared to the control group. The effect sizes for both treatments were approximately 1.0, indicating that the average couple receiving either treatment was better off at the end of treatment than 85% of couples in the control condition. By termination, 73% of couples receiving the insight-oriented therapy and 62% of couples receiving the behavioral therapy experienced significant improvement. In addition, couples in both treatment conditions generally maintained their therapeutic gains at 6 months following termination.

However, Snyder and colleagues followed up couples in their treatment study 4 years later and found striking

differences between couples treated with insight-oriented versus traditional behavioral therapy. At 4 years following treatment, 38% of the behavioral couples had experienced divorce, in contrast to only 3% of couples treated in the insight-oriented condition. Based on these findings, Snyder and colleagues argued that spouses' negative views toward their partner's behavior are modified to a greater degree and in a more persistent manner once individuals come to understand and resolve emotional conflicts they bring to the marriage from their own family and relationship histories.

IV. SUMMARY

An important source of couples' difficulties includes partners' emotional injuries from previous relationships resulting in sustained interpersonal vulnerabilities and related defensive strategies interfering with emotional intimacy. Insight-oriented couples therapy affords partners a unique opportunity to free themselves from recurrent maladaptive relationship patterns and pursue the rich emotional rewards that intimate relationships offer.

GLOSSARY

behavioral rehearsal A covert, imaged-based rehearsal of a desired sequence of behavior or course of action.

coverant A covert (internal) operant or response.

covert conditioning The reinforcement, punishment, or extinction of covert (private) events to alter their frequency.

extinction The decrease in the probability of a behavior due to lack of reinforcement.

homogeneity assumption The assumption that all categories of behavior, covert and overt, follow the same laws.

hypnotic susceptibility (trance capacity) The ability to enter a hypnotic trance and to experience a wide variety of perceptual alterations. It is relatively invariant across time and is normally distributed in the population. It may be related to the ability to vividly imagine.

implosive therapy (flooding) Reduction of fear responses by repeated exposure to images of the feared situation without being able to reduce the fear by avoidance.

interaction assumption The assumption that the categories of behavior—overt, covert, and physiological—interact with each other in a reciprocal fashion.

learning assumption The assumption that all behaviors are controlled by the same laws.

modeling (vicarious learning) An increase or decrease in the probability of a behavior that results from observation of a model being reinforced or punished rather than from direct reinforcement or punishment.

negative reinforcement Any consequence that increases the probability of an antecedent response by the withdrawal of the consequence.

operant Any individual response that operates on the environment.

positive reinforcement Any consequence that increases the probability of an antecedent response by its application.

Premack Principle The reinforcement of a lower probability response by a higher probability response.

private event An event or behavior observable only by the observing individual, not by the observing community.

punishment Any consequence that decreases the probability of an antecedent response by its application.

systematic desensitization Reduction of fear responses by repeated pairing images of the feared event with relaxation in a graduated hierarchy.

I. DESCRIPTION OF TREATMENT

In order to modify coverants, psychologists engage in covert conditioning or the conditioning by behavioral procedures in order to control private events. There are several types of covert conditioning procedures, each designed to achieve different results. Four of them, covert sensitization, covert extinction, covert response cost, and the self-control triad (thought-stopping) are designed to decrease the frequency of unde-

sirable behaviors. Two of them, covert positive reinforcement and covert negative reinforcement, are designed to increase the frequency of positive behaviors. Covert modeling can be used to either decrease or increase a target behavior. I will describe each in turn.

A. Covert Sensitization

This is a procedure designed to reduce the frequency of an undesirable behavior by pairing it in imagery with an aversive stimulus (e.g., a nauseous scene). Three aspects are important. First, classical conditioning is used by repeatedly pairing the undesirable behavior with the unpleasant scene. Second, escape conditioning is provided through the use of negative reinforcement whereby the reduction in the undesirable behavior is paired with positive feelings when the unpleasant scene is terminated. Third, it is helpful to relax the client first. For example, a therapist might instruct a client to graphically and in detail visualize how nauseous he feels when he sees a pack of cigarettes and then imagine himself feeling much better as he turns away from the cigarettes. This procedure has been used in hypnotic contexts as well as in imagery. The outcome probably depends on the client's ability to visualize, which in turn may be related to hypnotic susceptibility. This procedure was widely used at one time, more than any other covert conditioning procedure, and there has been research documenting its effectiveness, although other variables (such as expectancy) may be involved as well.

B. Covert Extinction

In this procedure, clients are instructed to imagine performing an undesirable behavior (the target behavior) and then not being reinforced for that behavior. For example, a client who talks too much will be instructed to imagine herself talking with no one listening.

C. Covert Response Cost

In this procedure, clients are instructed to imagine performing an undesirable behavior and then to imagine that they have no reinforcer for that behavior other than what is maintaining the response. This is similar to covert extinction except that in covert response cost there is a reinforcer but only the original one. There is no other reinforcer so there is a cost to making the response because other responses might provide more reinforcement.

D. Self-Control Triad (Thought-Stopping)

This procedure consists of three parts (hence the term "triad"). First, clients are instructed to shout "stop" to themselves (preferably not aloud, especially in public!) whenever they think of the undesirable behavior or thought. Second, they are instructed to take a deep breath, exhale, and relax. Third, they then imagine a pleasant scene as a reward for terminating the undesirable thought. Thus, negative reinforcement or escape conditioning is involved. Less obvious variations of this procedure have been used such as snapping a rubber band on one's wrist as an aid to stopping the thought or cognitive distraction from the intrusive thought to another image. The self-control triad can be useful for clients who are plagued by constant negative ruminations.

E. Covert Positive Reinforcement

In this procedure, clients are asked to imagine the positive target behavior and then to imagine a pleasant scene. For example, a client who has a fear of flying may be asked to imagine herself walking comfortably onto a plane, sitting in her seat, and then imagining a pleasant scene such as lying on a sunny beach. Thus, the pleasant scene acts as a positive reinforcer for the image of walking comfortably onto a plane.

F. Covert Negative Reinforcement

In this procedure, clients are asked to imagine an aversive situation or event, then to terminate this image, and immediately imagine a response to be increased in frequency. For example, a man might be asked to imagine himself arguing with his wife (an aversive event) and to switch immediately to imagining himself making an assertive response to her. Thus, the termination of the aversive event is reinforced by the image of the new assertive response.

G. Covert Modeling

In this procedure, clients are asked to imagine observing a model performing the target behavior and then to imagine either a reinforcing or punishing consequence applied to the model's behavior. For example, a client with a fear of authority figures may imagine a model acting assertively with her boss and being reinforced by the boss's change of mind. This should result

in an increase in the probability of assertive responses in the future. Or, an overly aggressive client may be asked to imagine a model acting overly assertive with her boss and being punished by the loss of her job. This should result in a decrease in the probability of aggressive responses in the future.

Coverant control is ideally suited for self-control training. Its reliance on imagery-based procedures makes it extremely flexible and adaptable to a wide variety of client situations. Therapists can train clients in their offices to use these procedures in their daily lives.

Covert behaviors can serve a variety of functions. First, they may act as antecedents of other behaviors. They become the covert cues for subsequent behavior. For example, fear and avoidance of many objects are due to covert images of what might happen if one is placed in the fear-producing situation. The most prominent examples of changing the cuing functions of these covert images are systematic desensitization and "flooding" or implosion therapy. Both of these procedures have been shown by research to be effective in modifying subsequent behavior, though probably not for the reasons originally thought. In systematic desensitization, relaxation is used to change the covert cues that arouse the fear and avoidance so that it is no longer aroused to the same degree, beginning with covert cues low on the anxiety-producing hierarchy and gradually moving higher. In flooding, one begins at the top of the fear-producing hierarchy and uses repeated exposure through imagery to the fear-producing situation until it no longer evokes the same response. Other techniques for changing antecedent covert cues, such as focused attention, hypnosis, biofeedback, meditation, and autogenic training may also be effective in changing subsequent behavior.

Covert behaviors can also act themselves as target behaviors to be changed. Perhaps the best-known example of this procedure is Donald Meichenbaum's original self-instructional training. In this procedure, negative self-statements, such as, "I know I'm going to fail!" are gradually replaced with more adaptive self-statements, such as, "If I take my time, I know I can succeed." Therapists model these adaptive self-statements and train the clients how to use them. This procedure has been applied to a variety of covert target behaviors, such as test anxiety, impulsivity, and schizophrenic "crazy talk." Thought-stopping, described earlier, is another example of covert behaviors as target behaviors. Indeed, the cognitive therapies developed by Aaron T. Beck and Albert Ellis consist in large part of modifying covert target behaviors, which are called

negative self-statements. Clients gradually learn how to identify their negative self-statements (negative covert target behaviors) and replace them with more positive and adaptive self-statements (positive covert target behaviors).

Covert behaviors can also act as consequences; that is, they can themselves function as reinforcers and punishers. Imagined consequences of specific actions have long been known to exert a powerful control on behavior and emotion. Thus, changing an image about the likely consequence of an action can change the action. Behavioral rehearsal, or the imaginal rehearsal of a desired behavioral sequence of action, is an example. In this procedure, clients are asked to imagine themselves engaging in a sequence of action they desire, which is reinforcing, as well as providing them with new ideas for action. This imagined course of action can be modified in discussions with the therapist. Covert sensitization, covert positive reinforcement, covert negative reinforcement, covert extinction, and covert modeling, as described earlier, are also examples of covert behaviors used as consequences.

II. THEORETICAL BASES

Although it has been known by other names for centuries, coverant control was first identified and described by that name by Lloyd Homme. The term coverant is simply a contraction of the terms covert operant and refers to internal responses, such as thinking, fantasizing, daydreaming, feeling, or imagining. They are responses than laypeople would call mental operations. Certain physiological sensations would also be classed as coverants. Thus, coverant control refers to control of private mental or physiological events, observable only to the observing individual, rather than to the control of events observable to everyone.

Coverant control is assumed to be derived from the same behavioral laws, primarily those of operant conditioning, that govern overt control, or the control of publicly observable behavior, and coverants are subject to the same laws of learning. This is known as the learning assumption. Furthermore, there is a continuity between overt and covert behavior such that conclusions about one class of behavior can be transferred to the other. This is known as the homogeneity assumption. Coverants can be increased in frequency via the technique of positive or negative reinforcement or decreased in frequency via the technique of punishment and extinction. Thus, coverant control is a behav-

iorally oriented control method, differing from overt behavior control only in the observability of the events. Coverant control is therefore an aspect of behavioral psychology, not cognitive psychology. However, coverant control is based heavily on the imagery process or, in some cases, hypnosis and hypnotic imagery. Indeed, it operates primarily on the use of imagining because this provides the vehicle by which the private events are assessed and the reinforcing or punishing consequences are administered. Essentially, the imagery processes act as mediating stimuli between the reinforcing or punishing consequence and the antecedent event.

Coverant control also uses modeling or vicarious learning as originally developed by Albert Bandura. He discovered by extensive research that it was possible to increase or decrease the probability of a behavior without an individual being exposed directly to reinforcing or punishing consequences. Rather, it was sufficient to observe a model being reinforced or punished for learning and behavior change to occur in an observer. Bandura called this "vicarious conditioning" and he argued that it is the basis on which most human learning occurs. Bandura also distinguished between a coping model (who made mistakes) and a mastery model (who did not) and found that the former was actually a more effective model. Perhaps this is true because clients can more easily identify with a coping model. Indeed, as Bandura has noted, people even respond in accordance with their perception of a reinforcer rather than an actual reinforcer itself.

Coverant control also makes use of the Premack Principle. The Premack Principle states that behaviors engaged in with a greater probability can be used as reinforcers for behaviors engaged with a lower probability or not at all. For example, studying behavior in students, which is a lower probability behavior, can be reinforced by watching television, which is a higher probability behavior. Thus, students may set a contract by which every 2 hours of diligent study will be rewarded by a half-hour of television. It is important to note, however, that the high probability behavior must be intrinsically reinforcing to the individual and not simply one that carries little or no reinforcement value.

Coverant control assumes that the various categories of behavior, such as overt, covert, and physiological, interact with and influence one another in ways that can be derived from basic laws of learning. This is known as the interaction assumption. In other words, thinking, behaving, and feeling all influence each other reciprocally. It should be noted, however,

that what are commonly called "emotions" or "feelings" may be essentially a situationally specific cognitive labeling of a physiological arousal, the emotion thus identified being dependent on the social context in which the arousal is noted and labeled. In addition, it is often difficult to identify a "first cause" for the content of this interacting system, although in most situations it is probably behavior.

Although it is not usually discussed as such, covert control can be based on classical conditioning. Many negative coverants (e.g., negative images) were originally conditioned by being paired with negative life events. For example, extreme trauma, such as occurs in wartime combat, can result in (by classical conditioning) very negative images that occur repeatedly as flashbacks. These flashbacks can be seen as a form of covert events. Repeatedly pairing these flashbacks, spontaneous or elicited, with more positive feeling states (such as relaxation) or positive self-statements may lead to a reduction in frequency and severity. In principle, any negative covert event might be reconditioned by being paired repeatedly with a more positive event or other coverant (image).

III. APPLICATIONS AND EXCLUSIONS

Coverant control only represents an extension of the basic laws of learning to internal, private events, that is, those observable only to the observing individual (the homogeneity assumption). Because these laws are thought to be universally applicable to humans, regardless of various aspects of human diversity (the learning assumption), no racial, gender, or ethnic groups should be excluded. Coverant control has been applied to a variety of populations, including outpatient adult clients, children, and the elderly, as well as residential school, and hospitalized clients. However, different events or consequences will be differentially rewarding (or aversive) to different cultural or other groups; indeed to different individuals within those groups. Therefore, behavioral psychologists should carefully assess which consequences are likely to be reinforcing or punishing to different individuals within and across these groups. It cannot be assumed that common reinforcers or punishers are reinforcing or punishing to everyone.

In addition, individuals vary considerably in the extent to which they are able to create vivid images and therefore to make use of imagery-based procedures.

This ability has been linked to hypnotic susceptibility, which is normally distributed in the population. Although those individuals who have difficulty creating vivid mental images may improve somewhat with practice, they are unlikely to become imaging virtuosos. Hypnotic susceptibility has been shown to be a relatively stable characteristic of human functioning.

Because the internal behaviors to be changed cannot be directly observed by others and the reinforcing consequences must be self-applied, it is especially important that clients be motivated and willing to disclose appropriate target behaviors. Clients who are not self-referred may lack the motivation to make coverant control methods useful. In addition, they are probably not appropriate for crisis intervention because immediate action may be required by an external agent.

There are also certain people for whom coverant control might be difficult or not applicable because of their inability to understand or follow instructions. For example, very young children may not yet possess the ability to concentrate and create vivid images. Individuals with severe mental or behavioral disorders, or significant intellectual deficits, may also have great difficulty using imagery-based procedures. However, even within these populations, certain individuals may have the capacity, at least in part and with training, to formulate and use images. Thus, no population should be excluded from this procedure *only* on the basis of group membership. Indeed, for all clients, regardless of group membership, it is very helpful prior to treatment to conduct an assessment of ability to use imaginative procedures.

IV. EMPIRICAL STUDIES

Of all the various covert conditioning procedures, covert sensitization has been the most empirically investigated. Early studies showed that it was effective for a wide variety of problems with lasting effects. Later studies by David Barlow and his colleagues in the late 1970s supported this conclusion. Joseph Cautela and Albert Kearney summarized research from the 1970s and early 1980s indicating that in general covert positive reinforcement and, to a lesser extent, covert sensitization was effective. However, the research evidence was mixed and the mechanism often unclear. Other studies from the 1970s indicated that coverant control was effective in increasing the rate of positive self-evaluations, reducing neurotic depression, losing weight, and reducing annoying personal habits. How-

ever, it was difficult to rule out the causal effects of other variables.

Curiously, almost no research appears to have been conducted on the effectiveness of coverant control since then. A survey of the literature up to early 2000 turned up almost exclusively publications describing theoretical arguments and procedural descriptions. One study published in 1981 by Joseph Cautela found covert reinforcement to be more effective than reciprocal inhibition in modifying pain response. Another study published in 1986, however, failed to support Cautela's theoretical explanation of covert conditioning as based on operant conditioning.

V. CASE ILLUSTRATION

Although covert sensitization is the procedure most commonly used and investigated in the coverant control literature, it has been applied mostly to the elimination or reduction of entrenched habit disorders such as smoking. Therefore, in this section I will present an example of a more versatile technique that can be applied to increasing the frequency of a wide variety of positive behaviors: covert positive reinforcement. It can be used to modify both maladaptive behavior and avoidance behavior. In the operant conditioning literature, positive reinforcement has been shown to be more effective in general than alternative behavior change methods.

"Joe" (not his real name) was a young man of 20 who was highly date-phobic. Although he had been popular in high school among the boys and had some casual female acquaintances, he had not had a real date other than a contrived encounter with an acquaintance of his aunt 2 years previously. That experience had proved to be extremely anxiety-provoking for him and he spent the entire evening in a sweat thinking of what to say next. His anxiety had rubbed off on the woman who talked less and less in the course of the time they were together. As a result, whenever he thought of calling a woman for a date, his mind flashed back to that one painful encounter and he became so anxious that he avoided thinking of dating to eliminate the anxiety. Interestingly, he was able to relate to adult women who were not potential romantic partners relatively easily and could even talk with women his age who were unavailable for other reasons. It was only when the female in question was a potential date that his anxiety surfaced.

The therapist soon determined that Joe's avoidance behavior was continuously reinforced by escape from

the anxiety-producing image of his agonizing first (and only) date. This image with its associated feelings was so powerful that it appeared to be unwise to attempt to eliminate it. Accordingly, the therapist decided to use covert positive reinforcement instead and to teach Joe this technique so he could use it whenever he interacted with a potential date.

The therapist's first task was to identify a positive reinforcer that Joe could use. After an extended discussion, it appeared that the best one was Joe's love of fishing. Nothing was as rewarding to him or as relaxing as sitting in a boat with his line and hook in the water. It hardly mattered if he caught anything; indeed the activity required to "land" a fish disturbed his reverie. Accordingly, the therapist asked Joe to relax, close his eyes, and to imagine the following scene as vividly as he could:

Joe, I'd like you to imagine sitting in a boat, fishing ... with your line in the water, your bobber floating a few feet away. It's a warm summer day and you can feel the sun on your body, feel its warmth penetrate your entire body. The boat is bobbing gently on the lake and you can hear the lapping of the water on the side of the boat. There is a very slight breeze, just enough so you can feel it but not enough so it is distracting. As you sit there, you can feel yourself relaxing more and more—with all the warmth and peace filling your body and your mind.

This scene was repeated with minor variations until Joe could easily visualize and experience it, along with the associated feelings of relaxation, peace, and warmth. The therapist then gave Joe the following instructions:

Joe, in a minute I'm going to ask you to imagine a scene as vividly as you can. When you have that image firmly in your mind, raise the index finger of your right hand (or left hand if Joe is left-handed). When you do that, I'm going to say the word "reinforcement" to you and I want you to imagine the fishing scene we practiced earlier. As soon as that scene is clear, raise your finger again. Ok?

After Joe had closed his eyes and relaxed, the therapist then presented the following scene:

Now, Joe, I want you to imagine that you meet a woman on the street who you know from your friends would like to date you. You begin to walk toward her. Raise your finger when this scene is clear. ("reinforcement"). Now, imagine her beginning to speak with you; raise your finger when this is clear. ("reinforce-

ment"). Now imagine yourself beginning to speak with her; raise your finger when this is clear. ("reinforcement"). Now, imagine yourself finishing your conversation with her and beginning to leave; raise your finger when this is clear ("reinforcement"). Good, now terminate that scene from your mind.

After several repetitions of this extended scene paired with the reinforcing scene, Joe was able to imagine himself meeting and speaking with available women. The therapist then asked him to practice this sequence at home on a regular basis. When he was able to do this, Joe was asked to practice it in an actual situation, taking care not to extend the conversation too long at first. With repeated practice, Joe was able to hold longer and longer conversations with women.

In conducting covert reinforcement, it is important to repeat the procedure many times in order to associate the aversive scene with the reinforcing scene. In this manner, the former may gradually become associated with the latter instead of with anxiety. The proper selection of the reinforcing scene is crucial because it should be important enough to overcome the considerable previous conditioning of the aversive situation.

VI. SUMMARY

Coverant control is a set of procedures that grew out of primarily operant conditioning methods and is applied to covert, or internal, behaviors rather than external. It uses many of the same techniques as overt conditioning and is based on the same theoretical explanations. According to this model, internal activities such as images, thoughts, and feelings, are considered to be behaviors following the same laws of conditioning as external activities. It is potentially quite flexible because it can be implemented anywhere by clients themselves. There may be individual differences in how vividly clients can visualize images and therefore use the techniques. Although some research findings have demonstrated support for the procedures, especially covert sensitization, others have not and it has not been shown that coverant control is generally more effective than alternative procedures. In addition, research has not clearly demonstrated that the hypothesized theoretical mechanisms actually account for the change. Since the early 1980s, the literature on the topic has consisted almost entirely of theoretical and procedural aspects and the number of articles has declined from the 1960s and 1970s.

GLOSSARY

analogue studies Studies similar to clinical studies but not using clinical patients or clinical level problems.

antecedent A preceding event, condition, or cause.

baseline Measures taken on a behavior before initiating a treatment program. This is used to evaluate the effect of a behavior treatment program.

cognitive restructuring A cognitive-behavioral procedure in which the client is assisted in utilizing different cognitive perspectives or frameworks in the process of treatment.

control group A contrast group used in experiments to help ensure that study findings are not due to confounding factors, such as subject expectation.

covert extinction An imaginal procedure in which the reinforcer is no longer delivered for a previously reinforced response that results in a decrease in the probability or likelihood of the response.

covert sensitization An imagery-based treatment in which clients imagine themselves engaging in an undesired behavior (e.g., overeating) and then imagine an aversive event or state. The treatment is designed to decrease the undesired behavior.

demand/request phase An experimental control phase in which a request is used to rule out the possibility that the request, or implied request, affected the behavior.

dependent measures Measures of a variable that is expected to change as a result of experimental events or changes in these events.

functional assessment Evaluation of the behavior and of antecedents and consequences associated with the behavior in order to understand the role of the antecedents and consequences in the occurrence of the behavior.

multiple baseline An experimental design that demonstrates the effect of a contingency by introducing the contingency across different behaviors, individuals, or situations at different points in time. A causal relationship between the experimental contingency and behavior is demonstrated if each of the behaviors changes only when the contingency is introduced.

picture rehearsal (or cognitive picture rehearsal) A therapeutic procedure developed by June Groden in which the client views and recites a sequence of scenes involving a behavior to be changed and the consequence of that behavior.

placebo An inactive substance or condition serving as a control in an experiment.

reciprocal inhibition Weakening the bond between an anxiety-evoking stimulus and an anxiety response by pairing an anxiety-inhibiting response with an anxiety-evoking stimulus.

reinforcement An increase in the probability or likelihood of a response when the response is immediately followed by a particular consequence. The consequence can be either the presentation of a positive reinforcer or the removal of a negative reinforcer.

response prevention Preventing a response in the presence of an event that usually produces it.

satiation A loss of reinforcer effectiveness that occurs after a large amount of the reinforcer has been delivered.

self-control triad The self-control triad, developed by Joseph Cautela, is a combination of three techniques: thought-stopping, relaxation, and pleasant imagery. When an individual wants to decrease the probability of a behavior, he or she says to himself or herself "STOP." He or she takes a deep breath, relaxes, and imagines a pleasant scene.

systematic desensitization The systematic presentation of successively stronger anxiety-producing stimuli in the presence of an anxiety-inhibiting response resulting in a reduction of anxiety.

target behavior The behavior to be altered during a behavior change program.

visual imagery A procedure in which one creates an image in one's mind of an object or event, generally with one's eyes closed.

I. DESCRIPTION OF TREATMENT

A. Definition of Covert Positive Reinforcement

Covert positive reinforcement (CPR) is a procedure that was developed in 1970 by Joseph R. Cautela under the rubric of covert conditioning. Other covert conditioning procedures are covert sensitization covert extinction, covert response cost, and the self-control triad. These procedures were designed to decrease the frequency of behaviors. Covert positive reinforcement and covert negative reinforcement increase the frequency of desirable behaviors.

Positive reinforcement occurs when the behavior to be increased is followed by a consequence or event that results in an increase in the probability of that behavior. Covert positive reinforcement occurs when an individual imagines the behavior to be increased and then imagines a pleasant consequence or reward. This results in an increase in the probability of that behavior.

There are three main ingredients in the CPR procedure: (1) identifying the antecedent event; (2) selecting the target behavior; and (3) selecting an appropriate reinforcer or pleasant event. The use of functional assessment of behavior or a behavioral assessment is a prerequisite to designing a covert positive reinforcement program and provides the information that is necessary to design the scripts for the covert positive reinforcement scenes.

B. Presentation Formats

1. Visual Imagery

In implementing CPR, clients are instructed to imagine a scene in which they are performing the behaviors

to be increased. The reinforcing scene should be clearly visualized within 5 seconds after imagining this scene. One pair of target and reinforcing scenes is referred to as a single trial. In 1986, Joseph Cautela and Albert Kearney stated that an intertrial interval of at least 1 minute is recommended in order to avoid inhibition of reinforcement and too rapid a growth of inhibitory potential.

The therapist first presents the scene asking clients to keep their eyes closed and imagine the scenes that are described. Sensory details should be included (e.g., hear the sound of the ocean, smell the flowers). The client then repeats the scene. When the client first imagines the scene, the therapist asks questions to see if the client is visualizing (e.g., what does the ocean look like?). Audio tapes can also be used for home practice. Cautela recommends that at least 60 scenes be completed (for a typical adult) over a period of time before results are expected. After completing the practice scenes, when a situation occurs that involves the target behavior, the client is taught to recognize the antecedent, and repeat to himself or herself the behavior that is practiced in imagery and then use the appropriate behavior that has been rehearsed in imagery.

2. Picture Rehearsal

There are some individuals who have difficulty in visualizing the scenes. This may include persons with developmental disabilities or those who report problems in getting a clear visual image. June Groden, Joseph Cautela, Patricia LeVasseur, Gerald Groden, and Margaret Bausman in 1991 developed an adaptation of covert positive reinforcement by designing scenes that can be presented using written scripts or pictures that depict the scene and put it into the same format as the CPR procedure.

C. Designing a CPR Program

1. Identify the Antecedent Event

Antecedents are those events that precede the target behavior. These events can be people, places, time of day, or situations that influence the occurrence of the target behavior. Information obtained from the behavioral assessment should be incorporated into imagined scenes. Often, there are many different antecedents that influence a targeted behavior. In this case, scenes can be designed so that the antecedents are rotated when practicing the different scenes, or an antecedent that is non-specific can be used. For example, if a person finds it difficult to socialize at parties or at work, the scene might either begin with "you are at a party" or "you are at work" or "you are somewhere" (nonspecific).

2. Identify the Target Behavior

Target behaviors can be identified in a number of ways: (1) self-report from either the client or in the case of children, legal guardians or caregivers; (2) paper-and-pencil surveys; or (3) natural observations. Establishing a baseline, which is taken prior to beginning any formal intervention, involves data collection to gather information about frequency, duration, and the topography of the behavior. The baseline data are then used to measure effectiveness of the procedure. It is also useful during the course of treatment. If there is not a positive change in the data or the trend line, modifications can be made to the scenes to incorporate new information and alter the scripts to reflect this new information.

3. Create a Personalized Menu of Pleasurable or Reinforcing Events

Each imagery scene in the CPR format should conclude with an imagined pleasant scene that is specific for each client. Information for these scenes can be obtained from self-report, paper-and-pencil surveys, or direct observations, particularly in free choice situations. Reinforcement sampling described by Teodoro Ayllon and Nathan Azrin in 1968 may also be used to acquaint individuals with reinforcers they may not have been exposed to previously. It is important to have a number of reinforcers from which to choose in order to prevent satiation (i.e., ice cream may not be as reinforcing to imagine following the consumption of an ice cream sundae).

D. An Example of a CPR Scene

In 1981 Avis Bennett and Joseph Cautela described the following CPR scene to increase the target behavior of not eating dessert:

Imagine you are standing at the dessert table with your friends. As dessert is passed, you politely refuse, and feel good about staying on your diet.

This is followed by a pleasant scene:

Imagine you are your ideal weight. You look really slim in your favorite color and style. Someone you like says to you, "Gee, you've lost weight. I've never seen you look so good."

E. Advantages of CPR

CPR has many advantages. All positive procedures are preferred over techniques that are aversive and put

the individual at risk for discomfort, stress, or other side effects. In addition to sharing the advantages of all positive procedures, the advantages of using CPR include the following:

1. Scenes in the use of CPR can be adapted to various cognitive levels and learning styles.
2. It allows for more opportunities for practice and repetition that can be done overtly. As the number of trials increases, learning becomes stronger.
3. Spatial and temporal restrictions are not limited since the procedures are done in imagination. Environments can be created that are not accessible in overt situations.
4. The opportunities for generalization increase since many more scenes can be practiced in different settings and with different people without having to go to those settings or having the persons actually present.
5. An individual's general level of reinforcement can be increased by imagining pleasant events.
6. In order to administer the therapy, it is not necessary to interrupt daily life functioning (i.e., unlike the administration of tokens in a classroom, which interrupts the classroom program, CPR can be administered in another setting, and the change will occur in the classroom through the imagined practice).
7. There is no need to use materials or equipment that are difficult to carry or that are interfering.

CPR can be a preventative procedure. Problematic situations can be anticipated. Scenes of stressful antecedents and the appropriate response to them can be practiced in imagery. The stressful and aversive antecedent does not actually have to occur for the practice to take place. This can avert a problematic behavior when the aversive stimulus actually occurs and the patient exhibits appropriate behavior.

II. THEORETICAL BASES

Covert conditioning is a theoretical model that involves a set of assumptions about imagery-based procedures that change response frequency. Covert is the term used because the client is asked to imagine the target behavior and the consequences. The covert conditioning procedures are based on three main assumptions:

1. Homogeneity: This assumption implies a continuity between overt and covert behaviors. The covert and overt processes share similar importance and similar properties in explaining, maintaining, and modifying behavior.

2. Interaction: Covert events can influence overt events and overt events can influence covert events. In addition, these events can occur concomitantly.

3. Learning: Covert conditioning is based on the assumption that covert and overt behaviors are governed by laws of learning, primarily operant conditioning, and that overt and covert behaviors interact according to these same laws.

III. EMPIRICAL STUDIES

Most of the studies on this topic appeared in the early 1970s and 1980s shortly before the period in which studies in learning/conditioning techniques for therapeutic purposes waned and cognitive-based ones captured experimenters' and clinicians' interests. Many of these studies were not written or reviewed with the scientific rigor that we often find now in collaborative studies. In fact, it is only recently that rigorous study guidelines are receiving general acceptance. Earlier reviews of CPR were published by Donald Scott and Anne Rosentel in 1975, Alan Kazdin and George Smith in 1979, and Michael Stevens in 1985. These concluded, with some reservations regarding study design and other problems, that evidence suggested that CPR was effective.

Literature utilized for this review were controlled experimental studies resulting from a literature search using the terms covert positive reinforcement and covert reinforcement. The search covered the period 1970, the time of the first article on CPR by Joseph Cautela, to the present. The search resulted in 34 articles. This literature contained both clinical research (8 studies), as well as analogue research, that is, research in which CPR was used to modify either clinical-type problems in persons who did not have them to the extent that they would be classified as patients, or non-clinical behaviors (26 studies).

A. Summary of CPR Effectiveness

In the clinical studies, the effectiveness of CPR was compared to one or more of the following conditions: an alternate treatment thought to have some empirical support; a placebo condition, in which the subjects thought that they were receiving treatment, but were

not actually receiving it; and no-treatment. In the analogue studies, CPR was compared to an alternate treatment, an expectancy or attention group (analogous to placebo controls for the clinical studies), and/or a no-treatment group. Some of these studies included additional comparison groups for the purpose of testing the theory on which CPR is based.

Overall, in the clinical studies, CPR was more frequently superior to alternate treatment and placebo comparisons. This was also the case, although to a lesser extent, for no-treatment comparisons. The analogue experiments indicate CPR to be generally or at least equal to alternate procedures, with mixed results for expectancy or attention controls and no-treatment control comparisons. Although the majority of studies were analogue, because CPR was developed as a clinical procedure, it is thought that the results of the clinical studies should receive emphasis in judging CPR's therapeutic efficacy.

B. Discussion of Comparison Studies

1. Clinical Studies

Of the clinical studies, five utilized group designs. In two of these the effectiveness of CPR as a technique for effecting weight loss was evaluated. Two other studies involved test-taking anxiety reduction, while another concerned self-concept enhancement. There were also three single-case design studies. Two of these involved improving social behaviors in children with developmental disabilities and the third involved fear reduction in a college student. In the group studies, CPR was found to be more effective than an alternate treatment in one out of one comparison. CPR was also more effective than placebo controls in three out of four comparisons and more effective than no treatment in two out of three comparisons. The findings of the single-case studies were somewhat supportive of CPR.

2. Analogue Studies—Clinical-Type Behaviors

There were 13 analogue studies in which CPR was used to modify clinical-type problems in persons who did not have them to the extent that they would be characterized as patients. Study participants were generally college students participating in the studies as part of a course requirement and not because they were independently seeking treatment. Three of the studies were on attitude change, concerning attitudes toward persons with mental retardation, physical handicaps, or self-esteem; five involved fear reduction; and five involved test-taking anxiety reduction.

In all, five out of five studies comparing CPR to an alternate procedure reported CPR to be equal to, or more effective than, that procedure. Four out of seven studies, including a placebo control, found CPR to be superior to the placebo condition. Nine of the studies utilized a no-treatment control group. Of these, two found CPR to be superior. Thus in this group of studies CPR was more frequently equal to or superior to an alternate procedure, slightly more frequently superior to placebo, but not superior to no treatment.

3. Analogue Studies—Non-Clinical-Type Behaviors

There were 13 analogue studies in which the target behavior was nonclinical, such as influencing over- or underestimation of circle size, and the subjects were frequently college students. In 1 of these studies, subjects were patients hospitalized in a psychiatric facility. In four of the studies, the target behavior was increased tolerance to experimentally induced pain. In three studies the target behavior was attitude change, and the remaining six involved influencing verbalizations, circle size estimation, eye contact, and yawning.

In four comparisons with alternate procedures, CPR was more effective than these treatments in three of four instances. CPR was more effective in one of four comparisons with an expectancy condition. When compared to no-treatment conditions, CPR was superior in four of nine studies. An additional study in this category found CPR effective, but it did not lend itself well to this type of analysis. Thus, CPR was generally superior to alternate procedures, but not superior to expectancy or no-treatment conditions.

Several studies addressed the question of whether or not, when CPR proved efficacious, operant conditioning was responsible for its effect, as Cautela proposed. Some of these studies cast doubt on this crucial assertion and offered alternate explanations, such as reciprocal inhibition or exposure and response prevention.

4. Interpretation Problems

The introduction to the empirical studies review noted problems in past CPR research, making it difficult to render valid conclusions regarding its effectiveness. These problems have been noted by other reviewers as well. In addition to those already mentioned, these studies suffered from either not containing as many as 25 subjects per condition (a number recommended by Dianne Chambless and Steven Hollon in 1998 to be the minimum number for detecting

differences between groups), different experimenters conducting different groups, or the experimenters conducting placebo or expectancy conditions not being blind to conditions. Frequently, subjects in these groups were not asked post-study whether or not they thought they were receiving treatment. A number of studies relied on subjects' reports regarding the extent they practiced CPR homework scenes that were assigned to them. Also, the articles frequently did not sufficiently describe the CPR procedures employed, used nonstandardized instructions and reinforcing stimuli, lacked no-treatment or placebo controls, and used unvalidated dependent measures. In addition, comparison treatments characterized in this review as alternate treatments considered to have some empirical support were often not carried out with as much richness as they might have been in actual clinical treatment. Nonuniform subject characteristics, such as motivation, and variable experimenter characteristics, such as competence in procedures used, also characterized the literature. Finally, it should also be noted that CPR is a clinical procedure that, for maximal effectiveness, should be carried out in a highly individualized manner in which the clinician is sensitive and adjusts to the idiosyncrasies of the client. Group studies in which instructions are often taped and the procedures predetermined would be expected to put it at a disadvantage.

IV. SUMMARY

In summary, CPR is a learning-theory-based therapeutic procedure in which imagined target, behaviors, and consequences are substituted for overt ones. The literature suggests its effectiveness, but characteristics of the studies make it difficult to conclude this with any certainty. Future, improved studies will hopefully clarify the merits and mechanisms of this innovative and potentially promising procedure. Joseph Cautela was certainly one of the pioneers in the use of imagery in therapy and its incorporation into cognitive behavioral therapy, behavioral medicine, and sports psychology.

GLOSSARY

- autobiographical memory** Memory for events from one's earlier life.
- automatic encoding** Committing to memory without any intention or effort.
- depth of encoding** Degree to which information is processed in a meaningful way when it is first encountered and committed to memory.
- episodic memory** Memory for specific personal experiences.
- flashbulb memory** Extremely vivid episodic memories that feel like they will never be forgotten.
- know-type memory** Memory for an event without the specific experience of encountering that event.
- long-term memory** Memory that lasts longer than a few minutes without active efforts to maintain it and survives the encoding of intervening events.
- mnemonic devices** Deliberate and systematic strategies to make remembering information easier.
- motor memory** Being able to do a physical action with greater facility after practice.
- reaction time** The time it takes to respond to a presented stimulus.
- reception context** In flashbulb memory research, remembering autobiographical information from when we received

the news of a flashbulb event, such as where we were, who was with us, how we felt, and so on.

remember-type memory Memory for an event that includes not only the recollection of the event but also the experience of encountering that event.

serial recall Remembering information in the order it was presented.

short-term memory Maintaining a limited quantity of information in memory for a brief period of time.

In memory research, covert or mental rehearsal refers to silently thinking about events or items with the intention of learning them, or, if already learned, strengthening or simply refreshing memory for them. In this article, the aim is to focus on what is meant by different types of covert rehearsal and to review findings from some intriguing empirical studies that have explored various aspects of covert rehearsal.

I. OVERVIEW

The function of rehearsal is to improve performance. To this end, most rehearsal in life is not covert but overt. That is, it is observable and necessarily resembles the performance itself, such as an orchestra rehearsal or basketball practice. When it comes to memory performance, however, overt rehearsal is less popular because, among other reasons, people are often reluctant to think aloud

and share their private thoughts with other people while learning new information; it is often faster and more practical to think silently, and not all thoughts are verbally communicable. In addition, in studying rehearsal, asking participants to share their mental activity can create restrictive and artificial task demands, cramp the rehearsers' style, and thus confound the purpose of the research. Thus, what is more often engaged in as well as more often explored in memory research is covert rehearsal. We engage in covert rehearsal in such cases as when we study for a test or try to memorize a list of names. Its function is to improve memory performance by enabling one to remember more events or items and with more facility. Various types of mental activity can be thought of as covert rehearsal; not all covert rehearsal is effective, or, leads to long-term memory improvement; and covert rehearsal is possible with both verbal and nonverbal stimuli.

II. TYPES OF COVERT REHEARSAL

In general, as the word implies, covert rehearsal involves repetition, or thinking about the material over and over again. However, in a less strict sense, any mental processing engaged in after as well as any "extra" mental processing engaged in during the occurrence of an event or the presentation of a stimulus item can be considered as covert rehearsal. In those cases, continual repetition per se is not necessary, although the concept of repetition is still there because any further thinking about a target stimulus by definition involves the repetition of that stimulus. Indeed, it is possible to consider any further mental processing of the target events or items as covert rehearsal even if it is a one-shot deal and does not involve any continual repetition. Among such types of covert rehearsal might be imagery, reorganizing the target material, or even involuntarily thinking about the target material on being reminded of it by an unexpected cue, although in this article we focus primarily on intentional covert rehearsal, the types that we engage in to improve memory performance.

Simple, continual repetition is perhaps the most basic and intuitively obvious type of covert rehearsal. If we want to commit something to memory, we can keep repeating it in our minds until we can recite it without needing to look at the stimulus anymore. We can then further rehearse it to make this recitation even more comfortable. Such simple repetition is perhaps most useful in trying to learn something verbatim, such as a poem or lines in a play, or when the order of the to-be-recalled items (e.g., in serial recall) is important. In addition, it is

probably the most commonly used type of covert rehearsal when we want to keep items in short-term memory, such as holding onto a phone number until we dial it, practicing our opening lines before starting a speech, or holding onto our words after having formulated just the right way of phrasing an answer to a question. It is the type of intentional covert rehearsal that probably requires the least amount of mental effort. Indeed, as R. S. Johnston, C. Johnson, and C. Gray showed in 1987, even 5-year-old children can engage in the effective use of such "inner speech" to remember words.

Other types of intentional covert rehearsal, especially those that are not necessarily dependent on simple repetition, require some creative thinking or thinking beyond the target stimuli at hand. For instance, imagery usually involves relating the target stimuli to pictorial or otherwise nonverbal entities or embedding them in more complex and usually perceptual scenarios. To be able to better remember, say, the word "viola," we may try to conjure up a visual image of the instrument, visualize its location in an orchestra, or try to mentally reconstruct how it sounds. Indeed, many mnemonic devices involve mentally thinking about the target stimuli further by arranging them in a different but more easily recoverable format. For instance, in using the method of loci, we combine imagery with a well-established map and mentally place the target stimuli in, say, different houses along the street we live on. Then, when it is time to remember, we try to reconstruct the to-be-remembered stimuli using the already known houses as cues. If the target stimuli are themselves nonverbal, such as dance moves, imagery may involve visualizing going through the moves or, in other words, mentally running through them; thus imagery can sometimes be confounded with simple, albeit nonverbal, repetition, as well.

The critical concept in all types of covert rehearsal is the concept of "further" or "extra" processing. Thus, for silent thinking to be considered to be rehearsal, it needs to occur after the initial encounter with the target stimulus, although the target stimulus need not have disappeared. If the target stimulus is still present, or the next stimulus not yet presented, there is an ostensible danger of confounding covert rehearsal with depth of initial encoding, a concept used to describe any elaborate mental processing that one engages in when one is presented with a target stimulus and a concept some psychologists keep separate from that of covert rehearsal. However, because in many contexts the fine line between deep initial encoding and rehearsal is quite blurred, especially if deep initial encoding involves mental repetition, this distinction may be unnecessary. Just as it is possible to say one is rehearsing one's lines or a piece of music even

when it is for the first time, perhaps what is considered deep encoding when one is presented with a target stimulus for the first time can be thought of also as covert rehearsal, as long as it involves “further” thinking about the stimulus. Thus, in this article, whether it involves mental repetition of the target stimulus or another strategy, any “extra” thinking about the target stimulus is considered covert rehearsal.

In addition to considering the type of mental activity involved, that is, whether it relies solely on simple repetition or involves another mental strategy, covert rehearsal may be classified in many other ways. For instance, it may be stimulus based rather than memory based in that we can keep referring to the target stimulus while rehearsing, or it may be experimenter controlled rather than participant controlled in that we rehearse what is presented to us and not what we choose. In addition, covert rehearsal may be classified in terms of whether it is effective or ineffective, that is, whether it improves memory performance or not. Not all types of covert rehearsal improve memory; sometimes, even when a person feels that his or her memory has improved because of rehearsal, such subjective feelings may not be accurate in terms of performance measures. Covert rehearsal may also be classified in terms of modality, that is, whether the target material or indeed even the mental activity involved in the process of rehearsing is verbal or pictorial or musical.

In the next two sections, the focus is on the effectiveness of covert rehearsal in different situations and on the different modalities in which covert rehearsal can be used, regardless of whether it is stimulus- or memory based or whether it is experimenter- or participant controlled.

III. EFFECTIVENESS OF COVERT REHEARSAL

In one sense, all rehearsal serves a function. For instance, simply repeating a set of phone numbers helps us remember them until we can dial them. But that involves only short-term memory recall. Usually, after a few minutes of distraction, we can no longer remember those numbers. Learning, however, often implies committing stimuli to long-term memory. We need to be able to think about other things and then still be able to remember what we had intended to learn. Thus, effectiveness of covert rehearsal refers to the success with which stimuli can be remembered later.

To this end, psychologists have made a distinction between rote and elaborate rehearsal. Usually, rote rehearsal

refers to simple repetition whereas elaborate rehearsal refers to using any other strategy such as imagery or organization. For instance, in 1973, F. I. M. Craik and M. J. Watkins showed that the amount of covert rehearsal engaged in with the intention of simply keeping a target stimulus in short-term memory had absolutely no effect on long-term remembering. In general, with verbal stimuli, such as lists of words or passages of text, covert rehearsal involving mindless repetition or shallow thinking, that is, rote rehearsal, is often quite ineffective in improving long-term memory compared to covert rehearsal involving thinking beyond the stimuli, that is, elaborate rehearsal. Indeed, M. Naveh-Benjamin and J. Jonides showed in 1986 that even when the stimuli themselves are not remembered, people can remember the frequency information; that is, when given a certain stimulus, they can remember the number of times that stimulus had been presented. Such frequency information, previously thought to be an automatically encoded aspect in memory, is also much better after elaborate rehearsal compared to rote rehearsal. In addition, using elaborate rather than rote covert rehearsal may tend to even change the qualitative nature of the memories, increasing or affecting the reporting of remember-type memories but not of know-type memories.

However, there do exist situations in which even elaborate covert rehearsal may not be effective. For instance, no amount of covert rehearsal, elaborate or rote, unless it is stimulus based, improves long-term implicit memory, that is when we are not consciously trying to remember the stimuli but our memory is measured indirectly by our performance on such tests as how fast we can read words off a screen or how well we can complete the missing letters of a given word. In such cases, the critical variable is the actual perceptual exposure to the stimuli, and silent thinking or covert rehearsal is entirely ineffective.

Psychologists have looked at the role of covert rehearsal also in a more global everyday memory setting while studying autobiographical memory and, more specifically, within the context of flashbulb memories. Although most silent thinking about real-life events tends to be in the form of inadvertent reminiscing rather than with the intention of improving our memory, such as when we keep reliving a championship game we participated in or cannot stop thinking about the last moments we spent together with a dying loved one, it is reasonable to suppose that such frequent and intense mental thinking or covert rehearsal is part of the reason why those moments may become flashbulb memories. Thus, exploring the assumed effectiveness of covert rehearsal in this context is also informative. In 1977, R. Brown and

J. Kulik postulated that rehearsal, both overt and covert, was an important variable in the formation of flashbulb memories for important public events, such as remembering, and never to forget, how we heard about John F. Kennedy's assassination. However, more recently, the effectiveness of rehearsal in the formation of flashbulb memories have been challenged by some researchers such as D. B. Pillemer in 1984, although these cases have dealt with primarily overt and "experimenter-controlled" rehearsal such as exposure to media coverage of the event. In a more recent study in 1997, A. İ. Tekcan and Z. F. Peynircioğlu specifically asked about the estimated number of times a person had thought about the event as well as the reception context to tell someone else about them. To the extent that the event was "thought about" first, such rehearsal has a large covert component. They found that this type of rehearsal did correlate with recall levels whereas strictly overt rehearsal such as exposure to media coverage did not. Thus, there is some evidence that in flashbulb memory research such rehearsal can indeed be effective and improve memory.

One area in which the effectiveness of covert rehearsal has been quite controversial is with nonverbal tasks, especially those relying on the performance of some skill. For instance, in 1989, C. A. Linden, J. E. Uhley, D. Smith, and M. A. Bush found no improvement in walking balance in the elderly following covert rehearsal of the actions. Similarly, in 1995, M. Lejeune, C. Decker, and X. Sanchez found no improvement in table-tennis performance in novice players following covert rehearsal, although covert rehearsal when combined with physical practice and observation did improve performance, and in 2000, D. R. Shanks and A. Cameron found no improvement in a sequential dot-location reaction time task following covert rehearsal. In 2000, Z. F. Peynircioğlu, J. L. W. Thompson, and T. B. Tanielian found that covert rehearsal did improve performance in free-throw shooting but not in a grip-strength task, whereas overt "psyching up" strategies improved performance in the grip-strength task but not in free-throw shooting. They concluded that covert rehearsal would improve nonverbal performance only when the task depended on the coordination of many fine and specific skills and not when the task depended on simple strength, focus, or concentration.

IV. COVERT REHEARSAL OF NONVERBAL MATERIALS

As mentioned earlier, covert rehearsal can improve performance in certain nonverbal physical tasks. Al-

though involving motor memory, improvement in such physical tasks has not been the focus of covert rehearsal studies for memory psychologists, however. Rather, the focus has been on exploring the effectiveness of covert rehearsal for remembering nonverbal stimuli in a list-learning or episodic-memory situation.

In 1980 and 1981 M. J. Watkins and T. M. Graefe explored whether effective covert rehearsal of pictures was possible. They presented pairs of thumbnail pictures or photographs of faces and after each pair cued one of the pictures for covert rehearsal. The cue came when the pictures were no longer present, thus the depth of initial encoding of the two pictures was held constant. They found that those pictures that were covertly rehearsed were better recognized than those that were not. In addition, they found that after a sequence of pictures were presented, and then any one of them cued for rehearsal, the rehearsed picture was better recognized than the others. Thus, the pictures could be conjured up in some fashion well after they had disappeared and covertly rehearsed in an effective manner. Later, in 1991, D. J. Read, R. Hammersley, S. Cross-Calvert, and E. McFadzen showed that in a face identification situation, just as with verbal materials, the timing of the covert rehearsal or how long after the presentation of the materials it occurred was crucial to its effectiveness.

Effective covert rehearsal was shown also in the nonverbal auditory domain, within the context of voice recognition. In 1982, M. J. Watkins and Z. F. Peynircioğlu presented pairs or sequences of short utterances, each utterance comprising a different phrase and spoken by a different though same gender person and afterwards cued one of these utterances for covert rehearsal. They found that the target voice in which an utterance was spoken was later more likely to be recognized among alternative same gender voices all saying the same utterance if the target utterance had been covertly rehearsed than not rehearsed. Later they also extended this finding from voices to natural sounds such as "thunder," "baby crying," or "a dentist drill." These natural sounds were also more likely to be recognized among alternative similar sounds if they had been covertly rehearsed than not rehearsed.

Thus, it appeared that nonverbal materials, whether visual or auditory, could be covertly rehearsed in an effective manner so that long-term memory for them was improved. What was unclear, however, whether such rehearsal was nonverbal in nature, as well, or whether people translated these nonverbal materials into verbal descriptions and then rehearsed these descriptions instead. To be sure, it would be quite cumbersome to label

or describe some of these materials, and the alternatives during the recognition test often shared similar verbal descriptions as the target materials. Nevertheless, a verbal rehearsal strategy with nonverbal materials could not be ruled out completely. To address whether effective nonverbal covert rehearsal was possible, in 1984, M. J. Watkins, Z. F. Peynircioğlu, and D. J. Brems presented participants with items that were depicted both pictorially and verbally. One half of these picture/word items were cued for rehearsal. For some of these cued items, participants were instructed to covertly rehearse the picture by keeping its image in mind after it disappeared from view, and for the other cued items they were instructed to covertly rehearse the name by silently repeating it. During the recognition test, one half of the verbally rehearsed items as well as one half of the pictorially rehearsed items were tested using a verbal measure, asking participants to complete fragments of words, and the other one half were tested using a pictorial measure, asking participants to identify degraded versions of the pictures. The results showed that covert rehearsal was effective only if the mode of testing matched the mode of rehearsal. That is, both verbal and pictorial covert rehearsal was effective, but it appeared that verbal rehearsal of an item did not improve memory for its pictorial depiction and pictorial rehearsal did not improve memory for its verbal label, showing that people were not simply translating pictures into words and rehearsing only verbally. Thus, effective covert rehearsal was possible in a nonverbal manner, as well.

Finally, in 1995, Z. F. Peynircioğlu looked at covert rehearsal of tones, materials that are quite difficult to label verbally for the layperson and thus are likely to be

rehearsed nonverbally. For simple pairs or triples of tones, even though physical repetition improved both short- and long-term memory and covert rehearsal improved short-term memory, covert rehearsal was quite ineffective for long-term remembering. That is, long-term memory for pitch or interval information alone could not be improved through silent thinking. Long-term memory for more complex musical materials such as 6-tone sequences or longer sequences with additional rhythmic information, however, did benefit from covert rehearsal. Thus, covert rehearsal of nonverbal materials can be effective and even carried out effectively in a nonverbal mode, but it seems that the to-be-rehearsed material needs to be meaningful or include many cognitive dimensions.

GLOSSARY

covert conditioning procedures A set of behavioral techniques that employ imagery as a way for clients to rehearse the performance of selected behaviors within the operant conditioning framework.

operant conditioning The process of increasing or decreasing the frequency of a behavior by altering the consequences that follow the performance of that behavior.

reinforcement An increase in the frequency of a behavior when that behavior is followed immediately by a particular contingent consequence.

reinforcer sampling The provision of a small sample of a potentially reinforcing stimulus in order to increase the use of the stimulus.

response priming Any procedure that initiates the first steps in a sequence of responses, and thereby increases the likelihood that the final response in the sequence will occur.

Covert reinforcer sampling is adapted from an operant conditioning technique (reinforcer sampling) that follows the principles and rules of the operant conditioning methodology, but has the stimulus presentation

occur via imagery instructions instead of by direct exposure to the stimulus. The covert reinforcer sampling procedure is designed to increase the number and range of reinforcing events available to clients by exposing them to the reinforcing elements of stimulus events or items without the direct manipulation of positive or negative consequences.

I. DESCRIPTION OF TREATMENT

Covert reinforcer sampling is employed in conjunction with other treatment interventions when the goal of therapy involves developing or strengthening reinforcers for a client. It is often used clinically with clients who are depressed and lacking access to or interest in pleasurable activities, clients who are living in environments in which stimulation may be severely lacking (e.g., in nursing homes, institutional settings), and for clients who frequently demonstrate a negative outlook on life.

The procedure is suggested for use after the therapist and client discuss the importance of a range of activities that a person may enjoy in his or her life and the problems that may develop from a limited venue of pleasurable experiences. Together the client and therapist develop a series of images that the client may find pleasurable, at least to a minimal degree. These images may involve activities (e.g., arranging a vase of flowers), settings (e.g., view of the mountains), interactions (e.g., shopping with a friend), or specific items (e.g., pictures

of grandchildren). The images may be about real or fantasized events, all of which occur on a low-frequency basis. The technique does not involve the presentation of either reinforcing or punishing consequences. The client is asked simply to imagine several of the agreed-on stimulus events in as much graphic detail as possible several times a day in blocks of 10 to 15 trials each time. It is important to include in the image as many different sensory aspects of the stimulus as possible (e.g., hearing the sound of the waves breaking on a beach, while seeing the sun setting on the water and tasting a hot dog). The stimulus material should be varied in order to avoid satiation of the reinforcer.

II. THEORETICAL BASES

Covert reinforcer sampling is derived from the operant conditioning procedure of reinforcer sampling, a variation on the technique of response priming, which is any procedure that initiates early steps in a sequence of responses. Reinforcer sampling is used to initiate the first steps in a low-frequency behavior by exposing the client to a small sample of the stimulus in order to encourage greater use of that stimulus. Once the behavior occurs on a consistent basis, the sampled reinforcer may be used to increase continued performance.

The adaptation of reinforcer sampling to an imagery venue is based on previous work with a large number of imagery-based behavioral procedures in which the client uses images to rehearse various behaviors and consequences in such a way as to produce a change in particular overt or covert activities. Many of these psychotherapeutic techniques were designed by Joseph Cautela, who referred to them as "covert conditioning procedures" and grounded them in operant conditioning methodology.

III. EMPIRICAL STUDIES

Covert reinforcer sampling has been evaluated in two case studies and one study in which it was compared with the traditional method of overt or direct reinforcer sampling. In the first case study, reported in 1976 by Patricia Wisocki, the procedure was employed along with several other behavioral techniques to help a client overcome a fear of social rejection. Covert reinforcer sampling was successfully used to help the client explore potentially reinforcing new social activities in order to enhance her social repertoire and increase the quality

and quantity of her social interactions. For example, in trying to interest the client in joining a hiking club, the therapist asked her to imagine the following scene:

Imagine that you are in the mountains on a cool, sunny day. Imagine that you are wearing heavy boots for walking, a backpack, a sweater, shorts, and a wide-brimmed hat. Imagine that you are walking with about five other people and you are all talking about the beauty around you. You see a stream nearby. It looks cold and inviting. You feel exhilarated—glad to be alive on such a day.

Scenes like this were inserted into each therapy session over a 3-month period, after which time the client became an active member of a hiking club, a church choir, an advanced French class, and a women's group. She met with friends two or three times a week, and planned and carried out social activities.

No attempt was made in this study to determine the efficacy of covert reinforcer sampling relative to the other procedures used with the client.

In the second case study, reported in 1993, Wisocki described the use of covert reinforcer sampling in a case of orofacial tardive dyskinesia experienced by a 77-year-old woman in a nursing home. The study took place over an 11-week period, including 2 weeks of an initial baseline, during which time the frequency of dyskinetic tongue thrusting movements was assessed during three 5-minute intervals during each morning, afternoon, and evening, for a total of nine intervals each day. That period was followed by 1 week of self-control instructions in which the client was asked to "try her best to relax her tongue" during the nine 5-minute sampling intervals taken in the original baseline condition. There was no decrease in the movements during this self-control phase. The tongue thrusting movements continued to occur at an average rate of 130 incidents during each 5-minute sampling interval. Relaxation training then took place over the next 2 weeks and resulted in a reduction in tongue movements to an average of 40 thrusts per interval. Covert reinforcer sampling was used during the next 2 weeks and resulted in a decrease of tongue movements to an average of 20 thrusts per interval. A second baseline, in which no treatment was provided but measurement continued, was implemented for 2 more weeks. Movements increased to an average of 60 thrusts per interval and continued at that level during the next 1 week when the client was asked to repeat the self-control instructions. Finally, the covert reinforcer sampling procedure was

reintroduced and resulted in a return to an average of 30 thrusts per interval.

Both the client and the staff working with her reported positive gains from the covert reinforcer sampling procedure. The content of the imagery scenes selected by the client stimulated discussion about the places depicted in them. They provided an occasion for the client to demonstrate her interests and showed her to have more socially endearing qualities than had been noticed previously by staff, which resulted in a reduction of the client's social isolation.

The additive design of this study did not allow for a test of the differential effects of the two interventions. Thus, it cannot be concluded that covert reinforcer sampling was more or less effective than relaxation.

Although the treatment was successful in reducing the number of dyskinetic movements, the client was not convinced that the efforts she was making to keep her tongue still were worthwhile and she demanded and received an increase in phenothiazine medication, which soon resulted in a return to severe tardive dyskinesia.

In 1980 Patricia Wisocki and Michael Telch examined the effects of covert reinforcer sampling and overt reinforcer sampling on the attitudes of a group of 56 college students, using a placebo group and a no-contact group as controls. The students' attitudes were first measured by an attitude scale. The 15 participants in the covert reinforcer sampling group were asked to imagine volunteering in a local nursing home and experiencing pleasure at interacting with the elderly residents. The imagery scene consisted of a description of a typical nursing home one would expect to encounter, including a description of various clients one might find in the setting. The scene went on to describe a positive encounter with a friendly older adult client and an ensuing positive interaction. The scene was read aloud three times during each of two 30-minute sessions and the participants were asked to imagine it in as much detail as possible for them.

The 12 participants in the overt reinforcer sampling group were taken to a nursing home and asked to interact with as many of the patients as they could during two 30-minute periods, an equivalent amount of time as given to the covert reinforcer sampling group. The 14 participants in the placebo control group were asked to imagine a scene depicting themselves volunteering to work with adults with mental retardation, using the identical procedure as provided in the covert reinforcer sampling group. The 15 students assigned to the no-contact control group simply completed the attitude scale before and after the study was completed.

Results indicated a significant increase in positive attitudes toward the elderly for both reinforcer sampling conditions. There were no changes in the attitude scale scores for the subjects in either control group. In comparing the two treatment groups, the researchers determined that the participants in the overt reinforcer sampling group increased their attitude scale scores significantly more than the participants in the covert reinforcer sampling group did. Further, participants who initially scored below the group mean on the attitude scale were found to respond significantly better to the overt reinforcer sampling procedure, while participants who initially scored above the group mean responded significantly better to the covert reinforcer sampling condition. Therefore, it appears that those subjects with an initially poor attitude toward older adults improved their attitudes more from direct contact with the population, while those with neutral or somewhat positive attitudes benefited more from the covert reinforcer sampling procedure.

IV. SUMMARY

Covert reinforcer sampling is an imagery-based procedure used therapeutically to increase the range and number of items and events that may be used as reinforcers for clients who experience a low frequency of pleasurable activities. It is derived from an operant conditioning paradigm. It has been shown effective in two cases where clients experienced a dearth of positive life experiences. It was also demonstrated to be equally effective as a direct reinforcer sampling condition in changing attitudes of college students toward elderly nursing home residents. Those in the direct reinforcer sampling condition, however, increased their attitude scale scores significantly more than those in the covert reinforcer sampling condition. Direct reinforcer sampling also appeared to be more effective with those participants whose initial attitudes toward the elderly were more negative, while covert reinforcer sampling appeared to benefit those whose initial attitudes were neutral or somewhat positive.

GLOSSARY

countertransference An emotional reaction of the therapist toward the patient, usually meant to include two elements, which are the irrational feelings based on the therapist's unconscious mental organization, and the feelings and responses of the therapist in reaction to the patient's unconscious transference feelings toward the therapist.

culture The concept encompassing the collective knowledge, shared beliefs, values, language, institutions, symbols, images, and artistic works of a group that represent, signify or allude to these values, beliefs, and ideas and result in a shared world view.

cultural competency The awareness on the part of the psychotherapist of the various cultural factors influencing the behavior of the patient. These factors include the cultural identity of the individual, the cultural explanation of the individual's illness, cultural factors related to the psychosocial environment and functioning of the patient, and

cultural elements in the relationship between the individual and the clinician. The idea of competency includes the ability to use this information in treatment planning and crafting effective psychotherapeutic interventions.

cultural formulation The process whereby the ethnic/cultural identity of the patient is used in the process of diagnosis.

transference The emotional reaction of the patient towards the therapist, in which thoughts or feelings related to earlier stages of development are transferred to the therapist.

I. DESCRIPTION OF CULTURAL ISSUES AND THE CULTURAL FORMULATION

There has recently been an increasing awareness of ethnic diversity within almost every country of the world. This awareness and the advocacy of various ethnic groups for equality in multicultural environments have resulted in an emphasis on cultural competencies in medical education and practice.

Cultural competency in psychotherapy has become an explicit goal in all mental health disciplines in the United States and provides a benchmark of quality in the public mental health systems in California, New York, and many other localities serving large minority populations. Cultural competency in psychotherapy requires that the therapist develop knowledge and skills predicated on an attitude of receptiveness to "foreign" theories of illness and alternative pathways of healing such as is exemplified in the following case of Carlos:

Carlos is a 26-year-old Puerto Rican born man who was referred by a local spiritual healer in New York for medical and psychiatric workup. He had a skin rash that worried him to the point of despondency. Over the course of six months he had become more and more depressed and feared that he might be suffering a fatal illness.

Carlos was treated with psychotherapy, at first twice a week for two months and later weekly for eight months. He was also prescribed imipramine hydrochloride, orally, which was increased during a two-Week period to 150 mg at bedtime. His symptoms improved. Several weeks later, Carlos said that he was going to have a religious intervention at a session in his spiritual healer's church. His psychiatrist was invited to attend and observe the session. There were about 25 to 30 persons in attendance at the healing center. In the churchlike room, there was an altar with many statues of "Saints" from the Catholic religion. In front of the altar there was a table with numerous religious paraphernalia, such as collars, prayer books, bottles of incense, and a cup with water. After some consultation with others in attendance in accordance to the norms and rituals of the center, Carlos was called in for his spiritual/religious intervention. The spiritual healer told him that he had to pray regularly in order to be protected from bad spiritual influences. He was also told about the woman in the neighborhood who put the "root" on him, with the intention of separating him and his wife. His wife acknowledged that she had actually considered that possibility all along. Later on, the spiritual healer put a cream on his abdomen, and massaged the area supposedly affected by the "root." Then he applied a lotion in order to make his digestive system, especially his stomach, less vulnerable to "rooting." Additionally, the spiritual healer gave him and his family advice as to how to protect their home from bad spiritual influences using water and special herbs. At the end of the religious session, everyone prayed together on behalf of Carlos. Carlos' daughters were present in the session, as were also many other children who came with members of their families. He subsequently became a devout follower of this healing center religion. His religious conversion made his wife very happy, since she had always gone to the center alone or with her two daughters.

Cultural competencies have been addressed in the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, DSM-IV), published in 1994. A special Task Force on Cultural Psychiatry was created by the American Psychiatric Association to identify "specific culture, age, and gender features" for each diagnosis in the DSM-IV. The Task Force emphasized that:

- Cultural pluralism has become a worldwide reality.
- Psychiatric diagnosis must be predicated on considerations of cultural factors.
- Cultural differences in the meaning of illness and of health put the clinician, who is unaware of nuances of the patients' behavioral-environment and belief system, in jeopardy of seriously misunderstanding.
- Misunderstanding can lead the clinician to judge variations in normal behavior, belief, and experience as psychopathology, when such is not the case.

The Cultural Formulation outlined in the DSM-IV focuses on the effects of culture on the expression of symptoms, definition of illness, and treatment considerations, and effectively enriches the traditional biopsychosocial model of treatment in psychiatry practice. The Cultural Formulation recommends that the clinician address the following factors involved in patient care:

A. *Cultural identity of the individual.* The clinician should specify the individual's cultural reference groups. Attend particularly to language abilities, use, and preferences (including multilingualism). For immigrants and ethnic minorities, note separately the degree of involvement with both the culture of origin and with the host or majority culture.

B. *Cultural explanations of the individual's illness.* Identify (1) the predominant idioms of distress through which symptoms are communicated (e.g., such as the case of Carlos—"nerves," possessing spirits, somatic complaints, inexplicable misfortune); (2) the meaning and perceived severity of the individual's symptoms in relation to norms of the cultural reference group; (3) any local illness category used by the individual's family and community to identify the condition . . . ; (see Part II of this Appendix, "Glossary of Culture-Bound Syndromes and Idioms of Distress" in DSM-IV); (4) the perceived causes or explanatory models that the individual and the reference group employ to explain the illness; and (5) current preferences and past experience with professional and popular sources of care.

C. *Cultural factors related to psychosocial environment and functioning.* Note culturally relevant interpretations of social stressors, available social supports (such as the spiritual center available to Carlos), and levels of functioning and disability. Special attention should be given to stresses in the local social environment and to the role of religion and kin networks in providing emotional, instrumental and informational support.

D. *Cultural elements of the relationship between the individual and the clinician.* Indicate differences in culture and social status between the individual and the clinician and problems that these differences may cause in

diagnosis and treatment (e.g., difficulty in communicating in the individual's first language, in eliciting symptoms or understanding their cultural significance, in negotiating an appropriate relationship or level of intimacy, in determining whether a behavior is normative or pathological, etc.).

E. *Overall cultural assessment for diagnosis and care.* The formulation would conclude with a discussion of how these cultural considerations specifically influence comprehensive diagnosis and care.

II. THEORETICAL BASES OF ETHNIC IDENTITY

The Cultural Formulation recommends that the clinician assess the ethnic identity of the patient as the first step in the process of diagnosis. This recommendation might seem familiar to most physicians, for they have been traditionally taught to begin the patient evaluation with "Identifying Information and Chief Complaint." Most clinical presentations begin with the phrase, "the patient is a 42-year-old, black male, who..." or "...is a 12-year-old, white female, who..." or "...is a 73-year-old, Hispanic male, who..." Such descriptors are taken for granted and by now have become almost universal in clinical conferences, ward rounds, and case reports. The ethnic/racial descriptor is most often ascribed by the examining physician rather than by the patient.

Eliciting the patient's self-perception of his or her own ethnic identity is, however, an important procedure in the diagnostic process and is also helpful in designing the treatment and management interactions that follow. How then does the physician validly describe the ethnic "identity" of the patient? The first step in this process is to ask the patient about cultural and religious backgrounds. Notice that the plural is used in "backgrounds," for the patient's mother and father may have different cultural origins. People who live in multicultural societies may have several ethnic traditions from which much of their identity is derived. In patients from minority cultural backgrounds, the identity acquired by the process of enculturating to mainstream American culture renders another layer of complexity. Modern mobility has resulted in many people growing up in different neighborhoods and even in different countries. This can add further dimensions to ethnic identifications. The dynamics of cultural influences on identity are as complex as psychodynamics are in the formation of personality. Although patients may be able to articulate some cultural influences with full aware-

ness, others may be so automatic and taken for granted that they are only discoverable by studied self-reflection and inference. In nearly all such cases, terms that we commonly use to categorize ethnicity may be too simplistic.

Giving the patient the opportunity to reflect on personal cultural identifications may allow for expressions that affirm the self and inform the clinician. Several caveats, however, must be considered in the process of assigning labels pertaining to ethnic identity. Much of the terminology now in official and common use to designate ethnic identity is actually quite questionable from a scientific perspective. For example, the ethnic categorization of people as black, Hispanic, Asian, and American Indian lacks precision and comparability because they have different referents; that is, Black refers to skin color; Hispanic to a language; Asian to a continent; and Indian to a heterogeneous group of aboriginal inhabitants within the United States.

Distinctions based on skin color have been used for purposes of social discrimination, oppression, and segregation. During the Reconstruction era following the Civil War, many families in the southern states were divided arbitrarily using the criterion of tone of skin color. Those members who could "pass" were considered "white," and those of darker hue were called "colored," "Negro," or "black." This issue remains problematic to their descendants to this day. Skin color is in fact a poor marker of ethnic or genetic differentiation.

"Hispanic" is another ethnic designator that is used as a political banner for many disenfranchised Americans but, like skin color, has dubious validity. "Hispanics," "Hispanic-Americans," or "Latinos" tend to be labeled as such regardless of country of origin and cultural background, thereby leading to clinical and research categories that are imprecise. "Hispanic" can apply to people from Spain or South America who speak Spanish. Are Spanish-speaking Filipinos to be considered "Hispanic" or "Asian"? Are Brazilians who speak Portuguese also "Hispanics"? Consider the cultural and possible genetic variability between "Hispanic" Argentinians of Jewish-European descent; Puerto Ricans of Afro-Caribbean descent; and Mexicans of Mayan Indian descent. All speak Spanish and are from "Latin" America. From the perspective of a racial grid based on skin color, one "Hispanic" group could be considered "white"; another "black"; and the third, "red."

Designations based on geographical place of origin are also inadequate indicators of ethnic identity. "Caucasian," "American Indian," "Asian American,"

and “African American” are examples of general categories used for this purpose. Caucasian refers to “white” people of European ancestry but would probably exclude those populations with epicanthic skin folds of the eye lids who actually live in the region of the Caucasian Mountains of Central Asia. “American Indian,” on the other hand, refers to a heterogeneous people from 260 different language groups, some descended from groups that migrated from North Asia during the last Ice Age and others, such as the Inuit (Eskimos), who have migrated more recently (witness recent arrivals of Eskimos from Siberia to Alaska). Ironically, these recent arrivals from Asian Siberia are not, however, considered Asian Americans.

The term Asian American commonly refers to people emanating from the Far Eastern countries such as Japan, China, and those of Southeast Asia, Vietnam, Cambodia, Laos, and Thailand. Asians from India, Pakistan, Iran, Iraq, Turkey, and so on, are usually not included in this category. Instead, they are often referred to as Muslims (a religious preference) or Middle Easterners, but as yet they have not been categorized as an official ethnic minority.

Without actively exploring these issues during the interviewing process, attributing racial and ethnic identities to the patient may be invalid and may even have pernicious results. For example, arbitrarily classifying patients according to perceived skin tones may not only identify but also reinforce historically derived categories of social discrimination and negative stereotyping. Therefore, clinicians need to be aware of and actively inquire about the patients’ self-attributions regarding ethnicity, race, social class, and religion. By exploring each of these items, the clinician can develop mutual understanding with the patient in regards to cultural and social influences on the mental disorder and its treatment.

III. THEORETICAL BASES OF RACIAL IDENTITY

There is no ready consensus these days as to what is meant by race, nor is there agreement on what is actually meant by “black” or “white.” The genetic heterogeneity of American society makes it impossible to define what is meant by race-linked terminology. In the southern United States it was census law that a drop of “black blood” made an individual black. However, it was commonly observed that a light-skinned woman

living as a black in one community might have an equally light-skinned sibling living as a “white” in another community where few had knowledge of the family’s relationships.

Despite such lack of precision and clarity with respect to racial classifications, race has taken on particular significance in the United States. The historical American experience with slavery has led to associating stereotyped concepts and stigma to dark skin. On the other hand, equally stereotypic notions of superiority and intellectual cleverness have come to be associated with light skin color.

The complexity of grouping people together on the basis of such arbitrary racial distinction is compounded by consensual identifications because of common cultural heritage. Hence, “blacks” can indeed look very different but still agree that they are African American in cultural outlook. Furthermore, only relatively recently has the notion of substantive variability in ethnic identity among blacks been examined. For example, one dark-skinned individual may be minimally Afrocentric and “mainstream” in political outlook, whereas another equally dark-skinned person may be resolutely Afrocentric. Some psychotherapists have observed that the same individual may change ethnic identity over the period of adult life with a Afrocentrism developing with maturity.

The importance of race as a dynamic factor in American life is practically ubiquitous in its effects, and the potentially problematic interaction between different racial groups is a significant element in practically every facet of life. Clinicians have come to recognize that race has some importance in the context of psychiatric practice, especially pertaining to the patient/clinician dyad and the clinician/supervisor dyad, which may be substantively influenced by racial considerations. Race can impact on clinical understanding, with significant consequences for the diagnostic process and ultimately for treatment decisions.

IV. APPLICATIONS OF CULTURALLY SENSITIVE PSYCHOTHERAPY

Cultural explanations regarding the nature and experience of illnesses are related to the initiation, process, and termination of psychotherapy. Patients often have cultural explanations for their stress and symptoms that differ from those of their psychotherapist. Many people who suffer from psychiatric disorders do not seek psychotherapy for this reason. Studies have shown

that patients who believe that their illness resulted from religious, magical, or other sources not considered valid by modern medicine were more likely to fail standard psychotherapy than those who shared a similar model of causation with their therapist. It is not uncommon in the cross-cultural treatment situation to hear patients state that religious problems contribute to their illness: that God is punishing them for past sins, that they are not in God's grace, or that their problems are God's will. Some patients believe that others have caused their sickness through voodoo or the "evil eye." Other examples of alternative nonmedical beliefs can be found in patients who follow modern popular health movements or who believe in traditional herbal practices that attribute psychological problems to imbalanced diets or to the toxic effects of sugar, meat, food additives, or other edibles. In contrast, patients who endorse medical model explanations and reject folk explanations of their psychiatric symptoms will be more likely to follow a psychotherapist's treatment advice. Similarity or difference in the explanatory model of the psychiatric illness between the psychotherapist and the patient may have a profound influence on the course of treatment. The use of psychotherapy in treating mental disorders that occur in nonmajority patients has therefore been a subject of consideration in planning psychiatric services. Many clinicians working with ethnically diverse populations have questioned several basic assumptions of psychotherapy as developed in Western Europe and the United States and its applicability to people raised in different cultural environments. For example, psychoanalytic psychotherapy is a talk therapy aimed at bringing insight and transformation to a personal, often unconscious, aspect of the individual self. According to this theoretical approach, even interpersonal relationships are "psychologized" and brought back for self-reflection in a person-centric construct focused on the individual as a unitary, active agent.

Some scholars in cultural psychiatry view this form of psychotherapy as a uniquely Western ethnotherapy that is best applied to those of this tradition (i.e., white, educated, middle class), and not used with members of other ethnic groups. A few might even regard psychoanalytic psychotherapy as a pernicious, harmful practice meant to reinforce the values of the elite majority while damaging further the self-esteem derived from traditional identity.

Although some of these arguments may be inspired by recognizing that self-esteem and identity are enhanced by the solidarity of accepting and identifying with one's ethnic or racial heritage, they ironically lend

support to the not-so-scholarly opinions of those psychotherapists who believe that, for a variety of reasons, minority or low socioeconomic status patients are not "good candidates" for insight-oriented psychotherapy. Such psychotherapists have observed that "minority" patients often express conflict by "acting out" rather than by verbalization and cognitive mastery, and that the early life traumas (common in lower socioeconomic status populations) preclude the more mature object-relational capabilities required for successful engagement in psychotherapy. Policymakers and agencies that are concerned with cost reduction in psychiatric services are also bolstered by these arguments to reduce basic psychiatric services to those who might most need them but cannot afford them.

Although psychotherapy has become an important treatment modality in general psychiatry, it has been for the most part reserved for the affluent members of society. Many surveys have revealed that minorities, particularly those of low socioeconomic status, receive less psychotherapy, for shorter periods of time, by less experienced staff.

A number of studies have indicated, however, that members of many major ethnic minority groups in the United States are as receptive to psychotherapy as members of the majority group. These studies find no differences between Mexican Americans and Anglo Americans in terms of referral, compliance, and resistance to psychotherapy, and they reveal that neither race nor ethnicity has any effect on the number of treatment sessions, treatment modality, or treatment environments. Some studies have also demonstrated the efficacy of culturally sensitive psychotherapy with Asian-American patients, refuting the cultural stereotype that Asians are unable to express themselves in emotional terms. It is well recognized by now that, even abroad in India and Japan, psychotherapy and psychoanalysis have obtained a valuable place as treatment modalities appropriately offered to many patients in these societies.

V. EMPIRICAL STUDIES OF PSYCHODYNAMICS AND CULTURE

Studies of the psychodynamics of people in Asian societies emphasize emotions as embedded in interpersonal relations, in which persons are rarely considered autonomous and separate from their society. Thoughts, feelings, ambitions, and desires are perceived to reside not in the individual, but in family and

close social networks. Some psychiatrists have reported that Japanese have no clear-cut conceptual demarcation between self and others. There seems to be “blurred ego boundaries” between self and significant others, which creates a sense of group identity rather than individual identity. The goal of one type of psychotherapy practiced in Japan (Nai-Kan—look within oneself) is to bring awareness to the patient of how ungrateful and troublesome he or she has been to parents, teachers, and benefactors. The patient is appropriately counseled as to how to show gratitude and alliance. In this process, patients realize that they have no right to expect that their personal wishes and desires will be gratified by others. Instead, they realize that they exist for the sake of others. Egocentric traits such as “sticking to a personal opinion” are seen to be neurotic and selfish. Therefore, the patient must come into harmony with group goals that may be equally assertive and competitive but will collectively serve the family, class, or company’s needs rather than personal needs.

Many Asian patients with such sociocentric orientations also have problems speaking to a psychotherapist about intrapsychic or interpersonal problems. They often have emotional and cognitive conflicts involving feelings of selfishness, ingratitude, and betrayal about considering such issues. Some psychiatrists have commented on the Asian patient’s desire to protect his “inner self” from exposure. Others have speculated that, in sociocentric societies, the inner self is undefined, with minimal referential vocabulary, or is psychologically undeveloped to the extent that the patient has little or nothing to report regarding an awareness of an inner self. Such patients will distrust talk therapy and, when severely symptomatic, will express their distress somatically rather than in psychological terms. Such presentations of illness may not only be defensive in function but may also reflect a context-dependent perspective in which organs, body parts, individuals, and groups are considered holistically balanced or imbalanced in a unified-interactive system.

Because many patients in Asian countries complain of somatic symptoms in time of distress, it is assumed that they lack psychological mindedness. Some studies have observed that the use of proverbs may provide a vehicle for expressing interpersonal and intrapsychic conflict. Asian societies use proverbs to express empathetic understanding and often point out dysfunctional defenses in a manner acceptable to the listener. Traditionally educated Vietnamese are required to memorize volumes of such verses, which are considered to be classics.

Many Vietnamese proverbs express psychological awareness of, and concern for, intrapsychic and interpersonal conflict. Proverbs are used to interpret and instruct family members and close friends in regard to their defensive handling of affects. In psychotherapy, proverbs are used in a gentle, indirect, nonconfronting way when approaching psychological or sensitive interpersonal issues, particularly in such culturally specific therapies as Nai-Kan and Morita.

VI. PSYCHOTHERAPY SPECIFIC TO CULTURAL GROUPS

Specific forms of psychotherapy practiced within unique cultural groups range from the laying on of hands and prayers that commonly occur in many Christian denominations to spiritual centers (*espiritismo centros*), evil-eye curing centers (*malocchio/mal de oio*), sweat lodges (southwestern American Indians), and root work (rural African-American communities), among many others. The merit of many of these culturally specific therapies is currently an issue of much interest and study, as at the Center for Alternative/Complementary Medicine at Columbia University. Culturally specific therapies often reaffirm traditional cultural values and reinforce group solidarity, providing support and identity to a patient in distress. In addition, many ethnic curing practices identify and explicate unique culturally related interpersonal conflicts that cause distress and provide mechanisms for appeasement or resolution.

As valuable as many of these specific cultural approaches may be for special and unique populations, their general applicability in multicultural environments seems limited. Some have suggested creating a broad array of culturally specific clinics or having each therapist or clinic achieve competence in administering the myriad culturally specific therapies required to bring an equal quality of mental health care to all diverse citizens. This would seem to be an organizational and quality assurance task of daunting proportions. In addition, sensitive civil rights issues may be encountered in triaging and assigning minority patients to culturally specific therapies, while majority patients are referred to standard treatments.

Integrating knowledge of the unique cultural values and beliefs into personal psychodynamics in the treatment of people from non-Western societies would seem to offer the most parsimonious and optimal approach to this dilemma. Familiarity with cultural traditions, val-

ues, and context as well as language ability are essential to such a cross-cultural psychotherapeutic enterprise. The following case study of a Japanese-American woman will illustrate these principles.

VII. PSYCHOTHERAPY TECHNIQUE AND CULTURE

The therapist's ability to listen openly in an empathetic, noncritical manner to what the patient is saying and to mutually decide on the goals of the treatment are fundamental to any treatment no matter what the ethnic group. These skills do not come naturally. Cross-ethnic psychotherapy must be self-consciously examined and learned. Psychotherapy requires that intimate conversations occur between socially distant individuals. In most cultures, intimate conversation is reserved for close family or acquaintances. Formal, polite, nonrevealing patterns of communication are used in conversations with outsiders. For example, it has been observed that bilingual Hispanic American patients tend to use Spanish at home and English in psychotherapy, even when the psychotherapist is bilingual. The formality of the treatment situation and the standardization of English by therapists enhance these tendencies. The patient in cross-ethnic psychotherapy may therefore establish early transferences based on previous formal relationships (e.g., with English-speaking teachers, store clerks, and ministers) where self-disclosure was kept to the minimum required to transact an interaction. One approach used in cross-ethnic psychotherapy to overcome this resistance is having the therapist use the more informal language when possible. Another is to discover with whom the patient does share personal information, contrast this mode of sharing with the more formal conversations in treatment, and ask that the patient talk in therapy as they talk to their confidants.

It may also be useful for the therapist to pay particular attention to and learn ethnic colloquialisms that characterize the patients' informal conversational style. Generally, the more knowledgeable the therapist can become regarding differences in use of vocabulary, communicative gestures, expressions of distress, and personal-culturally based values, the better will be the therapeutic alliance. For example, incorporating "dichos," or sayings that exist in Mexican-American and other Latino cultures, into psychotherapy provides useful approaches to mitigate resistance and reframing problems.

In addition to attending to the cognitive aspects of cross-ethnic psychotherapy, therapists should also become aware of their own unconscious reactions to patients of another race or culture. White therapists, for example, have been found to make more errors in speaking and have less forward lean, eye contact, and shoulder orientation when working with black patients. Body language may carry culturally specific meanings that can be easily misinterpreted and warrants exploration and understanding in cross-ethnic psychotherapy.

VIII. TRANSFERENCE-COUNTERTRANSFERENCE AND CULTURE

Cultural differences may fascinate the therapist and distract treatment from the reality of the patient's core conflict to inquiries of a more anthropological nature. An example is in the vignette of psychotherapy with a Brazilian-American patient, where substantial time was spent discussing cultural meanings of colorful and affect-laden interactions with friends during Carnival, while the patient's defensive use of hypomania was overlooked.

Conversely, many therapists deny that cultural differences have any relevance to psychotherapy, and they believe that all patients are or should be "just like me after all." The exuberance of this revelation may often pave the way to unwarranted assumptions regarding social values that may interfere with an insightful-empathetic enactment of mutual goal setting in cross-ethnic psychotherapy. In such cases, the therapist may overlook the special needs associated with specific minority membership to the point of cultural insensitivity.

Matching therapists and patients by race or ethnicity has been suggested as one way of avoiding such difficulties and facilitating the formation of the therapeutic alliance in work with ethnic subgroups.

For example, when African-American patients are matched with African-American psychotherapists, the therapists are less likely to misinterpret lifestyles as pathologic, and instead will readily recognize the strengths and positive aspects. For some patients the African-American therapist may be better able to evaluate the role of "black reality" as actual rather than as a defense or resistance to change. Such relatedness and understanding contribute to better rapport, communication, and empathy with the social reality of the patient.

Matching of therapist and patient also has its pitfalls. For example, African-American therapists can become overly concerned with the sociopolitical factors involved in their patients' dysphoria. This concern may result in emphasizing black political solidarity and perspective rather than focusing on the "personal" and familial problems unique to their client's life. Some therapists may reject "white theories" and propose theories that carry an overt or implicit political message. They may convey the message to the patient in a familiar moralizing, preacher fashion attempting to enlighten the patient regarding the social injustices he or she has endured. Some authors refer to the "blacker than thou" stance manifest in such countertransference reactions. Some patients who reject their own blackness may also project their own lack of self-esteem onto the therapist whom they erroneously perceive to be lacking in ability. Especially vulnerable may be patients who grew up in white neighborhoods. Such issues are explored most effectively, and the therapeutic alliance is enhanced by carefully working with the patient to help unfold the patient's personal life's story and to examine the patient's denied or repressed feelings and conflicts.

An "Afrocentric" approach to psychotherapy with African-American patients has been proposed as a way to recognize African influences in our society. This approach stresses person-to-person relationships, style and use of language, strong emotional expressiveness, and the spiritual orientation of blacks. Alternative forms of healing have also been advocated based on African traditional practices and folkways. These are explored and revitalized for use in current treatment programs.

Although ethnic minority patients may often prefer to be treated by therapists from their own ethnic/racial group, skin tone might have minimal relevance to shared cultural beliefs, values, and behaviors. For example, a Jamaican-American therapist of Rastafarian tradition may have few cultural values in common with a "black patient" whose father is a law professor and whose mother is Irish Catholic. In such a case, the status of the development of global racial identity may or may not be the core issue essential to treatment.

Defining "what is being matched" in matched versus mismatched therapeutic relationships is often accomplished by distinguishing ethnic and racial variables "distal" from those "proximal" in the treatment situation. Many studies of matching therapist and patient have used indicators that are distal (or remotely relevant) to the actual treatment situation. Distal indicators

might include skin color, declared ethnic identity, languages spoken, countries of origin, religion, and so on. Those factors may only superficially indicate the mutual values, behaviors, beliefs, and attitudes actually manifested in a shared therapeutic relationship. These factors are the proximal indicators of a therapist-patient match and are crucial to the valid assessment of outcomes. From this perspective, it is the actual behaviors and attitudes manifested within the treatment itself that determine the therapeutic alliance, the accuracy of interpretations, and the ultimate outcome. In this case, a match of therapist and patient is based on measures of the process of therapy itself rather than on global or declared ethnic/racial attributes of the parties involved.

In contrast, matching on the basis of superficial descriptors, such as nationality or race, indicates little about the ethnic identity, cultural orientation, or racial/ethnic group identifications of either the patient or therapist. The importance of designing therapist-patient matching strategies in terms of the substantive constructs underlying definitions of racial identity and culture, rather than superficial labels, is indicated by studies showing that therapist-patient similarities of values, locus of control, and semantic differentials are related to better outcome. In addition, studies showing that better outcome is related to similarity of demographic variables, such as marital status and socioeconomic status, indicate the importance of distinguishing ethnically specific matching variables from other characteristics that may influence the results of treatment.

Another apparent variable in the outcome of matching patient and therapist is the therapist's clinical skill. Many studies that attempt to determine the influence of ethnic matching on outcome are hampered by insufficient assessment of therapist competence as distinct from other therapist-related variables, including ethnicity. One methodological approach for estimating therapist competence, adopted by technological models of psychotherapy research, involves an independent rating of therapist adherence to the guidelines of operationalized treatment manuals. This methodology allows process-oriented evaluations of therapist behaviors and the degree to which they conform to the technical and theoretical parameters of the particular therapy model. Exclusive reliance on process variables allows specific measurements of treatment integrity and therapist performance as distinct from other therapist characteristics and independent of outcome assessment. Research strategies that specifically measure therapist adherence may, therefore, represent useful tools for researchers attempting to identify the separate contribution of therapist-patient ethnic

matching on outcome. These strategies may provide an initial methodologic framework to consider how culturally responsive activity by the therapist may be necessary in cross-ethnic therapies. In this manner, subcultural studies in the future might illuminate how culturally responsive adaptations intrinsic to the psychotherapeutic frame and process affect outcome.

IX. CASE ILLUSTRATION

Kimiko, a 26-year-old Japanese woman married to an American man, will serve as an example of how the unique experience of the self as embedded in family relationships can contribute to conflict in acculturating to a multicultural society such as that of the United States.

Kimiko had moved to the United States with her husband at the age of 23. Kimiko's reasons for beginning psychotherapy were depressed feelings and a lack of *Jibun* ("me" as a target of cognitive intentionality) or *Jiko-ishi Ki* (self-awareness). This lack showed itself as (1) inability to make choices when she had to express a personal preference; (2) her feeling that there was nothing to which she would like to fully devote herself; and (3) her sense that she was only able to pursue her own happiness indirectly by doing things for others that resulted in their happiness. Kimiko underwent 100 sessions of psychoanalytic psychotherapy with a Japanese psychoanalyst in the United States. A general theme of Kimiko's therapy was her discovery of self. Transference issues included a desire for a responsive, affectionately strong father. This desire was conditioned by Kimiko's relationship with her father who had been "reticent" or "absent." There was also an important maternal transference based on Kimiko's attachment to a nurturing and open relationship with her mother. The therapist was highly idealized in this regard, especially early in treatment. During her sixth hour of psychotherapy, Kimiko talked about her relationships with her mother, husband, and others:

Two days before my anniversary I received from my grandmother a card and a check from my mother. I know they always do something for me. But I was happy to receive so much from them even though I am economically independent ... They would be pleased to learn how I spent the money. ... They are always behind me. I can depend on them should something happen ... am not completely independent ... if an emergency happens I can receive help from them. I feel that this is *Amae* [dependency]. Even though I do not

meet them every day they are in my mind and when I feel lonely, I turn to them. I consider this as *Amae*.

Kimiko also reported a number of dreams during her psychotherapy. One of these dreams particularly captured her core conflictual relationship them: "My mother is seen far away. I wanted to call her but I could not vocalize. Her leaving home with somebody was seen remotely. I wanted to call her attention but I could not emit my voice."

Kimiko had separated from her family and culture when she moved to the United States with her husband. Themes of separation and dependency (*Amae*) are repeatedly experienced in her treatment. In addition, she complains of the lack of a sense of self, and her narrative reveals her embeddedness in the supportive family network. In the context of the United States, where independence of self is considered an asset, Kimiko feels particularly disadvantaged.

Therapists must be alerted to recognize when such contrasts occur between their own values and assumptions and those of their patients. Psychotherapists are advised to share their patients' world-view without negating its legitimacy. In the case of Kimiko, such a compromise was not an issue because she herself complained about her dependency and lack of sense of self. If Kimiko, with her depression, had experienced *Amae* as ego-syntonic, even laudable in terms of Japanese social values, the therapeutic process might have necessarily taken another course. In any case, the therapist may not be able to completely understand the patient's values but should be able to explore them empathetically and nonjudgmentally in a working, therapeutic alliance.

X. SUMMARY

The DSM-IV Cultural Formulation indicates essential principles of cross-ethnic and cross-cultural diagnosis of mental disorders. These principles include:

Knowledge of the concepts employed in studies of language, culture, and medical anthropology. Such concepts should be applied to the clinical context and include understanding:

- cultural concepts of world-view, emic-etic, values, and norms (ideal and behavioral);
- linguistic concepts of denotation-connotation, translation-interpretation, idioms and local jargon and referents;

- medical anthropology concepts of cultural “idioms of distress,” and cultural conceptions of illness and illness presentation.

Therapists must understand how culture and ethnicity can modify the importance of work, family, illness, and death in the lives of their patients. They should appreciate the ideal cultural norms with regard to family organization and loyalty (e.g., patriarchal-matriarchal authority, patrilineal-matrilineal inheritance, and patrilocal-matrilocal-neolocal residence). They should recognize when an illness represents a personal failure or moral lapse in the sufferer; when it suggests the action of a malevolent spirit that has been offended by the patient or a family member; when illness raises the question of a curse by an enemy; when the patient fears death from the malady; and in the patient’s culture, what follows after death.

Therapists should also appreciate the existence of certain culture-bound or culture-related disorders. They should understand the concept of pathoplasticity and the role played by culture in certain psychiatric conditions (e.g. eating disorder, substance-related disorders, and various somatoform, hysterical, or crisis-induced states).

Skill in the following areas:

- Diagnostic interviewing across ethnicities and cultures; methods of establishing rapport; the importance of facilitation and clarification; potential problems associated with confrontation and interpretation and education; ethnic differences in eye contact and interpersonal space (or “body envelop”) and nonverbal communication.
- Patient versus family interviewing; cultural differences regarding confidentiality and privacy; presence of a family member during assessment.
- When to use an interpreter; preparation for becoming an interpreter; conceptual models regarding interpreters; differences between translators and interpreters; problems in being an interpreter; and how to facilitate the work of a translator.

Patients’ histories can be approached in terms of their personal, family, and cultural histories. These histories are held by the patients as constructs, which can be detected by the use of keywords used over and over as they interact with the clinician. Family cultural background can be elicited from the patient’s personal explanation and meaning of the family’s developmental history through the generations. Another method of eliciting cultural identity is by using an interpersonal matrix that

involves assessing the patient’s viewpoint of particular topic areas—such as demographics (age, gender, and location), status (social, educational, and economic), and affiliations (ethnic, religious, and family)—and the behaviors, expectations, and values associated with these factors. This model helps the therapist understand that behavior can have different meanings depending on the patient’s ethnic identity and cultural perspective.

Attitude: Therapists should also be able to appreciate their own ethnicity and their ethnocentricity. They should appreciate the ethnicity of their patients and remain sensitive to the world-views of others. In particular, they should recognize how their own ethnocentricity may interfere with therapy and psychotherapy.

Therapists should be able to recognize that not all unfamiliar traits, behaviors, thoughts, or emotions in a patient are necessarily the result of psychopathology. Similarly, they should be able to consider that the unfamiliar dimensions of a patient may not be simply cultural in origin. Perhaps most important, the therapist must be able to recognize and deal with cultural countertransference, negative and/or positive.

The guidelines provided by the Cultural Formulation of the DSM-IV are fundamental to diagnosing and treating patients in a multicultural society. The cultural issues encountered in psychotherapy are especially dependent on these fundamentals.

Therapy (DIRT) and discusses its therapeutic effectiveness by reviewing the DIRT treatment trials that have been conducted to date.

GLOSSARY

cognitive-behavior therapy A therapeutic approach designed to change mental images, thought patterns and behaviors to help sufferers overcome emotional, behavioral, and psychiatric problems.

danger ideation reduction therapy (DIRT) Developed by Mairwen K. Jones and Ross G. Menzies in the mid-1990s. DIRT is a cognitive-behavioral treatment package for OCD sufferers who experience contamination obsessions and washing compulsions. It solely aims to decrease danger-related expectancies concerning contamination and disease.

obsessive-compulsive disorder (OCD) An anxiety disorder characterized by persistent and unwanted thoughts or images, and impulses to carry out repetitive behaviors or mental acts. Obsessions about contamination and compulsions involving washing are particularly prevalent in sufferers.

This article presents a brief description of the expectancy model that underpins this treatment approach and outlines the empirical findings related to this account. It also provides a description of each of the six treatment components of Danger Ideation Reduction

I. DESCRIPTION OF TREATMENT

Danger Ideation Reduction Therapy uses a variety of techniques to decrease patient estimates of the probability of dangerous outcomes. DIRT procedures include cognitive restructuring, filmed interviews, corrective information, microbiological experiments, a probability of catastrophe estimation task and attentional focusing. A core tenet of DIRT is that clients perform compulsive washing behaviors in response to faulty beliefs about contaminants in the environment and the ease with which contact with “contaminated” stimuli will lead to illness. Each component of DIRT aims to decrease the patient’s belief in the likelihood of dangerous outcomes with respect to contamination. DIRT does not involve exposure and response prevention or employ pharmacotherapeutic agents. In addition, DIRT differs from other cognitive therapy approaches to OCD because all maladaptive beliefs other than exaggerated threat expectancies are ignored by the package.

A. Cognitive Restructuring

This procedure combines features of systematic rational restructuring developed by Marvin Goldfried in

the mid-1970s and rational-emotive therapy developed by Albert Ellis and introduced in the early 1960s. The therapist encourages the patient to identify unrealistic thoughts related to contamination/illness and teaches the patient to reevaluate these thoughts, changing them to be more realistic and appropriate to the demands of the situation. Once constructed, participants are asked to rote-learn their reappraisals, reading and copying them on a daily basis. In later sessions, participants are shown how to apply their reappraisals to novel situations.

B. Filmed Interviews

This component involves the presentation of filmed interviews with workers employed in a range of occupations which involve regular contact with contamination-related stimuli. Occupations include house cleaning, laboratory work, printing, gardening, banking, and nursing. Each interviewee describes in detail the frequent contact with OCD-related stimuli (e.g., chemicals, garden soil, animal hair, bodily fluids, money). Interviewees are then asked about their health and level of sick leave over the course of their employment. The therapist highlights the absence of work-related illnesses in each interviewed employee.

C. Corrective Information

This component involves the presentation of a list of facts related to illness and death rates in various occupational groups (e.g., the number of health care workers who had occupationally contracted HIV). The information provided to clients highlights common misconceptions about illness and disease and the ease with which a variety of conditions can be contracted. Additional information is provided to participants concerning the problems inherent with excessive hand washing. This includes a one-page microbiological report that explains how vigorous washing can damage the integrity of the skin, causing cracks and fissures that break down the protective barrier to infection.

D. Microbiological Experiments

In this procedure the therapist discusses the results of a series of microbiological experiments concerning contamination. The experiments involved the researchers “contaminating” one hand by touching a number of stimuli commonly found to be anxiety provoking to OCD washers, (including garbage bins, toilet doors, and animal hair), while the other hand acted as a control.

Fingerprints from both hands were imprinted on sheep blood agar plates. Following the description of the experiments the therapist directs the patient to the research report findings which state that no disease-causing organisms were isolated from fingerprints on the sheep blood agar plates following contact with OCD-relevant stimuli. No potentially pathogenic organisms were isolated on either the control or the experimental task plates. The microbiological report concludes that none of the tasks involved contamination of the hand with any organisms that were other than normal commensal flora of the skin. Discussion of the results focuses on challenging patient’s previous excessive risk estimates associated with these tasks.

E. The Probability of Catastrophe

As described by Rense Hoekstra in 1989, this procedure involves comparing patient estimates of the probability of a negative outcome with an estimate derived from an analysis of the sequence of events that might lead to the feared outcome. Behaviors, such as throwing out the garbage, are broken down into the sequence of events required for contamination or illness to occur (e.g., bacteria present on garbage bin, bacterial transfer to hand, bacteria entering the body, initial immune system failure). Probability estimates for each step in the sequence are given by the participant. These are multiplied together to give a new estimate of the likelihood of illness. The therapist highlights the inconsistency between the patient’s initial elevated global estimates and those lower probability estimates obtained using the probability sequencing task. Homework consists of applying this method to novel situations.

F. Attentional Focusing

This use of this procedure, which is essentially a basic breathing meditation task, was described in detail in 1985 by Chris Clarke and Wayne Wardman. It involves a focusing task that aims to decrease the occurrence of danger-related intrusive thoughts by increasing the participant’s ability to attend to alternative cognitive targets in a rhythmic breathing exercise. Participants are taught to focus on a series of numbers while breathing in and to focus on the word “relax” while breathing out. Participants are instructed to breathe normally and not to slow or speed up the respiration rate. Participants initially train with their eyes closed in a quiet location with minimal noise and distraction. As training progresses across sessions, participants are instructed to increas-

ingly complete their daily focusing sessions in noisier environments while keeping their eyes open. Daily practice consists of two, 10-min focusing sessions.

II. THEORETICAL BASES

A number of models of anxiety propose that expectancies of danger are involved in the mediation of normal fear reactions and clinical anxiety and avoidance. Threat-expectancy accounts of the anxiety experienced by sufferers of OCD have been proposed for a number of decades. For example, in 1974 Anthony Carr argued that patients with OCD make very high subjective estimates of the probability of aversive outcomes. That is, they may more often anticipate danger or negative outcomes than nonobsessives in the same settings. The performance of compulsive behaviors is said to lead to the relief of anxiety through the reduction of the subjective threat.

Such expectancy models seem particularly relevant to OCD because researchers and clinicians have frequently identified themes of danger in the obsessional beliefs of sufferers of OCD. In addition, many patients with OCD are able to specify negative outcomes associated with not performing their rituals, for example contamination and disease for sufferers who fail to execute washing behaviors. Given this, theorists like Carr have argued that danger expectancies may mediate the anxiety and avoidance experienced by the sufferer of OCD. In two studies reported in the literature in 1997 and 1998, Jones and Menzies investigated the validity of an expectancy account of OCD with a focus on those sufferers whose dominant concerns involve contamination obsessions and washing compulsions.

In the first study, Jones and Menzies examined the potential mediating roles of danger expectancies and other cognitive variables that have been hypothesised to play a role in OCD, including responsibility, perfectionism, anticipated anxiety and self-efficacy. They obtained ratings from 27 patients with OCD before and during a Behavioural Avoidance Test (BAT) involving a compound stimulus of potting soil, animal hair, food scraps, and raw meat. Correlation and partial correlation analyses were conducted to investigate the relationships between the cognitive predictor variables and urge to wash, level of anxiety, time spent engaged in the task, and duration of washing in the posttest phase.

The researchers reported significant relationships between danger expectancies and each of the dependent measures. That is, correlations between BAT estimates of

danger and anxiety, urge to wash, and time washing were positive, significant, and moderate to high in size. Correlations between BAT estimates of danger and time in dirt were negative, significant, and moderate in size. Partial correlations were conducted between the postulated mediating variables and the four dependent variables, with alternative mediating variables held constant. Severity of disease or illness ratings were found to remain significantly related to all four dependent variables when non-danger variables were held constant. Likelihood of disease ratings remained significantly related to three of the four dependent variables when non-danger variables were held constant. The only relationship that appeared tenuous was between likelihood of disease ratings and time washing, which disappeared when self-efficacy or responsibility ratings were held constant. No alternative cognitive variable was found to be related to any of the four measures of OCD washing in partial correlation analyses when danger expectancy ratings were held constant. More important, the four dependent variables chosen covered a range of the prominent symptoms displayed by OCD washers, from subjective urges and distress to actual avoidance and excessive washing. The ability of danger expectancies to relate to all aspects of the disorder in this study was argued to provide considerable support for danger-based models of the condition.

Following this study, the BAT stimulus was utilized in a second experiment aimed at assessing the role of danger expectancies in OCD washing. In this study Jones and Menzies manipulated the perceived level of danger in the BAT by varying the pre-BAT instructions given to 18 participants. Participants were randomly allocated into a high-danger instruction condition or a low-danger instruction condition. In general, the data obtained were again consistent with a danger expectancy account of OCD washing. That is, as Jones and Menzies had hypothesized, participants in the high-danger instruction condition were found to have higher mean ratings for anxiety and urge to wash and showed greater avoidance and posttest hand washing than participants in the low-danger instruction condition. These differences were significant for time spent washing post-BAT and BAT duration. For this last variable, while all the participants in the low-danger condition were able to keep their hands in the container for the whole 5-min task, four of the nine participants in the high-danger condition withdrew their hands prematurely. Clearly, the fact that a task perceived as more likely to contaminate could lead to significantly increased washing and avoidance is supportive of disease-based models of OCD washing.

III. EMPIRICAL STUDIES

Since the development of DIRT, Jones and colleagues have carried out three studies examining its effectiveness. In the initial treatment trial, which was published in 1997, three patients with OCD whose primary concern involved contamination/washing were selected for the study after presenting at the Anxiety Disorders Clinic of the University of Sydney. At intake each patient had refused standard behavioral intervention (i.e., response prevention). Treatment consisted of between six and ten 1-hour weekly sessions. Treatment was terminated in each case when, in the judgment of the treating clinician (a) clinically significant gains were apparent with minimal symptomatology remaining, and (b) clients displayed a sound grasp of the cognitive model underpinning DIRT procedures. Substantial reductions on all four outcome measures were experienced by the three participants at posttreatment. Posttreatment scores on two of these OCD measures, the Maudsley Obsessional–Compulsive inventory (MOCI) and the Padua Inventory, were lower than typical group means for participants receiving exposure and response prevention in clinical outcome studies and were similar to scores obtained by “normal” control participants in several reports. On the basis of these results, Jones and Menzies argued that the DIRT package may prove useful in achieving and maintaining clinically significant improvements in OCD washers.

In a second study conducted by Jones and Menzies, 21 sufferers of OCD with washing/contamination concerns took part in a controlled DIRT treatment trial. Eleven of the participants received DIRT during eight, 1-hour weekly group sessions. Ten participants were placed on a wait list and did not receive DIRT or any other treatment. All participants were assessed at pretreatment, posttreatment, and 3-month follow-up using the Maudsley Obsessional–Compulsive inventory, Leyton Obsessionality inventory, Beck Depression Inventory, and a Self-Rating of Severity Scale. Participants who received DIRT showed significantly greater reductions in symptomatology from pretreatment to after treatment on all four outcome measures than participants who were in the control condition.

The researchers note that although clinical improvements were obtained in this controlled trial, these were not as large as anticipated. In particular, the posttreatment average MOCI score was higher than typical group means for participants receiving exposure and response prevention in clinical outcome studies and considerably higher than scores typically obtained by

“normal” control participants. Therefore, the findings from the second trial of DIRT were not as convincing as those found in the first DIRT trial.

Jones and Menzies suggested a number of reasons to account for the discrepancy in treatment effectiveness between the two DIRT trials. It was suggested that DIRT may be more beneficial when presented in individual sessions in which the therapist is more aware of the dysfunctional beliefs of the individual client and can then help the client identify suitable reappraisals. Also, participants may have been hesitant to discuss their concerns or ask for clarification of techniques in front of other group members. Finally, although the three participants in the first DIRT trial received treatment until clinically significant gains were apparent with minimal symptomatology remaining, this condition was not used as a guide to terminate treatment in the second trial. Instead, before the trial commenced the treatment protocol specified that treatment would involve eight sessions, regardless of clinical gains or the client’s understanding of the model underpinning DIRT procedures.

Annette Krochmalik, Mairwen K. Jones, and Ross G. Menzies conducted a recent trial of DIRT with severe, treatment-resistant cases of compulsive washing. The researchers examined the effectiveness of DIRT in five patients with OCD who satisfied *DSM-IV* criteria for OCD with Poor Insight. All patients were classified as treatment resistant, because they had failed to respond to at least two separate, 12-week drug trials using serotonergic agents and had also failed to respond to at least 15 sessions of exposure and response prevention just prior to being offered the DIRT intervention.

Unlike the previous controlled DIRT trial that involved group therapy, Krochmalik, Jones, and Menzies returned to an individual treatment format. Participants received a maximum of 14, weekly 1-hour DIRT sessions. Again, treatment was terminated earlier if clinically significant gains were apparent with minimal symptomatology remaining and clients displayed a sound grasp of the cognitive model underpinning DIRT procedures. Based on this criteria, the five participants received between 9 and 14 sessions in total.

The trial utilized four self-assessment measures (the Maudsley Obsessional–Compulsive inventory (MOCI), the Padua Inventory (PI), the Beck Depression Inventory-II (BDI-II) and the Self-Rating of Severity Scale), and one clinician-rated measure, the Global-Rating of Severity. Using the two-fold criteria of Neil Jacobson and Paula Truax, each participant was able to be classified as unchanged/deteriorated, improved but not recovered, or

recovered on three of the measures (the MOCI, PI, and BDI-II).

The researchers reported that at the post-DIRT assessment phase four of the five participants exhibited reliable decreases in scores on all measures. These improvements were maintained at 4 to 6-month follow-up. In addition four of the five cases met the criteria for recovery on the MOCI and the PI and three of the five cases met the criteria for recovery on the BDI-II at the follow-up assessment phase.

In summary, while one of the five participants did not benefit from DIRT, the other four participants did respond well to this recently developed treatment approach. Given that all four had previously been non-responsive to standard treatment interventions the authors concluded that DIRT may offer substantial promise for treatment-resistant cases of OCD washing and for individuals with OCD with Poor Insight.

IV. SUMMARY

A number of theoretical approaches concerning the nature of OCD have stressed the importance of cognitive biases. Physical danger or threat beliefs is one of the cognitive variables that has been proposed as a mediating variable in OCD. Two studies reported in the literature that have directly examined the role of danger expectancies in OCD have provided support for danger-based models of the disorder. These results reveal previously unexplored possibilities for the treatment of OCD washers. In particular, cognitive-behavioral treatments specifically designed to target and reduce danger-related cognitions appear to be both logically consistent with the findings and potentially effective. One such treatment package, Danger Ideation Reduction Therapy (DIRT), has been recently developed and empirically assessed in three small treatment trials to date. Overall, the results from these studies have provided support for the usefulness of this intervention. The importance of these findings should not be underestimated given that only moderately effective treatments are currently available for OCD, and those traditional treatments are typically associated with significant rates of patient drop-out and refusal.

On the basis of these initial studies it is too early to determine the future utility of this novel treatment approach. However, DIRT appears to have several potential advantages over behavioral and pharmacological treatments. First, unlike exposure and response prevention, DIRT does not require the patient to confront anxiety-provoking stimuli. This is particularly important because many sufferers either refuse exposure treatment or drop-out before completion because of its anxiety-provoking effects. Second, unlike clomipramine, DIRT does not produce any physical side effects. Third, DIRT is a highly structured treatment package involving films, structured reports, and exercises that are relatively inexpensive to package and administer. Fourth, DIRT appears to require relatively few sessions for its therapeutic effect. Finally, DIRT may prove beneficial for patients whose condition has not improved following standard OCD treatments and for those who manifest poor insight.

GLOSSARY

borderline personality disorder A psychiatric disorder characterized primarily by intense negative emotions (including depression, anger, self-loathing, and despair), disturbed interpersonal relationships, and self-damaging impulsive behaviors such as substance abuse and parasuicide.

dialectics A philosophical world-view that reality reflects an ever-changing transactional process.

parasuicide A term that refers to any intentional, acute self-injurious behavior with or without suicidal intent, including both suicide attempts and nonsuicidal self-mutilation. Considered the hallmark of borderline personality disorder.

randomized clinical trial A tightly controlled research design in which participants are randomly assigned to treatment condition. Random assignment allows one to conclude that post-treatment differences between groups are likely due to treatment effects.

Dialectical behavior therapy (DBT) is a multicomponent, cognitive-behavioral psychotherapy intended for complex, difficult-to-treat patients. Originally devel-

oped to treat the seriously and chronically suicidal patient, DBT has evolved into a treatment for suicidal patients who also meet criteria for borderline personality disorder (BPD), and it has since been adapted for BPD patients with presenting problems other than suicidal behaviors and for other disorders of emotion regulation. Treatment is based on a unique blend of behavioral psychology principles used to promote change, and Eastern mindfulness principles used to promote acceptance. This entry will describe the theoretical rationale, as well as the basic format of treatment, and will also briefly review the research on its efficacy.

I. INTRODUCTION AND OVERVIEW

Marsha Linehan and her research team at the University of Washington developed DBT during the 1980s as a treatment for the chronically suicidal patient who had a pattern of both suicide attempts and/or nonsuicidal self-injurious behaviors (i.e., parasuicidal behavior). DBT was soon extended to treat individuals meeting criteria for *borderline personality disorder (BPD)*, a disorder often characterized by parasuicidal behaviors. DBT has since been standardized in Linehan's 1993 treatment manuals, and evaluated in randomized clinical trials. The data (to be reviewed later in this article) suggest that it is more effective than usual psychotherapies offered in the community for treating women with BPD with primary presenting problems of suicidal behavior and substance abuse. DBT has also been

adapted to the treatment of eating disorders and dissociative disorders, and to families and adolescents. In addition, several large-scale mental health systems in the United States, Canada, and Europe have implemented DBT as a treatment for borderline patients across inpatient, day treatment, residential, case management, and crisis services.

DBT is rooted in standard cognitive and behavioral protocols, and it remains, first and foremost, a problem-solving, behavior therapy approach. Nonetheless, Linehan found that behavioral methods—though demonstrated to be effective with numerous other patient groups—required substantial modification when applied to a chronically suicidal population.

First, strategies that more clearly reflected the acceptance and validation of clients' current capacities were added in order to balance the behavioral emphasis on client change. That is, the “technologies of acceptance” drawn from principles of Eastern Zen and Western contemplative practices were intermingled with the “technologies of change” based on learning principles. Indeed, the balance of acceptance versus change is the overarching dialectic of treatment, hence the addition of the term “dialectical” to the name of the treatment.

Second, the complexity and severity of the patient group suggested that a comprehensive, multicomponent treatment approach was needed. Thus, therapy was divided into different modes of service delivery, with each component emphasizing one or more of the following treatment functions: (1) enhance patient motivation; (2) enhance patient capabilities; (3) ensure that new capabilities generalize to the patient's natural environment; (4) enhance therapist capabilities and motivation to treat patients effectively; and (5) structure the environment in a manner that will promote and reinforce patient and therapist capabilities.

The result is DBT in its standard format—an outpatient treatment program with four components: individual psychotherapy to address motivational enhancement and skills strengthening (most often weekly, one-hour sessions); highly structured group skills training to enhance capabilities (weekly for 2½ hours); as-needed phone consultation with the individual therapist to address application of new capabilities; a consultation meeting for DBT treatment providers intended to keep therapists motivated and to ensure that they are providing effective treatment consistent with the DBT approach (most often once weekly for 60 to 90 minutes). The fifth treatment function—structuring the environment—occurs as needed and may include case management interventions to find housing or to assist the client

in other ways to make concrete changes in his or her natural environment so that it will be as reinforcing of adaptive functioning as possible. However, attention may also need to be paid to any contingencies acting on the therapist that reinforce client dysfunctional behaviors (e.g., institutional policies that offer a greater number of low-cost services for clients who are unemployed and on disability).

Conceptualizing DBT in terms of its *functions* allows for flexibility in how the treatment is delivered. That is, DBT can be applied in any mode as long as the five treatment functions are addressed. For example, inpatient DBT programs may offer milieu and staff coaching to enhance motivation; a twice weekly skills group to address capability enhancement; staff coaching and day passes to address skills generalization; consultation meetings and continuing education classes to provide therapist support; and meetings with outpatient providers and family to structure the environment.

II. THEORETICAL FOUNDATION

Described next are Linehan's theory of the etiology and maintenance of BPD, and the theoretical perspectives that form the basis of the DBT model. Emphasis is placed on how each set of concepts impacts treatment.

A. Biosocial Theory of BPD

According to Linehan's biosocial theory, BPD behavioral patterns develop as the result of an ongoing transaction between a biological vulnerability to emotion dysregulation and an “invalidating environment.” That is, a cyclical interaction develops whereby an individual prone to intense emotional displays may elicit invalidation from those in the environment who have difficulty understanding the emotions. In turn, the experience of being persistently invalidated tends to increase emotional dysregulation and decrease learning of emotion regulation skills.

Emotional vulnerability is believed to be strongly influenced by biology, such that an individual is predisposed (perhaps due to high genetic loading for an emotional temperament) to have the following characteristics: (1) a low threshold for emotional stimuli; (2) emotional reactions that tend to be rapid and intense; and (3) a slow return to baseline, contributing to high sensitivity to the next emotional stimulus.

The primary characteristic of an invalidating environment is that the private experiences (emotions and

thoughts) and overt behaviors of the individual are often taken as invalid responses to events; are punished, or disregarded; and/or are attributed to socially unacceptable characteristics. In addition, although modulated emotional displays may be ignored or met by punishment, high-level escalation may result in attention, meeting of demands, and other types of reinforcement. Finally, an invalidating environment may oversimplify the ease of meeting life's goals and problem solving.

In addition to deficits in emotion regulation, pervasive invalidation may also lead to difficulties with accurately labeling emotions and difficulties trusting one's own experiences as valid. By oversimplifying problem solving, such an environment does not teach effective problem-solving skills, graduated goals, or distress tolerance but instead teaches perfectionistic standards and self-punishment as a strategy to try to change one's behavior. Finally, invalidation of modulated emotional displays in conjunction with reinforcement of escalated emotional displays teaches the individual to oscillate between emotional inhibition and extreme emotionality.

The transactional nature of the relationship suggests that only mild amounts of invalidation may be sufficient to result in BPD for the individual with a high vulnerability to emotional dysregulation. Conversely, a child with only moderate levels of emotional vulnerability may develop BPD with a sufficiently invalidating environment.

This model represents not only a model of etiology, but also a model of maintenance of BPD behaviors and current transactions. For example, a key theoretical assumption that guided the development of DBT is that suicidal behavior is an attempt to solve a problem—most often the problem of intense and painful emotions that the individual is unable to effectively regulate. Indeed, Linehan conceptualizes the patterns of behavior comprising the BPD diagnostic criteria either as direct consequences of dysregulated emotions or as response patterns that function to regulate out-of-control, aversive emotions. Other dysfunctional behaviors found in BPD and in other patient populations (e.g., binge eating, substance use) may also serve a similar problem-solving function. As such, the task for the DBT therapist is to target the dysfunctional behavior patterns that are functionally linked to emotional arousal.

The biosocial model also suggests that validation will be of critical importance in treating the individual with BPD. Not surprisingly, validation is one of the core

treatment strategies of DBT. The model further suggests that treatment providers, much like the rest of the patient's social environment, may also have a tendency to respond to the patient in invalidating ways. Indeed, the patient's behavior may be invalid in many respects. However, a DBT therapist must make a conscious effort to locate the "nugget of truth" in the individual's behavior so that he or she feels understood and accepted, and is thus able to move toward more skillful behavior.

B. Dialectical Philosophy

The feature most distinctive of DBT is its philosophical base in dialectics—a term that conveys two meanings. First, dialectics refers to a world-view that reality reflects an ever-changing, transactional process in which each action leads to its opposite—a reaction—the resolution of which is a synthesis of both positions. Within the therapy relationship, this suggests that multiple tensions will inevitably coexist, and must be addressed and resolved by the therapist.

The dialectical philosophy also conveys the assumption that individuals with BPD get caught between extremes of emotion and behavior, repeatedly going back and forth without ever learning a new synthesis or middle ground. Indeed, a central goal of DBT is to replace these rigid, dichotomous patterns with dialectical thinking and behavior. This overarching target guides the DBT therapist approach to all other target behaviors. That is, in all modes the therapist strives to reduce the incidence of extreme, polarized thoughts, emotions, and actions, and to increase the likelihood of balanced, integrated responses "to the moment."

C. Learning Principles and Behavioral Psychology

Consistent with other behavioral approaches, DBT assumes that all behaviors, whether adaptive or dysfunctional, are influenced by prior learning, are continually subject to environmental contingencies, and are thus situation-specific. This viewpoint has several important treatment implications. First, since all behaviors are caused, it encourages treatment providers to be nonpejorative toward patients, even in the face of aversive patient behaviors. Likewise, it may serve to reduce patients' self-blame, shame, and hopelessness regarding their behaviors and their lives.

Second, it suggests that behavior change requires careful assessment of the problem behavior and the environmental conditions under which the behavior will

occur. Attributing behavior to hypothetical constructs such as “need for approval” is not sufficient because such constructs do not specify the environmental determinants. Rather, the DBT therapist and patient work together to construct a behavioral chain analysis, which is a detailed analysis of events and situational factors before and after a particular instance (or set of instances) of the targeted behavior. The goal is to provide an accurate and reasonably complete account of behavioral and environmental events associated with the problem behavior. Close attention is paid to reciprocal interactions between environmental events and the client’s emotional, cognitive, and overt responses.

A chain analysis requires a clear definition of the problem behavior; identification of vulnerability factors (e.g., sleep deprivation or other conditions that influence emotional reactivity); and specific precipitating events that led to the problem behavior. Therapist and client then identify each link between the precipitating event and the problematic behavior to yield a detailed account of each thought, feeling, and action that moved the client from point A to point B. Finally, the reactions of the client and others that followed the behavior are identified. This detailed assessment allows the therapist to identify each point where an alternative client response might have produced positive change and averted conditions that led to problem behavior.

Reasons for the absence of a skilled response can generally be placed into one of four categories: effective behaviors are inhibited by skills deficit(s); effective behaviors are inhibited by faulty beliefs and assumptions; effective behaviors are inhibited by attempts to avoid aversive emotions; the environment is not supportive of the effective behaviors or is overly supportive of the problem behaviors. In turn, each of these problem areas is linked to a behavioral change procedure that is part of the problem-solving strategies described below.

III. DESCRIPTION OF TREATMENT

A. Levels of Disorder and Stages of Treatment

Unlike many other empirically supported, manualized psychotherapy approaches, DBT does not provide a session-by-session protocol for how treatment should proceed. Rather, DBT is designed to be a highly flexible model that can be readily applied to patients with disorders of varying severity and complexity. Linchan con-

ceptualized four levels of disorder, each level having a corresponding stage of treatment.

Level 1 disorders are characterized by behavioral dyscontrol and typically include disorders that are both severe and pervasive. The overall goal of Stage 1 treatment for Level 1 disorders is to help these patients increase control over their behavior and their lives. Standard DBT, which is the general focus of this chapter, is a Stage 1 treatment. Linehan’s treatment manual and the existing research data focus on Stage 1 DBT. Behaviors that are targeted for treatment at this stage are arranged hierarchically as follows: (1) reducing life-threatening behaviors (parasuicidal acts, including suicide attempts, high-risk suicidal ideation, plans and threats, as well as homicidal acts, plans, and threats); (2) reducing client and therapist behaviors that interfere with the therapy (e.g., missing sessions or arriving late, phoning at unreasonable hours, not returning phone calls, or pushing therapist or patient limits in any other manner); (3) reducing behavioral patterns that substantially interfere with a reasonable quality of life (e.g., severe depression, poor work behaviors, homelessness, criminal behaviors); (4) acquisition of sufficient life skills to meet client goals (emotion regulation, interpersonal effectiveness, distress tolerance, self-management, mindfulness); and (5) other goals the client wishes to address.

The second level of disorder is best described as “quiet desperation” (as opposed to the state of “loud desperation” in Level 1). The central problem at this level is avoidance of emotions and any environmental cues associated with them. A good example would be a patient with post-traumatic stress disorder. The goal of Stage 2 DBT is to increase the patient’s ability to experience emotions without trauma. Level 3 disorders are best described as problematic patterns in living that interfere with goals. Thus, treatment at this stage focuses on achieving ordinary happiness and a stable sense of self-respect. Finally, the fourth level of disorder refers to those individuals who have a lingering sense of incompleteness despite the fact that they are otherwise satisfied with their lives. The goals of Stage 4 DBT include developing the capacity for sustained joy via psychological insight, spiritual practices, and an expanded awareness of oneself.

Overall, the orientation of the treatment is first to get overt behaviors under control, then to help the patient to feel better, to resolve problems in living and residual disorder, and to find joy and, for some, a sense of transcendence. Because therapeutic change is usually not linear, progress through the foregoing hierarchy of be-

haviors is an iterative process. That is, attention is shifted away from a lower-priority target back to a higher-priority target if that behavior recurs (e.g., life-threatening behaviors).

With respect to each treatment goal, the task of the therapist is first (and many times thereafter) to elicit the client's collaboration in working on the relevant behavior and then to apply the appropriate treatment strategies as described in the following subsection. Treatment in DBT is oriented to current in-session behaviors or problems that have surfaced since the last session, with suicide attempts and all other life-threatening behaviors taking precedence over all other topics. Furthermore, the high priority that DBT places on discussing the "therapy-interfering" behaviors of the client or therapist (target 2) is also noteworthy. This direct targeting of the therapeutic relationship is typically very important in treating complex, multi-disordered clients and is unique to DBT.

B. Treatment Strategies

DBT addresses all problematic client behaviors and therapy situations in a systematic, problem-solving manner. The behavioral analyses and change procedures involved in problem solving are surrounded by validation of the client's experiences, especially as they relate to the individual's vulnerabilities and sense of desperation. Furthermore, in contrast to many behavioral approaches, DBT places great emphasis on the therapeutic relationship as a mechanism of change. In times of crisis, when all else fails, DBT uses the relationship itself to keep the client alive.

Treatment strategies in DBT are divided into four sets: (1) Dialectical strategies, (2) core strategies (problem solving and validation), (3) communication strategies (irreverence and reciprocal communication), and (4) case management strategies (consultation to the patient, environmental Intervention, and supervision/consultation with therapists). In all treatment strategies, a DBT therapist must constantly strive for a balance of acceptance and change.

There are also a number of specific behavioral treatment protocols covering suicidal behavior, crisis management, therapy-interfering behavior and compliance issues, relationship problem solving, and ancillary treatment issues, including psychotropic medication management. For additional description of these protocols, the interested reader is referred to texts listed in the Further Reading section.

1. Dialectical Strategies

Dialectical strategies are woven throughout all treatment interactions. The most fundamental dialectical strategy is the balanced therapeutic stance—the constant attention to combining acceptance with change. The goal is to bring out the opposites, both in therapy and the client's life, and to provide conditions for synthesis. Strategies include extensive use of stories, metaphor, and paradox; the therapeutic use of ambiguity; viewing therapy, and indeed all of reality, as constant change; cognitive challenging and restructuring techniques; and reinforcement for use of intuitive, non-rational knowledge bases.

2. Core Strategies

Core strategies consist of the balanced application of problem-solving and validation strategies. The problem-solving strategies are central to treatment and are drawn from behavioral psychology principles as described earlier. Included are a wide variety of behavioral assessment and behavioral therapy techniques that are used to directly target maladaptive behaviors. Problem solving is a two-stage process, involving, first, an analysis and acceptance of the current problem, and second, an attempt to generate, evaluate, and implement alternative solutions that might have been made or could be made in the future in similar problematic situations. Analysis of the client's problem behaviors, including dysfunctional actions, emotions, physiological responses, and thought processes, requires careful scrutiny of the chains of events (both responses of the individual and events in the environment) leading up to the problematic responses. This analysis was described earlier and is repeated for every instance of targeted problem behaviors until both therapist and client achieve an understanding of the response patterns involved.

The second stage, which is actually interwoven with the first, requires the generation of new, more skillful responses, as well as an analysis of the individual's capabilities and motivation to actually engage in the new behaviors. This process leads into application of change procedures, which are drawn primarily from cognitive-behavior therapy protocols and anchor the change end of the primary dialectic in DBT. They include management of contingencies in the therapeutic relationship, training in behavioral skills, exposure techniques with response prevention, and cognitive restructuring.

The acceptance pole of this dialectic is represented by the validation strategies. In essence, these strategies

involve the active acceptance of the patient by the therapist and communication of that acceptance to the client. Validation requires that the therapist search for, recognize, and reflect the current validity, or functionality, of the individual's current behaviors. Validation is used to balance and facilitate problem solving it can also promote self-validation, strengthen the therapeutic relationship, and reinforce clinical progress.

For heuristic purposes, validation can be conceptualized in six levels. The first three levels are basic therapeutic strategies for building and maintaining rapport. The second three focus on communicating accurately the valid and invalid nature of the patient's behavior and emotional responses. Level 1 validation involves listening to and observing what the client is saying, feeling, and doing, along with an active effort to understand and make sense of what is being observed. In essence, the therapist is demonstrating interest in the client and notices the nuances of both verbal and nonverbal response in the interaction. Level 2 validation is the accurate reflection, paraphrasing, and summarizing of the client's thoughts, feelings, and behaviors. At Level 2, validating statements remain relatively close to what the client said rather than adding to the client's communication. Level 3 validation refers to articulating or "mind-reading" that which is unstated, such as fears of admitting emotions or thoughts, but without pushing the interpretation on the client. The therapist conveys an intuitive understanding of the client; sometimes knowing clients better than they know themselves.

In Level 4 validation, the therapist validates the client's experience in terms of past learning or in terms of biological dysfunction (e.g., biological predisposition to emotional vulnerability). For example, during a first therapy session, a therapist might validate the client's fears that the therapist will be rejecting by saying, "It makes sense that you would have such concerns, given that you have been rejected by many important people in your life." Level 5 validation involves validating the client in terms of present and normal functioning. In the above situation, for example, a therapist might respond, "Of course you are concerned about me rejecting you; after all, this is our first therapy session and you really don't know what to expect." Finally, Level 6 validation calls for the therapist to show radical genuineness with clients. That is, the therapist must treat the client-therapist relationship as authentic and "real," wherein the therapist behaves as his/her natural self rather than acting in a role-prescribed manner. This involves not treating the client as fragile or as

unable to solve problems, but rather as a person of equal status who is capable of effective and reasonable behavior.

DBT does not specify the frequency or timing of particular types of validation. However, validation is required in every interaction, and when appropriate, it is generally preferable to use higher levels of validation over lower levels.

3. Communication Strategies

In DBT, the therapist balances two communication strategies, which represent rather different interpersonal styles. The modal style is the reciprocal strategy, which includes responsiveness to the client's agenda and wishes, warmth, and self-disclosure of personal information that might be useful to the client as well as immediate reactions to the client's behavior.

Reciprocity is balanced by an irreverent communication style that is used to promote change: a matter-of-fact or at times slightly outrageous or humorous attitude where the therapist takes the client's underlying assumptions or unnoticed implications of the client's behavior and maximizes or minimizes them, in either an unemotional or overemotional manner to make a point the client might not have considered before. Irreverence "jumps track," so to speak, from the client's current pattern of response, thought, or emotion. For example, if a client says "I am going to kill myself!," the therapist might respond, "But I thought you agreed not to drop out of therapy!" It is important that irreverence is balanced with reciprocity. Overuse of irreverence may alienate the patient, while too much reciprocal communication will result in minimal change.

4. Case Management Strategies

There are three strategies designed to guide each therapist during interactions with individuals outside the therapy dyad. First, the consultant-to-the-client strategy is the application of the principle that the DBT therapist teaches the client how to interact effectively with the client's environment rather than teaching the environment how to interact with the client. When absolutely necessary, however, the therapist invokes the environmental intervention strategy, in which he or she actively intervenes in the environment to protect the client or to modify situations that the client does not have the power to influence. The third strategy, the consultation-to-the-therapist strategy, requires that each DBT therapist meet regularly with a supervisor or consultation team. The idea here is that complex, multi-disordered clients should not be treated alone.

Furthermore, the consultant-to-the therapist strategy is used to find the synthesis or middle ground between the other case management strategies, one that argues for change via coaching the client (consultant-to-the-client) and the other that argues for acceptance by directly intervening on the client's behalf (environmental intervention).

IV. EMPIRICAL EVIDENCE

The empirical evidence in support of DBT is promising. In the original randomized clinical trial of DBT conducted by Linehan and colleagues during the treatment development phase, participants were chronically suicidal women diagnosed with BPD who had a recent history of parasuicide. Participants were randomly assigned to one year of either DBT or treatment-as-usual (TAU), a naturalistic control group in which participants receive psychotherapy as it is usually offered in the community. As hypothesized, in comparison to the TAU group, those who received DBT showed significantly greater reduction in rates of parasuicidal behavior, better treatment retention, fewer days of inpatient psychiatric hospitalization, less anger, and improved global social functioning.

Since that time, two additional randomized clinical trials have been reported comparing DBT to TAU. Linehan and her colleagues adapted standard DBT for substance abusers diagnosed with BPD and again found superior outcomes for one-year DBT as compared to one-year TAU. Furthermore, a research group independent of Linehan and colleagues found that six months of DBT produced better patient outcomes than six months of TAU in treating women with BPD.

Finally, several quasi-experimental studies from program evaluations and pilot studies have produced encouraging results, expanding the research base on the efficacy of DBT when adapted for other settings and when extended to treat different treatment populations. These include treatment on inpatient units and in forensic settings, and with suicidal adolescents, and women with binge-eating disorder. These studies do not have the scientific rigor of an experimental design, but taken together, they suggest that extensions of DBT across setting and disorder warrant further investigation.

In sum, the research evidence to date suggests that across studies, DBT reduces severe dysfunctional behaviors that are targeted for intervention (e.g., parasuicide, substance abuse, and binge eating), enhances treatment retention, and reduces psychiatric hospital-

ization. The data also suggest that, although DBT was developed for the treatment of patients with suicidal behavior, it can be adapted to treat BPD patients with comorbid substance abuse disorder and to other patient populations and settings.

Further research is needed, particularly to address the following questions: (1) Which components of DBT (e.g., specific treatment strategies) contribute to outcomes? For example, though preliminary, skills coaching seems to be a crucial ingredient in producing reductions in parasuicidal behavior. (2) Similarly, can we (and if so, *how* can we) improve the efficacy of DBT through additional treatment development? (3) To what different populations/settings can DBT be successfully adapted? (4) Is DBT effective in public health settings? The majority of studies have been conducted in controlled settings (e.g., academic environments) in which highly trained psychotherapists are delivering the treatment within a well-organized framework. However, DBT has now been adopted in a variety of "real-world" clinical settings, highlighting the need for research in this arena. (5) How long does DBT maintain its gains after treatment is over? Results are positive one-year post-treatment, but examination of additional longitudinal outcomes is needed (e.g., suicide rates at five-year followup).

Fortunately, research evaluating the efficacy of DBT is currently being conducted in several U.S. and European sites. Results from these studies should become available over the next several years, providing further information by which to evaluate the efficacy of DBT.

V. SUMMARY

Dialectical behavior therapy (DBT) is a multicomponent, cognitive-behavioral psychotherapy intended for complex, difficult-to-treat patients. Originally developed to treat the seriously and chronically suicidal patient, DBT has evolved into a treatment for suicidal patients who also meet criteria for BPD, and has since been adapted for BPD patients with presenting problems other than suicidal behaviors (e.g., substance abuse) and for other disorders of emotion regulation (e.g., binge-eating disorder). Treatment is based on a unique blend of behavioral psychology principles used to promote change and on Eastern mindfulness principles used to promote acceptance. DBT is conceptualized as occurring in stage based on severity and complexity of disorder, and thus can be applied to patients of varying degrees of severity.

As a comprehensive treatment, DBT serves five functions: (1) to enhance patient motivation; (2) to enhance patient capabilities; (3) to ensure that new capabilities generalize to the patient's natural environment; (4) to enhance therapist capabilities and motivation to treat patients effectively; and (5) to structure the environment in a manner that will promote and reinforce patient and therapist capabilities. In standard DBT, these five functions are divided up among four treatment components: weekly individual psychotherapy; weekly group skills training; as-needed phone consultation with the individual therapist; and a consultation meeting for DBT treatment providers. Other interventions (e.g., pharmacotherapy, case management) occur as needed.

Research evidence to date suggests that across studies, DBT reduces severe dysfunctional behaviors that are targeted for intervention (e.g., parasuicide, substance abuse, and binge eating), enhances treatment retention, and reduces psychiatric hospitalization. The data also suggest that, although DBT was developed for the treatment of patients with suicidal behavior, it can be adapted to treat BPD patients with comorbid substance abuse disorder and to other patient populations and settings.

GLOSSARY

attention The description of a procedure involving certain therapist behaviors that either precede or follow an individual's behavior. Attention is not *a priori* a reinforcer. Although it can be a powerful reinforcer for some individuals, for others, it can be a punishing stimulus or even a neutral event.

extinction A behavioral procedure that weakens a response by the consistent withholding of a reinforcer following the occurrence of an operant response that had previously produced that reinforcer.

functional analysis An experimental investigation that identifies the maintaining variables for a specific target behavior emitted by an individual; that is, it is based on the assessment of consequences maintaining a target behavior.

Differential attention is a procedure that helps a person to discriminate between a specific behavior and all other behaviors. The procedure can be used in a learning context for skill acquisition or in a treatment context for the reduction of a problem behavior.

I. DESCRIPTION OF TREATMENT

Differential attention involves two inextricably involved processes, reinforcement and extinction. Differential attention is a variant of generic differential reinforcement procedures that involve withholding reinforcement for a specified response from a response class and reinforcing other responses, depending on the reinforcement schedule. The typical outcome is response differentiation. In skill acquisition, there is an increase in the rate of the reinforced response relative to the rate of other members of the response class, and, in behavior reduction, there is a decrease in the rate of the problem response relative to the rate of other members of the response class.

II. THEORETICAL BASES

Contingent attention is typically used to increase responding. When used in a skill acquisition paradigm, attention is delivered following approximations to or the occurrence of a specific behavior while simultaneously withholding attention following the occurrence of all other behaviors. The basic process is one in which attention is differentially delivered only on the occurrence of a target behavior, resulting in skill acquisition or an increase in the rate of the behavior. For example, when increasing the social interaction of a socially withdrawn child, the teacher would provide at-

tention when the child was socially interacting with other children and not when the child was socially withdrawn, thus differentially reinforcing social interaction with attention.

When used in a behavior reduction paradigm, attention is delivered following the occurrence of socially acceptable behaviors while simultaneously withholding attention following the occurrence of a specific problem behavior. The basic processes involve both withholding reinforcement contingent on a target response (extinction) and delivering reinforcement contingent on other or alternative responses. For example, if a child engages in temper tantrums, his parents would withhold attention (i.e., ignore the temper tantrum) and only provide the child with attention when he is quietly playing with his toys and not engaging in the problem behavior.

Theoretically, the delivery of contingent attention can be on one of three basic schedules—continuous, ratio, and interval schedules—although in real life attention is usually delivered on a mixed schedule of reinforcement. To enhance rapidly the discrimination between a target and all other behaviors, attention is delivered on a continuous schedule; that is, attention immediately follows each occurrence of the target behavior. Continuous schedules of attention are used in the early stages of learning when a new skill or behavior is being acquired. Furthermore, continuous schedules of attention may be used for all socially acceptable behaviors, while a specific problem behavior is being ignored—that is, while the problem behavior is on an extinction schedule.

Once discrimination between the target and all other behaviors has been established, attention can be delivered on increasingly intermittent schedules, that is, on ratio and interval schedules. In skill acquisition, the target behavior is reinforced with attention after a fixed or variable number of times the behavior has been emitted (ratio schedules) or after fixed or variable intervals of time (interval schedules). In behavior reduction programs, the problem behavior is always ignored, and other behaviors may be reinforced with attention on ratio or interval schedules. For example, if attention is delivered when a specific problem behavior has not occurred for a prescribed interval, it is an instance of differential reinforcement of other behavior where attention is the reinforcement.

Theoretically, when attention is withheld from a behavior that was previously reinforced by attention, the behavior is said to be on an extinction schedule. Sometimes, putting a behavior on an extinction schedule re-

sults in an initial increase or burst of the behavior. Thus, extinction may not be a suitable procedure for reducing some behaviors, such as aggression or self-injury. Furthermore, regardless of the nature of the behavior being targeted for reduction, occasionally the extinction period is accompanied by an initial outburst of aggression by the individual. Therapists need to be prepared to deal with extinction-induced aggression should it occur. In addition, extinction is associated with a phenomenon known as spontaneous recovery, when the behavior briefly recurs spontaneously after a long period of its absence. Again, therapists need to be aware of this possibility and to be prepared to deal with it. A final consideration is that extinction requires consistency of application; that is, no instance of the target behavior must be followed by attention. Inadvertently attending to some instances of the target behavior may make the behavior more resistant to extinction and, theoretically, strengthen the behavior.

III. EMPIRICAL STUDIES

Differential attention has been used extensively in skill acquisition programs in classroom settings. In general, differential attention procedures have been used successfully to increase the academic and social skills of children with disabilities, without concomitantly decreasing other behaviors.

Differential attention has also been used to reduce problem behaviors in individuals with disabilities, especially those with developmental disabilities. The empirical literature on differential attention is limited because, by itself, it is not a very powerful procedure for decreasing severe behavior problems.

Individuals with developmental disabilities sometimes engage in aberrant behavior in specific social contexts when another person diverts their parents' attention from them. For example, Mark F. O'Reilly and colleagues assessed the motivation of aberrant behavior of two individuals with severe mental retardation. They observed that the aberrant behavior (hitting, pinching, property destruction, and self-injury) of these two individuals typically occurred when their parents interacted with someone other than them. Using a brief functional analysis methodology, the therapists established that aberrant behaviors actually did occur when parents diverted their attention from their child to a third person. Furthermore, they found that the two individuals did not engage in aberrant behavior when their parents gave them attention noncontingently—that is, when

they interacted with their children on a fixed schedule in the absence of aberrant behavior. Attention-maintained aberrant behavior was eliminated when the parents gave noncontingent attention to their children while engaging in social interaction with a third person.

Current research on attention-maintained problem behaviors indicates that not all forms of attention are functionally equivalent, suggesting that therapists may need to evaluate the effectiveness of different forms of attention as reinforcement before implementing treatment. For example, if a functional assessment indicates that aggression is maintained by verbal attention, then further analyses should be performed to examine what properties of verbal attention maintain aggression. A common finding is that response-relevant verbal attention (“Stop that! You are hurting me”) contingent on aggression maintains the aggression at higher levels than response-irrelevant statements (e.g., “You are looking good today”). This is in accord with research showing that, for about a third of the cases, attention in the form of reprimands and physical contact actually maintains destructive and aggressive behavior in individuals with developmental disabilities. Why this should be so is unclear. We suspect that, as appropriate behavior is infrequently reinforced in individuals with severe behavior disorders, these individuals engage in destructive and aggressive behavior because these behaviors result in a greater density of verbal attention, even though these are in the form of reprimands.

Differential levels of attention can be used as an establishing operation to influence the rate of occurrence of a problem behavior. An establishing operation can be defined as an antecedent condition that influences the probability of a behavior by increasing the value of consequent stimuli and the effectiveness of discriminative stimuli for a given response class. For example, changing antecedent levels of attention for attention-maintained behaviors will produce differential rates of the behavior. Thus, depriving an individual of all attention versus providing the individual noncontingent attention as establishing operations will result in high rates of the problem behavior following the former condition and low rates of the behavior following the latter condition.

Differential attention procedures are appealing for a number of reasons. First, the procedures incorporate an extinction component. That is, the relationship between the problem behavior and reinforcement is disrupted which, by definition, will result in a decrease or even an elimination of the problem behavior. Second, an individual can learn to produce responses that

are more appropriate because other, socially appropriate behaviors are differentially attended to. Third, differential attention is a portable procedure that can be used in the natural environment, and is not restricted to a facility or a clinic or for use only by professionals. Fourth, differential attention procedures have been demonstrated to be relatively effective across a wide variety of populations and mild behavior problems (e.g., children, adults, individuals with developmental disabilities, aggression, self-injury, hyperactivity, thumbsucking, noncompliance). Finally, differential attention is a reinforcement procedure, and contingent delivery of aversive stimulation is not required.

Although differential attention procedures have gained wide acceptance, several studies have reported that such procedures are relatively ineffective in comparison to other interventions. However, procedural and functional advancements have been made to enhance the effectiveness of differential attention procedures. For example, differential attention can be delivered based on the most effective time interval (i.e., inter-response time), or the “whole-interval” time period in which the individual is required not to engage in the target problem behavior.

Despite the possibility of enhancing the effectiveness of differential attention procedures, several potential limitations may remain. For example, (a) differential attention can be a cumbersome procedure to use (i.e., care providers are required to attend/observe the individual at all times either to reset an interval timer or to provide attention on a specified schedule in the absence of the target behavior), and (b) the extinction component of the procedure may produce side effects that are potentially hazardous to the individual (e.g., increased rate or magnitude of behavior, new forms of aberrant behavior, emotional responding). Moreover, the extinction component may be difficult to use consistently if the behavior is severe, potentially life threatening, or may be inadvertently attended to by well-meaning staff, peers, or visitors.

IV. SUMMARY

Differential attention is a widely used procedure in real life, especially in teaching new skills to humans and other animals. When used to decrease problem behaviors, it is often misused and problem behaviors are strengthened rather than decreased. As a treatment procedure, it involves both reinforcement (providing attention to all other socially desirable behaviors, if at-

tention has been determined to be reinforcing) and extinction (withholding attention, if attention has been determined to maintain the problem behavior). Without the extinction component, differential attention is not a very robust behavior reduction procedure. However, extinction is associated with a number of potential side effects that therapists should be aware of before instituting the procedure. For example, it may not be ethical to use extinction in cases of self-injury as the behavior may initially continue at high rates while being ignored. Generally, the rate of behavior change that results from the use of differential attention is much lower when compared to the use of more powerful primary (e.g., food) and conditioned reinforcers (e.g., tokens, money). If a rapid behavior change is desired, differential attention may need to be paired with other, more powerful procedures.

GLOSSARY

differential reinforcement of other behavior (DRO) involves the presentation of a reinforcer contingent upon the absence of the target behavior during a pre-determined interval of time. All other behavior, than the target behavior, is reinforced.

fixed momentary DRO Fixed Momentary DRO is a schedule where the interval length is held constant and reinforcement is delivered for the absence of target behavior at the end of the interval.

fixed whole-interval DRO Fixed Whole-Interval DRO is a schedule where the interval length is held constant and reinforcement is delivered for the absence of target behavior throughout the entire interval.

reinforcer A stimulus that when presented following a behavior will increase the probability of recurrence of that behavior.

target behavior Any behavior that is the focus of an intervention.

variable momentary DRO Variable Momentary DRO is a schedule where the interval lengths vary across an average value and reinforcement is delivered for the absence of target behavior at the end of the interval.

variable whole-interval DRO Variable Whole-Interval DRO is a schedule where the interval lengths vary across an aver-

age value and reinforcement is delivered for the absence of target behavior throughout the entire interval.

I. DESCRIPTION

Differential reinforcement of other behavior (DRO) was first described by Reynolds (1961). DRO is considered a behavior suppression intervention method as are positive punishment or negative punishment, extinction, and overcorrection. Differential reinforcement is unique within the category of behavior suppression strategies in that it relies on the contingent presentation of a reinforcer. DRO, also referred to as omission training is described as the presentation of a reinforcer contingent on the absence of the target behavior during a predetermined interval of time. Thus, a reinforcer is delivered if the individual does not emit the target behavior during a preset interval of time, regardless of other behaviors emitted. If the individual emits the target behavior (behavior that we wish to suppress), the delivery of the reinforcer is delayed.

The reader should know that there are several types of differential reinforcement. In addition to DRO, there is differential reinforcement of incompatible behavior (DRI), differential reinforcement of alternative behavior (DRA), and differential reinforcement of low frequency behavior (DRL). Other methods of behavior suppression are only briefly discussed in this article when comparing them to DRO. This article focuses on describing and discussing the basic elements of DRO, the different types of DRO contingencies, its efficacy

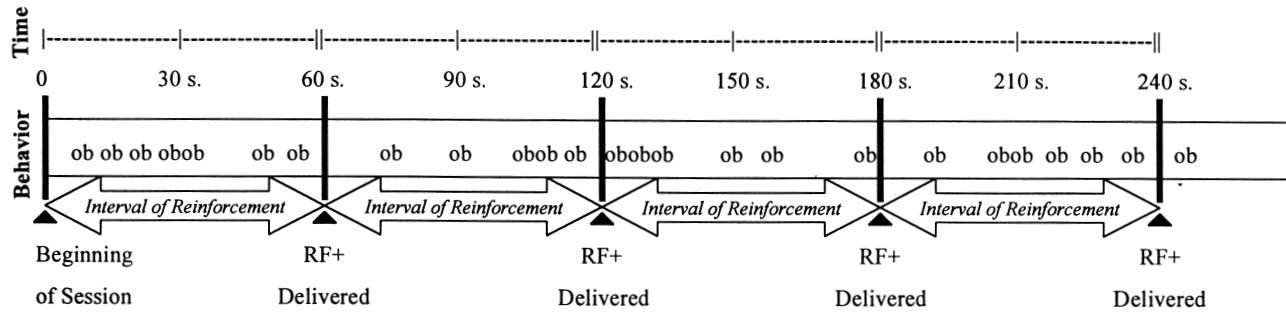

FIGURE 1 Temporal Parameter 1. *Interval of Reinforcement*: The interval of time during which the individual is expected to emit “Other Behavior” than the “Target Behavior” before a reinforcer is delivered. Interval of Reinforcement. Note: This is an example of an individual who is on a 60-s whole-interval DRO schedule. He is engaged in a variety of “Other Behavior” (ob) than the “Target Behavior” (tb) during the entire interval and thus receives his reinforcer at the end of every 60-s Interval of Reinforcement.

and generalization, positive and negative effects of DRO, and how to set-up a DRO intervention.

Although there was once concern that DRO treatment interventions were being underutilized, review papers have demonstrated consistently that DRO schedules are the most frequently used behavioral interventions for suppressing behavior. DRO procedures have also been rated as the most acceptable of the behavior suppression treatment approaches. DRO has been used to suppress a variety of problem behaviors, including: thumb sucking, stereotypies, aggression, food rumination, disruptive behavior, self-injurious behavior, inappropriate verbalizations, and “out-of-seat” behavior in the classroom.

Differential reinforcement of other behavior procedures consist of two basic behavioral elements: (a) reinforcement and (b) extinction. Reinforcement involves the presentation or removal of a stimulus immediately following a behavior that results in increased frequency of that behavior. In the case of DRO, the “behavior” is any behavior other than the target behavior. The extinction component in DRO involves the delaying or withholding of the reinforcer whenever the target behavior is emitted. Hence, we have two basic temporal parameters involved in establishing a DRO intervention: (a) the interval of time during which we expect the individual to refrain from emitting the target behavior (interval of reinforcement; see Figure 1), and (b) the interval of time during which the reinforcer will be withheld (delay interval) following the emission of the target behavior (see Figure 2). Reynolds referred to this as the resetting feature of the differential reinforcement schedule. Rieg, Smith, and Vyse demonstrated in the laboratory that it is not necessarily the absolute length of the interval of reinforcement or the delay interval that predicts the effectiveness of the DRO procedure as much as it is the relationship of these two parameters to one another. These authors concluded that the delay interval should

twice as long as the interval of reinforcement to gain maximum suppressive effect of the DRO intervention.

There are two types of DRO schedules: whole-interval DRO and momentary DRO. The distinction is based on the omission requirement. In whole-interval DRO, the reinforcer is delivered if responding has not occurred for the entire predetermined interval. Hence, the individual must be under constant observation. If the individual emits the target response at any point during the interval, the reinforcer is not delivered. In momentary DRO, the reinforcer is delivered if the individual does not emit the target behavior at the moment the interval ends. Within the momentary DRO schedule, it is possible for the individual to have emitted the target behavior at some point during the interval; however, if the target response does not occur at the precise moment the interval is elapsed, the reinforcer is given. A teacher that reinforces the absence of an undesirable behavior (e.g., physical aggression) at the very moment the bell rings to signal the end of recess is employing a momentary DRO schedule. The momentary DRO schedule is analogous to the momentary time sampling procedure described by Powell, Martindale, Kulp, Martindale, and Bauman. The momentary DRO procedure has the advantage over whole-interval DRO of being easier to implement and requiring less personnel time; whereas; Barton, Brulle, and Repp have also showed it to be as effective in maintaining behavior suppression as whole-interval DRO. These procedures are briefly presented.

In addition to the omission requirement parameter, another variant of the type of interval schedule is either fixed or variable in length. In a fixed schedule, the length of the interval is held constant. In a variable schedule, the length of the interval varies around a predetermined average value. Escalating schedules are also a third possible schedule variation. In escalating DRO schedules, a successfully completed interval results in the delivery of

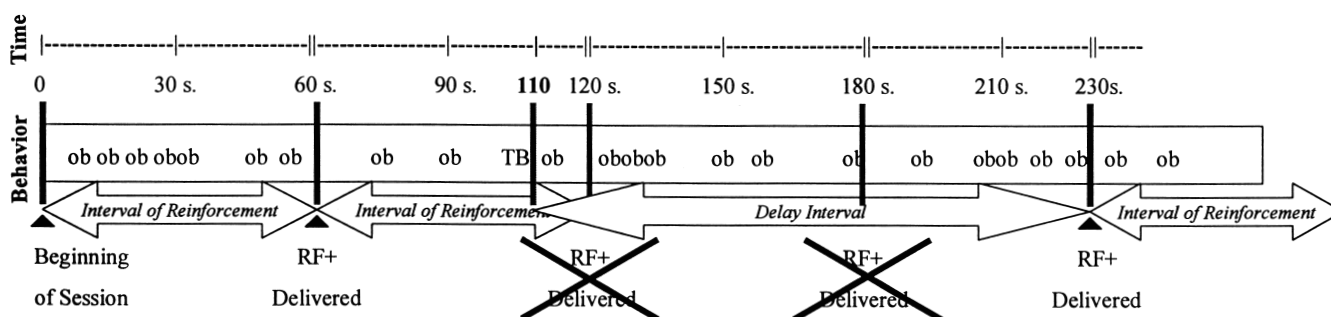

FIGURE 2 Temporal Parameter 2. *Delay Interval*: When the individual emits “Target Behavior” (tb), the time of delivery of the reinforcer is reset. The magnitude of the reset is the *Delay Interval*, which represents the time between the emitting of a “Target Behavior” and the delivery of the next reinforcer. *Delay Interval*. Note: This is an example of an individual who is on a 60-sec whole-interval DRO schedule. He is engaged in a variety of “Other Behavior” (ob) than the “Target Behavior” (tb) during the first interval and thus receives his reinforcer at the end of the first 60-sec Interval of Reinforcement. However, at the 110-sec mark of this observation session, he emits a “Target Behavior.” The next reinforcer is not delivered and the *Delay Interval* starts immediately following the emission of the “Target Behavior.” In this example, the *Delay Interval* is 120 sec. Hence, the individual does not receive a reinforcer until at least 120 sec after emitting a “Target Behavior.” In the above example, the individual did not emit a “Target Behavior” between the 110-sec and 230-sec mark, so a reinforcer was delivered at 230 sec. If he continues to emit only “Other Behavior,” he will continue to receive a reinforcer every 60-sec (*Interval of Reinforcement*).

reinforcement, but also in the increase of the length of the ensuing intervals. Repp and Slack decreased significantly various disruptive responses of students with mental retardation by using an escalating DRO schedule.

Lindberg, Iwata, Kahng, and Deleon presented a 2 × 2 diagram of the four possible DRO contingencies that can be created by alternating the omission requirement (whole-interval vs. momentary) and the type of interval schedule (fixed and variable): fixed whole-interval DRO, fixed momentary DRO, variable whole-interval DRO, and variable momentary DRO (see Table 1). Most DRO contingencies with human participants reported in the literature have been based on fixed whole-interval schedules. Furthermore, an important proportion of these studies have focused on problem behavior such as stereotypy and self-injury maintained by getting attention in people with mental retardation or other developmental disabilities. These four types of DRO schedules are now presented.

A. Fixed Whole-Interval DRO

In fixed whole-interval DRO, the interval length is held constant and reinforcement is delivered for the absence of target behavior throughout the entire interval. In his original description of DRO, Reynolds used a fixed whole-interval DRO in which pigeons had to abstain from pecking for a fixed period of time to have access to the reinforcer. Repp, Barton, and Brulle reported decreases in disruptive behaviors of young boys with

mental retardation using a fixed 5-min whole-interval DRO schedule. Reese, Sherman, and Sheldon reported a fixed whole-interval DRO schedule in combination with response cost and prompted relaxation to decrease the aggressive behaviors of a man with autism and mental retardation. For example, shorter intervals were used in this study during instructional demands versus leisure activities because the demands of the tasks were different and the contextual variables different.

B. Fixed Momentary DRO

Fixed momentary DRO is a schedule in which the interval length is held constant and reinforcement is delivered for the absence of target behavior at the end of the interval. Hence, the person is given a reinforcer if, at the end of the interval, the individual is not emitting the target behavior. All behavior that occurs during the

TABLE 1
Different Schedules of Differential Reinforcement of Other Behavior

	<i>Fixed length interval</i>	<i>Variable length interval</i>
Whole-interval	Fixed whole interval DRO	Variable whole interval DRO
Momentary	Fixed momentary DRO	Variable momentary DRO

interval is ignored and does not cause nondelivery of the reinforcer. Some researcher reported inconsistent strength of suppression of the target behavior while using a fixed momentary DRO procedure. For example, Harris and Wolchick compared the effects of a fixed momentary DRO schedule, time-out, and overcorrection on the stereotypic behavior of four young boys with autism and mental retardation. The authors reported that the DRO contingency produced a moderate decrease in the target response for only one participant; overcorrection was the only treatment that suppressed stereotypy in all four participants.

Some researchers have looked at the utility of the fixed momentary DRO schedule at maintaining the suppression of problem behavior once behavioral control has been gained. Repp, Barton, and Brulle compared the effects of fixed momentary DRO and fixed whole-interval DRO schedules. The results of the study suggested that fixed whole-interval DRO was more effective than fixed momentary DRO at suppressing responding of disruptive behaviors in four young boys with mental retardation, but that fixed momentary DRO maintained previous levels of response suppression attained with a fixed whole-interval DRO schedule. Derwas and Jones also compared fixed whole-interval DRO and fixed momentary DRO as treatments for the stereotypy of five men with severe mental retardation. In contrast to Repp et al., these authors reported that fixed momentary DRO was more effective than fixed whole-interval DRO in decreasing the target response for three of the five participants. They found that one participant responded to fixed whole-interval DRO but was maintained at a low rate in a fixed momentary DRO schedule, and that fixed momentary DRO actually increased the stereotypy of the other participant. With the exception of certain results reported by Derwas and Jones, research indicates that fixed whole-interval DRO is a more effective schedule than fixed momentary DRO to obtain initial suppression of problem behavior. One important limitation of the fixed momentary DRO schedule is its predictability. Individuals can quickly learn that they can emit any behavior during much of the interval as long as they pace themselves with the end of the interval they will receive the reinforcer, regardless of the target behavior emitted during the interval.

C. Variable Whole-Interval DRO

Variable whole-interval DRO is a schedule in which the interval lengths vary across an average value and reinforcement is delivered for the absence of target behavior throughout the entire interval. Very few studies

have examined the effects of variable DRO schedules in humans. Topping and Crowe reported that variable whole-interval DRO and fixed whole-interval DRO were equally effective (and more effective than extinction) in suppressing a key-pressing behavior in college student who had been previously trained to key press on either a fixed-interval or variable-interval schedule of reinforcement.

D. Variable Momentary DRO

Variable momentary DRO is a schedule in which the interval lengths vary across an average value and the reinforcer is delivered for the absence of the emission of the target behavior at the end of the interval. Sisson, Van Hasselt, Hersen, and Aurand reported limited effects of a variable momentary DRO schedule in decreasing disruptive and stereotypic behavior of three children. The authors reported that the 20-sec variable momentary DRO schedule decreased the stereotypy of only one of the participants, and that the addition of overcorrection was needed to ensure maintenance. Lindberg et al. compared the effects of fixed whole-interval DRO and variable whole-interval DRO schedules, and the effects of variable whole-interval DRO and variable momentary DRO schedules in three women with mental retardation who emitted self-injurious behavior maintained by attention from others. Results indicated that variable whole-interval DRO and variable momentary DRO were as effective as the more widely used fixed interval schedules. For all three participants the self-injurious behavior decreased to near zero rates. The study published by Lindberg et al. was more carefully designed than previous studies and demonstrated that variable momentary DRO schedules could be highly effective. The results are interesting because momentary schedules are easier to implement, requiring much less monitoring than fixed DRO schedules.

II. EFFICACY

Many earlier published studies used the DRO schedule in combination with other behavioral strategies when attempting to decrease a target response (e.g., the use of DRO and time out or the use of DRO and overcorrection). These earlier studies made it difficult to untangle the effects of the DRO schedule itself. A number of more recent clinical studies have examined the efficacy of DRO alone. These studies have also looked at the efficacy of DRO procedures when used alone in

suppressing serious and long-standing problem behaviors such as self-injurious behavior

A. Length of Interval

The length of the interval has been shown to contribute to the efficacy of the DRO procedures. Generally, a shorter interval length that is then extended in time will be more effective. A shorter interval offers a greater probability of successful experience (i.e., omission of target behavior) for the participant. The initial length of the DRO interval should be in relation to the mean interval length between target behaviors observed during a baseline condition. Repp et al. empirically demonstrated that a shorter interval resulted in greater suppression of the target behavior compared to an interval length that was twice the mean interval observed during baseline. However, Piazza, Fisher, Hanaley, Hilker, and Derby cautioned against an interval being so short that the person has difficulty discriminating when the target behavior resulted in nondelivery of the reinforcer. As pointed out by Mazaleski, Iwata, Vollmer, Zarcone, and Smith, withholding the reinforcer for a predetermined interval (i.e., extinction) whenever the target behavior occurs, might minimize the problems observed by Piazza et al. It has been demonstrated that DRO suppression strength is maximized when the delay interval (length of time before delivering a reinforcer following the emission of a target behavior) is greater than the interval of reinforcement (interval during which the target behavior must be suppressed before a reinforcer is delivered).

B. Functional Assessment

As noted by Vollmer & Iwata, the lack of efficacy of some DRO interventions are often due to the fact that the authors failed to conduct an a priori functional assessment of the target behavior. Thus, the selected reinforcer must be relevant to the function of the target behavior for this, or any, behavioral intervention to be optimally effective at suppressing a behavior. This is briefly explained in the next section.

III. FUNCTIONAL ASSESSMENT AND REINFORCER PREFERENCE

Despite the straightforward definition of DRO, that is the delivery of reinforcement contingent on the occurrence of any behavior other than the target behavior, many procedural and functional variations have been re-

ported in the literature. For instance, certain studies reset the time interval if the target response has been emitted, whereas others do not use the time resetting feature that was originally described by Reynolds. Certain studies use an arbitrary response-reinforcer relationship whereas others use a functional response-reinforcer relationship (i.e., certain studies conduct a functional analysis before implementing the DRO schedule). The efficacy of the DRO procedure is dependent on the congruence between the reinforcer salience as well as the reinforcer's relationship to the function of the target behavior. Emitting "other behavior" must produce consequences that are of equal or greater value to those produced by the target behavior; or else, the participant will continue emitting the target behavior. Hence, the reinforcer that is delivered for emitting "other behavior" must be able to compete with the reinforcers produced for emitting the "target behavior."

Functional assessment is a process of gathering data surrounding the emission of problem behavior. The data used to conduct a functional analysis is gathered via one or more of the following methods: direct observation, interview of individuals present when the problem behavior is emitted, direct manipulation of the antecedents and consequences, and rating scales.

Reiss and Havercamp have demonstrated that there are clear individual differences in reinforcer preference. In addition to this, Piazza et al. empirically demonstrated that the salience of one reinforcer may not necessarily be the same for two different behaviors within the same individual. Hence, it is important to clearly identify an inventory of reinforcer preferences for each individual and for different target behaviors we wish to suppress. Piazza et al. also found that a reinforcer stimulus for a simple behavior may often lose its salience to reinforce more complex behavioral chains such as the suppression of a well-ingrained problem behavior.

IV. MAINTAINING BEHAVIOR SUPPRESSION AND GENERALIZATION

As Barton et al. demonstrated, although a momentary DRO schedule may not result in as great of a change in behavior suppression as a whole-interval DRO schedule, the former has great potential in maintaining suppression of the target behavior. Barton et al. compared the suppression effects of whole-interval DRO and momentary DRO with nine school-aged students with severe to profound mental retardation and associated sensory and auditory impairments. Target behaviors for all

nine participants were observed and recorded during a baseline phase. Following the baseline phase, the nine participants were placed on a whole-interval DRO schedule to suppress their target behaviors. Then, the participants were randomly assigned to three treatment groups of three participants. The first group of three participants were maintained on the whole-interval DRO to observe its ability at maintaining suppression of the participants' target behavior (A-B treatment design). The second treatment group was moved from the whole-interval DRO to a momentary DRO schedule to study the latter's efficacy at maintaining the suppression of the target behavior (A-B-C treatment design). In the third treatment group of participants, the whole-interval DRO procedure was suspended, and the participants were returned to a baseline treatment state (A-B-A design). The purpose of this intervention was to measure the suppression maintenance effect of "no intervention" on the target behavior and allow comparison with the two other DRO procedures.

This study demonstrated that both whole-interval and momentary DRO were effective at maintaining suppression of the target behavior. The third treatment group (A-B-A) saw a rapid return to previous frequencies of target behavior when the whole-interval DRO intervention procedure was halted. The authors found that momentary DRO schedule was equally effective as a whole-interval DRO schedule in maintaining the behavior improvements. Because momentary DRO is less personnel intensive than a whole-interval DRO schedule, it may be the procedure of choice to maintain suppression of problem behavior. Because it does not demand constant eye-on supervision, the momentary DRO procedure may result in less resistance from direct-care staff and be less likely to be abandoned along the way.

V. NEGATIVE EFFECTS

Although some authors initially claimed that there were no negative effects associated to DRO procedures, this may not always be true. One concern with the use of DRO schedules is the possibility of inadvertently reinforcing a non-target behavior that could become a problem behavior. Skinner accurately described the effects of superstitious conditioning in the laboratory with pigeons. Superstitious behavior, or behavior that is irrelevant to the presentation of the reinforcer, is seen everyday (e.g., in gambling establishments). Inadvertent reinforcement within a DRO procedure might occur when the presentation of a reinforcer immedi-

ately follows a behavior that happens to occur at the end of an interval. For example, if a child is on a 10-min fixed whole-interval DRO schedule and the target behavior is being out of seat. At the end of a 10-min interval during which the child sat quietly but might have been throwing spit balls at a peer, the child will receive the reinforcer. In this situation, the child's throwing of spit balls might be accidentally reinforced.

Cowderly, Iwata, and Pace reported that their DRO procedure was associated with a intense emotional reaction on the part of the child. In their study, a 9-year-old boy with borderline intellectual functioning and severe scratching and skin-rubbing behavior became upset and cried each time he was told that he had failed to earn his reinforcer for the preceding interval because of the presence of self-injurious behavior. Some negative side effects can be avoided by conducting a systematic thorough reinforcer preference.

Generally speaking, DRO procedures are among the least restrictive procedures used to suppress problem behaviors. In addition, DRO procedures generally result in the least negative side effects and are the most accepted form of intervention.

VI. STEPS TO SETTING-UP A DRO INTERVENTION

1. Operationally define the target behavior. Use terminology that is observable and measurable and non-judgmental (i.e., yells, throws objects, and punches vs. gets angry).
2. Conduct a functional assessment of the problem behavior. Also useful may be a scatter plot.
3. Conduct a reinforcer preference inventory for the individual and identify the most salient reinforcers.
4. Establish the preferred type of schedule of reinforcement; Fixed whole-interval DRO, variable whole-interval DRO, fixed momentary DRO, variable momentary DRO. The choice of a DRO schedule may depend on the baseline frequency of the problem behavior as well as the availability of trained personnel to effectively carry out the procedure. A whole-interval procedure may work best initially to suppress the target behavior and can then be replaced by a less personnel-consuming momentary schedule. A variable interval schedule has the advantage of being more difficult to predict the time of delivery and results generally in learning (e.g., to suppress the target behavior) that is more resistant to extinction than a fixed interval schedule of reinforcement.

5. Determine the most efficient other behavior \leftrightarrow reinforcer interval (interval of reinforcement). Poling & Ryan described calculating the average interresponse time observed during a baseline condition to determine an efficient interval. A cooking timer is generally adequate, however, recording beeps at the predetermined intervals onto an audiotape can be less disruptive when an ear piece is used. The use of a handheld behavior observation system is obviously the most elegant and expensive.

6. Determine the most efficient target behavior \leftrightarrow reinforcer interval (delay interval—resetting feature). Uhl and Garcia suggested delaying the reinforcer (delay interval) for a duration that is greater than the interval of reinforcement.

7. Set up your data-recording materials.

8. Train the necessary people (e.g., direct-care staff, parents, teachers, etc.) on conducting the DRO and data recording.

9. Review behavioral data and revise DRO procedure as needed (i.e., you will want to gradually increase the interval once you've gained control of the target behavior).

VII. SUMMARY

In summary, DRO is the most commonly used procedure for suppressing problem behavior. There are several different types of DRO schedules: fixed momentary DRO, variable interval momentary DRO, fixed whole-interval DRO, and variable whole-interval DRO. There are several crucial elements to consider when selecting a DRO schedule. These elements include the function of the target behavior and the selection of an appropriate reinforcer, the frequency of the target behavior, the length of the interval of reinforcement, the use of a delay interval and its length, the choice between a whole-interval versus a momentary interval schedule, and the choice between a fixed or variable interval time. Numerous studies have shown DRO procedures to be among the most effective in suppressing problem behavior and maintaining suppression of problem behavior through the delivery of reinforcement contingent on the absence

of the target behavior. In addition to being an effective behavior suppression techniques, DRO procedures have also garnered the highest ratings of treatment acceptability from professionals and parents.

stimulus control Control over the occurrence of a response by a discriminative stimulus (S+).

I. DESCRIPTION OF TREATMENT

Discrimination training refers to the process by which an individual learns to perform a particular response in the presence of a designated stimulus (S+) while inhibiting this response in the presence of other stimuli (S-). A typical procedure used to train behaviors to come under discriminative control involves the presentation of two different stimuli, one that acts as a discriminative stimulus (S+), cueing the individual to respond, and one that acts as a cue for the response to stop (S-). If an individual performs the desired behavior after the correct cue, she or he will receive a reward. However, if the response occurs after the wrong cue is presented, no reward is provided. Such differential reinforcement of behavior after the presentation of different stimuli results in an increased likelihood of responding following the S+, and decreased response rates, or even an absence of responding, in the presence of other cues. For example, even people can be discriminative stimuli: A child might make a special request from mom if she appears to be in a good mood (S+). However, if mom is grouchy and stomping around the house (S-), the child is likely to keep quiet.

Stimulus discrimination can be thought of as the opposite of stimulus generalization, a process by which an

GLOSSARY

discriminative stimulus A neutral stimulus that predicts when the performance of a particular response will lead to a desired outcome.

extinction In classical conditioning, the weakening and eventual disappearance of a learned response that occurs when the conditioned stimulus (CS) is no longer paired with the unconditioned stimulus (US). In operant conditioning, the process in which a reinforcer is repeatedly left absent after the occurrence of a behavior, resulting in the inhibition of that behavior.

generalization The degree to which novel stimuli resembling the original discriminative stimulus (S+) or conditioned stimulus (CS) elicit a behavioral response.

generalization gradient A decline in the magnitude of a response with increases in the physical difference from the original stimulus (S+), or an increase in magnitude corresponding with decreases in the physical difference of the S+.

postdiscrimination gradient A term coined by Kenneth W. Spence in his 1937 paper on discrimination training. The postdiscrimination gradient is derived from the interaction of the excitation and inhibition gradients elicited by a single stimulus.

individual learns to respond the same way while in the presence of two or more similar stimuli. For example, an infant may see a dog, and be rewarded repeatedly by a parent for saying “dog.” Fairly soon, all four-legged, friendly neighborhood animals are called “dogs,” whether they be cats, goats, or guinea pigs. Of course, the more similar in appearance the new animal is to the original dog, the more likely the child is to call it a dog. This behavior demonstrates the idea of a generalization gradient, or the notion that the strength of a response to a given stimulus is a function of its similarity to the original discriminative stimulus. When an individual undergoes discrimination training, the reverse is true: Learning to respond differentially when in the presence of two stimuli is easier if those stimuli are very different. For example, it is easier for a child to learn the difference between red and blue than between red and orange.

Both the concepts of stimulus discrimination and stimulus generalization are dependent on the notion of stimulus control. When a given cue determines how likely someone is to perform a particular behavior, that behavior is said to be under stimulus control. For example, in a 1980 study, K. D. Brownell, A. J. Stunkard, and J. M. Albaum attempted to attain stimulus control over using the stairs rather than an escalator in a shopping mall, a train station, and a bus terminal. The stimulus used was a poster depicting a “healthy” heart climbing the stairs, and an “unhealthy” heart riding an escalator. The poster’s caption read: “Your heart needs exercise, here’s your chance.” Results indicated that the use of the stairs increased significantly during the time the “intervention” was posted. A reasonable conclusion of this study is that the poster exerted stimulus control over stair-climbing behavior.

Teaching an individual to respond discriminately when in the presence of different cues is a somewhat different matter. One of two methods of discrimination training typically are used. Simultaneous discrimination training is a technique in which both S+ and S– are presented at the same time. For example, suppose an individual was presented with a circle and an ellipse, and had to correctly identify which was the circle in order to earn a reward. This person has access to both stimuli at the same time, and must compare and choose between the two immediately. On the other hand, in successive discrimination training, the two stimuli are presented sequentially, or one after another. An example of this would involve presentation of a Pepsi and a Coke, which an individual would have to try one after the other, to correctly determine which was the Pepsi to get a reward.

Of these two techniques, simultaneous discrimination is most commonly used in applied settings, and is

thought to be superior to successive methods. Research comparing the two techniques has yielded comparable results; however, some studies have indicated that simultaneous presentation of stimuli leads to better generalization effects. For example, in a 1978 generalization study by Marion C. Panyan and R. Vance Hall, investigators examined the effects of both simultaneous and successive stimulus presentation in training two females with severe developmental disabilities on vocal imitation and tracing tasks. Each participant experienced both the concurrent and serial conditions. In the concurrent condition, the two women were required to practice a tracing task for 5 minutes, then a vocal imitation task for 5 minutes, and finally, to return to the tracing task for the last 5 minutes. Subsequent sessions reversed the order of task presentation. In the serial condition, the participants were required to gain mastery over either the tracing task or the imitation task first (or complete 200 trials) before moving on to the remaining task. Although no differences between serial and concurrent training methods in terms of number of trials required to gain mastery were found, concurrent presentation appeared to result in better generalization of skills to untrained items. In other words, if a participant was presented a novel consonant sound, she was more likely to demonstrate some skill in imitating it directly following a concurrent than a serial training session.

In addition to presenting cues in a simultaneous or successive manner, the schedule of reward distribution may also vary. In concurrent schedule discrimination training, an individual must choose between two response options simultaneously. For example, an individual has the option to press either a red button or green button. The red button signifies delivery of reward every 3 minutes, while the green button denotes rewards every 6 minutes. This reward schedule is likely to impact how often and when these buttons are pressed. If a multiple schedule is used, stimuli are presented successively, and reinforcement is given differentially in a sequential manner. Consider the example of a pigeon trained to peck a light that varies in color from red to green. When the light is red, the pigeon may be rewarded on an average of once per 2 responses, but when it is green, the pigeon’s pecks are rewarded on an average of once per 10 responses. If this is a smart bird, it will likely learn to peck the most efficient way to gain the most reinforcers—that is, pecking less often when the light is red, and at a higher rate when the light is green. To evaluate the degree of discriminative control, researchers look for differential response rates between the two stimuli.

In conditional discrimination, a process by which an individual is required to make a certain response during presentation of one stimulus and a second, different response, during the presence of a second stimulus, responding is said to be “conditional,” or dependent, on the stimulus presented. For example, in receptive labeling tasks, children with speech comprehension and production difficulties are required to point to or touch one of two different objects named by the teacher. First the child is presented with a cookie, which the teacher names for the child. When the child touches the cookie, she or he can have a taste of it. Next, when the child has reliably learned to reach for the cookie when the teacher says “Where’s the cookie?,” it is presented in conjunction with another item. If an apple and a cookie are presented and the instructor asks, “Where’s the cookie?,” the child must reach for the cookie. If the correct response is given, the cookie is delivered. If not, the cookie is removed for a brief period. Eventually, the child must respond correctly to randomly presented pairs of objects—this constitutes a conditional discrimination task, as either choice may be correct at a given time.

A number of factors influence the ease of discrimination training and the stability of stimulus control. Namely, these factors include degree of similarity between $S+$ and $S-$, as discussed previously. The “information value” of the stimulus is also important. If an employee is rewarded every time he or she performs a task for one supervisor but rarely when a task is performed for another supervisor, the instructions of the former boss may be more salient to that worker. Thus, the first boss may elicit a better, more consistent performance than the second. In addition, the effects of prior discrimination learning may also enhance the development of discriminative control. In 1952, the “easy to hard” effect was first described by D. H. Lawrence, who used rats to examine how well they transferred the learning of one task to a similar, but more difficult one. Results suggested that if a relatively easy task was taught first, performance was facilitated later when more difficult tasks were attempted. Finally, the differential outcome effect, which refers to the degree to which a particular response leads to a unique outcome, also plays a role in discrimination learning. That is, differential responding occurs more readily when a particular response results in a particular outcome, and when other responses lead to significantly different outcomes. Continua along which outcomes must differ include magnitude, delay of reinforcement, or quality of reward.

In the clinical realm, discrimination training is often used in a population of both adults and children with

developmental disabilities. For example, it has been used to enhance receptive and expressive speech, visual discrimination of relevant cues, the development of social skills, and to reduce problem behaviors such as aggression and pica. More diverse applications of discrimination training involve its use in biofeedback training, in marital therapy, and behavioral health.

II. THEORETICAL BASES

There are two dominant theories of discrimination learning, developed through the use of animal models. The first, conceptualized by C. L. Hull and Kenneth W. Spence in 1936, involves a few major assumptions. Simply put, Hull and Spence believed that a given stimulus had both excitatory properties (properties that would lead an individual to respond) and inhibitory properties (properties that would lead an individual to not perform a response). These properties, they argued, interacted: Whichever property predominated dictated whether an individual would respond. The $S+$, which by definition results in the performance of a particular behavior, has more excitatory than inhibitory strength. Other stimuli, especially if they are very different from the original discriminative stimulus, may have stronger inhibitory than excitatory effects. The opposite is true of cues highly similar to the discriminative stimulus. The underlying assumption of this idea is that both the excitation and inhibition to a given stimulus are thought to generalize to other, similar stimuli. This explains the generalization gradient phenomenon, as well as the fact that discrimination tasks comparing two very different stimuli are more difficult to learn than those contrasting similar cues.

In an extensive 1981 review, Werner K. Honig and Peter J. Urcuioli argue that the Hull–Spence theory of discrimination has a great deal of support from generalization studies, or experiments requiring rats or pigeons to discriminate between two stimuli. In these studies, the animal is presented with a variety of stimuli, each sharing some similarity with the $S+$. The rate of responding under each condition of the stimulus is recorded in a graph, which typically depicts the highest rate of responding (the peak of the curve). This peak is thought to correspond with the excitatory properties of a stimulus, and thus is often called an excitatory gradient. Similarly, an inhibitory gradient, or the lowest point of the curve, representing the lowest rate of responding, can be demonstrated in extinction studies, in which responses given in the presence

of different stimuli do not result in a reward. If Hull and Spence were correct in believing that each stimulus had both inhibitory and excitatory properties, this would allow an interesting prediction. Because each different stimulus evokes both excitation and inhibition, these tendencies interact to produce a gradient of responding called the postdiscrimination gradient. Further, they would result in a shift of peak responding *away* from the original discriminative stimulus. A vast number of animal studies have supported this hypothesis in their demonstration of a peak shift, or a displacement of the peak of the excitatory gradient away from the original S+. Some researchers have suggested that degree of displacement is directly related to the dissimilarity between S+ and S- cues. That is, if the S+ is vastly different than the S-, peak shift tends to be minimized. If the cues are similar, peak shift will be larger.

The first individual to demonstrate the peak-shift phenomenon was Harley Hanson, in his 1959 doctoral thesis. In the first phase, he trained pigeons to earn a food reward by pecking a key during the S+ stimulus, which was a colored light with wavelength at 550 nanometers. He then presented different groups of pigeons with a variety of cues differing along a continua of wavelengths, but continued to deliver reinforcement when they pecked a key subsequent to the presentation of the 550 nanometer light. The third phase of the experiment consisted of generalization testing, during which he presented light stimuli in varied hues (ranging from 480 to 600 nanometers). Hull-Spence theory would predict a displacement of maximum responding away from the original 550 nanometer S+ in the direction opposite that of the S-. Indeed, in discrimination groups, the maximum rate of responding did not occur at the original S+, but was shifted away, in the predicted direction. In addition, the degree of shift appeared dictated by the difference between S+ and S- cues. The more similar S+ was to S-, the greater the peak shift; the less similar, the less pronounced the displacement. Since this initial study, a number of other animal studies have also demonstrated this phenomenon, both in pigeons and rats.

In contrast to Hull-Spence theory, N. S. Sutherland and N. J. Mackintosh forwarded a competing theory in 1971. They posited the attention theory of discrimination, which they argued involved two processes. Primarily, they suggested that the attention of an individual is affected when that person is reinforced. That is, the individual's attention is drawn to salient features of stimuli around them. Secondarily, they ar-

gued that the brain comprises "analyzers" whose function is to receive and process sensory information. Each dimension of a stimulus is processed by a different analyzer. When discrimination training begins, the strength of an analyzer is correlated with the strength of an incoming signal. If a given stimulus has salient features, the individual's attention will be drawn to it. Further, if a subject attends to a particular stimulus, performs the appropriate response and is rewarded, the analyzer for that stimulus is thought to gain strength. Other analyzers corresponding to less relevant stimuli are thought to weaken. Sutherland and Mackintosh suggest that a "bond" develops between a specific response and its analyzer. This theory accounts for how the information value of a given stimulus affects the ease of discrimination learning.

A 1973 study by T. G. Waller examining consistency of reward delivery on runway performance in a rat model provided support for the attention theory of discrimination. Of four groups of rats, two groups ran an alleyway and were rewarded at the goal box on every trial. The remaining two groups received reward for this performance only 50% of the time. One group in each of the two conditions (100% reinforcement and 50% reinforcement) ran an alleyway that was gray in color, while the other group in each condition ran a vertically striped alley. In phase two of the experiment, all subjects were trained to choose between two goal boxes—one with stripes slanting to the right, and one with stripes slanting to the left—for a food reward. Attention theory would predict that of the groups originally trained to run the striped alleyway, the 50% group would learn the discrimination less readily than the 100% group, because their analyzer for this cue is weak relative to that of the 100% group. In addition, proponents of attention theory would expect that groups trained in the gray alleyway would learn the discrimination task equally well. Because these rats had no exposure to stripes, their analyzer strength for this stimulus would be about equal. Results indicated that rats trained in the gray alley learned the task at roughly the same rate, whereas of the rats that experienced the striped alley in phase 1, the 50% reinforcement group took more trials to learn the task than did the 100% reinforcement group.

III. EMPIRICAL STUDIES

A great deal of research from animal models supports the efficacy of discrimination training in a labo-

ratory setting. In addition, there is a wealth of clinical research supporting the effectiveness of discrimination training in real world settings, especially among populations that demonstrate difficulty with discrimination tasks. Discrimination training in the clinical realm has proven effective in teaching new skills, as well as modifying inappropriate behaviors such as impulsivity, either as a treatment modality in itself, or integrated in a multicomponent behavioral intervention. One way in which discrimination training is used in a clinical population was formulated in the 1960s by Ole Ivar Lovaas to teach autistic children receptive and expressive language skills. First, the child is taught receptive labeling, followed by speech imitation training. In receptive labeling, a teacher presents desired objects—such as toys or edibles—and gives a simple phrase or question, such as “cookie,” or “Where’s the cookie?” For children to earn this reward, they must perform a simple task such as pointing toward or touching the named item. If they do not complete the desired task, the teacher models the appropriate response for them, and then may physically prompt the child. However, no reward is given: acquisition of the desired item is contingent on the correct response. In this model, the teacher’s statement serves as a discriminative stimulus for the response of non-verbally indicating the object. After a child learns to indicate a given object in a reliable way without prompting, a new object is introduced, and the procedure is repeated. Finally, the two objects are presented simultaneously, and the teacher names either one, in random order, rewarding the child for correct identifications.

In addition to teaching language skills, the field is replete with studies demonstrating possible applications of discrimination training. For example, in a 1977 study, David Marholin and Warren Steinman examined the development of stimulus control in the classroom. Investigators explored reasons why children may exhibit appropriate behaviors in one classroom setting, but act inappropriately in another. Marholin and Steinman hypothesized that due to reinforcement and punishment given by a teacher, that teacher’s presence may serve as a discriminative stimulus for appropriate behavior. In the teacher’s absence, children’s behavior may devolve into disruption and off-task antics. To test this hypothesis, authors assessed the academic performance of eight children ranging in age from 10 to 12 years and demonstrating conduct problems as well as poor academic performance. The study was conducted in a typical classroom setting. Using an ABCBC design,

the first condition (A) served as a baseline, during which the children received no reinforcement, while during the second (B), the teacher reinforced appropriate behavior. The third condition (C) was characterized by reinforcement of both the rate and accuracy of on-task academic performance. Each session lasted for 30 minutes. For the final 3 sessions of each condition (A, B, and C), the teacher was absent for a 10-minute period. Two independent raters collected data on both appropriate and inappropriate behaviors, while the teacher was present and absent. Examples of appropriate behaviors included looking at books or handouts, getting out materials, writing answers, etc. Inappropriate behaviors comprised fidgeting, speaking out, or physical aggression.

Results indicated that the presence of the teacher made a big impact on children’s behavior. Specifically, the students demonstrated much higher levels of disruptive and off-task behavior while the teacher was not present, regardless of which contingency condition was in operation. Predictably, however, children engaged in more on-task behavior while they were reinforced for academic behaviors (remember, reinforcement was contingent on the teacher’s presence). On-task behavior was at peak levels when the children experienced condition C, under which they received reinforcement for rate and correctness of academic work. This differential rate of on-task behavior across teacher-present and teacher-absent conditions supports the notion that the teacher had become a discriminative stimulus for on-task behavior. Yet teachers are occasionally absent, so some attempt must be made to encourage generalization of on-task behavior to teacher-absent conditions. The authors suggested that reinforcement for the quality of a child’s work (as in condition C) rather than on-task behavior *per se* (as in condition C) may foster the transfer of discriminative control from the teacher to academic materials.

IV. SUMMARY

Discrimination training refers to the process by which a subject learns to respond differentially to two or more different stimuli. To bring a behavior under discriminative control, responses to the correct cue (S+) are rewarded, while responses to the wrong cue (S–), are not. The discriminative control of a stimulus may be assessed by an increased probability of responding to S+, and a decrease in, or absence of, responding in the presence of S–. Two dominant theories of discrimination

learning serve as underpinnings of discrimination training. Hull–Spence theory suggests that each cue has both excitatory and inhibitory properties, which summate algebraically to produce a response. Whether or not the subject responds in the presence of a particular stimulus is dependent on whether the excitatory strength of that stimulus outweighs its inhibitory properties. Hull–Spence theory draws empirical support from experiments examining the peak shift phenomenon. In contrast, Sutherland–Mackintosh attention theory of discrimination suggests that when a stimulus predicts a reward, that stimulus captures a subject’s attention. The relative salience of a stimulus is directly related to how readily a subject learns a discrimination task. A plenitude of research, typically animal studies, supports this theory. Discrimination training has been used for a variety of clinical issues, including social skills training, biofeedback training, and modification of severe behavior problems.

GLOSSARY

general clinical record Includes the patient's name, the date, duration of time spent with the patient, nature of the service and service code, and clinician signature.

health care documentation Requires that a record be factual, complete, legible, and maintained concurrently with provision of the service being documented.

privacy rule Creates a high standard of privacy for psychotherapy notes. These are identifiable but kept in a separate part of the health care manual.

protected psychotherapy notes Establishes an absolute privilege for information disclosed in psychotherapy or counseling.

I. PRINCIPLES AND PURPOSES

Standard principles of health care documentation require that a record be factual, complete, legible, and

maintained contemporaneously with the provision of the service being documented. Documenting psychotherapy services poses special challenges because of the extremely sensitive nature of the material brought forth in a confidential atmosphere of trust. Strong legal and ethical principles underlie the confidentiality of medical services in general. The confidentiality of psychotherapy is given a special status of privilege in state courts, and this privilege was extended to federal courts in the 1996 U.S. Supreme Court decision in *Jaffee v. Redmond*. The special status of psychotherapy notes is a significant element of the federal regulations that the Department of Health and Human Services (HHS) developed at the direction of the Health Insurance Portability and Accountability Act (HIPAA) of 1997, to take effect in 2003. These regulations may bring order and consistency to what has been a heterogeneous and sometimes controversial approach to documenting psychotherapy in actual clinical practice.

The health care record has multiple purposes and many potential readers, intended and unintended. For the clinician and the patient or client, it is a record of diagnosis and treatment that serves continuity of care both by the treating clinician and any succeeding caregiver. In an organized setting such as a hospital or clinic, it may facilitate knowledgeable treatment by circulating information among a number of caregivers. The record may also benefit future patients by contributing data to research. Medical information is often requested by third-party payers to assess the validity of health care insurance claims. In the era of managed

care, this information is often demanded in advance of authorizing payment for anticipated treatment services, often with controversial implications because unknown people in the managed care organization presume to judge the medical necessity of recommended treatment without any firsthand knowledge of the patient or assurance of training equivalent to that of the patient's therapist. With self-insured employers, medical information about employees may be reported back to employers to obtain payment.

If there is contention about the care given to a patient, as in malpractice litigation or an ethics investigation, the record may provide a relatively objective, contemporaneous account of what did or did not transpire; an old legal saw is, "If it isn't in writing, it didn't happen." Medical records may also be sought if the information therein is relevant to a civil lawsuit or criminal investigation, prosecution, or defense. There are detailed legal processes that attempt to strike a balance between protecting privacy and permitting access to all relevant information in pursuit of justice.

Needless to say, in view of its importance to the patient and its legal ramifications, the record should be professional and respectful. Humorous, flippant, or demeaning remarks about a patient have no place in a clinical record.

II. DILEMMAS AND CONTROVERSIES

The information documented in a psychotherapy record is of a different nature than routine clinical or administrative data. Whereas the latter includes history as narrated by the patient or others, observations and physical or mental examination findings by the clinician, laboratory data, treatment plans, prescriptions, and side effects, and so on, psychotherapy data are much more subjective. Furthermore, as acknowledged both by the U.S. Supreme Court in *Jaffee* and in the HIPAA rules, psychotherapy material is elicited in an atmosphere of privacy, trust, and complete freedom to speak one's thoughts. It may include repetitive thought patterns, dreams, fantasies, wishes, revelations of behavior that induce shame or guilt, or details of the intimate lives of the patient and other people. The psychotherapy cannot take place unless these things are addressed, and they will not be addressed unless the patient knows that whatever is spoken will not adversely affect either the patient or other people in relationships. This incontrovertible fact necessitates a higher level of

protection for the contents of psychotherapy discourse. The privacy of one's mental life and ideas is a most cherished value.

A powerful dilemma ensues: On the one hand, documentation protects the patient and the therapist and may facilitate treatment. On the other hand, documentation of the intimate mental contents of psychotherapy could expose the patient to embarrassment and damage. Although unlikely, disclosures of contents of the record could occur involving other facility personnel, courts, attorneys, law enforcement officials, researchers, insurance carriers, managed care companies, or employers making personnel decisions.

There is a wide variation in the way psychotherapists handle this dilemma, depending on the locus of treatment, the therapist's technical and theoretical orientation, the nature of payment, and the potential risks of invasion of the record. Many therapists, especially in solo private practice, keep minimal records. Some keep none, which forestalls access to any written psychotherapy information by third parties for any reason (although it does not preclude a subpoena of the therapist for testimony). However, it also exposes the therapist to serious legal risks and may detract from the continuity and coordination of care. In hospitals or multidisciplinary, ambulatory settings a detailed record may be required by institutional standards and the exigencies of coordinating care by a variety of caregivers. In training situations detailed notes may be essential for supervision or consultation with more experienced clinicians.

Some varieties of treatments require special approaches. In group therapy, the leader may make a general note describing the process of each meeting of the group, identifying individuals only by first name if at all, and then write an individual note for each patient's chart that does not mention other patients. For psychoanalytic treatment in a high frequency of sessions, an American Psychoanalytic Association practice bulletin states a rationale that requiring daily notes may actually be detrimental to the treatment process. This is because such a focused activity interferes with the free-associative attention state of the psychoanalyst that allows processing the analytic experience at multiple levels of consciousness.

Many therapists safeguard psychotherapy information by writing a factual clinical note that gives little detail about the psychotherapy contents, and then keeping personal notes in which the identity of the patient cannot be discerned and the intimate contents of psychotherapy can be detailed. This is a common

procedure when very close examination of the process of treatment sessions is necessary for supervision, training, or research. Audio- or videotaping may achieve similar educational purposes but necessitate special editing to remove identifying material. This practice is the only way in which the psychotherapy proceedings can be recorded and closely studied without exposing the patient to damaging disclosures. However, the custom is decried by malpractice defense attorneys because it creates a “shadow” record that cannot be corrected by the patient or used in a courtroom without a fight to support a contested subpoena. Yet, prior to the protections afforded by *Jaffee v. Redmond* or the HIPAA rules, it was the only way to create a detailed record for study or supervision, despite a slight degree of risk of invasion by a legal proceeding.

III. LEGAL REQUIREMENTS

Some states require that all health care services be documented. In other situations documentation may not be specifically mandated, but failure to maintain documentation may be interpreted in legal proceedings as a lapse in meeting a generally accepted standard of care in the community. Some professional organizations require documentation as an essential component of care, whereas others do not specify this. Maintaining confidentiality of psychotherapy records receives strong emphasis in health care professional organizations’ ethical codes. Hospitals and other organized settings may establish their own requirements for documentation, and systematic record-keeping practices are essential requirements of private and public accreditation organizations.

IV. FEDERAL PRIVACY REGULATIONS

The final HIPAA privacy rule was published in the *Federal Register* in December, 2000, to take effect in April, 2003 for most health care entities and 2004 for smaller plans, barring intervention by Congress or the Bush administration. It applies to all identifiable health care information recorded in any medium, written or electronic. Crucially for the integrity of psychotherapy, it creates a higher standard of privacy for “psychotherapy notes,” which would be identifiable but must be kept in a separate part of the health care record. Whereas only a low level of blanket con-

sent is required for the use of the general medical record for treatment operations or claims payment, the patient must give specific authorization for disclosure of psychotherapy notes. Authorization must be dated with a time limit and state the recipient of the information as well as the nature of the information to be disclosed. If the patient wishes to have psychotherapy records transmitted to another professional, an insurance company, an attorney for legal proceedings, and so on, that patient must sign an authorization to do so. Authorization is not required for disclosure of records if the patient sues the therapist or the therapist is investigated by a state licensing board or other oversight authority. The therapist is permitted (not required) to disclose without authorization information “necessary to prevent or lessen a serious and imminent threat to the health or safety of a person or the public.”

The implications of the HIPAA privacy rule are far-reaching for the procedures for maintaining documentation of psychotherapy in all settings, although technically they apply only if the practitioner communicates patient information electronically in any fashion. When the rule goes into effect, there will be three potential levels of documentation of psychotherapy services.

V. THE GENERAL CLINICAL RECORD

The basic clinical record or medical record for psychotherapy is similar to that for any other medical service. Elements that frame the notation include the patient’s name, the date, the duration of time spent with the patient when time is an essential part of the service code (start and stop times in some instances), the nature of the service and the service code, and the signature of the clinician. Service codes are usually drawn from the AMA’s *Current Procedural Terminology* (CPT). The clinical substance of the note may include any or all of the following: relevant history, symptoms and signs, observations and examination findings, laboratory findings, results of other tests such as CT or MRI imaging studies, standardized symptom rating scales, psychological tests, diagnosis, functional status, the treatment plan, prognosis, and progress. If the patient is receiving medications as well as psychotherapy, notations regarding prescriptions, therapeutic effects, and side effects are also part of the general clinical note. If the service is “psychotherapy with medical evaluation and management (E&M)” conducted by a psychiatrist, the E&M

services are generally delineated in the general medical record along with documentation that psychotherapy took place. As defined by the AMA's CPT, E&M services include elements of assessment, medical decision making, and management of the patient.

At the beginning of a treatment relationship the treating clinician conducts a full evaluation of the patient according to the procedures of the clinician's discipline. An initial psychiatric examination would include a history of the present illness; past psychiatric history; family and personal histories; general medical history that includes use of tobacco, alcohol, and other drugs or chemicals whether prescribed or not; a detailed mental status examination; perhaps some elements of a physical examination; a differential diagnosis and formulation of the case; and a plan for further evaluation and treatment. This full examination becomes the cornerstone of the basic clinical record. If the patient is being transferred from another clinician and the information from past evaluation and treatment is available to the new clinician, the initial note may be less extensive. Because a psychotherapeutic relationship may begin with the very first moment with a patient, sensitive material from an evaluation session may appropriately be protected in a separate psychotherapy note.

The treatment plan is a central part of the basic clinical record which proceeds logically from the formulation of the case. Stated with varying degrees of elaboration, the formulation is a case discussion that includes a diagnosis but also an assessment of the patient's personality strengths and vulnerabilities in the context of the treatment history, current reality situation, biological variables, relationships and support systems, and any other relevant factors. The descriptive diagnosis is often less influential than the other elements in determining the selection and structure of psychotherapeutic modality. The psychotherapy treatment plan may include the treatment modality (e.g., psychodynamic, cognitive-behavioral, or interpersonal; individual or group), the frequency and duration of sessions, and estimated length of treatment. In some situations it may also state provisional goals, the means of assessing progress or determining the suitability of the psychotherapeutic approach after a trial period, and provisional prognosis. If the clinical note will be reviewed by others in a treatment facility or for managed care, it is especially important that the treatment plan make clear the rationale for selecting this mode of treatment, but such clarity would be highly desirable at all times.

Progress notes periodically update the psychotherapy treatment plan and its underlying rationale; they are

usually sufficient for review of the treatment without raising the issue of disclosing intimate personal information from the ongoing psychotherapy. Likewise, sensitive material that warrants protection may emerge during a routine medication management visit in which only minimal psychotherapy is expected to occur.

Material from the actual course of psychotherapy, once under way, may optionally be recorded in the general clinical note, but it would not then be protected under the HIPAA privacy rule. Sensitive information would be difficult to redact if the record were circulated to other treating health professionals, called into court, or otherwise opened to others under the standard consent conditions of medical records. Medicare carriers specify that the goals of psychotherapy and themes of each psychotherapy session should be stated in the basic record and available for review. It is unclear whether this required disclosure will be superceded by the HIPAA privacy rule because the rule does not permit requiring authorization of disclosure as a condition of payment. Privacy advocates from the field of psychoanalytic psychotherapy consider even this degree of disclosure to be a violation of the principles underlying the *Jaffee* privilege.

The overarching principle of the basic clinical record is that it should be able to stand alone in documenting and justifying the rationale and course of diagnosis and treatment, without need for disclosure of information from psychotherapy notes. It is the basic, self-sufficient medical record of the care of the patient.

VI. PROTECTED PSYCHOTHERAPY NOTES

The 1996 U.S. Supreme Court decision in *Jaffee v. Redmond* established an absolute privilege for information disclosed in psychotherapy or counseling—absolute because it cannot be balanced against other interests in court proceedings in individual cases. Though strictly applicable to civil cases in federal courts, the decision has been influential throughout the U.S. judicial system. The issue is how psychotherapy information can be delineated from other clinical information. Segregation of information disclosed in psychotherapy is of course much more difficult if psychotherapy notations are sprinkled throughout a clinical record containing other medical information for which there might be a legitimate reason for access by the court. Third-party payers may appropriately, with the patient's consent, request the kinds of clinical information that are entered in the general clinical record, but they would have neither in-

terest nor entitlement to explore the details of psychotherapy sessions.

For such reasons many psychotherapists have traditionally kept separate records of the contents of psychotherapy sessions. These are sometimes called “process notes” because they detail the sequential unfolding of a psychotherapy session, often with the therapist’s observations of not only the patient’s communications and emotional states but also the therapist’s reactions, associations and thinking about transference, countertransference, and the strategy of response. Such elaborate notes would have no justifiable usefulness outside of the work of therapy. They are commonly employed in training settings or consultations to allow the supervisor or consultant to understand the subtleties and nuances of a treatment, especially the transference and countertransference or other elements that the therapist might not have recognized. Therapists may use such notes themselves to reflect on the process of treatment or to develop research findings. Segregated notes also serve as a repository for important, highly sensitive factual disclosures by the patient in the course of treatment, that could potentially be injurious to the patient or other people if revealed. Less detailed notes may also serve as a reminder to the therapist of what transpired at recent sessions, to heighten continuity of contact with the material. However, separate notes have been controversial for reasons to be discussed later.

Psychoanalytic and psychodynamic psychotherapies, with their emphasis on free association, dreams, fantasies, and transference–countertransference, obviously generate the kind of material that belongs in a separate psychotherapy note. Therapists using other approaches may be less likely to write separate notes. However, in cognitive-behavioral therapy, a patient’s daily, self-observing thought records may be key to documenting the patient’s progress in treatment. If a thought record contained highly sensitive, potentially embarrassing material, a therapist would be more likely to retain it and thus keep the integrity of the treatment record if it could safely repose in a segregated record. In behavior therapy, the patient may need to work on controlling highly objectionable or embarrassing behaviors; will these behaviors be documented? Meaningful grief work or role realignments in interpersonal psychotherapy may entail working with potentially damaging information about the patient and/or close associates. If trust is established, patients bring highly troublesome aspects of their personal lives into psychotherapy, regardless of the formalities of the chosen treatment modality. If such

information is to be documented at all, there must be a safe place for it.

Under the HIPAA privacy rule, keeping identifiable psychotherapy notes as a separate part of the record of treatment may become fairly standard practice, although it remains optional at the discretion of the therapist. The rule defines psychotherapy notes as “notes recorded (in any medium) by a health care provider who is a mental health professional documenting or analyzing the contents of conversation during a private counseling session or a group, joint, or family counseling session.” The definition excludes “medication prescription and monitoring, counseling session start and stop times, the modalities and frequencies of treatment furnished, results of clinical tests, and any summary of the following items: Diagnosis, functional status, the treatment plan, symptoms, prognosis and progress.” (The material excluded from psychotherapy notes belongs in the general clinical record.) Furthermore, “to meet the definition of psychotherapy notes, the information must be separated from the rest of the individual’s medical record.” However, the information remains identified as belonging to that patient’s record, and it can be disclosed with the patient’s specific written authorization for certain purposes. There are also very limited instances in which the notes may be accessed without authorization.

Controversy exists over the added, significant administrative burden of maintaining separate psychotherapy notes within the record, especially in institutional settings. As medical records are increasingly placed in central electronic databases, psychotherapy notes will have to be kept in paper form or in special, highly secure, segregated electronic files. On the other hand, privacy advocates hail the HIPAA privacy rule as a major advance in documenting psychotherapy while preserving strong protection of confidentiality.

VII. THERAPIST’S PERSONAL WORKING NOTES

Before *Jaffee* and HIPAA, the only way a therapist could record a completely confidential account of psychotherapy information was to maintain totally isolated, separate notes in a form that was devoid of all information that could indicate the identity of the patient. Such personal working notes are the sole property of the therapist, may be in any form, are often in a shorthand that would be unintelligible to anyone else, and may include personal

information about the therapist's own mental life as it pertains to the treatment process. They may be destroyed as soon as their purpose has been served, whether for supervision, consultation, research, or day-to-day continuity in the therapist's work with the patient.

Personal working notes are surrounded by controversy. On the one hand, they are immensely useful and, for many therapists, indispensable in treating, training, and research. On the other, they create a "shadow" record of which the patient is unaware. They are not totally immune to subpoena in litigation or child custody determinations or to oversight of the therapist by licensing boards, although such intrusions may be vigorously contested. Whereas some authorities on confidentiality of psychotherapy recommend that notes on sensitive material be kept apart from the official record, malpractice defense attorneys advise strongly against keeping any separate records. If the therapist does keep personal working notes, it is advisable to destroy them as soon as they have accomplished their purpose. However, they should never be destroyed after a subpoena has been served.

Will the HIPAA privacy rule end the practice of keeping personal working notes? Will they no longer be necessary? The rule applies only to identifiable records of patient care, so that personal working notes are outside its purview. Much that was previously recorded in personal working notes might now reasonably be documented in psychotherapy notes. In discussing psychotherapy notes, commentary on the HIPAA rule states that they could be comparable to what has often been called process notes. However, the strength of the privacy rule's protection remains to be tested in actual practice. Given that under certain conditions the HIPAA-delineated psychotherapy notes may be accessed with or without patient authorization, it is likely that therapists will keep at least some material out of the identifiable record altogether. For example, this may particularly apply to raw sexual or aggressive material, notes on the therapist's own emotional reactions, or potentially damaging factual disclosures about the patient or others.

VIII. CASE EXAMPLES

Following are brief examples of the kind of material in regard to psychotherapy that might be documented in the different kinds of records described earlier.

A. Medical/Clinical Record

Cognitive-behavioral therapy, initial phase, session 3 of 20, focused on recurrent self-deprecatory thoughts. Patient to keep thought record.

Or: Psychoanalysis, 50-min session.

Or: Psychotherapy re: marital problems, self-control, and assertiveness.

B. Psychotherapy Notes

Patient described a TV show with an infant tightly wrapped in blankets in a crib that prompted memories of a very restrictive early home environment and family stories about how she actually was swaddled as an infant. Father's passivity and disinterest contrasted with mother's very active direction that conveyed an expectation that women could not advance to positions of leadership. This was followed by self-deprecatory and fearful thoughts about her presumptuousness in thinking she could actually go to law school, and a fantasy that I would laugh at her. I said that she might still be influenced by the restrictiveness she grew up with, and she expected me to react as her mother might have.

Or: After much hesitation the patient revealed that he had started an affair with his secretary and was now very worried that he would be charged with sexual harassment.

Or: In cognitive-behavioral therapy, a file of the patient's detailed thought records as well as the therapist's strategies and observations.

C. Personal Working Notes

(No identification of the patient.) She is again railing against J. for his inattentiveness. I felt vaguely attacked. (Details of an elaborate dream involving plane crashes because pilots are inattentive to their duties.) Associations to the dream led to vacation spots, empty feelings she had when her mother was away, incidents when she had been nasty and bad things had happened. I raised the question whether she might be wanting to rail against me for going away next week and being inattentive to my duty to her, and maybe she was afraid harm would come to me because of her anger. She snorted and called me a lousy bastard, what right did I have to think I mattered that much to her! ... Etc.

(This note, written for supervision, might be much longer and more detailed with undisguised specific

information about the patient's thoughts and behavior as well as the therapist's thinking, emotions, and interventions. It would also probably be in a more telegraphic style than depicted here, because it would not be read by anyone else and would be destroyed after its purpose had been served.)

IX. SUMMARY

With the advent of *Jaffee v. Redmond* and the HIPAA regulations, documentation of psychotherapy has achieved an unprecedented level of protection, although many practical questions remain unanswered about how these protections will be implemented. Most therapists prudently maintain a general clinical/medical record of treatment that is factual, legible, and complete insofar as the objective clinical status of the patient is concerned. Psychotherapy itself may be documented in abstract terms in the general clinical record without details that are personal to the patient. As an option, therapists may record more specific information about the process and content of psychotherapy in psychotherapy notes kept in a separate part of the patient's identifiable clinical record. These notes have a

considerably higher level of protection from disclosure because specific patient authorization is required for disclosure. The therapist may also elect to keep highly sensitive or personal information in personal working notes entirely outside the clinical record.

- dose** Number of psychotherapy sessions.
- dose-outcome** An extension of the dose-effect methodology that tracks psychotherapeutic progress across sessions for an individual patient.
- effect** Percentage of patients improved or probability of improvement for one patient.
- HLM** Hierarchical linear modeling. A statistical procedure that uses predictor variables to estimate the likely outcome of a criterion variable; actual outcome of the criterion may be checked against the predictions for accuracy of the model.
- log-normal transformation** A statistical procedure performed on non-normally distributed data to fit them into a normal distribution.
- meta-analysis** A methodology that statistically combines and compares the results of several studies.
- patient profiling** A statistical procedure that uses hierarchical linear modeling to predict a patient's expected course of improvement based on the patient's intake clinical characteristics.
- probit analysis** Linear regression analysis where the dependent variable is dichotomous and ordinal (e.g., improved versus unimproved). The statistical analysis used in dose-effect designs.

Mental health researchers are quantifying the effectiveness of psychotherapy to better understand its benefits and, very importantly, to justify reimbursement as a health care treatment. These scientists want to answer the following questions: How does psychotherapy work? How quickly does it work? How much works for each of the various psychological problems? The answers are especially important because third party payers (such as managed health care) want to know about the general value of psychotherapy as well as its value in comparison to psychotropic medication. This article describes the dosage model that is a guiding model being used to understand and investigate the effectiveness of psychotherapy. Methodological variations of the dosage model (i.e., dose-effect, dose-outcome, and patient profiling) are reviewed as well as findings relevant to understanding the effectiveness of psychotherapy.

I. PSYCHOTHERAPY IS BENEFICIAL

Mental health research has demonstrated that psychotherapy is a valid treatment for alleviating psychological suffering. For example, in a landmark 1977 study, Mary Smith and Gene Glass employed a meta-analysis that statistically combined and compared the effect sizes of treatment, placebo, and control groups. Based on data from 475 studies, the authors found that psychotherapy is more effective than no treatment as well as placebo therapy. Their study demonstrated that

patients receiving psychotherapy were better off than approximately 80% of those who were not in treatment. Since Smith and Glass' work, hundreds of studies have also shown that psychotherapy is beneficial beyond no treatment and placebo conditions.

Interestingly, Smith and Glass reported no significant outcome differences among the different types of psychotherapy (such as psychodynamic, behavioral, and cognitive). Although the different therapies were effective, none were more effective than the others in treating the variety of problems. Other researchers have reported the same results. This phenomenon is known as the "dodo bird verdict" after the dodo bird in *Alice in Wonderland* who proclaimed, after a race, "Everybody has won and all must have prizes."

II. THE DOSAGE MODEL: DETERMINING HOW MUCH PSYCHOTHERAPY IS ENOUGH

Today the effectiveness of psychotherapy is understood in the context of the dosage model. The dosage model proposes that the psychotherapy session is a natural quantitative unit or dose of treatment similar to a dose of medication in milliliters or milligrams. This analogy is derived from the generic model of psychotherapy. The generic model asserts that psychotherapy is comprised of nonspecific and specific factors that contain active treatment ingredients. Nonspecific factors, which are common to all psychotherapies, include interpersonal variables such as positive regard, genuineness, and empathy. There are also active ingredients unique to each specific therapy. Examples of these specific factors include empathic reflections (used by client-centered therapists), interpretations (psychodynamic therapists), and positive reinforcements (behavior therapists). The active ingredients to which patients are exposed during the course of a session produce psychological and behavioral change. Similar to taking medication, participating in psychotherapy over time exposes the patient to more active ingredients. Therefore, more psychotherapy consequently results in greater improvement. This outcomes process of the more, the better has been validated in several studies.

Two issues emanated from the aforementioned effectiveness research: What was the nature of the positive relationship between dose of psychotherapy (such as number of sessions) and benefit? How many sessions are necessary to achieve sufficient benefit?

III. DIFFERENT METHODOLOGIES OF THE DOSAGE MODEL

The Dose-Effect Relationship

In their 1986 landmark article, K. Howard, M. Kopta, M. Krause, and D. Orlinsky answered the first question and began the movement towards answering the second. The authors introduced the dosage model, using dose-effect methodology, where effect is the percentage of patients improved or probability of improvement for one patient. Employing a log-normal transformation of the data, they found that patients in psychotherapy improve in a statistically predictable manner. This recovery process follows a negatively accelerated curve; that is, the more psychotherapy, the greater the probability of improvement with diminishing returns at higher doses (see Figure 1).

Howard and his colleagues further examined the dose-effect relationship using a meta-analysis design for 15 samples of data ($N = 2,431$ patients) which spanned over 30 years of research. Traditional measures of improvement (such as patient self-report and clinician ratings) were collected at various times dur-

FIGURE 1 Relation of number of sessions (dose) of psychotherapy and percentage of patients improved (effect). (Objective ratings at termination are shown by the solid line, $N = 151$ patients; subjective ratings during therapy are shown by the broken line, $N = 148$.) TABLE I
Results of Probit Analyses of Three Diagnostic Groups for Two Outcome Criteria:
Percentage of Patients Improved Across Sessions

Diagnostic groups	N	Number of sessions								
		0	1	2	4	8	13	26	52	104
Criterion: Research ratings of closed clinical charts										
Depression	69	6	13	20	31	46	57	73	86	94
Anxiety	21	0	0	0	5	25	53	87	99	99
Borderline-psychotic	23	0	0	0	0	3	11	38	74	95
Criterion: Patient ratings after each session										
Depression	974	22	31	37	44	53	60	69	77	84
Anxiety	425	15	22	28	36	46	54	64	74	82
Borderline-psychotic	402	3	8	13	21	33	42	60	75	87

N = Number of Patients. From Howard, K. I., Kopta, S. M., Krause, M. S., and Orlinsky, D. E. (1986). The dose-effect relationship in psychotherapy. *American Psychologist* 41, 163. Copyright 1986 by the American Psychological Association. Reprinted with permission.

ing therapy for each sample. The type of psychotherapy implemented was typically psychodynamic or interpersonal; patients presented with a variety of diagnoses. Data from each of the samples were analyzed with probit analysis. The results were then aggregated across samples to establish dose-effect estimates for specific amounts of psychotherapy—approximately 15% of patients improved simply by scheduling an appointment, 50% of patients improved by session 8, 75% by session 26, and 85% after a year of once-weekly psychotherapy. These figures continue to be used by administrators, clinicians, and researchers as treatment guidelines. For example, Howard and his colleagues suggested 26 sessions as a rational time limit for treatment or as a review point for cases that have not shown measurable improvement. Eight sessions are now considered the standard for establishing a treatment group for experimental clinical trials; that is, eight sessions are the dose at which a patient has been effectively exposed to psychotherapy.

Another finding was that different diagnostic groups demonstrated different dose-effect patterns. Dose-effect relations in Table I show that depressed patients responded quickest to psychotherapy, followed by anxious patients, and with borderline-psychotic patients responding at the slowest rate.

Subsequent authors have applied the dose-effect methodology to specific psychological symptoms, clinical syndromes, and interpersonal problems. For instance, Kopta and his colleagues in 1994 demonstrated that different symptoms respond differently to psy-

chotherapy. Patient recovery (such as return to normal functioning) was assessed across sessions by self-report questionnaire for 90 psychological symptoms. Based on dose-effect relations for 854 patients, the symptoms were grouped into three distinct symptom classes—acute, chronic, and characterological. Each symptom class was found to respond to psychotherapy at varying rates (see Figure 2). For example, acute symptoms (such as temper outbursts, feeling fearful, and crying easily) were found to remit most quickly in therapy. Approximately 50% of patients recovered on these symptoms by the session 5. Chronic symptoms (such as feelings of worthlessness, worrying too much, and being low in energy) demonstrated a pattern where approximately 50% of patients had experienced recovery by session 14. Characterological symptoms were found to respond most slowly to psychotherapy; for the majority of these symptoms, more than 40 sessions were necessary for patients to achieve a 50% probability of improvement. These symptoms were related to hostility and interpersonal difficulties (such as feeling that others are to blame for your problems, frequent arguments, and being easily annoyed).

Dose-Outcome Design

In a 1995 chapter, Howard and colleagues introduced the dose-outcome method. A logical extension of the dose-effect methodology, it's of particular benefit to the practicing clinician and case manager. Whereas the dose-effect method addresses how much

FIGURE 2 Dose-effect relations, averaged across symptoms, for acute, chronic, and characterological symptom classes. From “Patterns of Symptomatic Recovery in Psychotherapy,” by S. M. Kopta, K. I. Howard, J. L. Lowry, and L. E. Beutler, 1994, *Journal of Consulting and Clinical Psychology*, 62, p. 1014. Copyright 1994 by the American Psychological Association. Reprinted with permission.

psychotherapy is needed to benefit the “average” patient, the dose–outcome design answers the question “How is psychotherapy benefiting this specific patient?” Here, instead of percentage of patients improved plotted against dose, it’s measure of benefit for an individual patient (see Figure 3). With the dose–outcome design, the clinician monitors the patient’s progress across time using valid, reliable measures similar to monitoring blood chemistry in medicine. The clinician can use this information to make treatment adjustments over the course of therapy for individual patients.

Patient Profiling

Patient profiling extends the dose–effect and dose–outcome methodologies from tracking patients’ improvement to predicting improvement. In their 1996 article, Howard and associates introduced the strategy of using hierarchical linear modeling (HLM) to plot a patient’s expected course of improvement based on

seven intake clinical characteristics (such as level of symptomatology, duration of problem, and expectation of improvement). By giving differential weights to these characteristics, HLM produces an estimated improvement curve for each patient (see Figure 4). Actual patient progress, as measured by the self-report Mental Health Index (MHI), across sessions can be compared to predicted progress.

The dotted line in Figure 4 shows a patient’s expected Mental Health Index (MHI) score, based on the HLM procedure, while the solid line shows actual improvement. In this figure, the patient’s improvement was significantly different from the model’s predictions until session 20. The discrepancies between predicted and actual improvement were likely due to issues specific to this patient and their treatment. By tracking this patient across sessions, the therapist was able to make therapeutic adjustments to best serve the client. Impressively, the patient did achieve the expected gains by the 20th session, thus lending support to the patient profiling methodology.

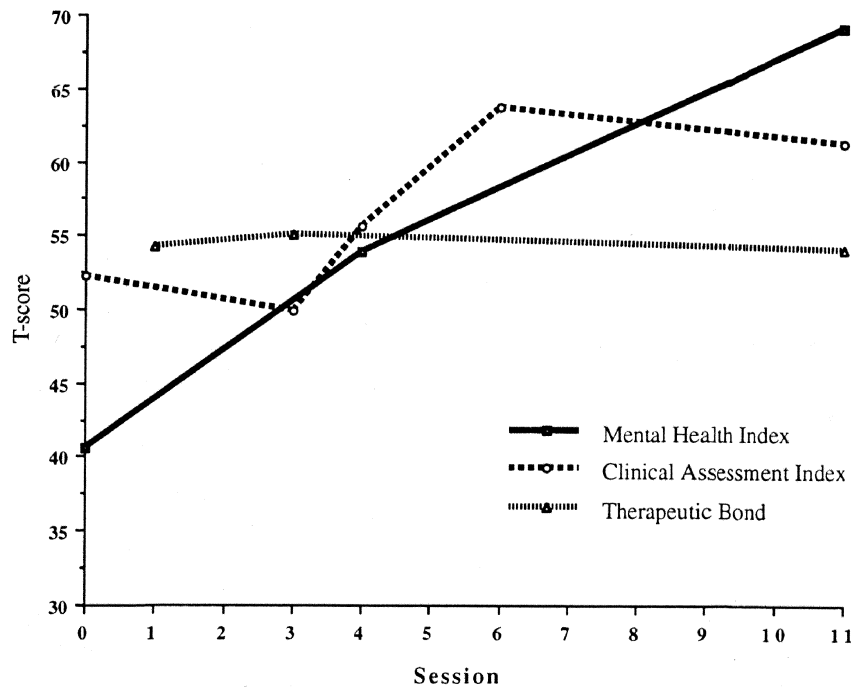

FIGURE 3 A dose-outcome design that illustrates the successful treatment of a short-term case. From "The Design of Clinically Relevant Outcome Research: Some Considerations and an Example," by K. I. Howard, D. E. Orlinsky, and R. J. Lueger. In M. Aveline & D. A. Shapiro (Eds.), *Research Foundations for Psychotherapy Practice*, 1995, p. 34. New York: John Wiley & Sons. Copyright 1995 by John Wiley and Sons. Reproduced with permission.

FIGURE 4 Course of the Mental Health Index (MHI): Patient responding to psychotherapy as expected after a change in treatment intervention at session 11. From "Predicting Patients' Responses to Psychotherapy: Are Some More Predictable Than Others?," by S. C. Leon., S. M. Kopta, K. I. Howard, & W. Lutz, 1999, *Journal of Consulting and Clinical Psychology*, 67, p. 699. Copyright 1999 by the American Psychological Association. Reproduced with permission.

Following the treatment of over 800 patients, Leon and colleagues reported in 1999 that patient profiling was overall 75% accurate in predicting patients' courses of therapeutic improvement, with a range of 94% for some patient types to 25% for others. Patient profiling provides information as to which patients may benefit from particular types of psychotherapy, whether therapy is progressing as expected for a given patient, and the likelihood that a patient has achieved maximum gains from therapy.

IV. SUMMARY

The dosage model has had a substantial influence on psychotherapy research. Howard and colleagues' seminal article in 1986 began a new era of naturalistic outcomes research, that is, researching psychotherapy as it's practiced in real clinical settings. We can now answer many questions that have long been proposed by professionals in the mental health field. For example, managed health care and other third party payers have information available on how much psychotherapy is enough. There are methods that allow clinicians and case managers to track patient progress across time, as well as predict how a given patient should respond to therapy based on initial clinical characteristics. Using dosage model methods, there is now the capability to answer a modified version of the compelling question asked by Gordon Paul in 1967, "How much psychotherapy is most effective for which patient with what type of problem?"

GLOSSARY

amplification For Carl Jung, amplification is analogous to Sigmund Freud's use of free association. The patient attends to a part of the dream that is disguised and yet stands out to arrive at a deeper understanding of the dream.

archetype A personified or symbolic form of an inherited idea derived from the total experience of the human race that is present in the unconscious of all individuals.

condensation The fusion of two or more ideas or mental images that produce the composite figure found in the dream.

configuration approach An approach that combines a number of variables, including signs, overall pattern of signs, and the combination of both to describe and differentiate an individual's personality.

countertransference All unconscious feelings of a therapist toward a patient or the total feelings of the therapist toward a patient.

day residue The material from the 24 hrs preceding the dream that influences the formation of dream images.

disguise function Freud's belief that to prevent the gratification of unconscious wishes the dream content has to be changed by the dreamwork.

displacement The second essential mode of dreamwork operation. The result of the rapid transfer from one idea or image to another characteristic of primary process.

dream censorship The distortion or disguise of the dream to prevent the gratification of unconscious wishes.

dream diction The dream's use of language, especially figures of speech.

dream of Irma's injection, Irma dream, dream specimen The title Freud gave to his specimen or model dream in Chapter II in his *Interpretation of Dreams* that he used to demonstrate his dream theory.

dream instigators The external or internal stimuli that are the sources of dreams.

dream sources The elements or causes of dreams.

dream symbolism The symbols used in dreams to distort the latent content.

dream wish Freud's theory that the gratification of the unconscious wish was the function of the dream.

dreamwork The work of the dream mechanisms that disguise or distort the content of the dream in line with the dream censorship and transform the latent content into the manifest content.

exceptional or unique position The dream holds a special place in psychotherapy. It is considered the best means to the royal road to the unconscious.

first or initial dream The first dream after knowing one is entering into therapy or is in therapy.

latent content The unconscious wishes and other material that is disguised and distorted by the dreamwork to conceal its unacceptable aspects.

manifest content The dream content that is recollected.

means of representation The use of pictorial metaphors to express certain ideas.

primary process A repository of aggressive and sexual drives from all stages of development.

relationality Stress on the relationship between the patient and therapist rather than on the patient alone. Countertransference as well as transference must be analyzed.

REM Rapid eye movements, which indicate the person is dreaming.

secondary elaboration An alternative term for secondary revision.

secondary process Freud's term for the laws that regulate events in the preconscious or ego.

secondary revision A process that attempts to supply the dream with consistency and coherence. It fills in the gaps, creates order, and molds the dream into an intelligible whole.

shadow The inferior or dark side of the personality. The sum of personal and collective events, which are denied expression in life due to their incompatibility with the conscious attitude.

symbolization The universal primal language representing association between ideas having something in common, although the relationship is not easily discernible.

structural theory Freud's metapsychological theory that there are three divisions of mental functioning: the id, the ego, and the superego.

topographical theory Freud's metapsychological theory that the psyche or mind was divided into three systems: unconscious, preconscious, and conscious.

transference The displacement and projection of feelings toward early objects onto the therapist.

unconscious A reservoir for unacceptable psychic material.

UTD Undisguised transference dream in which the patient sees the therapist as the therapist appears in therapy.

Dreams have had an important place in psychotherapy since Sigmund Freud's proposal that dreams are the royal road to the unconscious in 1900. A change in the number of sessions from five to one per week and a move toward brief therapy modalities has coincided with a change in emphasis from the latent content to the manifest content of the dream. Some kind of schematic method like the configurational approach to the manifest content helps to make the use of dreams more feasible in today's world of psychotherapy. Dreams still offer a rich source for helping patients to achieve greater self-

understanding, self-control, self-expression, and a more positive self-image.

I. INTRODUCTION

From antiquity the universal phenomena of dreaming has captivated human imagination, confused human logic, and controlled human endeavors. Dreams have been regarded as exceedingly important to a person's destiny, as messages from the gods, predictive of the future, expiatory of guilt, and the voice of conscience. Shamans, seers, and saints have used dreams to discern the source of sickness, or to set the course of nations. Poets, philosophers, and playwrights have sought to plumb the depths of dreams to lure audiences or readers into the world of fantasy, to play the strings of the emotions, and to recall the unthinkable. Cognitive, information processing, and neuroscientists find in dreams brain activity that can help understand REM, memory consolidation, and the "unconscious" state. But what about psychotherapy—how do psychiatrists, psychoanalysts, and psychologists of various persuasions use dreams to inform their work with patients?

II. THE LANGUAGE

Understanding the use of dreams in psychotherapy begins with seeing how the laws of poetic diction and the laws of dream diction, or dream formation, spring from the same unconscious source and have many mechanisms in common. Whereas the poet's task is to communicate experience that is accomplished by sound, the power to evoke imagery, and the use of figures of speech such as the simile, metaphor, metonymy, and onomatopoeia, the dreamer also uses figures of speech and will often employ words in which the sound of the chosen word will reflect the sense of the word. The psyche in its memory bank has many early personal experiences to choose from in which sound was fused with meaning. Words often have more than one meaning, have a history of displacement, are often connected to our first exposure to them (often their primary meaning), and may have a secondary or even a tertiary meaning. In our storehouse of words, the specific significance of our earliest use of a word is never lost. Words that sound alike, but are spelled differently, may be substituted for each other in establishing their meaning. This may also be true of words that rhyme with each other. Verbs that are very rarely distorted and

should be taken literally tell us about the dreamer's activities and date back to early life, whereas nouns are often ambiguous, idiosyncratic, or metaphorical with multiple meanings. The names of places can have special meaning when we break down the word into its parts (syllables). When deciding on the meaning of a specific word that has several meanings, the emotional impact of each word's meaning and how early it was first introduced to the dreamer will help determine its primary meaning in the dream.

III. THE VALUE

The major Greek philosophers, Plato and Aristotle, were among the early harbingers of a psychological approach to dreams. Plato was the first to see dreams as an expression of repressed unconscious wishes. For Aristotle, dreams were seen as essential in terms of their discharge function. However it was not until the beginning of the 20th century that the contributions of both Aristotle and Plato were combined by Sigmund Freud who came to the conclusion that unconscious wishes seek an outlet for discharge, which is unacceptable to the dream censor, and that if they emerge undisguised, sleep would be interrupted. Freud saw the dream as the guardian of sleep and felt that the deprivation of psychic discharge through dreaming led to derangement.

Later theorists said dreams were a reference to what is happening in the life of the dreamer, and what emotional problems and conflicts one is struggling with, or acting out. They claimed dreams provide insight into the repressed traumas of the past, offering clues to psychological and physical breakdown and how much stress the dreamer could take. Dreams tell us what is hidden, how it is hidden, and why it is hidden. They also tell us about present-day bodily experiences, and the forgotten experiences of childhood. They can express or sway opinion, under- or overvalue material, represent resistance, and may placate, control, manipulate, or assuage the therapist and therapy. They can also tell us how correct, valid, or wide of the mark our interpretations of the patient's associations may be, confirm or elaborate themes discussed in therapy, and tell us where we are in psychotherapy.

IV. FREUD

Within the field of psychotherapy the first major work that sought to address the use of dreams was

Freud's *Interpretation of Dreams* published in 1900. The book contains the Irma dream (Chapter II), the specimen dream chosen to be analyzed by the new technique, and Chapter VII, the final chapter, which explains Freud's unconscious wish fulfillment theory. Freud lays out the sources or instigators of dreams, and that dream content may be in the present or past and concerns experiences, affects, hopes, fantasies, conflicts, and the like. When something in the day (residue) makes contact with some past wish, the connection may result in a dream.

Employing a topographical model of the mind and using clinically promising connections between dreams and psychological symptoms that he discovered mainly in his self-analysis, Freud proposed that dreams were expressions of unconsciously repressed psychic material that appeared in the psyche as wish fulfillment. The unconsciously repressed material, or the latent content, represents the primary processing activity of the mind, which consists of all parts of dreams discovered through interpretation including dynamically unconscious wishes, preconscious material, and sensory and somatic stimuli. To interpret the latent content and bring it to conscious awareness, the patient starts with the manifest content, which comes from the conscious secondary processing activity. The manifest content consists of all aspects of what the dreamer consciously remembers after waking up and is retained in any given form, whether as pictures, incongruous situations, contradictory emotions, or other forms. Then through freely associating whatever comes to mind in relation to these forms, the words of the associations bring the forms of the unconsciously repressed material into conscious awareness providing insight into the etiology of the patient's symptoms and pathology. Insight in turn helps the patient to "make sense" of symptoms and provides a mutative affect in relieving the symptoms and diminishing the pathology.

The movement from the latent dream thoughts to the manifest dream content Freud calls the dreamwork. The dreamwork utilizes a number of dream mechanisms: condensation, displacement, symbolization, visual means of representation, and secondary revision in the service of disguising or distorting the dream content for purposes of carrying out the work of the dream censor. The latent dream thoughts are disguised so the unconscious wish is blocked from conscious awareness. Condensation fuses and telescopes several images and ideas into one. With displacement the dreamer transposes, for example, a person into an object and may displace an affect that the dreamer feels toward the person onto the object. The

dreamwork may use reversal, a variant of displacement, to reverse the action, the affects, or the person thus further disguising the dream. Symbolization supplements the distorting work of condensation and displacement by making it more difficult for the dreamer to uncover the latent thoughts. Symbolization allows the dreamer to regress to the activity of the infantile unconscious mind which consistently pulls together objects that appear to have common aspects. Symbols are chosen from a large available number of objects and used with regularity. Although some dream interpreters translate the dream from symbols immediately, it should be pointed out that considerable knowledge of the dreamer should precede translation of symbols, and the accuracy of interpretation depends on the dreamer's free associations. The visual means of representation can result in distortions of latent thoughts by the use of pictorial metaphors. Relationships induced by prepositions, conjunctions, or punctuation require visual means of representation, and these words can be easily distorted. Secondary revision uses secondary process thinking and the ego in its attempts to produce coherence, order, and intelligence into the dream. In its use of secondary process thinking, and its attempt to make sense, secondary revision has many opportunities to disguise latent dream thoughts.

V. THE FUNCTIONS

The possible functions of dreams are many and varied. Freud put forward the idea that one of the most important functions of the dream is the preservation of sleep. He considered the dream to be the "guardian of sleep." Besides being viewed as guardian, other therapists propose that dreams may function to communicate important aspects of the transference to the therapist; to release secret wishes from repression in an attempt to understand, master, and gain pleasure from them; to represent the attempted fulfillment of our innermost desires; and to serve a discharge role as a release valve for repressed instinctual drives.

Some thinkers have proposed that dreams may have curative or restorative functions. They may help us (a) work through tensions and problems from the previous day, (b) restore balance lost when we feel threatened, (c) more realistically handle emotional problems, (d) recover a sense of competence, (e) insure mental health, and (f) relieve painful stimuli from traumatic experiences.

For some brain researchers, dreams form no useful human function because dreams are considered to be the

result of randomly firing neurons, or at the most only help "clean house" serving as safety valves assisting the brain as it rids itself of unnecessary information (i.e., reverse learning). Some of these writers fear attempting to remember dreams may reverse this function causing harm. Other brain researchers find the function of dreams in the consolidation of that day's memories.

Rosalind D. Cartwright in 1993 pointed to an information-processing function for dreams. She states that the more unrecognized but encoded feelings and emotions from the day are examined by the sleeping mind to see how they fit one's most interior, intimate conceptions of one's self. For her, dreams also work on how to constructively solve interpersonal and other problems raised during the day.

VI. THE UPS AND DOWNS OF THE PLACE

Up until the publication of Erik Erikson's "dream specimen" paper in 1954 that commented on Freud's Irma dream, little attention had been paid by analysts to the usefulness of the manifest content of the dream or to the important place of the Irma dream as the point of the discovery of unconscious conflict. Freud had felt the manifest content was a "mere façade," "a piece of unscientific virtuosity of very doubtful value," and he could not understand how anyone could interpret on the basis of it alone. The followers of Freud equated manifest with the external layer and the most superficial layer, not deserving of serious consideration, while the latent was equated with the deepest layer, the *sine qua non*, or the unconscious and primary process.

The passage of time has seen within psychotherapy a move to fewer therapy visitations (once a week for most therapists), a move to briefer treatment modalities due to the pressure from HMOs, PPOs, and insurance companies, and a move to a more classificatory approach (i.e., *DSM-IV*) with the results that the manifest content has taken precedence in the handling of dreams in psychotherapy, especially in the 1980s and 1990s. Most authors of dream articles now agree on the importance of the manifest content, its helpfulness, and its ability to provide valuable information about the dreamer.

As the worth of the manifest content was once questioned, now the worth of the latent content is being questioned. Some authors have even gone so far as stating the manifest content is the dream, and desire to dis-

card the disguise function of the dream (nothing is hidden or latent), and to deny that a dream is an unconscious wish. The distinction between manifest and latent content of the dream is slowly disappearing. Often associations to the manifest dream are no longer required; it being interpreted in direct symbolic terms or at its face value.

VII. A LOVE–HATE RELATIONSHIP

U.S. therapists have had a love–hate relationship with the dream. *The Interpretation of Dreams* contained Freud's self-analysis, and following the publication of the book, dream interpretation became synonymous with psychoanalysis. The controversy whether the dream holds an exceptional and unique position in psychotherapy or whether it is just one of many types of material with which therapists deal in psychotherapy still goes on. One sees many types of material in doing therapy, all of which are important, but it is also true that dreams at times can give much insight into a patient's unconscious problems. Symptoms, defenses, affect, behavior, and other dimensions of therapy are all important, but the dream is still perceived by many as the best means to the unconscious. The decline in the position of the dream in psychoanalysis has been thought to be due to the increased popularity of the relationist/interpersonal school that places much less emphasis on dreams, to the development of the structural theory, to new views on narcissism, and to new theoretical approaches that place less importance on the id, primary process, and the unconscious, and more on the secondary process, the ego, the self, and adaptation.

VIII. THE CONFIGURATIONAL APPROACH TO THE MANIFEST CONTENT

In once-a-week therapy, the patient after describing his dream has little time for exhaustive dream analysis and free association to every part of his dreams. Robert C. Lane, Marvin Daniels, and Stephen Barber, who were influenced by a number of dream researchers, particularly Erik Erikson in his analysis of the manifest content of Freud's Irma dream in his "dream specimen" paper, recommended in 1995 taking a number of the patient's consecutive dreams and subjecting them to analysis using 20 categories. This then formed the con-

figurational approach to the manifest dream content. They defined the 20 categories and then analyzed 11 dreams of a patient in analysis. Lane and Daniels independently analyzed the dreams by each category with high reliability then combined their contributions and compared them to the treating analyst's independent clinical observations about the 20 categories. The 20 categories of the configurational approach are style and quality, length, locale, nature of problems and intrapsychic conflict, activities, distortion, characters, relationship between characters, somatic or body references, sensory emphasis, spatial, temporal, affect, transference, resistance, communication to the therapist, fixation points, and diagnostic indicators and prognostic indicators. Although the configurational approach has been criticized for being like a projective technique, there is little doubt that it offers a great deal of material to the therapist using only the manifest content.

IX. ONE-PERSON VERSUS TWO-PERSON APPROACH

In the 1950s, 1960s, and 1970s, the emphasis in dream theory was on the application of the structural theory to dream analysis, the role of the growth of ego psychology in the understanding of dreams, how one affected the other, and the application of the principle of multiple functioning to dreams, what is called a one-person approach to dreams. In more recent years, the relationists (object relations, interpersonal/intersubjective theorists, self-psychology) have stressed a two-person psychology, bringing into dream analysis the role of the therapist, countertransference, the therapist's dreams, and the UTD (occurrence of the undisguised transference dream). The relationists were following the lead of Sandor Ferenczi who was the first among Freud's early disciples to stress the communicative function of the dream. Ferenczi, in 1913, the innovator who became a model to follow, emphasized "mutual therapy" or the analyst sharing his thoughts, feelings, impulses, dreams, fantasies, and traumatic memories with patients. His work served as a launching pad for a number of interpersonal and relational therapists who wrote papers on the dream. In contrast to Ferenczi who highlighted self-disclosure by the therapist, Freud, highlighting non-disclosure, felt that the therapist should remain opaque to the patient, sharing nothing but what is shown to the therapist.

The relationist movement emphasized that the patient's dreams are related to the therapist's needs,

countertransference, counterresistance, and counter-anxiety; can serve as unconscious supervision of the therapist; and help the therapist become aware of unconscious countertransference needs and other material that may be interfering with the patient's progress. Dreams are said to function as both disguisers and communicators. They are a reflection of both intrapsychic process and interpersonal communication. Dreams help therapists to gain knowledge of the patient's transference, but also of the therapist's countertransference feelings, to make the patient's unconscious conscious, but also to make the therapist's unconscious conscious; both therapist and patient serve a teaching function.

One form of countertransference occurs when the patient has an UTD. There are few papers on this subject as few therapists have the wish to have patients write about them as therapists. Therapists eschew references to countertransference as they feel it implies something wrong about the therapy. The relationists criticize the idea that the dream is a "disguise" to be penetrated, that the material contains a "hidden wish fulfillment," and dispense with the idea of "latent" content, that is, the manifest content is the dream language to be understood, "not a nut to be cracked open and discarded." They view countertransference as crucial and find it in many different situations, while claiming the traditional school (classicists) wish to deny and bury it.

The two opposing groups differ when we examine the therapist's dreams about the patient. The traditional Freudian would treat this dream as a neurotic conflict in the therapist, to be worked through internally so as not to interfere with neutrality and anonymity, while the relationist would use the dream to attempt to better understand the patient. The classicist feels all countertransference reflects unresolved problems, while the relationist feels countertransference is ubiquitous to all relationships and can be positively or negatively utilized in the service of treatment.

Many classical analysts have commented on the communication function of the dream and stressed the countertransference and supervisory aspects of the dream, as well as the psychodynamic. They feel the dreamer needs to communicate with the therapist and does it through the dream. There is both the wish to communicate with the therapist and the resistance against doing so. The desire to communicate brings about recall of the dream while resistance renders it unintelligible. Several researchers have examined how resistance results in patients' failure to report, associate to, respond to, or connect to their dreams.

Today's revisionists view the dream as a whole, rather than having the dreamer associate to its various parts, the dream organization, how adaptive and creative the dream is, its self-regulation, and communicative function are all stressed. These various approaches to the dream remind us that whatever one's metapsychological stance, dream interpretation can be enriched through openness to new ideas, whether the stance stresses the intrapsychic or the interpersonal, the transference or countertransference, or concepts such as the unconscious supervisory aspect of dreams.

X. DIAGNOSTIC OR PROGNOSTIC SPECIFICITY

The question has been raised whether dreams can be used diagnostically or prognostically. Whereas one can learn much about a person's personality by submitting a number of the person's consecutive dreams for careful study using a configurational approach (to the manifest content), there seems to be some agreement that dreams can neither diagnose a patient nor predict an accurate prognosis. Disturbed dreams can be produced by normal individuals and healthy dreams by disturbed individuals. Every type of possible dream can occur in any nosological category. Therapists shy away from risking a diagnosis on the strengths and weaknesses of a person based on a dream protocol. Those writers on specific nosological categories have pointed out some general clinical findings (e.g., fear of intimacy and sense of alienation in borderline and schizophrenic patients), but clearly distinguishable specific diagnostic signs do not seem to be recognizable.

XI. THE INITIAL OR FIRST DREAM

The initial or first dream may be very transparent and often points to the patient's problem in a nutshell. The dream may occur very early in therapy when, the patient is relatively naïve in the language of the dream, the therapeutic alliance is not firmly established, and the capacity to free associate is still not developed. The patient at this point in time is not prepared for a deep interpretation. The therapist hardly knows the patient and the wisest way of responding to the first dream is to deal with the obvious, such as the patient's anxiety about and resistance

to the new experience of therapy. On the one hand, to say too much might lead to the loss of the patient, while to say nothing might cause the patient to feel the therapist is frightened of the patient or the patient's products, and lead to loss of the patient also. We should offer something or the patient might feel we're on the side of prohibition or repression and do not wish the emergence of material. We must be concerned not to encourage dreaming as this might lead the patient to feel we overvalue the patient's production, or being gullible, the patient may keep supplying dreams in a dependent manner. We should be careful not to shock the patient causing the patient to stop dreaming or to discontinue treatment.

XII. COLOR

The percentage of dreams in which color appears varies from 14% to 83% depending on how the inquiry is handled. Color has been found to represent a complex multiple function in dreams, and the implication of color in dreams shows a tendency toward multiple meanings. It may be used by the ego for both camouflage and communication purposes. It can both conceal and reveal and has been claimed to have a defensive screening purpose, to be related to the expressed affect, and have aesthetic considerations. Still others see color as representing a manifestation of the superego, a variety of id strivings including scopophilic and exhibitionistic impulses, exposure to primal scene material, and repressed anal contents, as well as ego identifications. Colors have been said to have symbolic meanings, for example: black—death, evil, or financial stability; white—purity, chastity, virginity; green—envy, money; red—blood, financial instability; yellow—urine, cowardice; and blue—sadness.

XIII. TYPICAL DREAMS

Freud devoted part of Chapter V in his dream book to typical dreams. The most frequent dream is the pursuit or attack dream. Second most frequent are dreams in which a love object is in danger; third, dreams of embarrassment and nakedness; and fourth, dreams of falling and flying.

Freud felt that the third most frequent typical dream, embarrassment and nakedness dreams, represented the wish to be little again when one ran about without

shame, a regression and return to the happy carefree time of childhood, as well as representing infantile desires of exhibitionism. In the embarrassment dream itself though, Freud felt observers do not notice the lack of clothing or involvement of the dreamer. Other writers have denied this conjecture.

Some authors feel the embarrassment dream represents guilt, inferiority feelings, the wish to be one's natural self, and the fear of disapproval from others. Still others feel that "nakedness" and "body exposure" were only one of a number of ways embarrassment can be represented in dreams. When nakedness and embarrassment appear, both must be understood.

Today we still feel embarrassment can stem from the patient's internal impulses such as infantile exhibitionism, or from external situations such as the patient's voyeuristic inclinations. These dreams are common in psychotherapy and most often concern the therapist's felt invasion of privacy (therapist's voyeuristic component), or the patient's embarrassment about revealing certain material in therapy (patient's exhibitionistic component).

XIV. OTHER THEORIES

As with the work of any pioneer, those who followed Freud were in many ways footnotes of agreement or disagreement, of continuity or discontinuity, of accommodating Freud with new understandings of dreams or of offering alternative understandings of how to use dreams in psychotherapy. Those who followed developed numerous theories on dream interpretation, however only the most publicized dream theories believed to offer a systematic and outlined approach to dream analysis are considered. These include the existential-phenomenological, Gestalt (not discussed), and Jungian in addition to Freud. All four theories note key concepts, the principal dream themes, and state major conflicts. Where they differ is in how the dream is handled.

The existential-phenomenological view on the dream is found in Clark Moustakas' book written in 1994. Moustakas deemphasizes pathology and not viewing the dreamer as an "object"—a case, a patient, or a client—but rather as a human being whose suffering is a unique experience and who is trying to come to terms with the problems in his relationships and life. Thus in line with his philosophy, Moustakas emphasizes the positive aspects of dreams hoping to help the individual to overcome the existential angst and therefore plays down the negative aspects. He pushes to the forefront the positive side of polarities such as success

versus failure, enchantment versus disillusionment, zest for life versus neglect of self and others, and commitment versus abandonment. He wants each person to achieve a happier and healthier lifestyle through self-expression, accomplishment, realization, fulfillment, and growth. Moustakas self-discloses, and personalizes, in the belief that it humanizes the therapy process. He rejects the classical analytic understanding of dream analysis and believes the dream is not a symbolic disguise, nothing is hidden or latent, and dreams are not wishful distortions of impulses. He sticks specifically to the manifest content eschewing the wish, disguise, distortion, symbolization, latent, and unconscious functions of dreams.

Carl Jung in 1974 in his book on dreams focused on the purpose of dreams and viewed dreams as attempts to achieve further growth, self-understanding, and individuation. The goal was for the integration of the hidden and unrevealed aspects of the personality (the shadow), with the waking personality. He rejected Freud's unconscious wish fulfillment theory, felt Freud's theory to be too narrow, and that Freud asked the question, "Why," rather than, "What for." He believed too much concentration on the past neglects the present, whereas too much concentration on the present tends to neglect the past. The dream to him was not a façade behind which lies hidden unconscious wishes. He saw dreams as part of nature, with no hidden deceptions.

Like Moustakas, Jung saw the manifest content as holding the whole meaning of the dream. The dream needed the dreamer to associate to the dream images, and he referred to this process as "amplification." He thought association would lead to an underlying "archetype" rather than an unconscious wish, and this would eventually provide the principle source for the explanation and resolution of the dream. He, like Freud, believed that the dream images were tied to the day residue, except he did not limit the residue to the preceding 24 hours.

He felt the material in the dream held successive layers and, if analyzed, would lead back to our cultural history and reveal the collective unconscious as well as the personal unconscious. For Jung, the unconscious was not a storehouse of evil, but rather a natural unity that maintains a neutral and not negative position, and is not dangerous, although the more it is thought to be, the more it will be. Symbols were given no uniform meaning to Jung, who felt all dream images to be important, each having its own special significance. Dreams to him did not conceal secret material; they taught both dreamer and therapist.

He also felt dreams seek to regulate and balance, the night and dream personality and the waking personality, the conscious and unconscious, the two parts of the shadow, and therefore saw a compensatory function in the dream. To Jung, the dream was an attempt to balance the two sides of the self, to establish equilibrium, and homeostasis.

He looked to future growth and achievement toward individuation, and therefore he saw a "prospective" function in dreams. He offered a large range of dream ingredients including the whole history of the race, myths, and legends from the past, fairy tales, and the origins of archetypes in our racial unconscious.

XV. THE BIOLOGICAL CHALLENGE TO DREAM THEORY

The biggest challenge to the dream theory that dreams have psychological meaning and are the fulfillment of unconscious wishes came from the brain researchers and neuroanatomists written in 1977 by J. Allan Hobson and Robert W. McCarley. Since the discovery of REM nearly 50 years ago, many brain researchers feel that Freud's theory of dreams is no longer in tune with the laboratory findings on sleep physiology. They play down past psychological traumas as psychological meaning in favor of memory consolidation and feel that dreams are "mental nonsense," have no psychological references, and should not be taken seriously. Thus, the biological conception of dreams is at odds with the psychological, with a tendency to neglect the nonbiological explanation.

The activation-synthesis explanation of dream formation of Hobson–McCarley challenged all psychoanalytic theories of dreams stating clearly that dreams are "inherently meaningless," random mental activity occurring due to chemical changes accompanying movement from non-REM to REM sleep. They state the dreamer and therapist create meaning to what is essentially random brain static.

In views similar to Hobson–McCarley, some neuroscientists propose that dreaming occurs when the brain stem stirs up emotions, mainly anxiety, anger, and elation. Neural gateways to the external world, memory, and rational thought shut down resulting in bizarre, internal visions that "speak" to the dreamer. In contrast to the Hobson–McCarley theory, and similar to Freud's concepts, Mark Solms in 2000 and others portray dreams as products of complex frontal brain activity that seek out objects of strong interest or desire depicting deep-seated goals in veiled ways to not arouse the

dreamer. A third position considers the data as inconclusive and views the way dreams function in different societies as socially constructed.

Whatever the position taken, as Michael Gazzaniga points out in the 1990s in his split-brain research, the human brain inherently seeks to make sense of all stimuli, including dreams, through the work of what he calls the “interpreter.” The interpreting, sense-making activity of the brain helps explain why psychotherapists and patients have found dreams very rich in meaning. Many therapists believe Hobson and McCarley have overextended their findings, and that whereas the wish may not cause the dream, it does not mean that dreams do not disguise unconscious wishes, or that wishes cannot influence dreams. Suffice it to say that there is still so little understanding of the relation of brain function to dreaming that no theory conclusively invalidates Freud’s. For psychotherapy, these theories neither replace nor supercede the usefulness of understanding dreams, nor do they deny the fact that dreams will always require interpretation.

XVI. CONCLUSION

In an age of brief therapy modalities, once-a-week sessions, the pressure from HMOs to limit treatment length, and a shift in emphasis from discovering the latent content to using the manifest content of the dream, today’s therapist may wonder whether dreams continue to take their lofty position alongside other material helpful to psychotherapy. In answer to this question, it is proposed that the use of dreams can function to broaden and enhance the therapeutic value of psychotherapy by providing useful data about the patient’s life, traumas, conflicts, relationships to significant others, resistances, symptoms, defenses, affect, and behavior. Effective use of dreams in psychotherapy can augment the therapeutic process enabling the pa-

tient to acquire greater strength to inhibit, restrict, select and criticize, spend less time in defensive functioning, and more time at work, play, and love.

GLOSSARY

anorexia nervosa A psychological and physical condition of semistarvation in which individuals weigh 85% or less of what would ordinarily be their healthy body weight, resulting in physical impairments and, in the 90% of patients who are female, cessation of menses. This condition is due to highly restricted food intake, often accompanied by excessive exercise and sometime purging by self-induced vomiting, laxative use, or other means. These behaviors are usually related to obsessional and perfectionistic thinking that focuses on a distorted body image and undue fears of becoming fat.

binge eating disorder A condition in which individuals binge eat large quantities of food in very short periods of time, often 1000 to 2000 calories or more at a time beyond their nutritional needs, at least several times per week for months on end, and have accompanying feelings of shame, disgust, and being out of control. In contrast to individuals with bulimia nervosa, they do not purge. As a result, these individuals often tend to be obese, some severely so.

bulimia nervosa A condition in which individuals binge eat large quantities of food in very short periods of time, often 1000 to 2000 calories or more, and then purge themselves of what they have eaten, usually by forcing themselves to vomit, and sometimes by means of laxatives, diet pills, diuretic pills, or excessive exercising. These behaviors occur

at least several times per week for months on end. The condition is usually related to overconcern with one's weight and shape, and is accompanied by feelings of shame, disgust, and being out of control.

eating disorders not otherwise specified (EDNOS) A mixed group of disorders that include psychological and behavioral elements of anorexia nervosa and bulimia nervosa but that, technically speaking, do not fully meet the strict criteria set forth in the diagnostic manuals. For example, this category might include individuals who have dieted down to only 12% below healthy weight, or who may still be having scant menses, or who may be binge eating and purging only once per week.

obesity A group of medical conditions marked by being at least 20% above recommended weight for age, height, and frame. Obesity is thought to result from a combination of genetic predispositions in the presence of excessive food intake and inadequate exercise. Except for individuals with severe obesity (e.g., 100% or more than 100 pounds overweight) types and levels of psychopathology in obese individuals tend to resemble that in the rest of the community at large.

Psychotherapeutic approaches to the treatment of eating disorders are varied. Different strategies have been used to treat anorexia nervosa, bulimia nervosa, and binge eating disorder depending on the specific disorder being treated, the severity and stage of the disorder, concurrent comorbid conditions, available treatment studies that address specific problems, and the

theoretical disposition of the clinicians. Systematic clinical trials that examine the efficacy of specified, manualized psychotherapies in the treatment of eating disorders have increased in number and in quality in recent years. These studies, typically involving cognitive-behavior therapy (CBT) and interpersonal therapy (IPT) for bulimia nervosa or binge eating disorder, have generally involved treatment studies that have sometimes been relatively uncomplicated with respect to comorbid conditions. Although the results of these studies merit serious attention, in practice many clinicians favor other psychotherapeutic approaches to the treatment of eating disorders that have not yet been subject to rigorous study, but that by virtue of the accumulated clinical experiences of diligent clinicians, also deserve careful consideration. This article will examine the useful information provided by the evidence-based studies thus far available, but also integrate the clearly helpful insights from accumulated clinical approaches that have not yet been subject to systematic study.

This article will discuss only the treatment of the primary eating disorders (anorexia nervosa, bulimia nervosa, binge eating disorder, and eating disorders not otherwise specified [EDNOS]). These disorders are thought to have a significant psychological component. In contrast, garden variety obesity is considered to be a general medical condition and not to be a psychiatric disorder, since, except for some individuals with severe obesity, rates of psychological disorders are no different among obese individuals than among the population at large. Even among those with severe obesity (e.g., 100% or more overweight) the psychological problems encountered appear primarily to be the results of obesity (e.g., self-disparagement and self-loathing due to being so obese).

In addition to the primary eating disorders, several other conditions occur among individuals with psychiatric disorders that may markedly affect eating behavior and weight. To list a few, individuals with severe depression often suffer a profound loss of appetite (true medical anorexia, not anorexia nervosa) and may not uncommonly lose 10 to 30 pounds. Some patients with so-called atypical depression actually experience an increase in appetite and food cravings ("hyperphagia") and may gain 10 to 30 pounds or more. Occasionally patients with psychotic delusions due to schizophrenia or other conditions may think that their food is poisoned and refuse to eat on that basis, losing weight in the process. Some patients with particular forms of brain damage may eat huge amounts of food and seem insatiable, gaining a great deal of weight in the process.

Many patients receiving antipsychotic or mood-stabilizing medications to treat conditions such as schizophrenia or manic-depressive illness (bipolar disorder) may gain weight as a side effect of these medications. Pharmaceutical companies are actively trying to find new types of medications with fewer weight-related side effects. Beyond these psychiatric conditions, a variety of serious general medical conditions need to be considered by clinicians evaluating patients with changes in appetite and weight. These include conditions causing poor appetite and weight loss such as cancers, HIV infections, tuberculosis, and diabetes as well as conditions causing weight gain, such as hypothyroidism and other endocrine problems and conditions causing the retention of fluids. Although all of these psychiatric and medical conditions are important and merit active treatment, discussion of their psychotherapeutic management is beyond the scope of this article.

I. DESCRIPTION OF TREATMENT PROCESSES

Comprehensive treatment for eating disorders generally requires attention to four distinct features of these disorders: (1) biological aspects, particularly nutritional status and the deleterious consequences of semistarvation and undernutrition on the one hand, or serious obesity on the other; (2) eating disorders related behaviors including restrictive and idiosyncratic eating patterns, eating binges, purging, ordinarily by means of vomiting or use of laxatives, and excessive, compulsive exercise; (3) eating disorder related thoughts, attitudes, and emotions, which may include distorted self-perceptions, overvalued ideas, and self-disparagement, all related to shape and weight, diminished cognitive complexity and increased obsessionality and perfectionistic thinking accompanying malnutrition, and increased nutrition-related emotional fragility with mood and anxiety symptoms; and (4) associated psychopathological and interpersonal problems, the frequent comorbid conditions of mood, anxiety, obsessive-compulsive, trauma-spectrum, personality and substance use/abuse disorders, and sometimes difficult family, interpersonal, and social situations accompanying many clinical eating disorders.

Treatment, accordingly, varies with the age, stage, severity, and chronicity of these conditions, with the family and social context, and with the presence and severity of comorbid medical, psychiatric, and interpersonal conditions. Current considerations suggest

that the initial treatment of the undernourished patient with anorexia nervosa and bulimia nervosa must focus on nutritional rehabilitation. Once that aspect of treatment is well under way, patients are usually more agreeable to participating in psychotherapy, and psychotherapy per se is usually much more effective.

A. Theoretical Bases for Psychotherapeutic Treatment Strategies

Several theoretical streams feed contemporary thinking about psychotherapeutic strategies for patients with eating disorders. These streams include an increased appreciation for biological influences on cognition, the importance of motivational state on patient participation in psychotherapy, developmental and psychodynamic perspectives, particularly those concerning early adolescence and early adulthood in women, learning theories, and a variety of family systems theories.

There are several reasons for thinking about biological issues when planning psychotherapies for patients with eating disorders. First, studies examining semistarvation in normal volunteers demonstrated that these subjects developed significant cognitive and emotional impairments. At 25% below their healthy weights these individuals showed significant psychopathology including loss of complex thinking, obsessional thinking (mostly about food), mood disturbance, irritability, fragmented and disturbed sleep, and social withdrawal. Furthermore, even after regaining the weight they lost, their cognitive and emotional impairments persisted for many months to a year or more. These observations suggest that the malnutrition itself contributes significantly to cognitive impairment and exacerbates many psychopathological features characteristic of anorexia nervosa (and some bulimia nervosa patients) including obsessional thinking, perfectionism, and other eating-disorder related attitudes as well as symptoms of anxiety and depression. Many of these psychopathological features improve substantially simply as a result of refeeding and better nutrition. Accordingly, current views hold that the psychotherapies for anorexia nervosa and bulimia nervosa should be tailored to the patient's degree of malnutrition and cognitive functioning.

Genetic, temperamental, and development issues inform theories concerning psychotherapy for eating disorders. Individuals who develop anorexia nervosa and bulimia nervosa may be more likely than others to show certain premorbid vulnerabilities such as familial

tendencies regarding weight and energy expenditure, obsessionalism, perfectionism, and/or proneness to anxiety, depression, low self-esteem, and uncertain sense of self. In some patients the co-incident occurrence of substance abuse problems may contribute to the initial appearance of eating disorders.

The clinical observations of Hilde Bruch underscored key features seen in patients with eating disorders that demand attention in psychotherapy, particularly distorted perceptions and misconceptions of body size awareness, interoception, bodily functions, hunger and satiety, and issues regarding control of body functions. Bruch also emphasized the diversity of psychological and family features to be found in these disorders. Her observations and ideas have endured and have formed the theoretical basis for therapeutic conceptions and interventions of decades of therapists using psychodynamically oriented and cognitive-behavioral techniques. The eating disorders inventory and the influential cognitive analyses of David Garner and colleagues, which identified common examples of "all or none" thinking in eating disorders patients, was heavily influenced by Bruch's formulations. These conceptions have, in turn, influenced the systematic cognitive-behavioral psychotherapies for patients with anorexia nervosa, bulimia nervosa, and binge eating disorder developed over the past two decades by David Garner, W. Stewart Agras, Katharine Halmi, Christopher Fairburn, Hubert Lacey, James Mitchell, Janet Treasure, G. Terence Wilson, and others.

Families of eating disorders patient display great diversity in dynamics and systems issues, ranging from reasonable health to extreme dysfunction. All parents with a child displaying the self-destructive behaviors and emotional turmoils of serious eating disorders will be upset by these events and display various signs of distress and emotional reactions about and toward that child. In addition to these expected responses, certain dysfunctional patterns have been thought to further contribute to the pathogenesis and maintenance of some patients' problems. Many of these dysfunctional family patterns are not specific to eating disorders but are thought to exacerbate a wide range of psychosomatic conditions and other psychiatric disorders. Salvador Minuchin and his colleagues described some families characterized by parental enmeshment with and overprotectiveness of patients, rigidity in maintaining the status quo, and avoidance of conflict resulting in lack of conflict resolutions in these families. Other difficulties have been attributed to psychological, physical, and/or sexual abuse, high degrees of negative expressed

emotion (in which one or more family members is highly critical and blaming of the patient), teasing, the perverse influences of competitive or narcissistic parents, parental intrusiveness and lack of respect for privacy or autonomy, and colluding with or enabling pathological behaviors in a family member. These observations have led to recognition that family assessment and family education, counseling, and/or psychotherapy may be very important in treating patients with eating disorders, particularly children, adolescents, and young adult patients who may still be living at home and/or be heavily involved with their families of origin. For adults in marriages or committed relationships, issues such as those described above may merit couples therapy.

Clinicians have increasingly appreciated the importance of the patient's motivational state for engagement in treatment and recovery. These views in turn have led to the development of psychotherapeutic strategies for eating disorders based on the transtheoretical models and motivational enhancement strategies based on the work of James Prochaska and Carlo DiClemente and, more recently, of William Miller, approaches that have been primarily used with patients suffering from alcoholism and substance abuse. These strategies try to move patients from what often appears to be a precontemplative state (denial, avoidance, minimization) to contemplative states, in which they may at least acknowledge the existence of a problem, to deliberative states in which they seriously consider the need for treatment, to action states in which they actually engage in treatment. Research studies currently under way focus on the potential value of motivational enhancement strategies at the beginnings of psychotherapy for eating disorders patients. Conceivably, motivational state will be found to correlate strongly with the brain's nutritional status. Individuals with starved brains may be less capable of self-awareness or "insight" and therefore more likely to appear unmotivated than those whose brains are receiving adequate nutrition.

B. Empirical Studies and Review of Treatment Efficacy

Most authorities agree that psychotherapies work best in the context of comprehensive care. This requires that treatments first attend to restoring good nutrition, then to reducing pathological behaviors, and finally, with those aspects of treatment well under way, to dealing with the psychological and emotional aspects of care. The patient's motivation to change and

psychological experiences in relation to behavioral challenges require careful attention throughout the course of treatment.

1. Anorexia Nervosa

Few controlled trials of psychotherapy for anorexia nervosa have been published, in part due to the tremendous difficulties of conducting such trials with this population, especially during phases when the patients are seriously underweight. Consequently, recommendations regarding the role of psychotherapy in early phases of treatment rely strongly on consensus opinions of experienced clinicians and clinical researchers. Investigators increasingly appreciate just how much malnutrition in anorexia nervosa contributes significantly to cognitive impairment and to increases in many characteristic psychopathological features including obsessional thinking, perfectionism, and other eating-disorder related attitudes, as well as symptoms of anxiety, depression, and emotional lability. With nutritional rehabilitation alone, many of these psychopathological features improve significantly. Accordingly, current views suggest that the initial treatment of the undernourished patient with anorexia nervosa must focus on nutritional rehabilitation and that the psychotherapy of anorexia nervosa should be tailored to the degree of malnutrition and level of cognitive functioning of the patient.

Decades of experience showed that classic psychoanalytic approaches were often futile and even harmful for patients ravaged by semistarvation states. It appears that anorexia nervosa patients are most capable of engaging fruitfully in psychotherapeutic discussions and processes only after their severe malnutrition has been reversed. For seriously undernourished patients, those whose weights are 25 to 30% or more below their healthy weights, nutritional rehabilitation often requires skillful nursing care, usually in the setting of an inpatient or day hospital program. Staff members on these units should be psychologically empathic, informed, and sensitive. Their day to day, sometimes moment to moment, interactions with the anorexia nervosa patients are best informed by our understanding of the nature of the psychopathological processes common to patients with these conditions. However, during this initial phase, while psychodynamically and cognitively informed empathic discussions and education with the patients are useful, the value of formal psychotherapy is uncertain, as patients are often not really able to commit to or engage in psychotherapy in a meaningful manner. Furthermore, several authorities

have described that group psychotherapy for patients with anorexia nervosa during this phase may actually be counterproductive, as patients sometimes compete for who can be thinnest or sickest, and sometimes learn maladaptive tricks from one another.

Once weight gain has started, and especially after weight has been restored to a healthy level, psychotherapy appears to be very helpful to help patients make sense of their experiences, come to understand how their symptoms may constitute maladaptive efforts at emotional self-regulation, explore their prior vulnerabilities and the antecedent life circumstances that led to the illness, deal with their families and peers, and learn to cope more adaptively with developmental issues, conflicts, and emotional regulation in their futures. At this point many clinicians use psychodynamically oriented therapies individually and in group settings.

Several psychotherapy trials for anorexia nervosa patients have been undertaken at the point when patients have regained some weight and are ready to leave the hospital. One notable result of CBT studies with anorexia nervosa patients has been a high dropout rate among patients enrolled in these studies. However, recent research with weight restored anorexia nervosa patients by Kathleen Pike and colleagues has also shown that CBT-based psychotherapies can be helpful in preventing relapse. CBT-based programs developed by Thomas Cash, focusing on distortions concerning body image, may be very helpful for patients recovering from anorexia nervosa and patients with other eating disorders as well.

Gerald F. Russell, Ivan Eisler, and colleagues have conducted controlled trials of family versus individual psychotherapy, starting with patients just being discharged from hospital treatment. Their results suggest that if only family therapy or individual is to be administered, for patients who are under the age of 18, family psychotherapy is of more benefit than individual psychotherapy; for older patients individual therapy appears to be more favorable. In actual practice clinicians combine family therapy and individual psychotherapy depending on the patient's circumstances and needs. The critical point suggested by this research is that for younger patients, still living with and/or heavily involved with their families of origin, assessing the entire family and involving the family in psychotherapeutic and psychoeducational activities is essential. Incorporating strategies based on many earlier observations of family-oriented clinicians, James Lock and colleagues have developed a manual for active family treatment aimed at acutely ill children and adolescents with anorexia nervosa and are in the process of testing it empirically.

A randomized controlled trial by Christopher Dare and colleagues showed that although results were modest, a year's treatment with focal psychoanalytic therapy and family therapy were each significantly superior to low-contact "routine" treatment with respect to weight gain and other measures for outpatients with anorexia nervosa. Many of the patients in the trial remained underweight at the end, although a number no longer met strict diagnostic criteria for anorexia nervosa.

Recent research underscores the fact that although good recovery is common for younger onset anorexia nervosa patients who receive good initial and ongoing care, recovery takes a long time even for such individuals, on the order of 5 to 7 years. General clinical consensus suggests that psychotherapy during the period of recovery, particularly during the first several years, may be very helpful for enabling patients to better deal with and make sense of their current and ongoing illnesses; recognize and work through prior vulnerabilities they may have had resulting from their early temperaments and life experiences with family and peers; regulate their emotions, particularly mood and anxiety; contend with personality issues concerning perfectionism, self-confidence, and self-esteem; and anticipate how to deal successfully with future challenges with which they will be forced to cope. A variety of psychodynamic, feminist, and relational themes may be addressed in these therapies.

For difficult-to-treat patients with refractory or chronic anorexia nervosa, much more research will be necessary before we can fully assess the potential benefits of various psychotherapeutic approaches. At present, many authorities believe that a humane, compassionate, supportive psychotherapeutic approach may be most helpful for such patients. Nonverbal, experiential therapies such as art therapy and movement therapy may be of adjunctive benefit.

2. *Bulimia Nervosa*

Initial assessment of the patient with bulimia nervosa for psychotherapeutic readiness, to assess comorbid psychiatric states and attend to them, and to determine what approaches are likely to be most helpful for the given individual is of critical importance to maximize the likelihood of successful treatment. For patients with comorbid substance abuse or dependence disorder, successful treatment of bulimia nervosa ordinarily requires that the substance abuse disorder be attended to first, or at least concurrently. The odds of successfully treating bulimia nervosa in the presence of untreated substance abuse or dependence disorder are

extremely small. As with any psychotherapeutic treatment, the clinician must remain alert to resistances and negative therapeutic reactions, some of which may result from patient factors and some from therapist insensitivities or errors in assessment or judgment. Quick attention to problems as soon as they are identified may be necessary to save treatments that might otherwise end prematurely and unsuccessfully.

The fact that binge eating and purging episodes are relatively easily counted has stimulated and facilitated psychotherapy research for this disorder. Accordingly, a large number of studies have examined the efficacy of several different types of individual and group psychotherapies for bulimia nervosa. Cognitive-behavior therapy (CBT) has been most extensively researched, and is the approach for which most substantial evidence for efficacy exists. Twelve to 20 sessions of CBT treatments, often manualized to permit reliable duplication from center to center, have proven to be highly effective in reducing the number of binge eating and purging episodes and in changing dysfunctional attitudes regarding weight and shape. The treatment is usually conducted in several distinct phases. Initial sessions are usually devoted to helping patients restore healthy patterns of eating and nutrition, enabling them to consume sufficient food without purging so that periods of hunger are avoided. Because hunger pangs are thought to trigger more than 50% of eating binges, reducing hunger often reduces binge eating. The initial phases of CBT involve careful quantitative assessments and diary keeping concerning eating patterns; the types, quantity, and time-course of food consumed during the day without purging; eating binges; *purges*; exercise; and associated antecedent, concurrent, and consequent thoughts, emotions, and associated behaviors. By the very act of keeping these diaries, patients already indicate their compliance, acknowledge concern about their problems, and show sufficient motivation to invest necessary time and psychological energy into recovery. Diary keeping promotes increased awareness of symptoms, so that eating binges and purges are less likely to occur “automatically” in semidissociated states, and also signifies that patients will share their behaviors publicly (at least with their clinicians). These factors may both contribute to the therapeutic benefits derived from this simple procedure.

The middle sessions of CBT are devoted to explicating and dealing with eating disorders related thoughts and emotions—to recognize, elicit, label, examine, and counter the underlying negative and pathological cognitions concerning eating, weight, and shape in relation to

self-evaluation and self-esteem. The late phases of CBT focus on helping patients better cope with the frustrations related to interpersonal and intrapsychic events that often trigger binge eating episodes. About 60% of patients with uncomplicated bulimia nervosa obtain substantial symptomatic relief from this treatment, even without the concurrent use of medications. After the initial series of CBT sessions have concluded, booster sessions, usually scheduled on a monthly basis for a year or two, have been helpful for maintaining improvements and preventing relapse.

Research suggests that for those patients for whom CBT will be an effective intervention, clear-cut improvements should be seen within 6 to 8 weeks. The absence of improvement during that time frame suggests that the patients will require an additional or different modality, for example, the addition of medication such as selective serotonin re-uptake inhibitors (SSRIs) such as fluoxetine to obtain substantial improvement. Some research suggests that adding SSRIs to CBT results in overall better outcomes in bulimia nervosa.

The extent to which complete abstinence from binge eating and purging is achieved varies from study to study, with remission reportedly averaging about 36% for CBT-based psychotherapy alone versus 42 to 49% for studies in which CBT is combined with medication.

Bulimia nervosa has also been successfully treated with interpersonal psychotherapy (IPT), based on the approach of Gerald Klerman and colleagues. Studies have shown that initial posttreatment responses to IPT are not as robust as those to CBT, but that over longer term 2 to 5 years follow-ups, the outcomes for IPT and CBT are similar with respect to reducing binge eating symptoms. Furthermore, since the forms of IPT used in these research studies were intentionally and systematically stripped of all reference to eating problems that could confound them with CBT, they were artificially devoid of subject matter that clinicians treating these disorders would ordinarily discuss and consider with their patients. Taken as a whole, these studies suggest that although CBT principles are more effective than IPT in reducing disturbed attitudes toward shape, weight, and restrictive dieting, a proper integration of IPT strategies in treatment may also be helpful. These strategies may afford reduced emotional tension and better ways of coping with IPT-related concerns of loss, disputes, role transitions, and interpersonal deficits, and thereby contribute to sustained and enduring improvement.

After symptom remission, traditional psychodynamic psychotherapies may be helpful for exploration of long-standing issues concerning development, enduring

psychological conflicts, repetitive self-destructive patterns, and enduring maladaptive aspects of the personality.

Studies of purer forms of behavior therapy without cognitive components have yielded conflicting results. In these studies, for example, researchers have utilized exposure and response prevention techniques, in which individuals who binge eat are prevented from purging. Results are conflicted, but some studies suggest that this treatment does not add to a solid core of CBT.

Several studies have shown CBT in group settings to be moderately effective. Group CBT programs requiring diary keeping, dietary counseling, and dietary management are more effective than those without such components, and programs requiring more frequent sessions at the beginning of treatment (e.g., several times per week) and longer sessions are more effective than those meeting less extensively. In practice, many clinicians favor combining individual and group psychotherapy for bulimia nervosa.

A sizable minority of patients with uncomplicated bulimia nervosa, on the order of 20%, may achieve significant benefit from working through structured, self-guided CBT-based manuals on their own. A number of self-guided programs have been devised and are widely available. For several of these manuals accompanying guides for therapists have been written as well.

Some research suggests that for some patients with bulimia nervosa certain forms of intense psychoeducation may be as effective as CBT. Anecdotal reports hint that some patients with bulimia nervosa may benefit from 12-step oriented programs and that programs such as Overeaters Anonymous may serve as useful adjuncts. Several investigators report that 12-step programs have generally not been successful for patients with anorexia nervosa.

Because large numbers of patients with bulimia nervosa suffer from concurrent mood disorders (primarily recurrent major depressive disorders, dysthymic disorders, and bipolar II disorders), and substantial numbers suffer from anxiety disorders, personality disorders (often demonstrating cluster B and C traits and qualities), histories of psychological, physical, and sexual traumas, and substance abuse disorders, treatment planning must take the comorbid features into consideration, and psychotherapy and psychosocial treatments must be modified to deal with these problems as well. Experimental psychotherapy programs directed by Stephen Wonderlich and colleagues are being tested for difficult to treat so-called multi-impulsive bulimia nervosa patients, that is, patients who in addi-

tion to having difficulty regulating eating behaviors also exhibit difficulties regulating emotions (particularly anger, irritability, and depression) and a variety of behaviors including sleeping (chaotic), shopping (overspending and shoplifting), sex (often impulsive, sometimes promiscuous), and substance use (abuse and/or dependence is common). For such patients, in addition to using traditional eating disorder-related CBT programs and medications as indicated, treatment programs may employ elements of dialectic behavior therapy (DBT) developed by Marcia Linehan and colleagues for patients with parasuicidal behaviors and borderline personality disorder, and intensive outpatient psychotherapies in which patients may be seen even several times per week as well as on a crisis basis.

As with anorexia nervosa, at some stages of treatment incorporation into psychotherapy of more traditional psychodynamic, feminist, and relational themes may be helpful.

3. Binge Eating Disorder

Psychotherapy research involving binge eating disorder has been largely based on treatments for bulimia nervosa and, because substantial numbers of binge eating disorder patients are overweight or obese, on psychotherapy treatment research for obesity. Because obesity is a common comorbid condition, researchers have been concerned with how to relate treatments designed to reduce binge eating behavior with those designed to enhance weight loss. Based on available studies, most experts agree that initial therapeutic aims should focus on reducing binge eating episodes. Once binge eating has been controlled weight loss programs may be more effective. Nevertheless, when results are examined at 5 years after treatment the enduring impact of weight loss programs is not very impressive. For obese patients, “non-diet” approaches that stress self-acceptance, improving body image, and improving health and fitness through exercise and better nutrition, are being developed as alternatives to unsuccessful weight loss programs.

While treatment continues, CBT, behavior therapy, and IPT all reduce rates of binge eating frequency by up to two thirds; however, these improvements tend to deteriorate after treatment is concluded. Denise Wilfley and colleagues conducted a well-executed group psychotherapy study for binge eating disorder using an IPT approach and showed this intervention to rival the effectiveness of CBT in both short and long term across multiple domains. Further, effect sizes for both IPT and CBT were comparable to the best results reported for

individual treatments. As for bulimia nervosa, in practice, elements of CBT and IPT are all useful for treating binge eating disorder, and some patients achieve benefit from self-help programs using professionally developed CBT-oriented manuals. Although no systematic research exists on this point, many patients with binge eating disorder anecdotally report that they receive considerable help from 12-step model programs such as Overeaters Anonymous.

II. CASE EXAMPLES

A. Anorexia Nervosa

Patsy was a 17-year-old high school student who had been suffering from anorexia nervosa since the age of 13. She was characterized by her family as a tenacious and diligent student, and she had been an excellent athlete in middle school and earlier in high school. Starting at ages 9 and 10 she clearly excelled in track and appeared to be headed for the State championship team. However, at age 13, shortly after she first started to menstruate, she started to diet severely in response to a casual remark by a friend at practice concerning her weight. At first her parents thought little of it, but within a few months she had lost considerable weight and the family took her to her pediatrician, who diagnosed anorexia nervosa and referred her to a child psychologist. The pediatrician also thought she was depressed and obsessive and started to treat her with paroxetine (Paxil), a selective serotonin reuptake inhibitor used to treat depression and obsessive-compulsive disorder.

Patsy started weekly individual psychotherapy but her psychotherapist paid relatively little attention to her eating or weight, and within a few months her weight fell further. She minimized the seriousness of her problem, and basically tried to write it off as normal for teenagers. She was at best ambivalent about admitting that her intermittent fatigue was due to undernutrition. Patsy also minimized her interactions with her family around meals, so that they were less likely to observe her very restricted dietary choices and ritualistic food habits. At her pediatrician's insistence she was hospitalized on a medical unit where under the pediatrician's direction and the help of a nutritionist she was required to eat a set number of calories or face gastric tube feedings. With this regimen she managed to gain enough weight to pull out of the danger zone, and she resumed outpatient treatment, adding regular visits to a dietician to her weekly psychotherapy and medication program. For the next year and a half Patsy basically

maintained her status quo, still minimizing her problem and not gaining additional weight. At this point, at about age 16, she was referred to an eating disorders specialist who made the following determinations: (1) Patsy would benefit from the addition of a structured cognitive behavior therapy program; (2) since Patsy was still living at home and highly involved with her parents, and her parents were at their wits end as to how to contend with her, family therapy was necessary; (3) developmental issues concerning her earlier childhood and budding adolescence, and interpersonal issues concerning her family and social life were all pertinent and merited ongoing discussion.

To help enhance her motivation at the start of this new therapeutic push, a bone densitometry test was ordered, which revealed that the amount of calcium stored in Patsy's bones was considerably less than average for young women her age. This piece of concrete information made quite an impression on her. Her motivation to improve increased, although the fears and obsessions that governed her restricted eating patterns were relentless.

With considerable effort, Patsy agreed to keep a diary of her food intake and exercise, and to also record the related thoughts and emotions that preceded, accompanied, and followed her meals. She agreed to try to limit the amount of exercise in which she regularly engaged, although at times, especially when she felt that she overate, her urge to exercise was very strong. Individual sessions consisted of a regular review of her eating patterns and exercising, and also left room for discussion of earlier and current events in her life. In particular, developmental issues focused on her dealings with inconsistent mothering, a somewhat absent and unpredictably angry father, and a difficult and competitive older brother. Current issues concerned her pining for a boyfriend (initially in a somewhat preadolescent manner, because thoughts of physical contact and intimacy were revolting to her), and problems in dealing with a very cliquish group of girlfriends, from which she often felt excluded, in part because her anorexia nervosa resulted in her standing out as deviant in her crowd.

In addition to weekly individual sessions, Patsy was seen together with her mother every other week; occasionally her father, a busy professional, would join these sessions. When her older brother came home from his out-of-town college, he, too, would occasionally join the family meetings. During the initial family meetings Patsy and her parents were able to air and discuss a number of chronic tensions and conflicts that never seemed to get addressed at home and that often

were swept under the rug. The parents were instructed to schedule family meals at which Patsy would be expected to eat, and to lovingly and without rancor or re-primation make sure that she ate a sufficient number of calories and increased her food choices. They were carefully instructed to avoid criticizing, belittling, or blaming her for her anorexia nervosa.

These efforts resulted in a slow, modest, but steady weight gain of 12 pounds, so that by the end of 20 to 30 weeks of outpatient treatment her menstrual periods resumed, accompanied by an increase in typical teenage pimples and thoughts about boys. She still had some obsessional thoughts about food, but she found that as her weight increased, and especially after her periods resumed she was less preoccupied and found it easier to drop her eating rituals. She maintained this progress during her senior year of high school and has been able to successfully go off to an out-of-town college where she is continuing in psychotherapy, but symptomatically much better.

B. Bulimia Nervosa

Jill was a 23-year-old administrative assistant who had been binge eating and purging since the age of 16. Although her mother was slim and even glamorous, her father's side of the family tended to be obese and Jill seemed to have inherited those tendencies. Throughout Jill's teen years her mother constantly urged her to watch her weight, to avoid getting too chubby, so that she would be socially popular. Jill did everything she could to diet, and she exercised rigorously. However, all of her efforts seemed inadequate to prevent a gradual increase in her weight, and she became demoralized at the seeming futility of her battle with the scale. When she was 16, discovering that she could keep her weight down by purging seemed an easy out. Over the next few years the binge eating and purging pattern increased, and she became progressively ashamed and secretive about her eating patterns. Gradually, binge eating and purging seemed to take on a life of their own and Jill became demoralized and depressed, aware that her symptoms were causing social impairment and physical problems. She suffered constant heartburn from gastric acid bathing her esophagus and was alarmed by serious and expensive dental problems.

Jill came for treatment when she first met a man she really cared about, who seemed to care about her as well. She realized that the odds of getting into a serious relationship with him would be jeopardized by her disorder; she feared that telling him about her bulimic symptoms would result in his dropping her, and she

knew that she did not want to threaten or destroy her chances with him by continuing her disorder in secret.

Jill and her therapist started by conducting a full review of her past history and current symptoms. Together they used a cognitive-behaviorally oriented treatment manual designed for individuals with bulimia nervosa. They started with twice-weekly sessions and gradually moved to weekly sessions. Highly motivated at this point, Jill dutifully completed her homework assignments, which focused on keeping a diary of her regular meals and binge eating episodes, together with records of her associated thoughts and emotions. She discovered that she was actually restricting her food intake somewhat, and that when she increased her regular meals the hunger pangs that often triggered her eating binges diminished considerably, making it progressively easier for her to eat normal meals without overeating.

As the initial phase of treatment worked well, over a period of about 2 months, therapy focused on her negative self-concepts regarding body shape and appearance, how she had come to deal with emotional issues concerning her mother by "stuffing my face," and on suggesting other ways that she might be able to cope with negative emotions and difficult family members. Jill also brought up ongoing events with her boyfriend, hoping that the therapist would "check me out" with respect to how she was handling new interpersonal and intimate experiences.

Over the next several months Jill's binge eating and purging episodes subsided considerably, to the point where they would occur rarely, and then only in situations where family conflicts and stress would erupt, usually during visits to her parent's home. She and her therapist worked on relapse prevention techniques, learning to identify circumstances and contextual triggers to which she was still vulnerable, giving her ways of dealing more effectively with these situations. Her therapy sessions were now scheduled on a monthly basis. Over the course of the next year Jill's weight increased by about seven pounds. Although she was not happy about this, she was much better able to tolerate the weight gain than would have been the situation in the past—and since her now fiancée did not seem to mind at all, she even seemed able to laugh about it.

III. SUMMARY

Although some progress has been made in psychotherapy studies for eating disorders, particularly for bulimia nervosa, substantial work remains to be done. We know little about what forms of psychotherapy might make a

meaningful difference at what stages for which types of patients with anorexia nervosa. Much research remains to be done on improving psychotherapies for patients with complex bulimia nervosa (e.g., those with substantial concurrent personality, "trauma spectrum," and/or substance related disorders). Additional studies are required on integrating psychotherapies with other components of treatment (e.g., nutritional rehabilitation and medications among others).

Future research is likely to follow several directions. First, investigators are likely to unbundle some of the current manualized CBT, IPT, and family psychotherapies and better integrate treatment components that seem most helpful. Research on the effectiveness of psychodynamic psychotherapies for eating disorders, including supportive-expressive therapies and therapies based on various theoretical models including self-psychology, are likely to be extended. Psychotherapies based on feminist and relational principles are likely to be subject to more systematic study as well. Finally, strategies based on computer and information technologies are already being applied to the assessment and psychotherapy of eating disorders. Treatment advances will undoubtedly evolve from these modalities, including individual and group formatted e-mail and web-based communications for administering or enhancing professionally guided and self- or peer-guided psychotherapy programs; personal digital assistants (PDAs) to help record and to remind patients to perform certain behaviors; and even virtual reality-based sensory stimulation to facilitate desensitization to certain behavior-inducing cues. We have much to learn about the psychotherapeutic treatment of eating disorders, and the future promises to be very instructive.

GLOSSARY

assignment A voluntary acceptance or rejection of an agreement to settle for payment by Medicare and Medicaid of 80% of a provider's customary fee. If a provider refuses assignment, he or she may bill the patient for the remainder, called *balance billing*. In 1986 Congress placed severe limitations on balance billing.

benefit design The delineation of all the covered services, procedures, and their costs that a health plan agrees to reimburse, as well as the exclusions, limitations, co-payments, and deductibles in the health plan contract. It is often used to make the health insurance more attractive than that of the competition.

capitation A type of prospective payment for health services based on the rate for each of a large number of covered lives rather than the units of service delivered. Because it is paid in advance at the beginning of each month, it is also known as the pm/pm (rate per member per month). This is

the usual method of payment to HMOs and PPOs that go at risk (guarantee to deliver the contracted services).

carve-out A contractual arrangement by a health plan (insurer) with an independent behavioral care company to assign to it the delivery and risk of all mental health/chemical dependency care. The company assuming the risk is called a carve-out.

case management The direct supervision of cases assigned to providers on a network, with final decision making over the practitioner. Usually conducted by telephone.

case rate The payment to a provider of a fixed fee to cover all services to a patient regardless of their nature or number. The case rate is sometimes fixed in relation to the severity of the patient's problem.

CPI The Consumer Price Index compiled by the Bureau of Labor Statistics (BLS) giving a value to all the goods and services. This is used as a measure of inflation. The BLS also compiles a MCPI (Medical Consumer Price Index) that is not widely used because of its inherent flaws.

deductibles First dollar amounts that the patient must assume before there is reimbursement for the covered costs by the insurer. For example, a policy may pay for a surgical procedure beyond the first \$300.

DRGs Diagnosis Related Groups, a method of payment to hospitals approved by the Congress for Medicare and Medicaid in 1983. There are almost 400 diagnostic groups, each of which has its limited length of stay in the hospital which, if exceeded, is not reimbursed by the federal government. Rapidly the DRGs were adopted by the private sector. There are no DRGs in psychiatry.

HMO Health Maintenance Organization. The major type of managed care company that may provide all the services to its subscribers directly (e.g., Kaiser Health plan), or

contract with hospitals and other providers to deliver the services (e.g., Foundation Health plan).

indemnity coverage Health insurance that reimburses the policy holder for covered services used and paid for.

NHI National Health Insurance, sometimes referring to the Canadian Plan, but more often alluding to one or more U.S. proposals for a one-payor (government) sponsored universal health care plan, the most recent of which was the ill-fated Rodham-Clinton Plan of 1993.

parity Proposals more or less mandating equality in expenditures between physical and mental health care, a number of which have been enacted into state and federal laws.

PPO Preferred Provider Organization, a group of physicians that contracts (usually with HMOs by way of an at-risk capitation) to provide comprehensive health care services.

precertification The requirement that a provider receive advance authorization before providing a health care service or admitting a patient to the hospital. This is very common in psychotherapy and psychiatric hospitalization.

provider Profiling The comparison of every provider's practices with those of his or her peers. An unfavorable comparison often has a sentinel effect, causing the provider to conform. A practitioner who does not conform may be excluded from a network.

RVS code Relative Value Scales originally designed by Dr. L. Hsiao of Harvard for Medicare and Medicaid reimbursement, but widely used in the private sector. The RVS determines how much will be reimbursed for a particular service.

service benefit Payment for covered services made directly to the hospital or other provider by the health plan. This differs from *indemnity* payments that reimburse the insured individual.

third-party payor This is an insurance term (payor, not payer) meaning the entity responsible for paying for an individual's health care bills, be it indemnity insurance, HMO, PPO, or government.

utilization review The ongoing evaluation of the practices of a provider with the intent of determining and curtailing unnecessary services.

I. A BRIEF HISTORY OF PSYCHOTHERAPY IN HEALTH CARE DELIVERY

Health policy regarding psychotherapy prior to the late 1950s was simple and straightforward: It was regarded as too economically elusive to be calculated in health insurance and was, therefore, universally excluded as a covered benefit. In fact, it was not until the mid-1960s that health insurance policies began in any noticeable number to include what was at first limited psychotherapy benefits. Prior to that time all psycho-

therapy was out-of-pocket, making the ability to pay rather than need the determining factor of who received the services of a psychotherapist. It did not matter whether it was with a psychiatrist or a psychologist, as the economic situation was the prevailing factor. But it must be remembered that medical/surgical services were not covered by health insurance until the 1930s, and then not in impressive numbers until the 1940s. How health care came to be part of an insurance benefit, and how eventually psychotherapy was included in such coverage, deserves our consideration as it is part of the evolution of public policy that continues to this day, with ongoing change extending well into the future.

A. American Health Care in the 1930s: The Robin Hood Model of Economics

This decade in history is known as the Great Depression, characterized by hunger, high unemployment, and economic stagnation. It was also the decade when medicine ascended fully to the stature of a profession, having established A and B grade medical schools, replacing the apprenticeships by which characteristically one became a physician in the 1910s and 1920s. Soon all but A grade medical schools were closed, upgrading the profession even more. The physician of the 1930s was proud, altruistic, well-educated, and dedicated. The Hippocratic Oath was taken seriously, and in spite of a shortage, the physicians saw everyone who wanted to see them, even if it meant a consistently 16-hour work day. A request for a house call was never denied. It was unthinkable to press a bill for payment, and no physician would even consider using a collection agency. Patients were seen and house calls were made even when a patient had not paid the accumulated bill for 3 or 4 years. Physicians knew people were strapped financially, and they saw themselves truly as caregivers without regard to compensation. The physicians of the period were overworked, never wealthy, and looked old before their time.

What about the patient who was financially well off? The physician simply doubled or even quadrupled the bill, depending on the patient's wealth, explaining it was up to those who could to pay for those who could not pay. This was an accepted practice, without exploitation or greed on either side. So there was remarkable availability of outpatient health care, regardless of ability to pay, whereas health insurance premiums would have been beyond the reach of most Americans in the 1930s. The system was not perfect, especially in

rural areas that required considerable travel to the nearest physician. Furthermore, some persons were too ashamed to see a physician if they owed money. What about the matter of hospitalization, however?

B. The Birth of Blue Cross and Blue Shield

For decades prior to the 1960s no one thought of a hospital as making a profit or even breaking even. Almost all were nonprofit and most were owned by religious (Catholic, Jewish, Presbyterian, Methodist, Seventh-day Adventist) and other charitable organizations, or were community sponsored. At least twice a year each hospital held a fund-raising drive to make up the shortfall. No one who needed hospitalization was turned away, regardless of ability to pay. The now ever-present insurance card demanded at the reception desk of every hospital was nonexistent.

To create a much-needed revenue stream the hospitals organized into an entity named Blue Cross. For those who could afford the monthly premium, small by today's standards, any needed hospitalization was prepaid. In defense, the physicians organized into a parallel organization named Blue Shield that paid for their services. However, "the Blues" Plans were hospital oriented and covered care only when it was hospital related. The joke of the era was that if you needed to have a hangnail removed you would first need to be hospitalized.

It was important to the policy makers that the hospital doors be kept open during the Great Depression, and a number of concessions were made to Blue Cross and Blue Shield, collectively known as "the Blues." They were separately incorporated in each state, with some states having more than one set of Blues Plans, and they were tied together by membership in the National Association of Blue Cross and Blue Shield Plans. Special legislation designated them to be medical services corporations (nonprofit) that were not only exempt from federal and state taxes, but had other competitive advantages, such as relief from the large financial reserves required of insurance companies and guaranteed discounts for their hospitalized patients. Hospitals and physicians survived, but the seeds for certain negative economic factors were sown in that era. For the first time a two-tiered system emerged in health care between those who could afford the inexpensive membership in Blue Cross and Blue Shield and those who could not and who increasingly were remanded to the county hospital. In addition, for the first time a third-party payor intruded into the previously simple Hippocratic

relationship between doctor and patient. It was the beginning of economic complexities that could not have been anticipated at the time.

C. The History of Capitation

A method of reimbursement for large populations that is based on a set amount of payment per member (enrollee) per month (known in the industry as pm/pm) also had its beginnings in the 1930s. The Ross-Loos Group in Los Angeles and Doctor Callan and Staff in the San Francisco Bay Area solicited subscribers from the general public, as employer-sponsored health insurance was still almost a decade away. This fact, with ready access to health care in spite of an inability to pay, made prepaid health care not very compelling, or even financially attractive. Consequently, the Callan plan suffered an early demise, while the better financed and more aggressively marketed Ross-Loos group survived to the present era.

Concurrently capitation was launched in a big way, but out of necessity, on the Mojave Desert. A then unknown industrialist, Henry J. Kaiser, had won the bid to build the aqueduct from Hoover Dam to Los Angeles, but he was unable to hire enough construction workers to do the job in spite of the high unemployment at the time. These workers were reluctant to take their families to the desert where only dirt roads existed and the rough terrain made the nearest health care facility 15 to 20 hours away. Just as Kaiser was about to fail, a young physician named Sidney Garfield approached him with an offer he could not refuse. For just 5 cents a worker hour he would build and staff the outpatient and inpatient facilities that would guarantee treatment for both his employees and their families.

That day in the early 1930s capitated health care, embodying both the management of care and the acceptance of financial risk, was born in a big way and for all time. While the facilities were being built Garfield launched a prevention program, spending a significant part of the capitation dollars to educate the workers and their families on the avoidance of hazards in the desert: rattlesnake and tarantula spider bites, scorpion stings, heat stroke, and heat exhaustion. He strongly believed this would pay off in reduced treatment costs in the future. He was right, of course, but by implementing this aspect he defined the concept that capitation, which allows for spending the money as the provider sees fit, includes prevention. It was not long before his ideas expanded to include wellness, an integral part of the most successful capitated programs today.

After the aqueduct was completed, Kaiser transported what was still called Sidney Garfield and Associates to Northern California to provide capitated health care to his thousands of shipyard workers during World War II. Then, following the end of that war, Kaiser invited Garfield to offer capitated health care to the general public. In 1946 the Kaiser Permanente Health System was founded as the prototype of the modern health maintenance organization (HMO), a name that was not to be coined by Paul Ellwood for another 15 years. Because capitated care did not have the deductibles, limitations, and exclusions common to health insurance at the time, the Kaiser Health Plan grew rapidly in the next few years to over five million enrollees in California, Oregon, and Hawaii.

The success of the Kaiser Health System eventually caught the attention of the policy makers in Washington, and in 1974 the Congress passed the HMO Enabling Act which provided start-up money to encourage the formation of new HMOs. Most of the new HMOs did not survive beyond the federal funds, but those that did were integral to the rapid rise of managed care in the 1980s.

D. The Rise of Employer-Sponsored Health Insurance

Once the United States plunged into World War II, a hidden enemy was inflation resulting from the overheated economy of total mobilization. The Congress quickly passed wage and price controls, inadvertently hampering the recruitment of workers from the farms to the war economy. Moving literally millions of rural workers to the large cities required incentives, and since higher wages were not permitted, offering complete health care was an acceptable alternative. Emerging from the Great Depression, these workers who flocked to the shipyards, munitions plants, and aircraft factories liked the security that employer-paid health care gave them. After the war the labor unions made it a centerpiece in their collective bargaining, and employers found the tax and other advantages preferable to granting higher wages. By 1950 employer-paid health care was a part of the fabric of our society, and the third-party payor was here to stay.

E. Outmoded Public Policy and Psychotherapy

While access to medicine and surgery was changing rapidly, making physical health care available to most

employed persons, mental health remained mired in an outmoded public policy that believed psychotherapy was not feasible under third-party payment. The development of the Blues had made available hospital care for acute mental conditions, but outpatient care continued to be excluded. For the most part mental conditions were treated in the ever-burgeoning state mental hospitals from which most persons who had been committed did not emerge.

In the meantime, the private practice of psychotherapy was growing rapidly as an out-of-pocket endeavor. The American public emerged from World War II with an insatiable interest in popularized psychotherapy, and especially psychoanalysis. New York, Boston, Chicago, San Francisco, and Los Angeles were the places where scores of psychoanalysts with heavy accents who had relocated from Europe flourished. In addition, doctoral-level psychologists who were trained under postwar government funding were flocking to private practice. This training in large measure was made possible by both V.A. stipends and National Institute of Mental Health (NIMH) training grants that graduated an increasing number of psychiatrists, psychologists, and social workers. NIMH also launched paraprofessional training, erroneously believing there would never be enough trained professionals to meet the post-World War II demand for psychotherapy. Universities took advantage of training grants and stipends and developed programs that included research in psychotherapy along with clinical training. Steadily the focus was shifted from psychoanalysis to brief psychotherapies because of a growing body of research that demonstrated the importance of behavioral and other treatment modalities. The usual arrangement for these newly trained psychologists was to affiliate with a practicing psychiatrist, add psychological testing to the services offered, and assume the psychiatrist's overload of patients. Fees were generally 10 or 15 dollars a session, and there were far more patients than there were practitioners. Eventually this had to change, and it was generally recognized that the private practice of psychotherapy would be severely limited without its inclusion in prepaid health care.

The first comprehensive prepaid psychotherapy benefit was written at the Kaiser Health System. Having discovered in the 1950s that 60% of all physician visits were by patients who either had no physical condition but were somatizing stress, or who had a physical condition exacerbated by stress or emotional factors, the physicians at Kaiser instituted a psychotherapy system in-house to which they could refer. Research on these somatizing patients revealed what has been termed the

medical cost offset phenomenon: The provision of psychological interventions interrupts the somatization cycle and reduces medical care by 65%, with a significant net saving over the cost of providing the psychotherapy. These experiments led the Kaiser system to make the courtesy physician referral-only psychotherapy a covered benefit available to all Kaiser enrollees. By the late 1960s the federal government sponsored a number of replications of the Kaiser studies, all of which led to the general acceptance that psychotherapy is feasible under third-party payment. In the passage of the HMO Enabling Act (1974) there were mandated 20 sessions of psychotherapy for federally chartered HMOs, and most private health policies had included a psychotherapy benefit. Private health plans emulated the 20-session benefit, renewable every year, while others went as high as a 50-session annual benefit. The outmoded policy had been changed, brought about by the public clamor for psychotherapy, coupled with the medical cost offset findings that such coverage was economically possible.

II. TOOLS AND PRINCIPLES FOR DECISION MAKING IN HEALTH ECONOMICS

Expenditures for health care services have risen more rapidly than expenditures on most other goods and services in our economy. In 1965 health care accounted for only \$35.6 billion, or 5% of the gross national product (GNP), which rose by 2000 to over \$1 trillion, or 12% of the GNP. Part of the increase is the result of increases in the population receiving such services, but much of it is the result of price increases for health care. The rapid and continuing increase in the amount of the nation's resources being devoted to health care raises important policy questions, especially since the government now pays over 40% of the total health care expenditure. Are these increases justified? Should the government continue spending so much on health care when there are competing needs in education, social security, and defense? If the resources were allocated differently, could a greater amount of health services be provided? These are the kinds of questions that are the subject matter of health economics.

A. Health Economic Tools

Health economics utilizes two basic tools, along with a set of criteria, for analyzing efficiency and distribu-

tion. The first tool is the use of the techniques of optimization, which seek to maximize efficiency and minimize costs in the allocation of scarce resources. Economists prefer to use the word allocation rather than rationing for obvious reasons, but the fact remains that in every society today there is a scarcity of health care resources, making rationing ubiquitous. Some economists argue that use of the term rationing would require public policy to come to grips with the realities, as has the state of Oregon. In a uniquely direct method the state listed all of the health conditions in terms of priority, from the most important (life threatening) to the least, and assigned a cost and frequency to each. In going down the list, when the cumulative costs exceeded the dollars available, the state drew a line and everything thereafter was not covered by Medicaid. Thus stroke is very high on the list, whereas anencephaly (a condition in which a child is born without a brain) is not covered. Most mental health services did not fare well beyond those needed for acute psychosis, and psychotherapy was all but eliminated. This is a very dramatic application of optimization in response to scarcity and costs, and no other government in the world has had the determination to so squarely face the issue. Economists continue to use the word allocation, with some going so far as to name as "silent rationing" such common health care optimizations as the criteria for medical necessity, waiting lists, benefit exclusions, deductibles, limitations, precertification, utilization review, provider profiling, and many other devices. In fact, managed care itself is regarded by many as a more humane form of rationing than the long waiting list for services common in the Canadian plan.

The second economic tool is the determination of equilibrium situations by which economics can predict such things as the final result in the demand for services. This is not easy to do, and health economics is replete with errors. For example, for years it was axiomatic that adding a new health profession creates new demand and increases costs. This was the argument used for many years to restrict mental health services to psychiatrists only, to the exclusion of psychologists and social workers. This axiom was true in indemnity insurance, but in HMO and other managed care settings, the appropriate replacement of physicians by nurse practitioners, orthopedic surgeons by podiatrists, ophthalmologists by optometrists, and psychiatrists by psychologists reduced costs, increased efficiency, and did not lower quality. Now, in the same vein, doctoral-level psychologists are being replaced in appropriate situations by practitioners with master's degrees.

Much of the effort in forecasting (i.e., equilibrium situations) has been the attempt to predict growth and costs in government entitlement programs, such as Medicaid and Medicare. Whether the application of the method has been less than precise, or whether politicians seek out economists who will say what the advocates want to hear, there has been a consistently large-scale underprediction of costs in every government health program. Macroanalysis, which relies on aggregate data most often derived from large-scale statistics gathered by various government agencies, is open to considerable interpretation, whereas microanalysis applied to smaller-scale outcomes research can be more precise.

B. Basic Health Care Decisions and the Criteria for Decision Making

Implicit in the use of the foregoing analytic tools is a set of criteria for evaluating the economic welfare of the patient. Health economics is driven by scarcity, so that basic choices must be made in output, production, and distribution, all toward achieving optimal health possible with limited resources.

1. Determining the Output of Health Services

The first set of health care decisions that must be made is the determination of the amount of money to be spent: How much should be allocated to, and what should be the composition of, health care services? Using a price system, what services and in what allocation would the health of the consumer be best served? For example, recently Medicare increased psychotherapy services in cases of bereavement and other conditions particularly affecting older adults, but curtailed as grossly ineffective the provision of psychotherapy to advanced Alzheimer's patients in nursing homes. Medicare has gone so far as to require the return of payments previously made for such services, resulting in millions of dollars in paybacks owed by a large number of psychotherapists.

2. Determining the Best Way to Produce Health Services

Health services can be provided (produced) in a variety of settings, from HMOs to solo practice, and in a number of financing strategies, from capitation to fee-for-service. Even within the same kind of setting there can be considerable disparity in efficiency and quality. Recently public policy has shifted toward the increasing use of HMOs and other managed care arrangements

by Medicare and Medicaid, with considerable cost savings to the government and advantages to the recipients, such as drug prescription coverage which did not exist in previous arrangements. However, a number of HMOs could not produce the required services with the capitation given them, one that resembled that of the general (employed) population rather than reflecting the higher costs for the care of the elderly or the indigent, and many have unilaterally pulled out of the program. The Health Care Financing Administration (HCFA) is in the process of adjusting the capitation rate to more realistic levels in an effort to halt the exodus of the HMOs from Medicare and Medicaid. From HCFA's point of view, these programs are a success because they have saved the government millions of dollars. On the other hand, patient satisfaction has been low. In the process of readjusting the rates, HCFA is seeking to learn from the handful of HMOs, such as Kaiser-Permanente, which consistently show strong patient satisfaction.

3. Determining the Distribution of Health Services

The third criterion is deciding on the distribution of health services. This may range from giving all persons all services, which is not possible in an environment of scarcity, or limiting services only to those who can pay, which is not in keeping with optimizing consumer health. Somewhere in between these two extremes is a wide range of options, and these run the gamut from NHI to medical savings accounts. A recent national debate has focused on the issue of *parity*, whether mental health expenditures should be equal to those for physical health. This concept, which has resulted in the enactment of a number of federal and state laws, will be more fully addressed in the discussion of supply and demand.

C. Values Inherent in Health Economics: Output versus Input

Health care can be viewed as an output of the health care industry, or it can be seen as an input to health. This is an important distinction that will determine much of public policy, but the resulting debate with its questioning of theoretical assumptions often stems from the fact that these two views are not mutually exclusive. The first of these sees health care as the output produced by physicians, hospitals, and all other providers in the industry. It is therefore important to measure how efficient is the output, and to determine

the combination of resources that will result in the best trade-off between cost and quality.

An alternative does not view health care as a final output, but as one input among many others that contribute to a final outcome termed “good health.” In this view improvements in health can be the result not only of treatment services, but also prevention programs such as health education, lifestyle change, pollution reduction, and even research and improved training of providers. There is no doubt that the good health that has resulted in the tremendous increase in longevity in the last hundred years is not only the consequence of improved medical care, but also the result of such factors as a safe food and water supply and inoculations. At the present time most poor health and disability results from lifestyles reflecting stress, poor eating habits, lack of exercise, alcohol and drug abuse, tobacco use, and automobile accidents.

The problem for the decision makers in allocating scarce resources is the difficulty in measuring cost efficiencies when expenditures are increased in an area that may or may not prove preventative. For example, money spent in health education to improve lifestyles may not appear as a saving in reduced cardiac and cancer diagnosis and treatment for years or even decades. Likewise, behavioral health programs to reduce stress require allocation of limited money now, whereas the benefit to the system in medical savings may be in the distant future.

In the present era of cost containment, with its fierce competition in managed behavioral care, the emphasis is on output rather than input. Managed behavioral care companies (MBCOs) are operating at a loss or, at best, on thin margins. It is likely there will be continued effort to reduce costs by limiting access and by reducing production costs (i.e., an ever-decreasing fee paid to providers). In a well-planned system, however, input must be balanced with output, otherwise the deficiencies of the present will be perpetuated. This is why in behavioral care the medical cost offset phenomenon, to be discussed later, is so important, as it demonstrates how output can be affected almost immediately by input.

D. The Complexity of the Health Care Market

Rather than being a single market, the health care sector is a complex of a number of interrelated, and often competing markets. The definitions of producer and consumer are not as simple as they are in the usual

economic sequence, for producers are also consumers, and vice versa. Let us take the situation found in managed care as an example. A managed care company (MCO) is at once a producer of services to its covered population, and a purchaser (consumer) of services from PPOs, hospitals, and other providers. There is, therefore, a series of health services consumers, with the patient ultimately designated the *end consumer*.

The MBCO that consumes hospital services is in competition with the hospital with which it contracts, inasmuch as the MBCO is in the business of diverting inpatient (hospital) care to outpatient care because it is more cost-effective. Nurse practitioners, as less expensive providers, replace primary care physicians (PCPs) where feasible and, in turn, many PCPs do the work of specialists. Each of these is a market, and each is competing for a market share in an environment of scarcity. Competing markets are throughout health care: orthopedic surgery versus podiatry, ophthalmology versus optometry, nurse practitioners versus physician assistants, and psychiatry versus psychology (and now psychology versus social work and other master's level practitioners). Some of these markets at times seem to resemble open warfare toward each other. But the economic trend is unmistakable: The health care sector is pushing knowledge downward, using wherever appropriate less expensive providers to do the routine diagnosis and treatment, while using the highly trained providers for the extraordinary diagnosis and treatment. This is accomplished by upgrading the less trained practitioners to recognize the limits of their training and to know when to refer upward.

There can be identified within the health care sector of our economy the education market, the research market, and the prevention market, all competing for a share of the limited dollars. The expectation that nonprofit entities will cost less than their for-profit counterparts does not hold, as many nonprofit hospitals and other providers have a different agenda than efficiency of production, and ultimately cost much more. In fact, the last decade has demonstrated that nonprofit hospitals, accustomed to the traditional Medicare and Medicaid cost-plus-two-percent reimbursement, went bankrupt when they lost this subsidy and had to compete on the open market. This is why the nonprofit hospital has all but disappeared, having been sold to its for-profit counterpart.

In recent years the pharmaceutical market, not thought by many as part of the health care sector, has emerged as a significant cost center. Newer drugs, especially in the psychiatric area, are remarkably effective

with few if any tardive side effects, but they carry a high price tag. Again it is difficult to assess immediately the eventual cost of these newer medications when weighed against potential savings in lengths-of-stay in psychiatric hospitals or duration of outpatient psychotherapy. Managed care for drug costs have emerged, with volume buying for HMOs and mail-order purchases for individuals becoming the trend.

Health economists have pointed out that the efficiency of the separate markets and their interrelationship affects the efficiency with which health care is produced, the cost at which it is produced, and the growth of expenditures. The continuing evaluation of each of these markets, therefore, is of significant concern for public policy.

III. SUPPLY AND DEMAND IN AN INDUSTRIALIZED HEALTH CARE ENVIRONMENT

Some economists would base demand solely on the need for health care, assuming that utilization of physician and hospital services reflects only the care that is actually needed. However, a number of factors determine demand, or even perceived need, and experience has shown that planning based solely on health care need is likely to result in either too few or too many resources.

A. Errors in Demand Based on Perceived Need

An example of the inaccuracy of using only need-based planning is the Hill-Burton federal legislation initiated in the late 1940s. The economists advising the Congress at that time estimated the need to be 4.5 hospital beds per one thousand population as the standard, with 5.5 beds per one thousand for rural populations where distance from home would be a factor. Federal funds were made available for building new hospitals and expanding older ones with the intent of achieving this standard thought to reflect actual need. The results were unfortunate, as this legislation inadvertently fueled a noncompetitive health economy. The hospital beds created far exceeded need, but since hospitalization is an expensive and often a lucrative procedure, the hospital industry saw to it that the beds were all utilized. The slogan of the time became, "A built bed is a filled bed," and the nation experienced its first government-induced inflationary health spiral. It was not

until the Health Reform Act of 1986, which eliminated guaranteed cost-plus reimbursement for hospitals and the DRGs that accompanied that legislation that the truth of the matter came to light: We had created literally twice as many beds as were needed. Not only that, hospitals had been routinely running up expenses since their margin was a percentage of costs: The higher the costs the greater the margin. The incentives were all in the wrong direction, a situation that is not an uncommon characteristic of well-meaning public policy.

The Hill-Burton legislation increased physician costs as well as hospital costs, although to a lesser degree. Physicians were offered various incentives by hospitals to help them fill the surplus of beds, the most frequent of which was the opportunity to have a hospital-based practice. As this was more lucrative than a solely ambulatory practice, many physicians seized the opportunity, thereby increasing overall physician costs.

During his administration President Lyndon Johnson sought to increase the number of dialysis machines in hospitals. The National Academy of Sciences, which lacks expertise in practice matters, was asked to estimate the need. Their recommendation was put into effect, and at the expense of the taxpayer, there was such duplication of available kidney dialysis machines that many were idle most of the time. But the cost of kidney dialysis did not come down, as the per-unit cost was increased to pay for the idle time.

In defense of health economists, perceived need is often different than actual need, or a perceived need may be correct but public policy creates incentives in the wrong direction. In behavioral care this became apparent shortly after the Congress enacted DRGs in medicine and surgery, leaving psychiatry without these restrictions. Almost overnight medical and surgical beds were emptied all over America. A number of hospitals, used to cost-plus reimbursement with no restrictions, went bankrupt before some astute hospital administrators saw an opportunity in the absence of DRGs in psychiatry. Empty hospital beds, as many as 50% in some general hospitals, were quickly converted to psychiatry and substance abuse treatment. These were huckstered on television, educating the public that the hospital was the appropriate place for a wide range of life's problems, and especially the usual difficulties of adolescence. Mental health/chemical dependency (MH/CD) hospitalization costs soared. Government was helpless in curbing the new inflationary spiral in MH/CD, which was now driving up overall health costs after medical/surgery costs had been tethered. Public policy shifted toward allowing the private sector to bring MH/CD costs

in line. Restrictions on the corporate practice of medicine and other laws and regulations were rendered moot, and the managed behavioral health care industry was launched in the mid- to late 1980s.

The spillover to outpatient psychotherapy, particularly in after-discharge counseling and treatment, created a new industry for psychologists who heretofore practiced on an outpatient basis. Going to the hospital to prepare a number of patients for ambulatory care often required only an hour, while billing reflected individual therapy sessions with each of a number of patients. Surveys began to reveal for the first time the existence of substantial six figure annual incomes for some privately practicing psychologists. A behavioral health boom clearly had been created, which rendered behavioral care less likely to foresee the shift in public policy that would bring severe restrictions on outpatient psychotherapy, along with those for hospitalization, by the new MBCOs.

B. The Nullification of the Supply and Demand Relationship

It has long been recognized that the “laws” of supply and demand have not operated in the health care sector as they do in the general economy. This is because the physicians (and therefore the hospitals and other providers) have traditionally controlled both the supply and demand sides of health care. It is the doctor who determines what treatment the patient needs, what procedures should be rendered, and how long the treatment should last.

On the *supply side* the government subsidized the education and training of health care practitioners not only to relieve the critical shortage of a few decades ago, but also to create a surplus of providers. It was widely believed that once there was an ample supply of doctors, costs would go down. This is true in every other industry; a glut of workers results in cheaper wages. As the number of physicians increased beyond the number needed, costs went up instead of down. And the greater the glut, the greater the costs. Physicians, being in control of both supply and demand, merely rendered more treatment, and particularly more procedures, to a declining number of available patients. In practice-building seminars physicians were taught that it is not the number of patient visits, but the number of costly procedures that these visits generate, that enhance physician incomes.

In health economics such practices are termed *demand creation*, which nullify the effects of oversupply

(i.e., too many physicians). Of all of the health professionals, behavioral care specialists (including psychiatrists, psychologists, social workers, marriage and family counselors, master's level psychologists, and substance abuse counselors) are in the greatest oversupply. It would be expected, therefore, that demand creation would be a prevalent practice among psychotherapists and others who treat behavioral disorders. Examples abound, but some of the most widely recognized include the following, although most of these have been curtailed in the new health care environment (see Section IV).

The most obvious example of demand creation is to place the declining numbers of patients available to each practitioner in increasingly longer psychotherapy. One patient seen for 3 years is equivalent to three patients seen for 1 year each. MBCOs have eliminated this practice for all but the relatively few patients willing to pay out-of-pocket.

When the American Psychiatric Association, which publishes the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), changed the definitions in DSM IV of attention deficit disorder (ADD) and attention deficit hyperactivity disorder (ADHD), it quadrupled the number of patients, especially children and adolescents, who would be eligible for treatment. The widespread medication of children and adolescents with psychotropic/stimulant drugs now includes increasing numbers of preschool children, prompting two White House Conferences on the subject in the year 2000.

Another form of demand creation is to create a syndrome for which the psychotherapist already has a treatment. Until recently multiple personality disorder (MPD) seemed to be increasing exponentially. Investigations by payors revealed that the number of patients ostensibly suffering from MPD was directly related to the number of therapists specializing in the therapy of MPD. Patients who had never shown a multiple personality in previous therapies suddenly developed the same when they began seeing a therapist who likes to treat MPD. Also, patients who changed therapists in the opposite direction (from one who specializes in MPD to one who does not) no longer complained of multiple personalities. The question is not whether MPD actually exists as a syndrome, but whether it exists in the sudden explosive numbers in which it was suddenly seen. It eventually became apparent that certain kinds of impressionable patients who want to please the therapist, and especially borderline patients, are highly suggestible and respond positively to all kinds of prodding, such as those designed to elicit the symptoms of MPD.

Another instance of demand creation, which disappeared as rapidly as it had emerged, was the so-called recovery of repressed memories of childhood sexual abuse, especially when it ostensibly involved incest. Many authorities believe the recovered memory was actually created by the hypnosis and other techniques designed to elicit it. During its heyday psychotherapists treating recovered memories proliferated and a significant number of accused persons (many of them the ostensible victims' fathers) went to prison, only to be subsequently found innocent on appeal, or to have their sentences commuted. Several psychotherapists have lost their licenses, and the courts have effectively put an end to the treatment of this syndrome.

The diagnostic criteria of depression are constantly shifting toward including more and more of what has previously been regarded as usual, normal mood swings experienced by all individuals as part of daily living. Undoubtedly much of clinical depression is missed by the physician, but some estimates that at any given time 40% of individuals seeing a physician may be suffering significant clinical depression requiring psychotherapy seems high to most observers. The movement to increase the awareness of depression has gained important advocacy from the wife of the Vice President of the United States, who herself suffered a depression when her daughter was killed in an automobile accident. It has yet to be determined how much may be an important unrecognized demand for which the health care system must develop means of identification, and how much might be demand creation being fostered by providers. In either case, depression that is real and undiagnosed will reveal itself in the health care system under a different guise that will, nonetheless, increase health care costs.

Economists would stress that even though the provider may be in a conflict of interest at times with efforts to control demand, few practitioners would cynically set out to inflate costs. Their avowed intent is that the patient should receive all necessary health services. Nonetheless, one authority has referred to a process of "unconscious fiscal convenience" in describing the conflict between providers and the health system.

C. Parity

There is a movement among providers and other advocates to equate physical and mental health in importance, and to devote equal resources to each. This call for parity has resulted in a number of federal and state laws mandating an equal allocation of resources, but none has resulted in any significant reallocation in favor of mental health. The federal law would exempt

any health plan for which compliance with parity would raise the premium by more than 3%, effectively rendering the law inconsequential. State laws, too, have not had a significant change in resource allocation.

If parity were a serious consideration, either the \$1 trillion annual health budget would have to be doubled, or the existing expenditure would have to reallocate half a trillion dollars each to physical and mental health. Both are seen by health economists as very unlikely events even though legislatively the concept of parity is gaining momentum.

One of the problems is that whereas medicine and surgery are more or less measurable, mental health can encompass an ill-defined range from the vicissitudes of daily living to mute psychosis. Of what is termed "mental health" treatment in the United States, 85% is reportedly provided by primary care physicians. This includes the prescribing of psychotropic drugs and the dispensing of advice and reassurance. How much of this primary care should be credited to the mental health side of parity? Until these problems are resolved, the implementation of parity will be elusive.

D. Mutually Misperceived Demand: The Importance of Medical Cost Offset

In the mid-1950s the Kaiser-Permanente Health System in Northern California discovered that 60% of its patient visits to a physician were by patients who had no physical disease, or whose physical problem was not of sufficient severity to warrant the magnitude of patient debility or discomfort. In that era the relationship of stress to physical symptoms was not readily understood. Today we regard these patients as somatizing: the translation of emotional problems (including stress) into physical symptoms. The 60% of patients' visits to physicians were by persons who were manifesting the physical concomitants of stress, or whose stress was complicating and exacerbating an existing physical illness. This finding was verified in 1967 by testimony to Congress from the American Medical Association that set the figure at 65% to 70%. The reason this phenomenon was discovered at Kaiser-Permanente is because that early HMO did not require that a diagnosis be rendered in order for the physician to be reimbursed. The Kaiser physicians were on salary, while in indemnity insurance the physician must submit a reimbursement form that bears a diagnosis. If one is not established, the physician provides a provisional diagnosis, while in the Kaiser system no diagnosis had to be submitted when

there was none. Thus, after repeated visits yielding negative findings in spite of extensive investigation (laboratory procedures, x-rays, MRIs, and other tests repeated several times), the physician could enter in the patient's chart the finding of "no significant abnormality." The patient then characteristically seeks out another physician and repeats the cycle.

This is both a patient and provider misperception. The patient is convinced a physical disease exists and will eventually be found. With the repetition of tests the patient, rather than being reassured, is increasingly convinced that the next round of examinations will reveal the disease. This is in keeping with what would be expected under psychological reinforcement theory. The physician, who is trained to pursue physical illness until it is found, becomes an inadvertent accomplice in the somatization cycle.

Initial research at Kaiser-Permanente found that brief psychotherapy (5 to 8 sessions) reduced medical utilization by 65%, and that the patient did not resume somatizing. The National Institute of Mental Health (NIMH) has sponsored dozens of replications of this research and has found medical cost offset, more than sufficient to cover the cost of the psychotherapy, present in a variety of settings. However, the more organized the delivery system, and the more primary care and behavioral health are integrated, the greater the medical cost offset. Why, then, after 40 years of research is there not a greater implementation of psychological interventions with the somatizer?

The answer lies in the inelastic barriers found in the health care system. In most health plans data are not obtained in a way that can connect the necessary cause and effect (i.e., tracing back medical visits for those who received psychotherapy). Furthermore, most behavioral care currently is being provided by carve-outs, separate companies that do not connect at all with the computers gathering data on medical and surgical visits.

For this and other reasons, the policy makers at NIMH and the Substance Abuse and Mental Health Services Administration (SAMHSA) are actively encouraging through research and demonstration projects the integration of behavioral health within primary care, and the inclusion of medical cost offset as an economic tool.

IV. THE NEW COMPETITIVE ENVIRONMENT: WINNERS AND LOSERS

The delivery of health care services in the United States changed dramatically in the 1980s. Public policy

in the 1970s favored increased regulation, with a trend toward rate regulation of hospitals, and even the serious consideration of giving hospitals public utility status. The advocacy for national health insurance (NHI) had gained more momentum than at any time in the history of health care. Senator Edward Kennedy was chairing the U.S. Senate Subcommittee on Health that was holding highly visible hearings on a developing plan for single payor, government-sponsored universal health care termed NHI. Then suddenly the political climate did an about face, but not because of any change in the Democrats' control of the Congress. Rather, the shift was the result of an economic crisis discussed below. Senator Russell Long, chairman of the U.S. Senate Finance Committee and a fellow Democrat, replaced Senator Kennedy with Senator Herman Talmadge, a foe of NHI.

A. Why NHI Failed: The Economist's View

NHI would constitute a wide-scale, comprehensive redistribution of health care services. Because there would be no aspect of the health care sector that would not be significantly affected, its potential implementation galvanizes every stakeholder to adopt a strong pro or con position. The AMA opposed it because in the 1970s physicians held virtual monopoly status. The private health insurance industry opposed it because it was burgeoning, and it wanted no increase in a federal health bureaucracy that might impede its growth. The welfare sector favored it because it would bring universal health care to every citizen, and would guarantee the continuation of a welfare system that was already under fire and threatened with cutbacks.

Most health economists opposed NHI because the very nature in which it was proposed would ensure it would go the way of Medicare, Medicaid, and other federal health programs that from their inception were designed to be inefficient. All proposed NHI plans had the incentives in the wrong direction, encouraging higher costs, waste, and even fraud. The American public seemed to agree with the warnings of most health economists since they were seeing firsthand the inefficiencies of such government services as the post office, and hearing daily in the media how the welfare system, Medicare, and Medicaid were out of control financially. The ultimate reason was the fact that the inflationary spiral in health care was considerably higher than that of the general economy, and most authorities pointed to the federal government as the culprit causing the almost out-of-control costs increases. For these

reasons President Nixon's efforts to expand the private health sector through such initiatives as the HMO Enabling Act (1974) were enacted by Congress, while President Carter's request that the Congress enact strong government restrictions on hospitals as a way of reigning-in costs was rejected. In both cases there was clearly a bipartisan public policy in favor of private initiatives rather than government interference.

Rising inflation in the 1960s stimulated the demand for private health insurance. With inflation employees moved into higher tax brackets, and the unions began to bargain for larger health benefits as these were not taxable. The inflationary economy enabled business to pass on increased health costs to consumers. In the meantime, with sharply increased health benefits employees ceased to worry about health costs and the interest in NHI all but disappeared. During this time, however, private health insurance increased 10-fold from \$31 billion annually in 1965 to \$370 billion in 1990.

It should be noted that NHI surfaced again as a serious, but aborted consideration in the first term of the Clinton Administration. The First Lady led the widely publicized Rodham-Clinton Task Force, chaired by Ira Magaziner. It was hampered because it operated in secrecy and no one was certain what the objectives were. There was more than one published version, and a complete list of the five-hundred-plus task force members was published much later and only in response to a court subpoena. Violation of the "sunshine laws" provoked a number of lawsuits, and several of the prominent health economists who had been invited to participate eventually defected. When the courts forced a publication of the members of the Task Force, it was discovered that most were government employees. Unlike the movement for NHI during the 1970s, this most recent plan was short-lived.

B. Other Factors Encouraging a Competitive Health Care Market

From an economist's standpoint, the massive increases in medical expenditures by both the public and private sectors were equivalent to a huge redistribution of wealth, from the taxpayer to the health sector. The forces pushing events in that direction were all but out of control, and in such instances an economy will inevitably seek to tether them. The trend, as it continued to evolve, was clearly in the direction of market competition rather than government regulation.

The supply of physicians had been increasing steadily for two decades, especially since the enactment in 1963

of the Health Professions Educational Assistance Act (HPEA). New medical schools were built and existing ones were significantly expanded. This did not have an immediate effect on costs, for the virtual monopoly status of medicine continued until other factors curtailed its influence. Once this happened, the effect of supply (increased number of physicians) on demand (lower costs) became apparent.

The HMO Act of 1974 has already been discussed as a precursor to the emergence of a competitive market. At the time the Kaiser-Permanente Health system, almost alone among HMOs, was the prototype used to draft the legislation. Edgar Kaiser, the son of the late Henry J. Kaiser, decided that the Kaiser Health plan would give away the technology in the interest of creating as many HMOs as the economy would need. Kaiser physicians were assigned to mentor the fledgling HMOs, and the HMO industry was launched.

HMO hospitals were needed to service the new HMOs, and in 1979 the Congress amended the laws that were inhibiting the building of new hospitals. The existing hospitals opposed the new legislation as it would threaten their revenue. On the other hand, the HMOs needed hospitals that would operate on the new capitated health economy.

Two provisions of the HMO Act deserve mention, as these further enhanced the market effects intended in the creation of the HMOs. The first required all employers to offer as a choice to their employees at least one federally chartered HMO plan. Secondly, these HMOs were exempt from restrictive state practices. Without these two provisions the fledgling HMOs would undoubtedly have been stifled.

The elimination of "free choice" of provider in Medicaid in 1981 opened the door for the states to put their Medicaid services out to bid. Under the guise of patient sovereignty (i.e., freedom to choose a provider), the AMA bitterly opposed this legislation initiated by the Reagan administration as it threatened the core of medicine's monopoly status.

Again during the Reagan administration, in 1983 a new method of paying hospitals for Medicare was introduced. Called DRGs (diagnosis related groups, previously discussed), this had a profound effect on lengths of stay in hospitals. By the time this legislation was enacted, market competition had already advanced in the private sector, and the two initiatives (public and private) ended forever the hospital as a source of runaway health costs.

The introduction of lower-cost health care substitutes by employers enhanced market initiatives. For

the first time outpatient surgery, outpatient detoxification, partial hospitalization, and a number of other alternatives to costly hospitalization became part of the benefit package. Manufacturing had become increasingly concerned with how many dollars health insurance was adding to each unit of production. This was of particular concern to the automotive industry that had become engaged in fierce competition with Japanese car manufacturers. The addition on the average of \$800 in health insurance premiums to the cost of every automobile placed American carmakers at a disadvantage. This was only the first of a number of steps taken by American business, not the least of which was the formation around the country of “business groups on health” that educated business leaders and pressured the health care sector for financial accountability.

A necessary step to foster competition was the enforcement of antitrust laws for the first time in the health sector. Professional societies and state practice acts inhibited market competition by limiting advertising, fee splitting, corporate practice, and the delegation of tasks. Providers could engage in boycotts, essentially ending competition where they chose. Up until 1975 when the Supreme Court ruled against the American Bar Association, it was generally believed that so-called “learned societies” (which included the health professions) were exempt from antitrust laws. Encouraged by this decision, the Federal Trade Commission (FTC) began that same year to enforce the antitrust laws in the health sector, and it charged the AMA with anticompetitive practices. The courts ruled against the AMA in 1978, and on appeal in 1982 the Supreme Court upheld the lower court decision. This completed a steadily growing public policy in favor of market competition in the health sector.

C. The Jackson Hole Group

During the 1970s and early 1980s a group of health economists concerned with the inflationary spiral in health care met regularly at Jackson Hole, Wyoming. They included such notables as Alain Enthoven (Stanford), Paul Ellwood (Minnesota), Stuart Altman (Brandeis), and Uwe Rinehardt (Princeton). Their influence was largely through their writings and lectures, particularly the widely read articles by Enthoven, and their message was clear: Health care needed market competition to tame the inflationary spiral. They also believed the time was right inasmuch as the Congress, the courts, the FTC, and the business community had paved the way over the past decade and a half. It was

Enthoven who gave their concept the name of managed competition.

The influence of the Jackson Hole Group on public policy was profound, although little known by the public at large. Enthoven had been a consultant to the Kaiser-Permanente Health System in its earlier years, and Ellwood was prominent in the HMO movement in Minnesota. California and Minnesota, until recently, were the states with the greatest HMO membership concentration.

The Jackson Hole Group in various ways continued as advisors to government as well as to the emerging managed care industry. What is generally forgotten is that in the Rodham-Clinton plan for government-sponsored universal health care, the concept of managed competition was the centerpiece. Several members of the Jackson Hole Group were members, initially, of the Rodham-Clinton Task Force. They became disenchanted and left the task force after seeing the plan's determination to include market competition alongside incompatible, severe government regulations.

D. The Present Competitive Market

Managed care companies began to emerge in rapid succession alongside HMOs in the early 1980s, gained rapid momentum by 1990, and by 2000 there were 175 million Americans receiving their health care through some kind of managed care. In a little over one decade the health sector had emerged from a series of cottage industries to full industrialization. Those stunned by this unprecedented growth have asked why health care had to industrialize in the first place. Economists would point out that is not the question. Any sector of the economy that accounts for 12% of the GNP must inevitably industrialize. The real question is why it took so long, when manufacturing industrialized in the early 1900s, retail in the 1950s, and transportation in the early 1960s.

E. The Industrialization of Behavioral Care

Industrialization occurs when an economic endeavor emerges from individual, family, or small group proprietorship with limited production (known as cottage industries) to large-scale production employing large work forces and utilizing innovations in technology, organization, and consolidation resulting in increases in both productivity and its resulting lower cost to consumers. Examples of industrialization are

manufacturing (1900s), mining (1930s), transportation (1950s), and retailing (1970s). The industrialization of the automobile is illustrative. Previously hand-built in “garages” at high cost and low productivity, Henry Ford’s introduction of the assembly line resulted in the manufacture of the automobile within the affordability of most Americans. However, industrialization results in a shift of control of the product from the worker (or craftsman) to a capitalistic structure, often resulting in labor strife. When health care was the last major economic sector (14% of the GNP) to industrialize from solo practice and individual hospitals to HMOs, PPOs, and hospital chains, labor strife was revealed in the large-scale dissatisfaction on the part of providers who seemingly lost control of the dispensing of health care.

Of particular significance to psychotherapists is the industrialization of behavioral care, which occurred separately, but in parallel to the industrialization of medicine and surgery. This resulted in the carve-out, discussed earlier, and the reason for that separate entity. DRGs had tethered medical and surgical costs so drastically that hospitals experienced as much as 50% bed vacancies. They converted these to adult and adolescent psychiatric hospitalization and the seemingly ubiquitous 28-day substance abuse hospitalization. Behavioral care costs soared, and at a time DRGs reduced medicine and surgery to an 8% annual inflation rate, behavioral care was driving the entire health spiral upward with its own annual inflationary rate of 16%. With the absence of DRGs in MH/CD, third-party payors felt helpless in the face of this inflationary spiral and began dropping the MH/CD benefit. In time the MH/CD benefit might well have disappeared were it not for the emergence of carve-out managed behavioral care, which offered to increase benefits, lower costs, and cap the benefit package for 3 to 4 years.

During the rapid growth of the managed care industry in general, managed behavioral care also grew phenomenally from zero in the mid-1980s to 75% of the insured market by 2000. This was also the era of the mega-merger in American business, and the health care industry became part of what economists have termed “merger mania.” At one point in time there were literally hundreds of small MBCOs. By 2000 mergers and acquisitions had greatly reduced their number. One MBCO (Magellan) achieved a 40% market share, and when added to Value/Options and United, the top three companies accounted for 60% of market share. Even more startling is the fact that the top 10 companies account for 95% of the managed behavioral care market.

F. Who Are the Economic Winners?

Those who pay the bills for health care are the undisputed winners. This includes employers, insurers, the federal government (which is the largest purchaser of health care in the world), state governments, and ultimately the taxpayer. In 1996 both health care and behavioral care had been reduced to an acceptable annual inflation rate of 4%, the lowest it had been since 1960. Unable to design and implement DRGs for MH/CD, the government had left the problem to the private sector. It paved the way by removing outdated laws and regulations, and then stood back while the MH/CD inflationary rate was tethered by the competitive market and without government interference.

The health care system is also a prime winner, because industrialization saved the health care economy from the bankruptcy predicted by many health economists. It also preserved the MH/CD benefit when otherwise it would probably have disappeared by 1990. When revenues in medicine and surgery dropped precipitously with DRGs, hospitals substituted significant increases in MH/CD services in an effort to recapture income and avoid losses. There resulted a brief spike in the inflation rate of MH/CD to an annualized 16%, prompting a trend by insurers to drop the MH/CD benefit. This was quickly interrupted when the behavioral care carve-outs demonstrated they could go at-risk for these services, relieving the insurers from what they feared would be out of control psychological/psychiatric costs.

G. Who Are the Economic Losers?

The psychiatric hospital, which in 1985 was regarded on Wall Street as a growth industry, is undoubtedly the major loser in the new health care economy. In the mid-1980s it was experiencing a financial boom when psychiatric hospitalization increased markedly. The boom was short-lived because the MBCOs directed their immediate attention to the runaway psychiatric hospitalization rate. Draconian measures quickly brought the rate down by as much as 85 to 90%. The attempt to make up the loss of medical/surgical income through the conversion of empty beds to behavioral care, as much as 50% in a few hospitals but generally about 25%, quickly vanished. For several years thereafter hospitals, and especially psychiatric hospitals, remained in financial difficulty. Some hospitals had to close their doors, but most sought relief through consolidation and mergers with

for-profit hospital chains. This strategy was successful, in that by 1998 the hospitals were less subject to extreme price pressures previously exerted by the managed care companies. Also, by that time they had learned to be competitive.

The impact on the independent solo practice of psychotherapy took somewhat longer to be apparent, but it was no less devastating. The psychotherapist had ample time to heed the warnings, but psychology and social work practices were experiencing their greatest boom and economic hard times just ahead seemed unlikely. Psychiatry had just remedicalized, placing emphasis on biological treatments, which enabled psychologists and social workers to proffer themselves the preeminent psychotherapists. By 1997, however, the private practitioner of psychotherapy was well aware of the tenuous nature of practice following the implementation of stringent measures to tether outpatient psychotherapy costs. These included a series of reduced negotiated fees, utilization review, case management, precertification, treatment plans, and provider profiling. Therapist accountability was introduced into the system, which spurred psychology to significantly increase the empirical study in effective psychotherapies. The MBCOs had the capacity, but little inclination to initiate outcomes research. They left it to federal agencies, predominantly NIMH and SAMHSA, to fund such research that ultimately demystified psychotherapy for the buyers and to some extent the consumers. Henceforth payors, having a greater understanding of the treatment process, did not hesitate to disagree with the unsubstantiated recommendations of the provider. Furthermore, network panels were filled to capacity and were closed. By 2000 nearly 40% of those who had been in the private solo practice of psychotherapy had changed occupations because they could no longer earn their livelihoods in their chosen career.

H. A Critical Retrospective: What Went Right?

The tethering of health care inflation is undoubtedly managed care's greatest accomplishment. Managed care demonstrated that there could be unprecedented cost containment by merely introducing management into a previously undisciplined practitioner cottage industry. That there were also untoward side effects to such an industrialization will be discussed below.

The growth of managed behavioral care to the point it encompassed 75% of the insured market by 2000, in just a little over a decade, reveals an unprecedented

economic need. The managed behavioral care industry accomplished in 10 years what the auto industry required 50 years to accomplish, and the airline industry 30 years.

Accountability was introduced into psychotherapy for the first time, and the era of data-based treatment has just begun. The mechanisms for evidence-based treatment are in place, and soon there will emerge standardized treatment protocols and eventually even practice guidelines. In the meantime, psychotherapists must justify and document treatment plans and outcomes, and goal-oriented therapy has become standard.

There is for the first time a potential for a real continuum of care. It is a little recognized fact that managed behavioral care has resulted in the expansion of services as well as an appropriate substitution of services. Not only have both the numbers of persons seeking services and the number of practitioners providing services increased, but psychiatric hospitalization and private practice psychotherapy have both declined in favor of a continuum of care with expanded services. These have included increases in psychiatric rehabilitation, day treatment, consumer-run peer support, residential treatment, and crisis intervention. Since these services are cost effective when compared to full psychiatric hospitalization or long-term psychotherapy, this expansion of services has resulted in less money expended for behavioral care in 1998 than in 1988, a fact that many authorities find disturbing. Although solo practitioners of psychotherapy may experience the decline in demand for their services as painful, economists see the expansion of care into a continuum as desirable.

In contrast to the previous system, managed care has provided for the first time a nationally organized system of care. This could become the vehicle for the coordination of care on a national scale, something never before possible. So far, however, the industry has demonstrated only lip service, with no notable efforts toward coordinating such care.

The industry has made rapid strides toward self-regulation, with the National Council for Quality Assurance (NCQA) and the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) taking the lead. Voluntary regulation undoubtedly will make unnecessary some government regulation, but it will not be sufficient to deter all statutory regulation. No industry goes from zero to 75% of the market without incurring outside regulation.

Value, defined as price plus quality, has been difficult to address in health care, and particularly in behavioral care. The American people have come to believe that

more is better, permitting the system to provide too much hospitalization, too many prescriptions, unneeded surgeries, and millions of unnecessary procedures because the patient so demands, it benefits the practitioner, or it quells the fear of malpractice in a litigious world. These do not add up to value. Now that health care is organized and competitive, the buyer for the first time has the opportunity to address value pricing and the clout to defend it in the legislature, the courts, and the marketplace.

I. A Critical Retrospective: What Went Wrong?

The loss of clinical focus resulted in managing costs, not care. Managed behavioral care began as a system that managed care through efficient and effective psychotherapy and thereby contained costs through improved care. In such a clinical system the practitioners were highly trained in both short-term and long-term therapy, with the skill to know when the patient needs one or the other. Once practitioners lost their initial leadership in managed behavioral health care, it was inevitable that the baton would pass to business interests. It is not expected that business interests would appreciate and comprehend the clinical process, but it does not follow that they should be rejecting of it. Perhaps because of fierce hostility from the practitioner community, perhaps out of sheer expediency, or probably a combination of both, the industry disregarded the available techniques that contained costs through clinical effectiveness and relied instead on the familiar “bean counters,” as insurance actuaries and financial managers are known.

As competition mounted, the managed behavioral care companies gave in to pricing pressure. The companies began underbidding each other until the inevitable happened: More and more contracts were signed that were below cost, with no hope of delivering a quality service as agreed. Insurers, employers, and government, elated that inflation was curbed, joined in the frenzy to ratchet down prices even more, while the MBCOs took the public criticism for their poor access and unreasonable denials. The buyers escaped without blame for their part in the price squeeze.

Just as hospitals and practitioners began accommodating lower payments, price pressures on the MBCOs forced them to pass the losses by squeezing the providers. The timing could not have been more disastrous. Outraged providers joined with consumer groups and national anti-managed care coalitions were formed. With fees already at unprecedented lows, the practition-

ers seemingly felt they had little else to lose. The disgruntled bear was transformed into a ferocious grizzly.

Managed care lost the public relations battle. Patients are grateful and loyal to their doctors, not to the health plan. In patient satisfaction surveys the health plan often gets the halo effect from satisfaction with the doctor who is part of that health plan. In surveys where the health plan and the physicians are clearly separated on the questionnaire, doctors are rated high while health plans are rated low. So when practitioners conveyed their rage at managed care to their patients, the latter became a potent, angry constituency that put pressure on employers, legislators, and insurers. A series of television exposés followed, as well as a number of successful movies that portrayed managed care as evil (e.g., *As Good As It Gets*, starring Jack Nicholson). The loss of the public relations battle has resulted in mounting pressures on the Congress and the state legislatures to increase the regulation of the managed behavioral care industry.

J. A Critical Retrospective: What Are the Surprises?

The failure to change practice patterns is surprising in view of the profound impact managed care has had on the health sector. All kinds of practitioner behaviors have been altered, but practice remains a fragmented system where collaboration is still essentially referral from primary care to specialty care and back again. As a nationally organized system it might be expected that managed care would seize the opportunity to make behavioral health part of primary care. A few HMOs are slowly moving in that direction, with most perpetuating a system wherein psychotherapy remains essentially specialty practice. There is one notable exception to the general lack of interest in the integration of behavioral health with primary care. The Kaiser-Permanente Health Plan, with its 4.4 million enrollees in Northern California, has announced its goal that behavioral health and primary care will be integrated into teams and co-location by 2002. In the meantime, lacking the inclusion of behavioral health within primary care, prescriptions for psychotropic drugs (especially SSRIs) have skyrocketed, neutralizing the cost savings derived by ostensibly having eliminated long-term therapy.

In every series of industrialization, the industry found itself initially at odds with its own workforce. Whether it was the automobile, shipping, transportation, or retail industries, their early history was fraught with militant union movements and paralyzing strikes.

As these industries matured, characteristically there was an accommodation between management and labor. Perpetual warfare with its own workforce, the provider in the case of health care, seems to be modulating in medicine and surgery, but increasing in managed behavioral care. This is unfortunate because through the therapeutic transference relationship the psychotherapist's stated hostility toward the managed care company can have a profound impact on the patient's perception of the care received. The MBCOs have to do much more to rectify the rift that exists between themselves and their own providers.

The most surprising glitch has been the extent of the merger mania that characterizes the managed behavioral care sector. In preceding instances of industrialization there has been a period of consolidation, where the successful companies swallow up the unsuccessful. As has been discussed earlier, three companies have a 60% market share and 10 companies have a 95% market share. The merger mania has far exceeded the need to consolidate, suggesting instead an economy of scale. The competition is too fierce to allow for monopoly control, but there is a monopsony that drastically limits the product(s) available to the buyer. This will be discussed in Section V.

V. ECONOMIC PRESSURES ON HEALTH CARE, PSYCHOTHERAPISTS, EDUCATORS, AND POLITICIANS

There are indications that the next several years will result in changes in the health care sector even more dramatic than those seen in the last decade. The pressures of change are already impinging on the behavioral health care system, the psychotherapist, the education establishment that trains behavioral care providers, and the politicians who have a constituency composed of a vast health industry on one side, and the consumers of behavioral care services on the other. Each of these will have its own set of problems as it makes its particular contributions to the future health care system.

A. Economic Pressures on the Behavioral Care Industry

Quality, access and the concept of good enough treatment are all issues challenging the behavioral care

carve-out industry at a time when financial margins are thin and their stocks are in disfavor on the NASDAQ. Pricing pressures have resulted in practices that health economists have termed "low-balling," purposely below cost just to get the market share, and having no intention of providing the contracted services. Similar to this is "bottom-feeding," the seeking out of contracts with entities that provide substandard services, or merging with competitors that are known to provide substandard services. Such practices will not only have a devastating effect on the financial bottom line, but also they make the delivery of a quality product improbable or impossible. Caught in an economic vise, the carve-outs resort to more stringent definitions of what is to be treated and what constitutes sufficient treatment. Inevitably this will lead to complaints of poor quality, denial of access, and a lack of adequate treatment.

It is costly when a patient reenters a managed care system because the previous treatment has been inadequate. Savings generated by shorter treatment than had been necessary are wiped out by relapse, and especially by relapse requiring more costly treatment (e.g., failed short-term psychotherapy that now requires hospitalization of the patient). The carve-out has the right to limit therapy to that which is necessary, the concept of good enough treatment, but the industry needs better measures of determining the economics of "good enough" that go beyond mere savings per initial episode. A unit cost of production extends far into the future before it can be declared that the unit has been successfully delivered, with the desired beneficial effect on health, and at the cost anticipated.

The industry is currently too competitive to be classed as a monopoly even though a few companies control the market. However, since they are all essentially providing products indistinguishable from one another, the buyer has limited choice. Such a state where product differentiation does not exist is known in economics as a monopsony, and was seen in the auto industry when only oversized, gas-guzzling V8s were available to the buyer until the Japanese invaded the American market with budget-sized cars. Those companies that apply sound economic policy to the determination of the good enough treatment will succeed in balancing cost, quality, and access and emerge with a truly differentiated product.

The decreased behavioral health costs reflect the success of the MBHOs in bringing about cost containment, but the dollars available to MH/CD keep shrinking and they may have passed the critical level

necessary to sustain the good health of the patient (consumer). A healthy outcome at the right cost is the ultimate measure employed by most economists. It is doubtful that substantially more resources can be allocated to behavioral care in response to cries for parity without significantly raising costs. The next wave in the economic evolution of health care must be the integration of behavioral health with primary care, the anticipated “carve-in,” which can give true parity (a seamless system between the physical and the psychological) while at the same time producing medical cost offset. Where all of the fat has been taken out of the behavioral care system, the medical/surgical system still suffers an overload of patients who are somatizing. The potential savings in the health system that can be realized by treating the somatizer in an integrated setting are impressive. Most medical cost-offset studies report savings of 5 to 15%. The problem is that the present carve-out arrangement cannot address meaningfully the somatizer. The medical/surgical sector “dumps” the psychologically troubled patient on the carve-out in order to save money, while the carve-out, in turn, does not care what the somatizing costs are as these are absorbed by the medical/surgical capitation, not its own. Consider an integrated system that adequately addresses the source of medical overutilization: A 7% savings in medical care would exceed the total dollars spent annually today on all mental health and chemical dependency treatment costs.

The carve-out pays lip service to the concept of integration, but it is one of the forces opposing change. It is an entrenched industry covering 175 million lives and it is loath to enter a market for which it has lagged in developing the necessary technology. It remains for one large system, such as the current retooling at Kaiser-Permanente in Northern California, to prove successful before integration becomes attractive. At such a time as the concept proves to be both financially and medically viable, large employers and perhaps even the federal government will demand it. At the present time selling integration to the current health industry is about as difficult as selling an electric car to an automotive industry and public committed to the internal combustion engine.

The year 2000 saw again the consistent figure of 25% of Americans who do not have health insurance or have it only intermittently. This group is bimodally distributed, reflecting two distinct groups. There are those who are above the poverty line and are not eligible for Medicaid, but cannot afford private health insurance. The second group is composed of young couples and

individuals in the 25 to 45 age range who have made a decision to rely on the good health associated with younger ages and use what would be health care premiums to grow their small business. Some in the second group have reached a compromise by setting aside in a savings account a portion of what health insurance would cost. It may be a matter for public policy to address the health care needs of the group that cannot afford health insurance. However, a challenge to the managed care industry is the design and implementation of a product that would be attractive to the entrepreneurial-minded small business owners in the second group, the owners of the so-called mom and pop store.

B. Economic Pressures on the Provider (Psychotherapist)

The rage experienced by providers is understandable, but it is time they acknowledged the enduring nature of the changes that have occurred in health care, abandoned their fierce opposition in favor of constructive engagement, and became part of the solution.

This does not mean that providers, having lost their virtual monopolistic status, must abandon their drive for regulation and legislation as a way of regaining that monopoly. But while they pursue redress and restoration of some of their former prerogatives the professions cannot afford to be outside the decision-making arena of the health system upon which they rely for their livelihoods.

Continuous quality improvement underlies much of what managed care is all about. This demands evidence-based, standardized treatments evolved through ongoing outcomes research. It is up to the providers to develop the database and the feedback loop to establish what now must intuitively be accepted as good enough treatment. When the appropriate database has been developed, resulting in protocols and treatment guidelines, the industry will be on firmer economic ground with expectations of good consumer health, reduced relapse rates, and value (cost plus quality). The challenge to the provider is to set aside animosities and join the health care arena in order to improve it.

The managed behavioral care industry will continue to rely on master's-level therapists for the majority of the treatment process, especially after more protocols and manuals are in place. To justify in the future the place of the doctoral-level psychologist, there will have to be a paradigm shift from the Ph.D. psychologist as a psychotherapist to a greatly expanded role. This will include such expertise as clinical supervision

of subdoctoral therapists, outcomes and quality improvement research, program planning, and the ability to understand business from the clinical side and contribute as a provider to important economic decisions. This necessitates an *overhaul of the curriculum* in the education and training of providers, which will be discussed below under challenges for education.

The next wave in the evolution of behavioral care will be its *integration with primary care*. Behavioral care providers will have to learn to function in a primary care setting where the emphasis is on the group management and treatment of chronic diseases. The behavioral care specialist will need considerable education in health psychology, and the training to function as part of a primary care team. This will require a substantial paradigm shift, and the current education and training curriculum will have to be overhauled accordingly.

It must be noted that the profession of psychology has dedicated its resources to obtaining prescription authority for licensed psychologists. This is fiercely opposed by the medical profession, and especially by psychiatry. Practicing psychologists are hoping that the ability to prescribe medications will save their solo practices by mitigating the effects of managed behavioral care. Most health economists believe such prescription authority for psychologists will occur because it is part of the general trend in the health economy to push knowledge downward. Thus, nurse practitioners are doing much of the work of primary care physicians (PCPs), while the PCPs are doing work that traditionally was part of specialty care. When and if such prescription authority is granted to licensed psychologists is not clear at this time. But even if it occurred tomorrow, it would not obviate the necessity of the paradigm shifts necessary for the Ph.D. psychologist to become a participant in the future health system.

C. The Economic Pressures on Education and Training of Behavioral Care Providers

One of the reasons why there have not been more capitation arrangements with providers is the fact that most practitioners lack the knowledge and expertise to design, price, and implement a capitated contract. Those provider groups that have learned to do so have gained considerable freedom from intrusion into their treatment decisions. But in exchange for this autonomy they have accepted risk, and all of the responsibility that comes with that. The present curriculum trains providers for a traditional third-party indemnity insurance system that is

fast disappearing in favor of capitated arrangements. An appropriate curriculum would acquaint the psychologist with the changes in the distribution and expected frequency of modal problems to be treated in a capitated arrangement as opposed to the traditional fee-for-service system. The assumption of risk, and risk management are integral parts of this training, as are many entrepreneurial aspects integral to the new delivery system.

A significant part of the curriculum involves business training, and it will be argued that the modal graduate student in psychology may not be interested in that aspect. This may or may not be true, but the 40% drop in applications to clinical psychology doctoral programs in the 3 years of 1998 to 2000 suggests that potential students are already expressing concern with the diminishing job market in doctoral-level psychology. When the field of doctoral-level clinical psychology and its curriculum are redefined, with an attendant response by the job market, a different type of applicant will be attracted.

In the year 2000 there are two major university doctoral programs undertaking a complete curriculum overhaul, and to a greatly redefined doctorate they are adding a certificate in the business administration of health. The latter would be a postgraduate program open to psychiatrists and social workers as well as psychologists. This might well replace the discernible trend in psychiatry and doctoral-level psychology to pursue the master of business administration (MBA) degree in schools of business, as the new postdoctoral program in graduate schools of psychology would be tailored to their career needs.

D. Economic Pressures on the Political System

The political system has experienced concerted efforts by providers and other constituencies to more stringently regulate HMOs and managed care. Among the legislation under serious consideration have been parity laws, a Patients' Bill of Rights, and laws to inhibit incentives to providers for cost containment. All of these and others are under active consideration by the Congress and state legislatures, and although some laws have been passed, advocates are expressing disappointment in the progress to date. The reluctance on the part of politicians is that public policy at the present time is in favor of the free market forces that have tethered the inflation rate of health care, in general, and the costs of Medicare and Medicaid, in particular. By transferring much of the programs to managed care,

with the subsequent savings in Medicare and Medicaid, the federal budget in these government programs was balanced.

Politicians at the present time are trying to balance the complaints about HMOs and managed care with the inevitability that the industry must be part of the solution if there is to be one. Along with the professional societies exerting pressure, by 2000 the National Alliance for the Mentally Ill (NAMI) emerged as a potent force advocating the strengthening of the 1996 mental health parity law. The bill under serious consideration in the year 2000, called the Mental Health Equitable Treatment Act, would require full insurance parity for schizophrenia, bipolar disorder, major depression, obsessive-compulsive and panic disorders, posttraumatic stress syndrome, autism, anorexia nervosa, and ADD. It takes its lead from the states that have passed some kind of parity law, and cuts directly to parity only for a list of disabling disorders, eliminating the diffuse nature of much mental health diagnosis and treatment. Thirty-four states had passed some kind of parity law by 2000, suggesting the federal government would follow suit, within a reasonable time, especially since current Congressional efforts are bipartisan.

There is not as much agreement on the Patients' Bill of Rights bill. Although some form of the law seems destined for passage, absent the right of the patient to sue the HMO the law would have no teeth. Consumer groups and the trial lawyers' associations are pushing hard for the patient's right to sue, but Congress seems reluctant to turn health care over to the lawyers. Economists argue this would result in a renewed inflationary spiral, threatening to create an insurance premium too costly for most employers. They further argue that the wrong parity legislation, along with opening the system up to a plethora of lawsuits, economically might spell the end of employer-sponsored health care.

An idea currently debated is the option of creating one's own tax-free medical savings account. This puts the patient squarely in charge of her or his own health care, with complete patient choice and the restoration of the doctor-patient relationship as it was before the intrusion of the third-party payor. This idea has proved intriguing to many economists, business leaders, consumer groups, and some few members of Congress, but it still lacks widespread support. On the opposite end of the spectrum are those economists who advocate the greater involvement of the federal government, and call for the renewal of proposals for government-sponsored single-payor universal health care.

VI. SUMMARY

This century, and especially the last 15 years, have seen profound changes in the way health care, including behavioral health care, are delivered in the United States. During that time health care rapidly evolved from a cottage industry to full industrialization.

Prior to World War II diagnosis and treatment were an out-of-pocket, fee-for-service transaction between the patient and a solo practitioner. Blue Cross and Blue Shield were founded in the 1930s to create a revenue stream during the Great Depression for the beleaguered hospitals and the overworked and often not paid physicians. Hospitals were charity-owned or community-based and were never expected to come near breaking even financially. Semiannual fundraisers kept the hospitals afloat for the benefit of the citizenry. But once "the Blues" were formed, the third-party payor intruded into the doctor-patient relationship, and for the first time there was a lowered sensitivity on the part of the patient to health care costs.

World War II saw the rise of employer-sponsored health insurance as a way of attracting workers to the defense industry at a time when wages were frozen by law. After the war consumers liked the concept of the employer paying for health care, and the employers saw certain tax and financial advantages to such an arrangement. Unions made health care a prime issue in collective bargaining. Soon employer-sponsored health insurance was an accepted notion in society, with its increased erosion of the patient's sensitivity to rising costs. More became better.

In the late 1950s through the Hill-Burton hospital funding legislation, and in the 1960s with Medicare and Medicaid, the government stepped into health care in a significant manner and inadvertently began to fuel a noncompetitive medical economy. The inflationary trend in health care began to worry the government and economists. But the government's efforts to contain it seemed to only fuel the inflation further. During this time it must be noted that psychotherapy was not part of health insurance coverage, and such services continued to be out-of-pocket. The demand was still sufficient to support ever-increasing numbers of psychologists joining psychiatrists in the independent practice of psychotherapy. Patients were limited to those who could pay.

By the 1970s the government was becoming alarmed at the rapidly accelerating inflation in health care and took active steps to curtail it. At first there were strong efforts toward government-sponsored universal health

care, but this notion died because neither the practitioners nor the consumers wanted it. In 1974 the government went in the opposite direction with the HMO Enabling Act, thus signaling that it was encouraging free market solutions rather than government-sponsored universal health care. A number of economists known as the Jackson Hole Group persuaded the decision makers that managed competition could bring down inflation. This legislation was patterned after the Kaiser-Permanente Health system established on the west coast right after World War II. It had attracted a great deal of attention, but it had not been emulated up until that time. The government, therefore, launched in the mid-1970s the HMO industry not only with start-up funds, but also with legislation granting the HMOs a competitive edge.

During this same period the attitude of the health insurance industry toward psychotherapy as a covered benefit began to change. This was because of consumer pressure on the one hand, and the experiments at Kaiser-Permanente with the first comprehensive prepaid psychotherapy benefit. Their medical cost offset research discovered that brief psychological interventions could reduce medical costs with the somatizing patients, who comprised 60% of medical visits to physicians, more than sufficient to pay for the psychotherapy. Prepaid psychotherapy became a standard benefit by the end of the 1970s, resulting in large numbers of psychologists and social workers entering the independent practice of psychotherapy.

In the late 1970s to the mid-1980s the government accelerated its efforts to foster managed competition in the health field. Free choice of provider in Medicaid was eliminated in 1981, and the way Medicare paid hospitals was drastically altered in 1983. Payment was by number of days allotted to nearly 400 conditions, called diagnosis related groups (DRGs). This emptied medical surgical beds, but the government did not know how to institute DRGs in psychiatry where now the inflationary spiral existed, fostered by the transfer of empty beds to psychiatric and substance abuse hospitalization. It took the path of unleashing the private sector. It began applying the anti-restraint of trade laws against the health professions, removing prohibitions to advertising, the corporate practice of medicine, and

other impediments to the free market. The managed behavioral care industry was born in the mid-1980s and now, along with managed health care, covers 170 million Americans.

The annual rate of inflation in health care was reduced from 12 to 4% by 1993, the lowest it had been since 1960. Behavioral care had the same low rate of 4%. The winners were those who pay the bills: insurers, employers, the federal government (which is the largest purchaser of health services in the world), and the taxpayers. The losers were the psychiatric hospitals and the private solo practitioners of psychotherapy. The beleaguered professionals were understandably enraged and have adopted an aggressive posture against managed care. The Congress and state legislatures are being pressured for a change in policy from the present market economy to increased regulation of the HMOs and managed care companies. In behavioral care the lobbying is for mental health parity, already passed in 34 states, and a Patients' Bill of Rights with provisions allowing patients to sue their HMOs.

GLOSSARY

didactic learning Educational experiences that focus more on the acquisition of specific content knowledge than on the experiences or behavior of the student.

evaluation Structured assessment of a learner's knowledge, skills, and attitudes that become part of the learner's official academic record.

experiential learning Educational activities in which the learner must use the experience of the learning situation itself (in contrast to those that focus on learning specific content).

feedback Educational exchange in which the learner is presented observations about his or her performance but those observations do not become part of the learner's academic record.

I. OVERALL CURRICULUM DESIGN

The development of psychotherapeutic competence requires the same basic elements common to many

other educational processes. There must be goals and objectives that guide the overall educational plan and determine specific curricular components. Students must be provided a set of organized and sequenced learning experiences to enable progressively more sophisticated mastery of content. These experiences include didactic introduction to basic concepts, supervised experiential learning, and opportunities for progressively independent practice of psychotherapy. Along the way, steady feedback of information about the educational progress and attainments of the students enable them to make "in-flight" alterations of their professional development. An evaluation process (distinct from feedback) assures the student, institution, and public that the psychotherapist is competent to practice independently at the conclusion of the educational process.

In a way that is more quantitatively than qualitatively different from other types of professional education, the person of the psychotherapist changes dramatically during successful psychotherapy education. Even though the same is true to varying degrees in many professional and clinical educational programs, this change of the sense and use of the self as a psychotherapist is especially profound. For this reason, the development of competence in psychotherapy involves a prolonged period of personal vulnerability on the part of learners. The educational process and educational institutions involved in psychotherapy education must therefore pay attention to the potential for hurtful shame and the stifling of creativity,

which occurs if this vulnerability is not recognized and taken into account in constructing educational experiences. There are parallels between being a learner of psychotherapy and being a patient in psychotherapy. Psychotherapy educational programs must strike a balance between treating its learners as mature adults mastering the elements of a respected profession, while also providing a “safe enough” environment for students experiencing disturbances of their internal sense of themselves preceding the development of confidence and affirmation arising from the mastery of a profession.

II. DIDACTIC LEARNING

Most educational systems for psychotherapy begin with didactic learning situations in which basic concepts of psychotherapy are presented. The main mental health disciplines in which psychotherapy is practiced are psychiatry, psychology, and social work. Each of these core disciplines has a wide variety of subspecialties. Each provides subspecialty training in different conceptual models for psychotherapy, such as psychoanalysis, cognitive therapy, interpersonal therapy, and behavioral therapy. Each conceptual model informs therapy based on the constellation of participants in the therapeutic enterprise, such as individual, group, family, and marital therapy.

Psychotherapy may also become an important endeavor of individuals from other disciplines, such as family medicine or religious education. Psychotherapy-like endeavors can also be part of disciplines such as human relations (employee assistance program services) and business administration or management (group or employee relations consultants).

Based on the above diversities of pathways leading one to do psychotherapy, those with administrative responsibility for psychotherapy education (a) can have a wide variety of primary disciplines and (b) must not assume the core competency of their learners in the “basic sciences” of psychotherapy. Even the so-called basic building blocks of psychotherapy education vary depending on the educational context in which psychotherapy education takes place. For example, psychotherapy practiced by medical professionals is more likely to consider neuroscience and studies of brain function as a basic science on which psychotherapy education is built. In contrast, social work professionals are less likely to see the study of the brain as fundamental to psychotherapy and are

more likely to consider psychotherapy built on principles arising from sociology, anthropology, and other behavioral sciences.

What then can be considered basic concepts that should inform all psychotherapy education? This chapter will proceed with the basic assumption that individual psychotherapy is the fundamental cornerstone for developing broad psychotherapy competence. Other therapeutic constellations, such as group, family, or marital therapy will be considered subspecialty applications of that basic competency.

Didactic experiences in psychotherapy education should expose learners to the major conceptual models that inform approaches to understanding and helping patients. Although these very basic concepts can be described in lecture format, it is important that psychotherapy students also have interactive seminars in which basic readings are assumed to have been read by participants. The educational exchange in seminars emphasizes a discussion of abstract concepts leading learners beyond memorization of presented material towards an ability to discuss concepts (the unconscious, cognitive schemata, role conflicts, desensitization, etc.) that are of essential importance to the respective basic conceptual models. Neither lectures nor seminars give learners an in-depth appreciation of the concepts, however. A transition from book learning to experience must be accomplished in a manner that is safe for the public while providing “real” learning experiences for the developing psychotherapist.

III. EXPERIENTIAL LEARNING AND THE DEVELOPMENT OF SELF-AWARENESS

Experiential learning of basic concepts in psychotherapy education includes the use of role-playing, simulated patients, and structured experiential learning activities. In 1978, Dr. Jerry M. Lewis of the Timberlawn Foundation in Dallas, Texas, developed one of the best elaborated structured approaches to learning psychotherapy in *To Be a Therapist*. His work has influenced psychotherapy education in many psychiatric settings. In *Learning Psychotherapy*, Dr. Bernard Beitman advocated a specific evolution of the combination of structured experiential and didactic learning. Lewis focuses more on the internal experience of the learner, especially empathic understanding and patience to organize specific educational components. In contrast, Beitman focuses more on the technique of

the psychotherapist/patient interaction and utilizes educational research studies. Both of these specific models have greater influence in psychiatric education than in other mental health disciplines thus far. In general, however, psychotherapy education in psychology graduate education is more tied to research in psychotherapy outcome and process.

In addition to learning conceptual models for structuring the content of a psychotherapeutic process, the therapist must learn how to structure and use a relationship for therapeutic purposes. To a casual observer psychotherapy may seem to be like an ordinary conversation. In fact, there is nothing magical about psychotherapy. Although there are predictable and repeated elements of psychotherapeutic relationships, formalized rituals (customary in relationships between individuals involved in religious-based relationships) are generally assessed as unhelpful in psychotherapy. As rituals, they become end points instead of a means to accomplish a specific psychotherapeutic goal. In psychotherapy, the therapist does make particular and purposeful use of an interpersonal relationship.

Psychotherapeutic relationships are, therefore, both artificial and transcendent. They are artificial in that the elements of naturalistic human interactions are structured for a particular purpose of human design. They are transcendent in that the therapist abstains from the use of relationships for ordinary human purposes. His or her actions or activities are used for the purpose of helping another individual to achieve the agreed upon goals of the relationship. This does not mean that a therapist tolerates personally abusive activities from a patient. It does mean that a psychotherapist responds with equanimity and therapeutic intent to the patient's behaviors or communications, which in ordinary relationships would likely lead to retaliatory aggression or the pursuit of personal gratifications on the part of the therapist.

In didactic and experiential settings, the psychotherapist learns a type of active listening that is part of all psychotherapeutic relationships. The listening is "active" in that when the therapist is silently listening, he or she is also recording and conceptualizing the content of a patient's communications and is also steadily attempting to experience what is being described by the patient *from* the patient's perspective (empathic understanding in the psychodynamic frame of reference). This "vacillation of ego states" within the mind of the therapist, from a dispassionate scientific observer of information to intimate vicarious immersion with the

person of the patient, is fundamental for psychotherapeutic activity.

The therapist's availability at both the emotional and cognitive level also requires progressive self-awareness on the part of the therapist. That awareness involves attention to the personal, private, idiosyncratic mental contents of the therapist, *and* observation of moment-to-moment exchanges between patient and therapist. The former self-observations are important steps in empathic understanding of the patient and learning from countertransference reactions. The latter observations provide clues about the degree of engagement, genuineness, and authenticity of the therapeutic alliance. The use of audiotape or videotape recordings of interviews and therapy sessions is indispensable in developing therapist self-awareness. Actual observed interviews are helpful for learners who are not involved in the therapeutic relationship being observed, but the opportunity to review recorded therapeutic relationships of one's own therapeutic encounters is a different dimension of learning, which is essential for developing therapeutic competency.

IV. SUPERVISED CLINICAL WORK WITH PATIENTS

Very early on in psychotherapy education, supervised clinical experiences with patients are necessary to transform concepts learned from books or classrooms into actual human encounters. At least some of the aforementioned experiential learning activities in a situation without clinical responsibility should precede attempts at psychotherapeutic relationships with patients. Psychiatry residency programs take as a fundamental aspect of physician behavior the dictum *prima non nocere*, or "first do no harm." In psychiatric practice, patient care is somewhat artificially but commonly separated into general psychiatric care (providing medications and general management for a patient's psychological difficulties) and psychotherapeutic care. Videotaped encounters of interviews with patients for whom the learner is providing general psychiatric services, but not psychotherapy, are often viewed in interviewing seminars for first-year residents prior to their assuming psychotherapeutic responsibilities with patients. The videotaped interviews are subsequently viewed in a classroom setting. The emphasis in such settings includes obtaining information in order to make a diagnosis. Attention is also paid to the resident's ability to listen and to gather information in a sensitive,

tactful, and well-timed manner. These activities are seen as building blocks for learning psychotherapeutic relationships. Discussions of how the resident subjectively responds to the patient communications and observations of verbal and nonverbal communications and their consequences begin the development of therapist self-awareness. For most psychiatry training programs, these very rudimentary skills are all that is expected for first-year residents.

The student psychotherapist should also have the opportunity to observe more senior practitioners actually doing interviews and psychotherapy. Seminars often employ videotaped therapy of the senior practitioner, but one-way mirror viewing of therapy may also be useful.

Many programs offer an experiential conference to help students identify and enhance their empathic abilities and learn to listen to the way in which a patient moves from topic to topic in an unstructured interview (the associative process). These conferences were a major contribution of Dr. Lewis's model of psychotherapy education mentioned previously. Learning experiences for the psychotherapist must eventually include observed and supervised therapeutic relationships involving brief and longer-term individual psychotherapies utilizing psychodynamic, cognitive, interpersonal, and behavioral conceptual framework to organize the therapy. Analogous experiences should take place for conducting group, family, and marital therapy. The brief therapies learned should be both those that are brief because of a clinical decision to employ a focal or targeted psychotherapy and those therapies that are brief because of external limitations or constraints on the treatment relationship. These different determinants for pursuing brief therapeutic relationships involve very different issues for the therapist-patient relationship.

Individual supervision is a special learning context for psychotherapy education. This format arose out of the earliest attempts to structure learning about psychotherapy. There are several analogies between the supervisor-supervisee relationship of individual supervision to the patient-therapist relationship of psychotherapy, but there are also important differences. The notion of individual supervision came out of the Berlin Psychoanalytic Congress in 1922, when the first requirements for formalized training in psychoanalysis were developed. In individual supervision, the supervisee (psychotherapy learner) and supervisor meet on a regular basis over a defined period of time—at least a

one-year duration in most psychotherapy programs. The purpose of these meetings is to learn about both patients and the therapist. Both the therapist's self-awareness and the therapist's awareness of the therapeutic process are objects of scrutiny. The various analogies to the therapeutic relationship are most poignant when what is described as a "parallel process" emerges. This concept was well articulated by R. Ekstein and R. Wallerstein in 1972 to describe situations in which problems being reported by the patient to the therapist emerge in the relationship between the supervisee and supervisor.

A variety of theories exist about why this extraordinary process occurs. Nonetheless, it is a common occurrence in the psychodynamic psychotherapies and a source of powerful learning for the supervisee. It is also considered an indicator of the supervisor's competence to be able to identify and make use of such experiences. As with other parts of the supervisory relationship, the goal of exploring such a process is to learn how factors within the student therapist interfere with his or her therapeutic activity. This exploration and focus is different from, but analogous to, learning about experiences in the patient-therapist relationship, as indicators of a history of the patient's personal difficulties. The distinction between the therapeutic and supervisory task and focus may seem simple in concept. It is actually quite a complex issue. Supervisees predictably feel quite vulnerable when parallel processes occur or they discuss personal conflicts or inhibitions as therapists. It is important that a strong educational alliance is developed and maintained in individual supervision. That supervisory alliance enables learning during times in which the self of the therapist feels exposed and vulnerable.

V. ROLE OF PERSONAL THERAPY IN PSYCHOTHERAPY EDUCATION

Personal therapy is an even more personal step than individual supervision in learning about psychotherapy. Personal therapy in the form of psychoanalysis is required by psychoanalytic institutes and some psychotherapy programs, especially those with a psychodynamic conceptual orientation. It is difficult, however, to "require" a personal therapy experience under any circumstance, and required therapy distorts the therapeutic relationship to some degree. Much has been made in the literature about psychoanalytic educa-

tion, about how the “training analysis” of the psychoanalytic student (“candidate”) significantly influences the process of psychoanalytic education. A positive experience of personal therapy, however, greatly enriches and provides a new level of personal conviction about the therapeutic process. Personal therapy is, therefore, an important, even if elective, part of psychotherapy education.

With respect to group therapies, analogous experiential learning formats for the learning therapist also exist. A.K. Rice, or the “Tavistock” type of group learning experiences, helps individuals learn about the generic group processes that are part of any working group. In general, National Training Laboratory (NTL) groups are helpful in learning how to give and receive feedback, and A. K. Rice groups provide education about issues of power and authority, the delegation of authority, and principles of leadership effectiveness. Other types of group learning experiences are less frequently incorporated into formal psychotherapy training programs but may be encouraged by program directors as ways to broaden the student therapist’s accustomed sense of self.

VI. FEEDBACK AND EVALUATION

In each of the preceding learning experiences, an evaluation instrument must be developed to assess the progress of the future psychotherapist. The student therapist’s participation in didactic seminars is routinely evaluated by the seminar leader. Many programs use paper-and-pencil tests to assess the conceptual grasp of didactic material. The first broadly used test of cognitive knowledge was only recently developed by the psychiatry residency program at Columbia University. Videotaped diagnostic interviews and videotaped therapy sessions are an extremely important part of the evaluation process, as well as learning experiences. Such tapes are a critically important measure of the beginning therapist’s ability to have his or her first independent clinical encounter with patients.

Didactic seminars in more advanced stages of psychotherapy education usually involve presenting individual cases for discussion of how to organize treatment for the patient. It is particularly useful to have an educational conference in which a single case being treated by a psychotherapy learner is presented over time throughout a series of meetings for an entire course of treatment. This “continuous case conference” is usually supervised by a senior member of

the educational team. The conference leader helps connect the important themes and processes from one session to the other and integrates an actual therapy with a conceptual model or models. Both the primary presenter at case conferences and the learning group are evaluated with respect to their ability to observe and articulate matters about the patient and the therapist.

Again, because of the powerful sense of vulnerability in learning to become a psychotherapist, it is often helpful to structure initial feedback about their skills and weaknesses before providing a formal evaluation. This principle has also been found to be helpful in many aspects of medical education.

Reports from individual supervisors are generally considered the most important source for evaluation of psychotherapeutic competence. Such evaluations should be systematically solicited by the program director and reviewed with the student therapist on a regular basis. They should assess therapeutic competency and describe both strengths and areas for improvement to be pursued in future components of the training program.

Outcome measurements are difficult matters for psychotherapy education, but they are achieving increasing importance in measuring quality and competence. Outcome measures include both measures of patient satisfaction with the therapist and therapeutic process and the use of rating scales to measure change in signs and symptoms of patients being treated by the psychotherapy student.

VII. SUMMARY

In conclusion, a psychotherapy curriculum involves substantial immersion in a mix of educational experiences that are both personal and professional. There is much hard data to be learned and mastered. Individuals who are quite competent in some aspects of their discipline may function poorly or have to work hard to develop different aspects of themselves to become competent in psychotherapy. The experience of personal change during psychotherapy education often leads individuals to seek personal therapy for themselves as part of developing professional competence. Although mastery of concepts is an important criterion to bring to bear in judging a particular therapist, a good therapist also has to develop an extraordinary set of personal qualities to be used in their efforts to understand and attenuate human suffering.

GLOSSARY

common factors Active ingredients that are common to all forms of psychotherapy and contribute to positive patient outcome.

patient variables Characteristics of patients related to psychotherapy outcome.

psychotherapy outcome The effects of psychotherapy on patient status.

specific intervention variables Therapeutic techniques or interventions unique to a specific form of psychotherapy.

Psychotherapy, defined within the broader context of the field of psychology, is a skilled and intentional treatment process whereby the thoughts, feelings, and behavior of a person are modified with the intention of facilitating increased functioning and life adjustment. Psychologists, psychiatrists, and clinical social workers are authorized to provide psychotherapy to children, adolescents, and adults in individual, group, couples, and family therapy sessions. Although there are hundreds of different psychotherapies that conceptualize and treat problems in different ways, most are varia-

tions of three general paradigms: psychodynamic, cognitive-behavioral, and humanistic-phenomenological. For decades researchers have assessed the positive and negative effects of psychotherapy on patients. This entry will review research that has established the effectiveness of psychotherapy within the aforementioned paradigms, review factors important to psychotherapy outcome, and discuss the negative effects associated with psychotherapy.

I. EFFECTIVENESS OF PSYCHOTHERAPY

In 1952, Hans J. Eysenck published a review of the effectiveness of psychotherapy, concluding that 74% of patients, drawn from 24 studies and diagnosed as neurotic, were found to make progress considered equivalent to a similarly diagnosed group of individuals who received no treatment over a two-year time period. Since Eysenck's review, a large body of research has been directed toward determining whether psychotherapy assists patients to solve problems, reduce symptoms, and improve interpersonal and social functioning beyond the improvements that can be expected from existing social supports and inner homeostatic mechanisms. From the early 1930s to the 1960s, this was a much debated topic. The 1970s, 1980s, and 1990s saw an increase in both the number of studies undertaken and the quality of studies used to evaluate the outcome of therapy. This research has left little doubt that pa-

tients who undergo treatment fare substantially better than untreated individuals.

One mathematical technique, meta-analysis, is used to summarize large collections of empirical data. It has been successfully used to estimate the actual size of treatment effects in terms of percentage of patients who improve under various treatments compared to untreated controls. In general, meta-analytic reviews suggest that the average person receiving a placebo treatment is better off than approximately 66% of the untreated sample, while the average person receiving psychotherapy is better off than 80% of the untreated sample. This information indicates that while clients who receive placebo treatments show more improvement than untreated individuals, this improvement falls well short of that occurring in clients who undergo a course of psychotherapy.

Not only has research on the outcome of psychotherapy clearly demonstrated the effectiveness of treatment, but this finding is enhanced by data suggesting that the road to recovery is not long and that treatment gains are maintained. For example, multiple studies have found that approximately 75% of clients can be expected to have recovered substantially after 50 sessions or nearly a year of weekly psychotherapy and that even with as few as 8 to 10 sessions about 50% of clients have shown reliable improvement. Notwithstanding these findings, the amount of therapy needed to produce effects continues to be debated. The pattern of changes during psychotherapy has also been examined, with several studies suggesting that different symptom clusters improve at different times during treatment: symptoms of poor morale respond most quickly, followed by improvement in symptoms of chronic distress, with symptoms related to the patient's character or personality traits improving at the slowest rate.

In addition to finding that the road to recovery is relatively short for many patients, researchers have discovered that improvement tends to be lasting. There is no evidence to suggest that psychotherapy will permanently safeguard a person from psychological disturbance, but many patients who undergo therapy achieve healthy adjustment for an extended period of time. Many studies, including meta-analytic reviews, have shown that the effects of psychotherapy are relatively lasting. However, there is some evidence to suggest that maintenance of treatment effects is worse in cases of substance abuse disorders, eating disorders, recurrent depression, and personality disorders. Research has also shown that the maintenance of treatment effects

can be enhanced by efforts directed at this goal in the final sessions of therapy.

II. FACTORS IMPORTANT TO PSYCHOTHERAPY OUTCOME

In addition to the research focused on supporting the effectiveness of psychotherapy, considerable emphasis has been placed on studying factors related to positive patient outcome. Findings from this research fall into three general categories: patient variables, common factors, and specific intervention variables.

A. Patient Variables

Although a number of studies have investigated the impact therapists have on psychotherapy outcome, there is surprisingly little evidence that suggests therapists or their techniques are the central and essential factors affecting patient outcome. On the contrary, it is in fact the patient who is most likely to determine successful outcome. The literature focusing on the study of patient variables is too voluminous to fully summarize here; therefore, only the most important findings are reported.

Each patient entering treatment brings a diverse array of factors when presenting to the clinician. These include, but are not limited to, a variety of psychological disorders, physical complaints, historical backgrounds, stresses, and the quality of their social support networks. Patient variables found to have a relationship with outcome are severity of disturbance, motivation and expectancy, capacity to relate, degree of integration, coherence, perfectionism, and ability to recognize and verbalize focalized problems. Therefore, patients suffering from challenging symptoms as well as relative deficits in numerous patient variable categories are likely to experience negligible improvement during treatment. For example, the borderline, alcoholic patient with suicidal tendencies who is forced into treatment, believing that most marital problems are a result of an insensitive spouse, is likely to benefit less from treatment than the depressed patient who voluntarily begins treatment, is low in perfectionism, and is determined to make personal changes that will lead to marital harmony.

Although patient variables have been conveniently categorized, the impact each has on the outcome of therapy is not equal. In general, the severity of the disturbance is generally the patient variable that is most

related to outcome. Patients with serious mental disorders, such as schizophrenia, schizoaffective disorder, and bipolar disorder, are typically treated primarily with psychotropic medications, suggesting the challenge these disturbances provide for psychotherapy alone. Personality disturbances also appear more resistant to change even in long-term treatments that last years.

B. Common Factors

Because outcome researchers have consistently failed to find sufficient evidence indicating superior effects for particular theoretical systems of psychotherapy, some researchers have concluded that psychotherapy equivalence is a result of factors common to all theories of psychotherapy. Whereas some view these beneficial ingredients as both necessary and sufficient for change, others believe that these ingredients act in coalition with techniques that are unique to particular interventions. It is important to note that regardless of the position held, factors common to all treatments are likely to account for a substantial amount of the improvement that occurs in psychotherapy.

In a review of the empirical research, Michael J. Lambert and Allen E. Bergin grouped many factors common across psychotherapies into three categories: support, learning, and action factors. Support factors that contribute to positive patient outcome include catharsis, warmth, respect, trust, empathy, therapist/client collaboration, reassurance, and decreased sense of isolation. Learning factors include insight, affective experiencing, corrective emotional experience, cognitive learning, advice, feedback, and reconceptualization of problems. Action factors include behavioral regulation, cognitive mastery, encouragement of facing fears, practice, reality testing, and success experiences. The common factors included in these categories seem to operate most actively during the in-session process of therapy. When common factors are present, they result in a client experiencing an increased sense of trust, security, and safety, along with a reduction in tension, threat, and anxiety. These conditions, in turn, promote a client's awareness of problems and his or her ability to take appropriate risks by confronting fears using new and more adaptive coping mechanisms and behaviors. With success in implementing new behaviors, clients become increasingly motivated to resolve problems related to their intrapersonal and interpersonal functioning.

Factors receiving the most attention in the literature are the common factors considered to be the core of the therapeutic relationship (e.g., empathy, respect, and

collaboration). A number of related terms such as acceptance, tolerance, therapeutic alliance, therapeutic relationship, working alliance, and support are also used to describe these ingredients. Several studies designed to explore which therapist variables distinguished most consistently between more effective and less effective therapists have found that a client's perception of empathy is important to outcome because less effective therapists have been found to demonstrate lower levels of empathy. Empathy, rather than technique, has repeatedly been shown to be the best predictor of outcome.

Related to these findings are studies investigating the therapeutic relationship, which have suggested that a positive working alliance between the patient and therapist is a necessary condition for patient improvement. Even behavior therapists, who place little theoretical emphasis on relationship variables, have repeatedly found evidence supporting the importance of the therapist–client relationship. In several studies where patients were asked about the most important factors of their therapy, they tended to endorse the personal qualities of their therapists, using adjectives such as “sensitive,” “honest,” and “gentle.” Additional evidence supporting the necessity for a strong working relationship is the positive association repeatedly found between scores on measures of early treatment alliance and psychotherapy outcome. Although a significant amount of evidence points to common factors as mediators of patient change, the notion of beneficial ingredients unique to specific therapies cannot be ruled out, as occasionally such interventions, independent of common factors, can be shown to contribute to successful outcomes.

C. Specific Intervention Variables

The drive to empirically validate the efficacy of specific interventions is due, in part, to the field of psychotherapy's commitment to theoretically based approaches, as well as the influence of political and economic forces. Collectively, these factors have led to the use of comparative outcome studies, which generally avoid the ethical and methodological problems associated with no-treatment and placebo controls, while enabling researchers to study the effectiveness of particular techniques or theories by comparison. For the most part, comparative studies have yielded equal effects for all types of psychotherapy. Some evidence suggests, however, that specific interventions are related to superior outcome in the treatment of some disorders.

Specific behavioral treatments have been found to be effective in treating patients with anxiety disorders. To date, two treatments—systematic exposure and applied relaxation techniques—have been shown to be efficacious in treating a variety of anxiety disorders. Exposure is a broad term that encompasses both interoceptive and situational exposure interventions. Interoceptive procedures attempt to reliably produce panic-type sensations, with the intent of severing or weakening the patient's associations between certain bodily cues and their respective reactions to panic. The technique of situational exposure, also known as *in vivo* exposure, refers to the patient's repeated intentional encounters with a feared stimulus. Given the focus placed on the catalyst of fear, it is not surprising that clearly identifying the stimulus that induces the patient's reactions is crucial for the success of these procedures.

Evidence suggests that the most effective treatment strategy includes identification of feared stimuli, periods of exposure to the feared stimuli sufficient in length to reduce the patient's level of anxiety, and a focus on thoughts providing self-efficacy or performance accomplishment. A general strategy employing the use of exposure techniques appears to be the most efficacious intervention for agoraphobia. Similar exposure techniques have been shown to be successful for social phobic, panic, and post-traumatic stress disorder patients as well.

The results of a form of relaxation, referred to as applied relaxation, appear to show promise in treating specific anxiety disorders. Applied relaxation entails instructing patients in the skill of progressive muscle relaxation. Patients are generally taught how to progressively relax specific muscle groups. Whereas the evidence supporting the use of applied relaxation techniques alone is mixed in the panic disorder literature, it appears there is support for treating generalized anxiety disorder with relaxation training. Additional evidence suggests that the treatment of specific disorders is most successful when particular interventions are combined with specific theory-based therapies. For instance, panic disorder is treated most effectively when a cognitive-behavioral theory of therapy is used in conjunction with behavioral techniques.

Like anxiety disorders, there is some evidence supporting the use of specific behavioral techniques in the treatment of depression. However, in the case of depression, these procedures are not more effective than cognitive, interpersonal, and psychodynamic-interpersonal therapies. For example, behavioral activa-

tion alone, which refers to a patient scheduling activities that promote mastery as well as pleasurable activities, has been found to be as effective as cognitive therapy. Whereas behavioral activation is a procedure that makes concerted efforts to involve patients in constructive and pleasurable activities, cognitive therapy emphasizes the modification of maladaptive thoughts, beliefs, attitudes, and behaviors of individuals. Although some researchers predicted the superiority of cognitive therapy's ability to successfully treat depressive patients, the results of large, well-controlled studies suggest that interpersonal and psychodynamic-interpersonal therapies are efficacious as well. In contrast to the focus that cognitive therapy places on maladaptive thoughts, beliefs, and behaviors, interpersonal theory perceives depression as the consequence of problems in the interpersonal history of the patient.

As eating disorders are generally characterized by harmful cognitions surrounding weight and physical image, cognitive and behavioral interventions have been the most extensively researched treatments. In particular, cognitive-behavioral therapy has been the focus of much research in the treatment of bulimia nervosa, showing promising results. However, it appears that interpersonal therapy provides generally equivalent results when long-term followup findings are considered.

Reviews of the treatment of substance abuse disorders suggest that various therapy modalities have been found effective in treating patients. Therapies that provide generally equivalent results are cognitive, cognitive-behavioral, and psychodynamically oriented therapies. Whereas patients abusing alcohol have been treated, with similar success, using psychodynamic, cognitive-behavioral, and psychoeducational treatment modalities, opiate-dependent patients have been treated with cognitive and supportive-expressive psychodynamic therapies with generally equivalent results.

Some caution should be applied when interpreting the above findings, however, as the results mentioned are typically based on randomized clinical trials. To date, there is little evidence suggesting that these findings generalize to the clinical setting. The question of whether one technique is comparatively unique and more effective than another is a consistent topic in the literature of psychotherapy. There is currently little evidence supporting the superiority of particular interventions, although future research may note unique contributions. For instance, there is a growing body of

evidence suggesting that the use of therapy manuals allows for the detection of discernible differences in the behavior of therapists, while at the same time enhancing the effects of specific therapy procedures. Perhaps these contributions will allow for more accurate comparisons in outcome studies. The search for specific techniques and common factors that distinguish successful treatment has proved to be difficult because of the myriad factors that likely exist in the interactions between therapists and clients.

III. NEGATIVE EFFECTS OF PSYCHOTHERAPY

Findings from study of the progress and outcome of patients undergoing psychotherapy have resulted in both expected and unexpected conclusions. Most patients receiving treatment improve, a minority of patients remain unchanged, and contrary to the intent of psychotherapy, a small percentage of patients actually worsen as a result of, or at least during, treatment. Independent reviews of the literature suggest that some patients fail to achieve beneficial gains from treatment. Although accurate estimates of patient deterioration are difficult to make because the results of such incidents are not often the focus of psychotherapy outcome studies, estimates of patient deterioration vary between 0% and 15%. Similar to patient improvement, it appears that the phenomenon of deterioration is equally prevalent across theoretical orientations. In addition, treatment failures are reported in all client populations, treatment interventions, and group and family therapies.

Despite what appears to be an equitable distribution of treatment failures, specific factors have been associated with deterioration. Consistent with the influence that patient variables often have in treatment success, patient characteristics appear closely linked to treatment failure. Severity of mental illness alone is predictive of unsuccessful outcome, and severe levels of mental illness in combination with specific interventions designed to breach, challenge, and undermine entrenched coping strategies and defense mechanisms are more likely to result in treatment failure. Consequently, psychotic, borderline, schizophrenic, and bipolar patients are those patients who most frequently experience deterioration during the course of treatment. Similar findings have been reported in the psychoanalytic literature, as patients lacking quality interpersonal relationships, low-anxiety tolerance at the inception of

treatment, and low motivation were more likely to worsen when treated with psychoanalysis and purely supportive therapies, whereas patients treated with supportive-expressive psychotherapy obtained better outcomes. Deterioration is not unique to individual therapy, however. Reviews of group psychotherapy outcome have reported a positive correlation between treatment failure and patient variables such as low participation, poor self-esteem, poor self-concept, and more significant needs for fulfillment. Additional personal characteristics associated with patient deterioration include hostility, interpersonal dysfunction, and negative expectations of treatment.

These findings suggest that it is important to consider the type of intervention most appropriate for a particular client. However, harm is not attributable to the patient and intervention alone. The results of studies investigating therapists' contributions to the phenomenon of deterioration have suggested that specific therapist behaviors can lead to treatment failure. For instance, research investigating the relationship between therapists' emotional adjustment, empathy, directiveness, support, and credibility, and patient outcome found that therapists' empathic abilities were the most predictive of patient outcome. Additional findings have suggested that effective therapists are also likely to provide more direction and support than ineffective therapists. Some researchers have also found that less effective therapists tend to emphasize values such as having a life of comfort and excitement, whereas effective therapists consider intellectual values, such as reflection, as more important.

Some research has also suggested that therapist "negative reactions," including disappointment, hostility, and irritation, are associated with patient deterioration. In addition, there is some indication that client deterioration is more prevalent when clinicians underestimate their client's illness or overestimate their client's progress in treatment. Research exploring the importance of leadership styles in group therapists suggests that confrontational and aggressive group therapists tended to have more treatment failures in their groups. These therapists were observed to be more likely to insist on immediate client disclosure, emotional expression, and change in attitude.

There is a growing body of literature which suggests that if patients who are experiencing deterioration during psychotherapy are identified early in the treatment process, then steps can be taken to assist them in obtaining a more favorable outcome. Primarily, these studies have involved providing regular feedback re-

garding patient progress to therapists so that they can make needed adjustments in their treatment of clients who are having a poor response to therapy. However, in an attempt to further improve the outcomes of patients who are experiencing deterioration, several research groups have begun to extend the practice of providing regular feedback regarding patient progress to others involved in the treatment process, such as clients and clinical supervisors. The impact of providing individuals other than therapists with feedback regarding patient progress remains unclear.

IV. SUMMARY

Years of clinical research have produced compelling evidence for the value of psychotherapy. Contrary to Hans J. Eysenck's controversial publication regarding the efficacy of psychotherapy, outcome studies have confirmed that patients benefit from treatment in a variety of domains. According to the dose-effect literature, benefits derived from therapy transpire in relatively brief periods of time. For many clinical disorders, generally one-half of all patients return to normal functioning in 5 to 20 sessions. An additional 25% of patients experience a similar level of substantial improvement when dosage levels are increased to 30 to 50 sessions. The benefits from treatment appear to be durable, as the results of followup studies suggest that the effects of treatment last at least one to two years subsequent to treatment. Although researchers have produced empirical evidence supporting the effectiveness of psychotherapy, they are just learning to understand why patients tend to improve.

Not all patients experience equal effects from treatment, and this finding has inspired the investigation of factors facilitating both positive and negative change. The results of such studies have indicated that a patient's level of disturbance is most predictive of outcome. However, desire to change, interpersonal skills, and awareness of relevant problems have all been found to be related to outcome. In addition to patient variables predictive of successful outcome, there are characteristics of a therapeutic relationship that facili-

tate a patient's sense of trust, safety, and security. According to patients' reports, therapist empathy and a strong therapeutic alliance are most predictive of treatment outcomes.

Although the use of specific interventions has shown promising results in the case of particular disorders, in general the search for superior treatment strategies has been disappointing, and according to some researchers unnecessary, given the complexity of potential interactions between therapists, clients, and modes of therapy. Regretfully, not all patients improve from treatment; in fact, some actually worsen. Although knowledge of this phenomenon is somewhat limited, there is some evidence that suggests that treatment failure is best predicted by severity of mental disorder. Furthermore, factors inhibiting the development of a strong therapeutic alliance also predict negative outcome. There is evidence to suggest that providing regular feedback regarding patient progress to therapists helps improve the outcome of patients who are experiencing deterioration during psychotherapy.

GLOSSARY

effect size A common metric in meta-analyses that represents the magnitude of a difference between a treatment and a control group.

generalizability The ability of the results of a study to extend to other situations and patient samples.

meta-analysis A procedure to quantitatively summarize the cumulative findings of a body of literature.

therapist adherence How closely the participating therapist follows the treatment manual and techniques that have been specified.

therapist competence The ability of the therapist to conduct therapy according to the specified theory in a way that maximizes the possibility of client change.

treatment manuals Typically describes in detail the theoretical underpinning of a specific therapeutic approach, the strategies that should be used, and suggestions for dealing with specific issues in treatment.

I. EFFICACY IN PSYCHOTHERAPY RESEARCH

The efficacy of treatment is determined by a clinical trial or trials in which many variables are carefully con-

trolled to demonstrate that the relationship between the treatment and outcome are relatively unambiguous. Efficacy studies emphasize the internal validity of the experimental design through a variety of means including random assignment, blinding procedures for raters, careful selection of patients, manuals to standardize treatment delivery, training and monitoring therapist adherence to the treatment, and managing the “dose” of treatment by conducting analyses that include only patients that have received a specified amount of treatment. These and other strategies are used to enhance the ability of the investigator to make causal inferences based on the findings (e.g., is cognitive-behavioral treatment more effective in treating panic disorder than psychodynamic treatment?).

In contrast, the effectiveness of a treatment is studied in natural clinical settings when the intervention is implemented without the same level of internal validity that is present in clinical trials. Effectiveness studies emphasize the external validity of the experimental design and attempt to demonstrate that the treatment can be beneficial in a typical clinical setting in which fewer experimental variables are controlled. Typically, clients are not preselected to represent a homogeneous sample, treatment dose is not necessarily controlled, and therapist adherence to treatment guidelines is neither highly specified nor monitored. Therapists tend to be those working in clinical settings and may or may not receive the same level of prestudy training as therapists in efficacy studies.

It is only natural that some confusion between efficacy and effectiveness exist. Historically these two terms were often used interchangeably. Meta-analytic methods for estimating treatment effects have typically included both types of studies when calculating the “effect size” that represents the magnitude or size of difference between a treatment and a control group. The use of the term “effect” within the context of inferential statistics and experimental design naturally leads to descriptions of the studies as evidence for the effectiveness of treatment. As a result, even recent literature often does not incorporate the modern distinction between efficacy and effectiveness.

The study of efficacy through clinical trials has many benefits for psychotherapy research. The methodology of clinical trials allows for improved internal validity through minimizing attrition by having patients commit to prespecified treatment length prior to receiving treatment. Thus, efficacy trials are praised for their ability to determine the specific factors that contribute to therapy outcome by controlling for confounding variables. Another way that clinical trials increase internal validity is by controlling the types of patients included in the study. Prospective participants of a clinical trial are usually screened to ensure that participants meet predefined criteria. Screening for inclusion in studies often includes meeting specific criteria for diagnosis and meeting certain cutoff scores on various measures. Participants are often excluded from a study if they meet diagnostic criteria for additional disorders. This is done in an attempt to limit the number of clients with comorbid diagnoses and thus minimize between-participant variance and avoid confounding variables.

Efficacy studies also employ the use of treatment manuals to standardize treatment delivery between therapists. Treatment manuals typically describe in detail the theoretical underpinning of the therapeutic approach, the strategies that should be used, and suggestions for dealing with specific problems that arise during treatment. The use of therapy manuals and more experienced therapists presumably reduces the effects of the therapist’s contribution to outcome, allowing for more clear comparisons of treatment procedures. The use of manuals is presumed to magnify the differences between therapies by reducing the “error” that could be introduced by specific therapists.

The standardization of treatment delivery between therapists is further ensured by training therapists prior to the study, monitoring therapist adherence to the treatment during the study, and supervising therapists who deviate from the treatment protocol. Thus, therapist competence is ensured, enabling researchers

to draw appropriate conclusions regarding treatment differences. Another key element in efficacy studies is managing the “dose” of treatment by ensuring that each patient has undergone the complete treatment and thus a sufficient dose to ensure a positive response. Thus, efficacy studies are able to identify the impact of therapy from a fixed number of sessions across treatment groups.

Limitations of efficacy research are usually associated with its strengths. The main limitations are associated with the degree to which results can be generalized to routine practice. The results of these studies tend to show the maximum benefits that can be derived from treatments. In routine clinical practice, clinicians must help patients even when they have multiple disorders, are extremely disturbed, or are even subclinical. They cannot undergo extensive training, monitoring during practice, or supervision. Patients often receive multiple treatments (e.g., medication, group therapy) simultaneously with the treatment of intent.

II. NIMH COLLABORATIVE DEPRESSION EFFICACY STUDY

An exemplary study of treatment efficacy is the Collaborative Depression Study conducted by the National Institute of Mental Health (NIMH) in 1989. This study was the combined effort of investigators who were equally interested in two psychotherapy modalities as well as the pharmacological treatment of patients with depression. This approach clearly marked a change in research strategies from examining therapy as usually practiced (effectiveness) to studying “ideal” therapy as guided by manuals and competency ratings (efficacy).

In 1989, Irene Elkin and other principle investigators reported on the comparative outcomes of this study, which compared a standard reference treatment (antidepressant imipramine plus clinical management) with two psychotherapies (cognitive-behavioral therapy and interpersonal psychotherapy). These three treatments were contrasted with a drug placebo plus clinical management control group. Although each of these two psychotherapies had been shown to be specifically effective with depression, this study was the first head-to-head comparison of these two psychotherapies. Since the initial publication, a large number of papers have been published regarding various aspects of this study.

Participants in this study were referred from psychiatric outpatient services, self-referrals, and other mental health facilities. An initial 560 patients were interviewed by clinical evaluators using the Schedule for

Affective Disorders and Schizophrenia interview to eliminate participants with comorbid diagnoses. Inclusion criteria included the diagnoses of a current episode of major depressive disorder, and a score of 14 or higher on an amended version of the 17-item Hamilton Rating Scale for Depression. Remaining candidates for the trial were excluded if they had additional psychiatric disorders, two or more schizotypal features, history of schizophrenia, organic brain syndrome, mental retardation, concurrent treatment, presence of specific physical illness or other medical contraindications for the use of imipramine, and presence of a clinical state inconsistent with participating in the research protocol (e.g., high suicidality). The 250 patients who passed the clinical and medical screening gave consent to be entered into the study and were randomly assigned to a treatment condition based on a separate computer-generated random order for each of three sites: Pittsburgh, Oklahoma City, and Washington, D.C.

The 28 therapists (18 psychiatrists and 10 psychologists) were carefully selected, trained, and monitored in the specific treatment they offered. A different group of therapists conducted treatment in each of the treatment and control conditions, with the exception of the two pharmacotherapy conditions (imipramine plus clinical management and pill placebo plus clinical management), which were conducted double blind by the same therapist. Patients were assigned to therapists within treatments according to availability, and each therapist saw between 1 and 11 patients.

The treatments were carefully defined and followed manuals that spelled out theoretical issues, general strategies, major techniques, and methods of managing typical problems. Clinical management was a component of both pharmacological conditions to ensure clinical care and to maximize compliance. Because the clinical management offered patients support, encouragement, and occasionally direct advice, this condition may have approximated a "minimal supportive therapy" condition. However, because specific psychotherapeutic interventions were not used, improvement attributed to the "minimal supportive therapy" is indicative of common factors present in all conditions, and not specific therapeutic interventions.

During the training phase of the study, all therapists received additional training in their respective approaches and met competency criteria in carrying out their assigned treatment. Throughout treatment, therapists were monitored to ensure their adherence to their respective approaches and to determine whether the treatments could be differentiated from one another. The treatment approaches were observed by researchers and were

correctly classified more than 95% of the time, ensuring that differences found between treatments were indeed due to the difference in therapeutic approaches.

Psychotherapy sessions were each 40 to 50 min long, whereas the initial pharmacotherapy session was 45 to 60 min long and clinical management sessions 20 to 30 min long. Treatments were intended to last 16 to 20 weeks, however the total sample averaged 13 sessions. Those who completed therapy averaged 16.2 sessions, while early terminators averaged 6.2 sessions.

Eleven of the 250 patients dropped out of the study before the first treatment session. Of the remaining 239 patients entering treatment, 77 (32%) terminated before completion (had less than 12 sessions of treatment) either because they chose to or because they were withdrawn by the study staff. On investigation of differences between early terminators and those who completed treatment, it was determined that early terminators across all the treatments were significantly more severely depressed at intake than those who completed treatment.

Outcome was assessed on termination of treatment and follow-up intervals on measurements of depressive symptoms, overall symptoms, and general symptoms from both the perspective of a clinical evaluator and the client. Outcome was analyzed for pretreatment–post-treatment differences and predetermined levels of clinical recovery. Post hoc explanatory analyses were carried out comparing patients with different levels of depression severity.

Numerous comparisons were made, and the results of the study are very complex. Confounding variables influencing outcome included initial severity of the patient's condition, research site differences, and the attrition rate of the patients. However, each of the treatment conditions, including the control condition, evidenced significant improvement from pretreatment to posttreatment. The results for cognitive-behavioral therapy (CBT) and interpersonal therapy (IPT) fell in between the imipramine plus clinical management group (IM-CM), which was the most effective, and the placebo plus clinical treatment group (PLA-CM), which was the least effective, although the psychotherapy outcomes were closer to the more effective IM-CM condition.

The initial severity of depression proved to be a significant variable in treatment outcome. For the patients with less severe depression, there was no evidence of the effectiveness of any treatment over PLA-CM group. However, the patients who were more severely depressed and functionally impaired did extremely well with the IM-CM condition and poorly on the PLA-CM condition, with the psychotherapies falling in between.

The results suggested that the psychotherapies needed to be offered for more than 14 sessions with the patients with more disturbances, as many continued to show symptoms of depression at the end of treatment.

Among the more interesting findings were comparisons of the two psychotherapies with the PLA-CM control group. This latter condition was intended to control for the effects of regular contact with an experienced and supportive therapist, the general support of the research setting, and the effects of receiving a “drug” that was thought to be helpful, thus answering the question of whether the psychotherapies had any effects beyond what could be achieved through this rather extensive control condition.

There was limited evidence of the specific effectiveness of IPT and no evidence for the specific effectiveness of CBT. Surprisingly, there was also little evidence for superiority of either therapy in contrast to the placebo plus clinical management. The therapies were effective, but the patients who received the placebo plus clinical management also improved. These results are consistent with the common finding that the relationship that develops between therapist and patient is a potent force in enhancing treatment outcome. This positive alliance was found in the clinical management conditions (drug/placebo) as well as in the psychotherapy conditions.

In head-to-head comparisons of IPT and CBT, no significant differences were found in any of the major analyses or in comparison with patients with more and less severe disturbances. This similarity held up even on measures that were thought to be differentially sensitive to the two therapies. However, in some post hoc comparisons, modest evidence of specific effects could be found. Although all patient groups improved by the end of treatment, superior recovery rates were found for both IPT and IM-CM, when compared to the PLA-CM control group.

III. SUMMARY

Clinical trials provide evidence of the degree of effectiveness of a specific treatment compared to various control groups under rigidly controlled experimental

conditions that allow researchers to make causal inferences about the causes of improvement. Clinical trials involve taking a theoretical rationale for the disorder of interest, a hypothesized chain linking change mechanisms to specific interventions, and operationalization of interventions that promote the likelihood of replication. They also include the identification and careful selection of a target population and use of measures that are appropriate to the disorder and relevant to symptomatic recovery and daily functioning. Therapists are carefully selected, trained, monitored, supervised, and their adherence to treatment manuals and competence are ensured. The data that result are subjected to appropriate statistical analysis including the extent to which differences between treatment and control groups are probable. They attempt to delineate the mechanisms through which psychotherapy operates. Because of the rigorous design demands, clinical trials are limited in their ability to generalize to routine practice, thus they must be followed by effectiveness research paradigms.

GLOSSARY

conditioning The term conditioning is used for the establishment of conditioned reflexes. The classical or respondent conditioned reflex first described by Pavlov is produced by regularly following a stimulus (the conditioned stimulus) by an unconditioned stimulus, that is, a stimulus that in a motivated animal or person produces an unconditioned reflex. A conditioned reflex, which is similar to the unconditioned reflex, commences to occur to the conditioned stimulus. The familiar example is the occurrence of salivation to an auditory stimulus that is regularly followed by the presentation of food. An avoidance conditioned response is one that attempts or successfully avoids an unpleasant stimulus, such as an electric shock. The attempt could be withdrawal of a limb when the shock is administered to the limb. The successful avoidance could be pressing a bar or jumping a hurdle in response to a signal that is followed by the shock if the response is not made. This form of conditioning in which a response is followed by a pleasant or unpleasant stimulus is termed operant or instrumental conditioning.

extinction Gradual failure of a previously conditioned response to occur to the conditioned stimulus when the latter has not been followed by the unconditioned stimulus on a number of occasions.

reinforcement The presentation of the unconditioned stimulus following the conditioned stimulus. Partial reinforcement is intermittent in that the unconditioned stimulus is at times omitted. Conditioned responses established by partial reinforcement are more resistant to extinction than those established by consistent reinforcement, that is, they take longer to fail to occur when reinforcement is consistently ceased.

U-scores U-scores of sexual orientation use the Mann-Whitney U-test to provide a statistical assessment of the degree to which individual men show increased penile volume responses to ten 10-second films of nude women versus ten of men. The resulting U-score approaches 100 the more their ten responses to the pictures of women were greater than the ten to the pictures of men, and approaches 0 for the reverse. When the scores are 23 or less or 77 or more the difference is statistically significant. Scores of over 77 were obtained by 90% of men identifying as heterosexual.

I. DESCRIPTION OF ELECTRICAL AVERSION

Electrical aversion is the administration of electrical shocks following exposure to cues that stimulate inappropriate urges or behaviors (respondent conditioning) or following the carrying out of the behaviors (operant conditioning). Its aim is to weaken or eliminate those urges or the motivation to carry out the behaviors, so that they are carried out less frequently or ceased. The electrical shock is usually administered to the treated subject's limbs either by attached electrodes at an intensity determined by the

subject to be painful but not unbearable and not emotionally distressing, or by devices such as a cattle prod or a remote control device at a level that is unbearably painful and emotionally distressing.

II. CASE ILLUSTRATION

At her initial consultation Ms. J. D., aged 27, reported the presence of jealous obsessions since her first emotional relationship with a man when she was 18. The thought that her boyfriend could be sexually attracted or in love with another woman preoccupied her almost continuously and was extremely distressing. It would cause her to repeatedly accuse the boyfriend of being in love with other women but only staying with her because he felt obliged to. His assurance that he was not would only briefly relieve her of the thought that as she said “the terrible things in my mind are true.” If between relationships she formed a friendship with a woman she considered attractive, when she met a new boyfriend she would cut off the relationship with the woman, for fear the boyfriend would find her attractive. Also she would put pressure on her boyfriend to limit any kind of social interactions with women she saw as attractive. This behavior had frequently caused boyfriends to whom she was strongly attracted to terminate the relationship. Ms. J. D. added that “otherwise they would never have let me go.” She said that from the time she was 18 to 22 the thought was present “24 hours a day; it was all I could think about” and frequently it would cause her to become “hysterical,” that is emotionally out of control. She said because of the continuous preoccupation she stayed in secretarial employment below her ability so that she could continue to work. When she was criticized for her behavior she said she would try and control it, although the thoughts would remain distressing. Finally she felt she would stop work and any social activities as otherwise she would attempt suicide. She said when she told her mother this, her mother said she would be sent to a mental asylum, and this caused her to continue her normal life.

Prior to the initial consultation Ms. J. D. had had psychiatric treatment for several years that included administration of the antipsychotic agent thioridazine and the antidepressant agent amitriptyline, and encouragement to accept that her thoughts were not true. However, she felt that in contrast to the behaviorally oriented psychiatrist she saw in the previous year, her initial psychiatrist would advise her but not encourage her to depend on herself. The second psychiatrist attempted to rid her of the obsessive thoughts by a satiation procedure, instruct-

ing her to write them down repeatedly. Nevertheless, although she felt very guilty about the behavior with her current partner, she could not control it. She added that a few months previously she found she had a lump in her breast and hoped it was malignant as death would relieve her of her distress concerning her obsessive thoughts. She constantly experienced headaches that she attributed to her distressing thoughts and was unable to enjoy any activities due to the constant preoccupation. When people talked to her she would answer vaguely as her mind was continuously on the thoughts.

It was not possible to clarify whether Ms. J. D. believed her boyfriend was in love with another woman or feared he was, that is phenomenologically whether the thought was a delusion or an obsession. It is commonly considered that patients with obsessive-compulsive disorder do not believe their obsessive thoughts are true, and that patients who do are suffering from a delusional disorder. However, in my experience this is not always the case, and patients who have a particular belief can have an illness that has all the features of obsessive-compulsive neurosis rather than delusional disorder in terms of the age of onset, life history, and response to cognitive behavioral treatment and selective serotonin reuptake inhibitor medication.

I considered that her illness had the features of obsessive-compulsive neurosis and I treated her initially with clomipramine, increasing the dose to 150 mg at night. This medication had been established in controlled trials to be specifically effective for this condition. My decision was also influenced by the fact that her mother had a depressive illness that responded to this medication and her brother had been diagnosed with a schizophrenic illness with obsessive features that responded to a mixture of clomipramine and a phenothiazine. However, Ms. J. D. showed little response to the introduction of clomipramine.

In view of the severity of her condition and the fact it had not responded to medication or satiation therapy, I decided to try electrical aversion in an aversion-relief procedure. Ten phrases expressing her thoughts, such as “Being upset when I see my boyfriend talking to an attractive woman,” “Being upset at the thought of my boyfriend flirting with another woman,” as well as an eleventh statement “Feeling confident of my boyfriend’s love” were each written on separate filing cards. The cards were placed upside down in front of the patient with the card with the eleventh statement after the 10 and on top of about 20 blank cards. Electrodes were attached to Ms. D.J.’s first and third right hand fingers from a device constructed to deliver an electrical shock consisting of 1 millisecond pulses every 10 milliseconds and

of 1 second duration. The voltage of the shock to be administered was decided prior to treatment, as she determined it to be unpleasant but not upsetting. In her case this was 85 volts.

She was then instructed to turn over the first card and read it aloud. Immediately when she completed reading the phrase she received a shock at the level determined. This procedure was repeated with the following cards every 10 seconds until she had read the phrases on all 10 cards. She then read the final card and did not receive a shock. The aim was that the statement on this card would be reinforced by the relief of knowing when reading it that it would not be followed by a shock. The 10 cards were then shuffled and the procedure repeated four more times. Shuffling the cards was done so that she would not realize when she was about to turn over the card with the eleventh statement so that the relief would not be experienced until she saw the phrase. She received this treatment twice a week for 4 weeks. By the fifth session she reported that the thoughts were less frequent and much less distressing, so that she was able to go out with her boyfriend and not be constantly watching him or be concerned if he talked to other women. The treatment was ceased after the tenth session when she felt her improvement was maximal. In the final session I noticed that she laughed when she read the phrase "Being upset at her boyfriend being sexually aroused at the sight of a girl in a see-through nightie." After the session I asked her again if she initially had believed the thought that her boyfriend loved another woman or just feared it. She said "Before this therapy I did believe it, now I believe he loves me. I can almost laugh about the things on the cards. I can look at other women and think my boyfriend loves me. I feel flattered when I look at them."

I continued to see her every few months for the following 2 years, during which time she obtained employment in a much more demanding position as a private secretary to a prominent politician and subsequently married the boyfriend she had been seeing at the time of her initial consultation. She said that issues of jealousy were no longer a problem in their relationship and added that in the past she would seek reassurance from other people. Now she depended on herself and felt much more secure.

III. THEORETICAL BASES AND EMPIRICAL STUDIES

Contingent shock is the administration of highly painful electrical shock to subjects immediately following their carrying out markedly injurious behavior to others or more commonly to themselves, such as eye

gouging or finger biting. Its aim is to produce immediate cessation of the behavior and prevent its future occurrence. This form of contingent shock has been accepted without question to be a form of avoidance conditioning. It had been repeatedly demonstrated to be effective in single-case studies. Duker and Seys in 1996 reported its use by a remote control device in 12 profoundly mentally retarded subjects whose behavior was resulting in life-threatening self-injuries. In a follow-up of 2 to 47 months the behavior was almost completely suppressed in 7 subjects, so that physical restraint was no longer necessary. In a further 3 it was moderately effective, but they still needed daily administration. In 1997 Diden, Duker, and Korzilius carried out a meta-analysis of over 50 predominantly single-subject studies. They found contingent shock to produce an effectiveness score that markedly exceeded that of other procedures used to treat self-injurious behaviors.

The theoretical basis of therapies using lower levels of aversive stimuli proved much more controversial when it was investigated intensively from the 1950s to the 1970s, the period this form of aversive therapies was commonly used. Although there has been no generally accepted resolution, currently little interest is shown in how these therapies produce their effects, reflecting the general decline in empirical research of cognitive-behavioral approaches.

A. Conditioning of Anxiety-Relief

In his monograph *Psychotherapy by Reciprocal Inhibition* published in 1958, which stimulated the widespread introduction of behavioral modification procedures to psychiatry and psychology, Wolpe suggested that "anxiety-relief" responses might be directly conditioned to convenient stimuli and subsequently used to counter anxiety. He based the suggestion on the observation that if a stimulus was repeatedly presented to an eating animal just before withdrawing its food, that stimulus acquired the property of inhibiting feeding even when the animal was in the middle of a meal. Wolpe argued that by analogy it might be expected that a stimulus that consistently coincided with the termination of a noxious stimulus might acquire anxiety-inhibiting effects. He pointed out the possibility was supported by experiments showing that approach responses were conditioned to a stimulus repeatedly presented at the moment of termination of an electric shock, in contrast to the avoidance that is conditioned to a stimulus that preceded an electric shock.

Wolpe investigated the validity of his suggestion by attempting to reduce patients' anxiety. Electrodes

attached to their left forearm and palm were connected to an induction coil fed by a 6-volt battery. Tests were made to determine a level of shock that each patient found very uncomfortable without being unbearable. The patients were then instructed that the shock would be repeated and they were to endure it until their desire to have it stop became very strong, at which point they were to say aloud the word "calm." The shock would then be immediately terminated. After 30 to 60 seconds the procedure was repeated 20 to 30 times at a session. Wolpe emphasized that patients were reassured they would never be shocked without warning, and that such warnings should be given every time a shock was administered, as otherwise some patients became very anxious between shocks. Wolpe reported that most patients reported a feeling of relief at the cessation of the shock, which was sometimes greatly out of proportion to the discomfort that went before. Many found that after one to three sessions using the word "calm" could diminish the intensity of anxiety evoked in the course of day-to-day experience.

B. Avoidance Conditioning

Wolpe also reported studies using electrical aversion to produce avoidance reactions to obsessional stimuli that produced intense and excessive approach responses. He stated that the essence of the method was to administer a very unpleasant electrical shock to the subject in the presence of the obsessional object, citing the successful use of the procedure in the 1930s for the treatment of both alcoholic addiction and fetishism. As used by Wolpe the shock was administered not in the presence of the stimulus, but its mental image, by asking subjects to imagine it. The subjects were instructed to signal when the image was clear, when a severe shock was administered to their forearm. This was repeated 5 to 20 times a session. Wolpe reported a case illustration of its successful use in a woman with what he termed a food obsession. She found foods with a high salt content or that were fattening irresistibly attractive. Following treatment she reported that on imagining any such food she immediately had a feeling of fear and revulsion, accompanied by an image of the shock situation. She no longer experienced the previous misery of hours debating "Should I eat; should I not?"

The reintroduction of electrical aversion by Wolpe led to the procedure being widely adopted in the 1960s using moderate levels of shock to reduce behaviors subjects found unacceptable. These included homosexual, gambling, and paraphilic behaviors and alcohol

and other substance abuse. It also stimulated the use of high levels of contingent shock to inhibit harmful behaviors in developmentally delayed subjects. Its use in the treatment of anxiety was rarely followed up.

C. Bearable Electrical Aversion in Treatment of Homosexuality

Throughout the 1960s the assumption persisted that the milder form of electrical aversion was a conditioning procedure resulting in an aversion to the stimulus or behavior that preceded administration of the electric shock. This assumption was first questioned in 1969 in relation to its use in the modification of homosexual interest or behaviors. As pointed out in a 1977 review by McConaghy, it was this use that was most subjected to empirical investigation, both in relation to its efficacy and mode of action. This was most likely because the response of homosexual men could be assessed not only by their self-report of changes in their feelings and behaviors but also by apparently objective laboratory assessment of changes in their sexual orientation. It was also this use in homosexual men that was strongly and persistently criticized, most recently by King and Bartlett in the *British Journal of Psychiatry* in 1999.

The first influential study in which an aversive procedure was employed to treat a significant number of men who identified as homosexual was reported by Freund in 1960. An emetic agent was administered to the men daily and while its effects lasted, they were shown slides of dressed and undressed men. In a second phase of treatment they were given 10 mg of testosterone propionate and 7 hours later were shown films of nude or seminude women. Freund reported only the men's subsequent heterosexual adaptation. In 10 men (15%) it was short term and in 12 (18%) it lasted at least several years. Freund termed the procedure conditioned reflex therapy. His report was published in the influential monograph *Behaviour Therapy and the Neuroses*. The editor, Eysenck, accepted that the procedure acted by conditioning but pointed out that the principles of conditioning and learning theory must be known and adhered to by practitioners if such procedures were to be effective and not harmful. He stressed the importance of exact timing of the administration of the conditioned stimulus in relation to the unconditional stimulus and that this could not be achieved in regard to the onset of the effect of emetic agents. He considered better results would be obtained with electrical shock, the onset of which could be exactly timed. Subsequently an increasing number of

studies were reported using electrical shock rather than emetic agents in the treatment of homosexuality.

1. Anticipatory Avoidance Conditioning

Following Eysenck in emphasizing their conviction that if conditioning techniques are to be employed in psychiatry, they should represent the systematic application of the methods and findings of experimental psychology, in 1964 Feldman and MacCulloch introduced anticipatory avoidance aversion therapy in the treatment of homosexuality. They concluded from a review of the literature that for the response to be most resistant to extinction a conditioned avoidance technique should be used. The training trials should be well spaced, electrical shock used rather than nausea-producing agents, and reinforcement should be partial (see Glossary). Subjects were shown a slide of a male, which they could remove with a switch provided, but were instructed to view it as long as they found it attractive. If they left it on for 8 seconds they would be given an electrical shock to the calf that was terminated when they removed the slide. The level of shock employed was that which inhibited their feeling of attraction. On two-thirds of occasions they could remove the slide before 8 seconds so avoiding the shock, the reinforcement trials. On one-third of occasions their attempts to remove the slide were unsuccessful, so they received the shock. These nonreinforced trials meant that the avoidance response was only partially reinforced. Randomly on about half the occasions when the subjects removed the slide of the male it was replaced by the slide of a female. MacCulloch and Feldman in 1967 reported the response of 41 male and 2 female subjects, concluding that 25 were significantly improved in that they showed ratings of 0 to 2 on the Kinsey 0 to 6 scale, where 0 is exclusively heterosexual, and 6 exclusively homosexual. Thirteen of the 25 were heterosexually active with no homosexual fantasy or behavior.

2. Aversion-Relief Therapy

In an alternative development in 1964, Thorpe and colleagues argued that as photographs symbolized the behaviors to be treated with aversive therapy, words might be equally effective symbols and their use would avoid the necessity of obtaining suitable photographs. They also noted that in sessions of aversive therapy when subjects recognized by a signal that administration of unpleasant stimuli had finished they experienced great relief. They decided to incorporate this relief into the treatment of homosexuality in men that they had developed, which they termed aversion-relief therapy. With

aversion-relief, as used in the case illustration reported, subjects were shown a series of words or phrases every 10 seconds. All but the last word or phrase related to the behavior being treated, for example, "homosexual" or its synonyms. The last word related to behavior to be encouraged, such as "heterosexual." Each time the subject saw a word he was to read it aloud. He received a painful shock to his feet, except when the last word was shown. Thorpe and colleagues reported subjects quickly learned that they received no shock with the last word and experienced marked relief. The series of words were shown five times in a session, which was carried out daily. The responses of three subjects were reported at 4-weeks follow-up. Two subjects reported negative feelings to homosexuals or homosexual thoughts during or following treatment and the third that he had no homosexual desires in situations where in the past he had experienced them. All three reported more heterosexual interest.

3. Contingent Electrical Shock

In 1969 Bancroft reported the use in 10 homosexual men of electric shock contingent on their showing a distinguishable penile circumference response to photographs of males. Up to four further shocks were given at 15-second intervals unless penile circumference decrease occurred. At the time it had not been recognized that as shown by McConaghy in 1974 a percentage of men in response to stimuli they find sexually arousing initially show penile circumference (but not volume) decreases. In such men their responses of arousal to pictures of males would be indexed as decreases and not followed by shock, while their reduced arousal to pictures of males would be followed by shock. This may have contributed to outcome of the subjects treated, the poorest in the literature. One year or more following treatment two and possibly a third reported reduced homosexual desire and one reported no homosexual desire.

A related contingent treatment was used in the treatment of male child molesters by Quinsey and colleagues in 1980, although evidence had by then been advanced that penile circumference decreases could paradoxically index increased sexual arousal, and vice versa. The subjects were given biofeedback of their penile circumference responses as if the responses correctly indexed their arousal to pictures of adult and child nudes. The subjects received electrical shock to the arm when they showed circumference increase to the pictures of children. The only outcome reported was change in their penile circumference responses to the pictures following treatment, although again by this time the ability of many men to consciously modify

their penile circumference responses had been reported. In their 1995 review of sexual reorientation therapy for pedophiles, Barbaree and colleagues considered this the only well-controlled study that convincingly showed the effectiveness of electrical aversion with child molesters.

4. Comparison Studies of Aversive Procedures in Homosexuality: No Conditioning Evident

The first comparison study of aversive procedures was reported by McConaghy in 1969 with a year follow-up reported in 1970. It and a subsequent series of studies reviewed by McConaghy in 1977 were designed to determine the effects of aversive therapy in male homosexuality and whether they were consistent with it acting by conditioning. In the studies, in addition to subjects' self-reports, their penile volume responses to 10-second duration moving films of male and female nudes were investigated before and after treatment and at follow-up. McConaghy in 1998 reviewed evidence showing that penile volume compared to penile circumference assessment provided a more valid assessment of individual subjects' stated ratio of heterosexual/homosexual interest and, when advantage was taken of its much shorter latency, was much more resistant to modification by the subject.

In the initial study 40 men who requested aversive therapy to reduce or eliminate homosexual interest or behaviors were randomly allocated to two procedures. Twenty received apomorphine aversive therapy to photographs of nude men and 20 received electrical shock aversion-relief therapy using phrases, with the shocks delivered to two fingers of the subjects' hands. The level of shock was that subjects found painful but not unbearable. At 1-year follow-up half the subjects considered their homosexual urges to be reduced and half, mainly the same men, that their heterosexual desire had been increased. A quarter of the subjects had had no homosexual relations since treatment and a quarter reported that the frequency of such relations was reduced. There were slight but nonsignificant trends for more men to report increased heterosexual interest following aversion-relief and more to report reduced or no homosexual relations following apomorphine aversion. Using U-scores (see Glossary) of the men's penile volume responses to the film assessment, prior to treatment 10 of the 40 showed scores of over 50, indicating predominantly heterosexual orientation, with 1 of the 10 having a score of over 77. Following treatment 15 showed scores of over 50, with 2 having scores of over 77.

McConaghy pointed out that the conditioned response to a stimulus reinforced by a painful electrical shock to

the fingers was hand withdrawal, and to a stimulus reinforced with apomorphine is nausea. Following treatment no subjects reported these responses, despite their reporting reduction in homosexual desire. It was suggested that this reduction could not be produced by conditioning in view of the absence of the expected conditioned responses. Workers including MacCulloch and Feldman and Thorpe and colleagues in 1964, and Solyom and Miller and Schmidt and colleagues in 1965 had reported reduction in homosexual feelings following aversive procedures in homosexuality. They did not report the presence of expected conditioned responses, but did not appear to have attached any significance to this.

In the follow-up reported in 1970, McConaghy pointed out that although only seven subjects considered their sexual orientation had changed from predominantly homosexual to predominantly heterosexual, other criteria of evaluating responses were also important. Some men who remained exclusively homosexual and continued homosexual behaviors they found acceptable, reported they were no longer continuously preoccupied with homosexual thoughts and felt more emotionally stable and able to live and work more effectively. A number of these men were able to control compulsions to make homosexual contacts in public lavatories, which had caused them to be arrested one or more times previously. Six of the nine married men at follow-up stated their marital relationship had markedly improved, including two who had ceased having intercourse with their wives some years prior to treatment.

Although there were no statistically significant differences in outcome between aversion-relief and apomorphine aversion, it was considered that the trends toward slight differences required investigation by replication. A further 40 men seeking treatment for homosexuality were randomly allocated, 20 to receive apomorphine therapy as in the first study and 20 to receive the anticipatory avoidance treatment developed by Feldman and MacCulloch. The latter treatment was used as being theoretically the most effective, if it did act by conditioning. At follow-up there were no consistent trends for the outcome of the two procedures to differ, both producing results comparable with those of the first study. Changes in subjects' penile volume responses to the films of men and women following the two procedures were also similar and comparable to those found in the first study. The two studies had therefore demonstrated that three markedly different aversive procedures produced comparable outcomes, yet as conditioning techniques one, apomorphine therapy, could be expected to be poorly effective and one, anticipatory avoidance, maximally effective.

5. Backward Conditioning and Forward Conditioning Equally Effective

A third study further replicating the findings concerning the outcome of electrical aversive therapy in homosexuality and strengthening the argument that the procedure does not act by conditioning was reported by McConaghy and Barr in 1973. Forty-six men seeking to control unacceptable homosexual interest or behaviors were randomly allocated to receive either anticipatory avoidance, classical conditioning, or backward conditioning. Anticipatory avoidance was carried out as in the previous study. With classical conditioning subjects were shown for 10 seconds at 4-minute intervals slides of males they had selected as attractive. For the final second of exposure of the slide and for 1 second following its removal they received a painful electrical shock to two fingers of one hand. The backward conditioning approximated the avoidance procedure in terms of frequency and duration of the presentation of the slides of males and females but with the electrical shocks preceding rather than following the presentation of the slides of males. There were no consistent trends at 1-year follow-up for one therapy to be more effective than another. The proportion of men reporting decreased homosexual interest and increased heterosexual interest was similar to that in the previous two studies. The change in the sexual orientation of the men as determined by penile volume assessment was also similar.

As backward conditioning is accepted to be a relatively ineffective conditioning procedure, the finding that it produced a similar outcome to forms of conditioning accepted to be effective, strongly supported the conclusion that the outcome of electrical shock aversive procedures in homosexuality is not the result of conditioning. In addition, if conditioning played a role in the outcome of aversive procedures it would be expected from conditioning research that the outcome would be greater if more intense shocks were employed. In the 1973 study no relationship was found between outcome and the intensity of voltage selected by the subjects.

6. Positive Conditioning Ineffective: Electrical Aversive Therapy Superior to Placebo

In the early 1970s studies were reported in which a small number of homosexual men were treated by having them view slides of women in association with those of men with the aim of increasing their sexual arousal to women by positive conditioning. McConaghy in 1975 reported a fourth study comparing this treatment with aversive classical conditioning. Thirty-one homosexual men were randomly allocated to one or other of the procedures, half of which were

presented in forward and half in backward conditioning paradigms. Subjects' penile volume responses were recorded throughout all procedures. No penile response conditioning occurred to the slides of women in the positive conditioning procedure although unconditioned penile responses continued to occur to the slides of males throughout treatment. Also there was no difference in the changes in sexual interest or behaviors reported by the men who had received the positive conditioning in a forward as compared with a backward paradigm. It was concluded that the positive conditioning procedure had no specific therapeutic effect but acted as a placebo therapy.

At 3 weeks and 1-year follow-up, more subjects who received the electrical aversive treatment as compared with positive conditioning reported reduction in homosexual interest and behaviors. The differences were statistically significant for reduction in homosexual interest at 3 weeks and reduction in homosexual behavior at 1 year. The outcome following aversive therapy given in forward and backward forms did not differ. At 3 weeks following both the aversive therapy and positive conditioning a similar number of subjects reported increased heterosexual interest and behaviors, but at 1 year there was a trend for more subjects to report this following aversive therapy. It was concluded that the aversive therapy produced specific reduction of homosexual interest and behaviors in contrast to the placebo effects of positive conditioning.

7. Aversive Therapy Does Not Produce Specific Change in Penile Volume Assessed Sexual Orientation

The changes in subjects' penile volume response assessment to the 10-second films of men and women from before to after all treatments in the fourth study were similar to the changes in the heterosexual direction that followed the aversive therapies in the three previous studies by McConaghy and colleagues. If these changes were a specific effect of treatment they should have been greater following the aversive as compared to the positive conditioning placebo procedure, since the reduction in homosexual interest produced by the aversive therapy was significantly greater than that following the placebo. As the penile volume changes were comparable, it was concluded they were nonspecific and unrelated to the treatment effect, but resulted from subjects consciously or unconsciously modifying their penile volume responses to appear more heterosexual. Freund had shown in 1971 that 5 (20%) of 15 homosexual men were able to do so without treatment. In the four studies, of the men assessed

prior to treatment 117 showed predominantly homosexual and 33 predominantly heterosexual orientation. Following treatment 53 showed predominantly heterosexual orientation. This change in 17% was within the range of the men Freund showed could produce in their penile volume responses voluntarily.

It was concluded that the specific reduction in homosexual interest and behaviors produced by electrical aversive therapies was not accompanied by any change in the subjects' sexual orientation as determined by physiological assessment of their sexual arousal to films of males and females. This conclusion was based on the only series of studies in the literature that used a highly valid measure of sexual orientation to measure the influence of aversive therapy on sexual preference. It casts strong doubt on the value of the continued use of aversive procedures to change the sexual preference of rapists and pedophiles. These changes have never been investigated using subjects' penile volume responses, but only their penile circumference responses. As pointed out by McConaghy in his 1998 review, these responses are of much lower validity and more open to voluntary influence.

D. Electrical Aversive Therapies Produce neither Aversion nor Indifference but Control

In the discussion of the previous study in 1975 McConaghy pointed out the rarity with which homosexual subjects reported negative feelings to homosexual stimuli following treatments that associated these stimuli with aversive experiences. Presumably it was the expectation of such aversions that prevented therapists from initially paying attention to their absence. McConaghy suggested that the procedures be termed aversive rather than aversion therapies. Apart from being more accurate it seemed the negative publicity given aversive therapies resulted in part from the incorrect belief that they produced aversions and hence reduced treated subjects' ability to carry out behaviors they considered acceptable. This publicity was reinforced by the widely acclaimed film of Anthony Burgess's 1972 novel *A Clockwork Orange*, which demonstrated the forced use of an extreme aversive procedure to produce a disabling aversion to violence in the protagonist.

When it was generally accepted that aversive procedures did not produce aversion, their outcome was widely accepted to be one of indifference. Wolpe in 1986 argued that this indifference was due to classical conditioning, even though no conditioned response was observed. He did not refer to the findings of the equal

effectiveness of backward and forward conditioning reported above, which would exclude the treatment response being due to conditioning. Also the finding of McConaghy's 1975 study that there was no specific change in the penile volume responses of homosexual men to films of men and women following aversive electrical shock therapy made it clear that the subjects were not indifferent to homosexual stimuli. As early as 1972 McConaghy had referred to subjects treated with aversive therapies being able to cease potentially harmful homosexual acts they had previously experienced as compulsive such as making contacts in public lavatories, while continuing acceptable homosexual behaviors in private. In a 1990 review McConaghy pointed out that superficial questioning could lead to the conclusion from successfully treated subjects' self-reports that they experienced indifference to those stimuli that caused them to carry out behaviors or experience feelings beyond their control prior to treatment. Careful questioning of such subjects elicits the information that, when confronted with such stimuli, they still experience attraction to them. However, the urge to respond behaviorally, or to become preoccupied with fantasies concerning the stimuli is much reduced or absent. He referred to the 1967 finding of MacCulloch and Feldman that six subjects who responded well to aversive therapy for compulsive homosexuality still displayed an occasional and very slight degree of homosexual interest in directly observing males, without, however, any subsequent fantasy.

1. Electrical Aversive Therapy Equivalent to Covert Sensitization

As early as 1965 Gold and Neufeld pointed out that some therapists have ethical and aesthetic objections to the use of physically unpleasant stimuli in aversive therapy. They recommended an alternative procedure later termed covert sensitization. Instead of a physically aversive stimuli being used, a homosexual subject while relaxed was instructed to visualize a psychologically aversive fantasy, such as while engaged in homosexual activity seeing a policeman standing nearby. In later developments the subject was instructed to visualize approaching an attractive male and then seeing he was covered with scabs and gave off a terrible stench, making the subject feel sick and vomit. He turned away and started to feel better. In 1980 Lichstein and Hung reviewed studies employing covert sensitization, pointing out the paucity of controlled studies evaluating the procedure. They considered that only one study controlled for expectancy effects. The control procedure was for subjects to visualize deviant images repeatedly without nauseating images after having been told that

this would be therapeutic, whereas visualizing them with nauseating images as in covert sensitization would increase their deviant behavior. This seemed to be so opposed to common sense it would seem unlikely the subjects would have an expectancy of success with the control procedure. In fact, the authors reported one did not and continued to use the covert sensitization procedure against instructions. Also the study discounted subjects' self-reports of improvement and relied totally on their penile circumference responses as measures of outcome. From the findings of this methodologically faulty study, Lichstein and Hung concluded that the addition of nauseating aversive images increased the therapeutic effect of desensitization to the deviant images.

In a subsequent randomized controlled study reported in 1981, McConaghy and colleagues found covert sensitization to be as effective as electrical aversive therapy. Twenty men seeking treatment for homosexual urges and/or behaviors they experienced as compulsive were randomly allocated, 10 to each procedure. As it had been demonstrated there was no specific change in the penile volume assessment of sexual orientation in homosexual subjects treated with electrical aversion, it could not provide an objective evaluation of treated subjects' outcomes. Reliance could be placed only on their self-reports. These reports therefore were obtained in interview by an assessor who took no other part in the study and was blind to the nature of the treatment the subjects received. Subjects were followed-up for 1 year. The response to both procedures was similar to that to the aversive procedures in the previous studies.

2. Behavioral Completion Model of Electrical Aversive Therapy

Evidence reviewed by McConaghy in 1977 indicated that the outcome of aversive therapy in homosexuality was similar to that of systematic desensitization. It had been observed clinically that many subjects seeking treatment reported they had tried to control homosexual or paraphilic urges in situations where they had expressed such urges previously. However, when attempting this control they experienced increasing tension that they found so aversive as to force them to act upon the urges. It was theorized that a neurophysiological behavior completion mechanism existed that produced heightened arousal, experienced as tension, if subjects did not complete a habitual behavior, when they were exposed to cues to carry out the behavior, such as situations where they had carried out the behavior previously. The association of excitatory and inhibitory stimuli in aversive procedures was considered to reduce or inhibit this arousal. Evidence that conflict-

ing stimuli produced activity in forebrain structures in cats with resultant reduction in anxiety and fear was provided by a 1977 study of Thomas and De Wald.

On the basis of this theory McConaghy developed as a possible replacement for aversive therapies, an alternative behavior completion procedure, initially termed imaginal desensitization. The subjects was first trained to relax and then while relaxed were instructed to visualize being in situations where they had previously carried out the behavior they wished to control. When they signalled they were visualizing this while remaining relaxed they were then instructed to visualize not completing the behavior but carrying out an alternative such as leaving the situation until they signalled they were doing so and were remaining relaxed. Electrical aversive therapy had been reported in uncontrolled studies to be effective in gambling.

E. Alternative Behavior Completion Superior to Aversion-Relief in Compulsive Gambling

Alternative behavior completion was evaluated in relation to an aversive procedure in compulsive gamblers rather than subjects with compulsive sexual urges, because the outcome in most gamblers could be checked with their partners independently of their self-reports. Their self-reports were obtained in interview by an assessor blind to the nature of the treatment. McConaghy, Armstrong, Blaszczyński, and Allcock in 1983 reported the outcome of 20 gamblers randomly allocated, 10 to alternative behavior completion and 10 to aversion-relief. At 1-year follow-up significantly more subjects (7 of 10) receiving the former treatment showed reduction of gambling urges and behavior than did those (1 of 10) who received aversion relief. A 2- to 9-year follow-up of these and additional gamblers was subsequently reported in 1991. Their outcome was also checked with partners when possible, as well as in interview by an assessor blind to the nature of the treatment. Again a significantly better response was found in 33 gamblers randomly allocated to alternative behavior completion compared to 30 allocated to other behavioral procedures including aversion-relief. Twenty-six of the former showed cessation or control of gambling compared with 16 of the latter.

F. Electrical Aversion in the Treatment of Alcoholism

As compared with its use in homosexuality, empirical studies of electrical aversive therapy for alcoholism were

limited in number and methodological adequacy. A probable contributing factor was the report by Garcia and Koelling in 1966 that in animals aversions to tastes were much more easily established to malaise produced by ionizing radiation than to electrical shock, whereas the reverse was true for aversions to visual and auditory stimuli. In his 1977 review pointing out the lack of randomized controlled studies evaluating electrical aversion in treatment of alcoholism, Lovibond recommended that to develop aversive control of excessive drinking, illness and malaise may be a more appropriate stimulus than electric shock. However, Smith, Frawley, and Polissar in 1997 reported a slightly superior abstinence at 6 and 12 months in patients treated for alcoholism with electrical as compared to chemical aversion.

IV. APPLICATIONS AND EXCLUSIONS

In 1978 Marshall cited reports from 1965 that use of aversive stimuli on occasions resulted in an increase in aggression, so that satiation could be more suitable in treating rapists many of whom have a significant aggressive component. I am unaware of therapists since 1965 reporting increased aggression resulting from use of aversive procedures, despite their increased use in the following decade. I have never noted its occurrence in the well over 200 subjects in whom I have used electrical aversive therapies. King and Bartlett in their 1999 criticism of the use of electrical aversive therapies in the treatment of homosexuality stated that the damage they wrought was not considered and that anecdotal evidence suggested it was considerable. The anecdotal evidence was of course post hoc, requiring the illogical assumption that any negative experiences subsequent to an event are a result of that event. No similar criticism appears to have been made of the use of aversive procedures employing levels of electrical shock selected by the subjects to treat other conditions.

In the first two studies by McConaghy and colleagues using electrical aversive procedures, the homosexual subjects showed no evidence of disturbed behavior at follow-up 6 months or 1 year later. In the first study four subjects who felt they had not responded adequately requested further therapy. In the third study one subject lost all sexual feelings following treatment, but at follow-up stated they had returned. In the year following treatment two subjects experienced fairly severe depression, and four others had episodes of milder depression. All six had had many similar episodes prior to

therapy and it was considered only the first subject's response could be attributed to the treatment. In the fourth study four subjects were admitted to psychiatric units for periods of up to 6 weeks in the year following treatment. All had received psychiatric treatment prior to the aversive therapy. Three who had received positive conditioning (i.e., without aversive stimuli) were admitting following drug overdose, for depression, and for a schizophrenic reaction, respectively. The fourth, admitted following a drug overdose, had received aversive therapy. This finding indicated that if aversive procedures produce negative consequences they were less likely to do so than nonaversive placebo procedures.

As opposed to the post hoc evidence of resulting harm, a 1985 study by McConaghy and colleagues comparing alternative behavior completion with covert sensitization aversive therapy provided prospective evidence that the two procedures had positive rather than negative effects on the psychological state of most subjects treated. Their state and trait anxiety as assessed by the Spielberger scale was significantly lower at the year follow-up than prior to treatment. Further prospective evidence concerning aversive therapies was provided in the 2- to 9-year follow-up of compulsive gamblers treated either with alternative behavior completion desensitization or aversive procedures including electrical shock. Subjects' mean state and trait anxiety, neuroticism, psychoticism, and depression scores prior to treatment were in the psychiatrically ill range. At follow-up the scores of those who showed cessation or control of gambling were in the range of the healthy population. The scores of those whose gambling remained uncontrolled were virtually unchanged.

It would seem established that aversive procedures are effective and appear to have no specific negative consequences compared to placebo. However, therapies not using aversive stimuli are clearly preferable if they have been shown to be equally or more effective than aversive procedures. In fact, due to the negative reaction of many therapists to aversive procedures using electrical shock, they appear to have been largely replaced by alternative procedures, although, unlike electrical aversive therapy, few have been demonstrated in methodologically adequate studies to be more effective than placebo therapy. Kilmann and colleagues in their 1982 review of studies of treatment of paraphilias found that covert sensitization was used in about one-tenth of these studies until 1974 and one-half of those published from 1975 to 1980. In 1983 Marshall and colleagues concluded it was the preferred form of aversive therapy in the United States. In his 1996 review of

the management of sex offenders over the previous 20 years, Marshall referred to his development of satiation and masturbatory reconditioning as alternatives to aversive therapy because the latter did not appear always to be effective and typically, and "quite properly," generated bad press. These alternative procedures as well as covert sensitization were offered to all offenders he treated, although he stated the evidence in support of their value was not remarkable. He added that at times olfactory aversion was used also. In 1973 Maletzky described the addition of an aversive odor, for example of decaying tissue, when aversive images were suggested to the subject following the instruction that they visualize carrying out unwanted behaviors. He termed the procedure assisted covert sensitization.

Alternative behavior completion does not appear to be used in North America despite the evidence from randomized control trials that it reduces the strength of compulsive urges to a significantly greater extent than electrical aversive therapy and covert sensitization. The latter finding was reported in 1985 by McConaghy and colleagues in the randomized controlled study of 20 subjects with compulsive sexual urges. In opposition to the methodologically faulty conclusion reported by Lichstein and Hung, addition of nauseating aversive images did not increase the therapeutic effect of desensitization. The need for replication of the study was suggested on the basis that effective therapies not using nauseating images could be less damaging to the self-esteem of subjects treated. This has not been done and use of such imagery remains the preferred option outside Australia. The 1987 review by the Council on Scientific Affairs of the American Medical Association, which retained the term aversion, emphasized the lack of controlled research in its evaluation. It made no reference to the extensive series of randomized studies of McConaghy and colleagues that led to the development and evaluation of alternative behavior completion as superior to covert sensitization. In regard to the use of aversive procedures in unwanted sexual behaviors, the Council decided that the literature contained predominantly uncontrolled multifactorial studies, and concluded that the most positive results were reported with covert sensitization.

In relation to the treatment of obesity, the Council pointed out the findings of early uncontrolled studies reporting that weight loss with covert sensitization were not replicated by later controlled studies. They considered that the successes in the earlier studies were due to placebo and expectancy effects. They further concluded that controlled studies showed either no or a temporary effect from covert sensitization for smok-

ing, and the evidence supporting the efficacy of electrical aversive procedures in alcoholism was weak. Lawson and Boudin in their 1985 review also concluded that the use of electrical aversion in the treatment of alcoholism was associated with a high degree of attrition and was relatively ineffective. They considered that there was a growing consensus that its use for this condition could no longer be justified. In their 1996 review of 339 alcoholism treatment outcome studies reported between 1980 and 1992, Floyd, Monahan, Finney, and Morley found electrical aversion therapy to be used in only one study. However, in their 1997 study, Smith, Frawley, and Polissar found that patients treated with electrical or chemical aversion had a significantly superior outcome to matched inpatients from a treatment registry. Landabaso and colleagues in 1999 concluded from a 2-year follow-up of 30 patients treated for alcoholism that combining electrical aversion with naltrexone was effective when the aversive therapy alone had proved ineffective. The AMA Council considered in view of the inadequacy and contradictory findings of studies, that no conclusions could be drawn concerning the effectiveness of aversive procedures in drug abuse. Occasional case studies of a few subjects, such as that by Garcia Losa in 1999, have reported positive results with electrical aversion.

The Council concluded the best accepted use of aversive techniques is for the reduction of self-injurious behavior in mentally handicapped subjects, citing evidence that they were successful in 25% of those in whom such behavior is severe. They quoted the conclusion of a national task force convened in 1982 that when behavior is dangerous and has not improved with less intrusive procedures, increasingly aversive techniques up to electrical shock for the most severe, are appropriate. Understandably, as pointed out by Van Duser and Phelan in 1993, its use is of significant concern to treated subjects' relatives.

Apart from this use of markedly painful stimuli, it would appear that aversive therapy using moderately painful electrical stimuli remains used only rarely in conditions that have failed to respond to more conventional therapies. It was this form of treatment that historically was extensively researched in homosexual subjects and gamblers to elucidate its mode of action. This research provided the major findings that it did not act by conditioning and that although not producing aversion or indifference, and not changing the sexual preference of the homosexual subjects, it gave both groups of subjects control over urges they previously had experienced as compulsive. The demonstration

that this was possible led to the development of equally or more effective procedures to achieve the same outcome and hence have largely replaced this form of aversive therapy. Unfortunately, the interpretation has persisted as evidenced by the statement of King and Bartlett in 1999 that such aversive therapy was used only to sexually reorient homosexuals rather than to enable them to cease unacceptable while continuing acceptable homosexual behaviors. This has resulted in widespread failure to utilize the procedures developed from its use that would enable homosexual men to maintain safer sexual practices who wish to do so but are unable due to lack of control.

V. SUMMARY

A brief description of electrical aversion is provided followed by an illustration of its use in a woman with severe obsessional jealousy who had failed to respond to medication and other behavioral techniques. Electrical aversion was introduced as "anxiety-relief" to reduce anxiety by cues associated with termination of a painful shock, and as avoidance conditioning to inhibit excessive approach responses to stimuli by following them with painful shocks. Electrical aversion became widely adopted in the 1960s in two forms. One used high levels of contingent shock in developmentally delayed subjects to inhibit their severely harmful behaviors. The other form used levels of shock determined by the subjects to reduce behaviors they found unacceptable, such as compulsive homosexual behaviors, gambling, paraphilic behaviors and use of alcohol and other substances. A series of randomized controlled trials of its use to reduce men's unwanted homosexual feelings or behaviors provided evidence that it achieved this aim in comparison to a placebo procedure. It did so not by producing aversion or indifference but by increasing their control. The studies further showed that the procedure did not act by conditioning, nor did it alter the men's physiologically assessed sexual orientation. It was suggested it acted by inhibiting a neurophysiological behavior completion mechanism that compelled subjects to complete habitual behaviors against their will. This theory led to the development of alternative behavior completion as a therapy not involving aversive stimuli, which was shown in further randomized control trials to be more effective than

electric aversion in reducing compulsive sexual and gambling urges. Alternative behavior completion was also shown to be more effective in reducing such urges than covert sensitization, an aversive procedure developed to avoid use of physical aversive stimuli, replacing them with imagined aversive consequences. In the treatment of sex offenders in the United States it would appear covert sensitization has largely replaced electrical aversive procedures. The expectation persists there that all aversive procedures modify the sexual preference of the subjects treated despite valid evidence to the contrary. High levels of contingent electrical shock are still used in developmentally delayed subjects. The historical importance of the research evaluating electrical shock aversive therapies in the development of the theory concerning compulsive behaviors is pointed out.

GLOSSARY

in vivo desensitization Instead of just imagining feared situations, *in vivo* desensitization gradually and systematically presents the actual feared stimuli or events. For example, a client who fears dogs would be encouraged to approach the animal closer and closer, and eventually be willing to touch it and pet it and thus conquer the fear.

reciprocal inhibition Based on C.S. Sherrington's observation that certain nerve impulses cease firing when others are elicited, J. Wolpe proposed a model of psychotherapy wherein anxiety is diminished or extinguished when paired with more powerful anti-anxiety responses.

systematic desensitization A counterconditioning procedure in which unpleasant (anxiety-provoking) stimuli are presented when clients are pleasantly relaxed. Less threatening events are presented first, and gradually, more frightening circumstances are introduced. Treatment continues until the most anxiety-generating event on the hierarchy no longer elicits anxiety.

I. DESCRIPTION OF TREATMENT

Emotive imagery is the use of positive emotion-arousing mental pictures (imagery) to counterbalance

fear or anxiety. Thus, an exciting, pleasant, enjoyable image is introduced to offset the negative feelings generated by disturbing events. Repeated pairings of this kind may completely neutralize the anxiety.

Children's phobias had been treated mainly by exposure (gradually feared objects or situations would be introduced to the child) or by feeding (the child would be given ice cream or candy while the feared items were brought closer and closer—as in the famous case by Mary Cover Jones in 1924 wherein a child overcame his fears of rabbits and furry objects). The search for clinically effective anxiety-inhibiting responses added deep muscle relaxation to the aggregation, but it proved time-consuming and difficult or impossible to achieve with many children. Feeding has obvious disadvantages in routine therapy. Consequently, Arnold Lazarus and Arnold Abramovitz explored the possibility of inducing anxiety-inhibiting emotive images in place of relaxation and published a report in 1962. Emotive images refer to those classes of “mental pictures” that are assumed to arouse feelings of self-assertion, affection, pride, mirth, and similar anxiety-inhibiting emotions. Although Lazarus and Abramovitz first used the procedure with children, it was subsequently found to be equally applicable to adults.

With children, the technique of emotive imagery covers the following steps: (a) The range, circumstances, and intensity of the child's fears are established, and a graduated hierarchy is drawn up, from the least feared to the most feared situation. (b) The therapist establishes the nature of the child's hero-images

(usually derived from television, movies, and fiction). (c) The child is asked to imagine a sequence of events, within which a story is interwoven concerning his or her favorite hero or alter ego. (d) As a natural part of the narrative, the least anxiety-provoking items are first introduced. The child is instructed to signal by raising a finger if he or she feels afraid or unhappy or uncomfortable. In response to a raised finger, the phobic stimulus is withdrawn from the narrative and the child's anxiety-inhibiting emotions are aroused once again. The procedure is repeated, usually over several sessions, until the highest item on the hierarchy is tolerated without distress.

A case in point concerns a 9-year-old boy who became afraid of going to school. A sadistic teacher had subjected him to unfair criticism, and although this teacher had left the school, the boy nevertheless developed a full-blown school phobia. The lad was tested and scored very high in intelligence: his mental imagery pertaining to the school environment revealed pictures of receiving unfair punishment at the hands of nasty teachers. His negative images persisted despite the fact that his present teachers were kind and understanding.

The boy's favorite heroes were Batman and Robin. Emotive imagery was woven into the following story:

"Please sit back, get comfortable, take in a deep breath, hold it, and now exhale. Just breathe normally in and out. Now I want you to imagine that Batman and Robin have asked you to help them catch a criminal. Can you imagine that?" The child nodded affirmatively, and judging by his overall demeanor and facial expression, he was fully invested in the drama. The narrative was continued. "Robin hands you a special wrist radio so that he and Batman can contact you whenever necessary. Nobody must know the secret, that you are going to help Batman and Robin solve a crime right in your own school. Then Batman tells you that he has put a secret message in your school locker. He says: 'When you get to school tomorrow morning, go to your locker as soon as possible and read the message. Then destroy it!' Of course you don't want to tell Batman and Robin about your fears. You go to school the next morning and head straight for your locker. Picture yourself going to school. As you ride to school in the bus, you are wondering what the message will say. The bus drives into the schoolyard. The bus stops, you get out and walk slowly to your locker. You don't want to rush there because you don't want to make anyone suspicious."

At this juncture, the boy was asked to describe what was happening—how he was feeling and where he was heading. He described the school building, the hallway along which he was walking, the other children, open-

ing his locker. When asked how he was feeling, he made no mention of fear or anxiety. In place of the fear was the curiosity, the fun, the excitement, and the drama—what would the message say? The emotive imagery was continued.

"You open your locker and there you see a slip of green paper. It has the emblem of a bat on it and you know who the sender is. You slip it into your pocket, and some of your friends come up to talk to you. As soon as you manage to do so without being seen, you read the message from Batman and Robin. It says: 'We will signal you on your wrist radio during your first recess. Over and out!' You go to class. The teacher gives you some work to do. You are sitting at your desk. You wonder what Batman and Robin will want you to do next. You continue with your work. The nasty teacher who left the school walks into the classroom. You look at him, but you can't let that bother you. Bigger things are at stake. What will Batman and Robin ask you to do?"

The nasty teacher was then made the focus of attention with the aim of changing the boy's fear to feelings of indifference. The image of the particular teacher who had supposedly engendered the boy's phobic reactions was now being revamped and revised. The fact that he had no need to be afraid of this teacher was explicitly woven into the tapestry of the narrative. Of course, when Batman and Robin finally contacted him on the wrist radio they stressed that the "nasty teacher" was in fact the person they were after. The boy was asked to keep the nasty teacher under surveillance. Robin said: "That man may get to be very nasty, but just ignore him."

At this point, the boy, verbalizing his own pent-up aggressions, insisted on finishing the story himself. He described how he would help Batman and Robin lure the nasty teacher into a trap so that they could capture him and remove him to the nearest jail. At the end of the session, the boy was asked if he would try out his own Batman and Robin fantasy in school the next day. Observe that he was not asked whether he would go to school the next day. The "demand characteristics" of the situation placed the emphasis on how the boy would carry out his own fantasy projection *in school*. This boy was highly motivated, very responsive, and most receptive to emotive imagery. Thus, it took only a single emotive imagery session for him to return to school and to experience no further problems in that regard.

Some people may be concerned that the emotive imagery procedure plays tricks with a child's mind and encourages him or her to daydream and to dwell on fantasy rather than reality. No negative side effects have

ever been observed in a wide range of children treated by this method.

Although emotive imagery was first conceived as a rapid way of overcoming many children's phobias, its use with adults is also worth emphasizing. For example, a 22-year-old man who feared rejection was extremely reluctant to ask a woman out on a date. Yet he complained how lonely he felt and how much he wished to establish a good male–female relationship. Consequently, he was asked to form an image in which he approaches an attractive woman, asks her out, and is flatly turned down. The therapist said, "Try to picture this scene without feeling upset." After trying this out for a few days the client reported: "The only way I can visualize this without becoming upset is by firmly believing that the only reason she said 'no' to me was because she had a jealous boyfriend whom, she feared." He was told to take the risk of actually approaching women and asking them for dates while keeping the image and thought of the jealous boyfriend firmly in mind.

He followed this suggestion and took the emotional risk of approaching a woman he had long admired. "As I looked at her I went into my mind game, my mental act. I convinced myself that due to her jealous boyfriend she would have to turn down anyone who asked her out. Once I had established this in my own mind, I simply asked her if she would like to have dinner with me and perhaps go to a movie. I was ready for her 'no thanks' and almost fell over when she said, 'Thank you, I'd like to.' I did similar things with four other women and only struck out once—and it really didn't bother me because I 'knew' about the 'jealous boyfriend.'" As this young man discovered, people who acquire proficiency in the use of imagery have a remarkable built-in tool.

II. THEORETICAL BASES

As originally presented, emotive imagery was regarded as a reciprocal inhibition technique. Wolpe's formulation of the Reciprocal Inhibition Principle stated that:

If a response antagonistic to anxiety can be made to occur in the presence of anxiety-evoking stimuli so that it is accompanied by a complete or partial suppression of the anxiety responses, the bond between these stimuli and the anxiety responses will be weakened.

Whereas Wolpe regarded reciprocal inhibition as a master key to the cure of neurosis, the limitations of

this single principle were spelled out during the 1960s when a broad-based social and cognitive learning theory came into being. At the same time, many differing schools of thought incorporated a diverse range of imagery procedures into their repertoires. Thus, the contemporary view is that imagery techniques are not simple one-on-one "pictures in the mind" that exert therapeutic properties. Instead, without delving into complex neurophysiological processes that underlie all behaviors, images are tied to various cognitions, affective reactions, and sensory responses that have behavioral and interpersonal properties and consequences. The modern social cognitive perspective draws on direct and observational experiences and places emphasis on symbolization, self-regulation, forethought, and communication.

Those who wish to study in full the theoretical bases of any form of imagery will need to explore such diverse areas as verbal coding, observational learning, structure versus function, pictorial metaphors, and many other complex mental operations. For practical purposes, it is unnecessary to comprehend these nuances, and it is sufficient to conclude that a mental image should not be likened to a photograph in the mind but should be portrayed as a motion picture with many dramatic undertones.

III. EMPIRICAL STUDIES

Although an extremely rich clinical array of imagery techniques has been described, of which emotive imagery is but one of perhaps hundreds, there are no proper empirical studies to support the efficacy of this domain. There are no replicated studies, no measures of validity or reliability, and no operational definitions. Purists may contend that treatment techniques should be held in abeyance until such time as there are data to support them. From a practical perspective, it is necessary and advisable to proceed on the basis of clinical reports. It has been pointed out that many medical procedures were put to good use before scientific studies elucidated their precise mechanisms of action. Clinicians can point to cause-and-effect sequences which suggest that emotive imagery is a robust method that transcends mere suggestion, placebo, and the like.

IV. SUMMARY

Clinically, it has been shown that by conjuring up positive emotion-generating mental images, children's

fears and phobias can often be overcome quite rapidly. Adults may also benefit from the use of this procedure. The theoretical underpinnings are rather diffuse and tenuous, and there are no hard data to substantiate its effects. Nevertheless, from a purely clinical standpoint, the use of emotive imagery is worthy of note.

GLOSSARY

common factors Procedures that occur in all types of therapies regardless of the theoretical orientation of the therapist.

engagement Involvement in therapy assessed by client return for therapy after the initial, or intake, interview.

EQ An acronym signifying engagement quotient that is calculated by dividing the number of clients a therapist sees for more than one session by the total number of clients seen by that therapist.

HCVRCS An acronym for the Hill Counselor Verbal Response Category System that enables grouping of therapist verbalizations into 12 divisions.

session evaluation questionnaire An instrument that allows clients and therapists to judge a session according to its depth, smoothness, arousal, and positivity.

Engagement in therapy is a process whereby client and therapist become involved in the therapeutic endeavor. This article will present engagement as a basic therapeutic task that must occur for any type of treatment to be effective.

I. OVERVIEW OF ENGAGEMENT

Many clients seek help, and after an initial or intake session, they do not return for further therapy. These clients are frequently more troubled than clients who continue in treatment. Client nonreturn after intake is not a minor problem. At some agencies, nonreturn rates run as high as 50% or greater. Sometimes clients report that they received sufficient help in just one session, but this is not the case for most clients. At other times, clients are prevented from returning for treatment by physical or financial barriers. Most nonreturning clients continue to have concerns that go unresolved and prove costly to them and to those with whom they interact. Clearly, these clients, and their therapists, did not become involved, or engaged, in the treatment process. If they had, the clients would most likely have returned for further treatment after intake.

There are many effective treatments for use with a wide variety of problems. But even the most efficacious treatment will not work if the client does not attend scheduled sessions. Regardless of the type of therapy being practiced, for therapy to proceed, and ultimately succeed, engagement must occur in the first session. Thus, engagement is a common factor across therapies.

II. CONCEPTUAL UNDERPINNINGS OF ENGAGEMENT

The concept of initial engagement in therapy originated from some observation that I made in 1985 at a

university counseling center I directed. In an attempt to determine why some therapists in the setting were very busy while others were not, I charted the number of clients seen by each therapist for varying numbers of sessions. Some therapists saw a large number of clients for only one session. Other therapists saw few clients for just one session, but saw many clients for more than 10 sessions. In addition to seeing fewer clients for one session, these therapists also saw fewer clients for intermediate (2 to 9) sessions. Because treatment at the center was short term (10 to 15 sessions in duration), these data showed that some therapists were engaging their clients at intake in an ongoing therapeutic process.

I calculated an engagement quotient (EQ) for each therapist. EQ is the number of clients seen for more than one session divided by the total number of clients seen. It can be considered a fielding percentage for therapists. Therapists get chances (total number of clients seen) to field (engage) clients, and their EQ is the percentage of clients who return to see them after the first session. I found that higher EQ therapists had more positive supervisory ratings. I also found that EQ correlated significantly and positively with number of clients seen for more than 10 sessions, but did not correlate with number of clients seen for intermediate numbers of sessions. This latter finding provided statistical confirmation of my suspicions that therapists with higher EQs were engaging their clients at intake in an ongoing therapeutic process.

My initial conceptualizations about engagement were that certain client and therapist characteristics, such as severity of clients' problems, motivation for therapy, and therapists' experience, would relate to engagement. Because therapy is a verbal process, I also believed that therapists' ability to shed light on problems and formulate a treatment plan in a manner that is understandable to clients would facilitate client engagement in the therapeutic process. To do this, I believed that therapists who were skilled diagnosticians and possessed verbal abilities that enabled them to communicate relatively complex problem and treatment conceptualizations clearly to clients would be better engagers. Empirical studies have investigated these conceptualizations.

III. EMPIRICAL STUDIES

A number of engagement studies have been conducted to determine the factors associated with engagement and how engagement occurs. This section presents a brief review of these studies.

A. Waiting Lists

Many clinics and agencies have postintake waiting lists, because they are unable to continue seeing clients immediately for ongoing treatment. Although in 1980 C. Folkins and colleagues found that length of the waiting list was a factor in client postintake return for treatment, studies by James Archer in 1984 and by T. R. Anderson and colleagues in 1987 found that longer waiting list length was not a deterrent to engagement. Although the results of waiting list research are equivocal, it does not seem advisable for agencies to place impediments, such as long waiting lists, in the way of clients' timely continuation in treatment.

B. Client Factors

Investigators have sought to determine if some types of clients are more likely to become initially engaged in therapy than others. In 1992, Raymond Richmond found that clients who were younger, less educated, and members of minority groups were more difficult to engage. He also found that very disturbed clients who had been diagnosed as psychotic or who were prone to unusual thoughts, mannerisms, and hallucinations were more difficult to engage. Clients with suicidal intent were also less likely to return after their initial session. These difficult to engage clients were also less likely to have been self-referred. In 1998, Mark Hilsenroth and his colleagues found that clients diagnosed with antisocial or borderline personality disorders were also less likely than were other clients to return for therapy following the first session. In another study done in 1995 Hilsenroth and colleagues observed that clients who had uncooperative, hostile relationships outside of therapy were less likely to become engaged. These types of clients seem to be those who most need treatment, yet they are the most difficult to engage. The investigators speculated that the difficulties that these clients have interacting with others interfere with the development of good working relationships with their therapists.

Research by me in 1986 and in 1992 and by Larkin Phillips in 1985 has shown that clients who are perceived by their therapists to be more motivated, psychologically minded, and generally better candidates for therapy are more likely to be engaged than clients viewed as poorer candidates for therapy. I also found that clients who had previously been in therapy were more likely to become engaged than clients who had not. In line with these findings, Alfred Heilbrun in 1972 and Daniele Longo and colleagues in 1992 found that clients who rated themselves as more ready

for counseling were more likely to become engaged. In 1995, Kevin Smith and colleagues found that clients who had already started to address their problems on their own were more likely to become engaged in therapy than were clients who had not. Similar findings have led some authors, such as Alfred Heilbrun in 1972 and Charles Lawe and colleagues in 1983, to try to increase client motivation and readiness for therapy with some type of pretraining using written, audio, or video descriptions of what to expect in therapy. Although client pretraining has generally been successful in increasing engagement, studies have not specified precisely what this pretraining entailed; therefore others would not be able to replicate their procedures.

To summarize, it appears that clients who are harder to engage initially in therapy are those who were referred to therapy by others, are not ready to participate in the therapy process, have personal characteristics that interfere with successful interpersonal relationships, and are frequently more disturbed than clients who are easier to engage. Therapists cannot change these clients' behaviors unless they attend therapy sessions. Thus, the burden of engagement of these clients falls to therapists.

C. Therapist Factors

Because some therapists are able to engage a higher percentage of clients than others (i.e., have higher EQs than other therapists), several researchers have sought to determine what characteristics these therapists possess that are associated with engagement. Several authors have examined therapist gender as it relates to engagement with equivocal results. For instance, in 1979, Nancy Betz and Sandra Shullman found that women therapists engaged better than did men. In 1983, Douglas Epperson and colleagues found that men therapists were better engagers, and in 1984, I found that therapist gender did not relate to engagement. Whereas I found that more experienced therapists were more likely to have higher EQs, several studies including the ones by Betz and Shullman, Epperson and colleagues, and Longo and colleagues have found that inexperienced therapists engage their clients at the same rates as experienced ones.

Several studies have investigated whether or not higher engaging therapists are those perceived by clients as having higher levels of the interpersonal influence characteristics such as attractiveness, trustworthiness, and expertness. This has not proved to be the case. Studies by Glen Martin and colleagues in 1988, Kathy Zamosny and colleagues in 1981, and me in 1989

found no relationships between these therapist characteristics and client engagement. In 1986, I also found that therapist characteristics such as empathy, warmth, and genuineness, which in 1957 were posited by Carl Rogers to influence client change, do not relate directly to client engagement. However, I also found that therapists with higher EQs were rated by all clients, not just those they engaged, as more understanding than therapists with lower EQs.

In line with conceptualizations that therapists' verbal and diagnostic skills might influence engagement, in 1986 Warren Tryon and I investigated these skills using psychotherapy practicum trainee therapists' scores from the Graduate Record Examination (GRE) and Millers Analogies Test (MAT) as well as their grades in a clinical diagnostic course sequence. Verbal scores on the GRE, verbal-quantitative GRE discrepancy scores, MAT scores, grade in clinical diagnosis, and grade in advanced clinical diagnosis all correlated significantly and positively with therapist EQ. Therapist age also correlated highly and positively with EQ. We concluded that higher-EQ therapists' greater diagnostic skills combined with their greater verbal facility enabled them to identify client problems and clarify client problems. (We also believed that older therapists might use their own life experiences to understand clients' problems.) Superior verbal ability would also enable therapists to conceptualize and communicate treatment plans. As indicated above, a relationship between empathy and engagement has not been found. It may be that therapists' use of verbal skills to identify and define problems is an indication of therapist empathy. There have been, however, no studies of this possible relationship.

To summarize, few therapist characteristics have been consistently associated with engagement of clients in therapy. Engagement may depend less on who therapists are than on what they do. In this regard, the finding that therapists who are more verbally proficient and who have better diagnostic skills are better engagers suggests that they are using their verbal facility to involve clients in therapy.

D. Characteristics of the Engagement Interview

The best way to determine what therapists are doing in an engagement interview is to investigate the initial interview itself. Most studies have queried client and therapist about the interview immediately after it is finished. Thomas Greenfield in 1983 and Anna Kokotovic and Terence Tracey in 1987 found that clients who were more satisfied with the initial interview were more likely

to return for further therapy. In 1990, I asked clients and therapists to rate their experience of the intake interview using William Styles' Session Evaluation Questionnaire (SEQ), which was developed in 1980. Both clients and therapists rated engagement interviews as significantly deeper than nonengagement interviews. Thus, both participants in engaged therapy dyads felt the intake was deeper, more full, more powerful, more valuable, and more special (the SEQ depth items) than did nonengaged participants.

These deeper, more satisfying engagement interviews also consume more time than do nonengagement interviews. In four different studies (two in 1989, one in 1990, and one in 1992). I found that engagement interviews averaged about 55 minutes, but initial interviews after which the client did not return for further treatment averaged only about 43 minutes.

Thus, client and therapist are involved in time-consuming activities during an engagement interview. What are they doing? From my own clinical experience, I know that clients frequently come to intake with vaguely defined problems. During the intake interview, therapists help them to clarify these problems and focus on how to work on them. In 1986, I conceptualized that this clarification process might even seem to clients as if therapists were identifying concerns for them. Clients who gave stronger endorsement to an item stating this were significantly more likely to return for a second appointment after intake than were clients who agreed less with this item.

In 1989, I hypothesized that this problem identification process involved teaching clients about their concerns. I developed a three-item scale for both clients and therapists that asked to what extent the therapist identified client concerns, provided the client with new ways of understanding himself or herself, and taught the client about himself or herself. Items were rated on five-point scales with higher ratings indicating more teaching about concerns. Higher ratings of these items by therapists related significantly and positively to engagement. Clients rated therapists who had higher EQs as teaching them significantly more than lower EQ therapists. Thus, providing clients with new perspectives on their problems is positively related to engagement in the counseling process and may be what is consuming time in an engagement interview. The results of these studies dovetail nicely with the research that showed higher engaging therapists to be more verbally and diagnostically proficient. Teaching requires the ability to communicate well verbally. Diagnostic skills would enable the therapist to know what to teach.

In my 2002 article, I discuss how I recorded a psychodynamically oriented therapist's intake interviews with 11 of her clients. I used Clara Hill's Counselor Verbal Response Category System (HCVRCS), developed in 1993, to organize the therapist's verbalizations into 12 categories. Seven of the 11 clients returned for a second interview (i.e., became engaged). To explore the pattern of therapist verbalizations during the interviews, I examined the use of the most frequently employed verbal responses (i.e., numbers of minimal encouragers, closed questions, and information) for the first third, second third, and final third of engagement and nonengagement interviews.

In engagement interviews, the therapist's number of closed questions and minimal encouragers started high and steadily decreased during the course of the interviews, and the therapist's number of information verbalizations started low and steadily increased during the interviews. These verbal patterns suggested that in engagement interviews the therapist used questions and minimal encouragers to clarify client problems, and once clarified for the therapist, the therapist provided clients with diagnostic information about their problems and how therapist and client could work together to ameliorate them. Review of the transcripts showed this to be the case.

In nonengagement interviews, therapist use of closed questions and minimal encouragers started low, increased from the first to the second third of the interviews, and then fell in the final third. Information verbalizations fell from the first to second third of the interviews and increased again in the final third of the interviews. This suggested that in nonengagement interviews, there was less initial problem clarification, and perhaps as a result of this, less information was given to the clients later in the session. The clients then did not return to the therapist for further therapy.

The pattern of therapist verbalizations associated with client engagement in the study cited above may be one of several possible patterns. In 1979, William Stiles found that use of verbal categories depended on therapists' theoretical orientations. Thus a psychodynamic therapist may use different types of verbalizations to clarify problems and suggest a treatment plan than a cognitive-behavioral therapist, but both may successfully engage clients.

To summarize, an engagement interview is longer, deeper, and more satisfying than an initial interview after which the client does not return. Therapist verbalizations during an engagement interview are consistent with a pattern that suggests that the therapist is teaching the

client about the client's problems and how they will be addressed in therapy.

IV. SUMMARY

Engagement is a common factor in all types of therapy. To have their problems addressed effectively, most clients must stay in therapy for several sessions. To do this, clients must be involved, or engaged, in the therapy process. If they are not engaged, they will leave therapy before it has really begun.

Most clients have sought help from other sources prior to entering therapy. These other people may have been supportive, genuine, and understanding, but they did not provide sufficient help to ameliorate clients' problems. Clients expect more help from a professional psychotherapist than what they have received from family and friends. If therapists do not demonstrate to clients that they will be able to provide this help, clients have no reason to spend their time and money getting therapy. The research presented earlier indicates that engagement occurs when therapists listen to and reformulate clients' problems to make them clearer to clients and thereby set the stage for addressing them in therapy.

Some types of clients are easier to engage. Those who have had therapy before, have fewer interpersonal difficulties, are self-referred, and have already begun addressing their problems are more likely to become involved in the therapy process. The harder task is for therapists to engage more difficult clients who are usually more disturbed.

Some therapists are better engagers than others. These therapists tend to have better verbal and diagnostic skills than less engaging therapists. It appears that they use these skills to clarify client problems and to teach clients about their problems and how to address them. One way to do this is for therapists to question clients a lot at the beginning of the initial session and to gradually provide clients with more information about problems as the session progresses.

Engagement needs much further study. Future research should investigate the effects of client and therapist race and ethnicity on engagement. Client verbalizations relative to engagement need to be studied as do the effects of therapist theoretical orientation on therapist verbalizations associated with engagement. As with most areas of research, the engagement studies raise as many questions as they answer.

GLOSSARY

affectedness One of the three basic aspects of dasein's way of relating to the world. It involves "being found in a situation where things already matter." This is the affective coloration or tone in which we find ourselves, when we encounter a situation. It can be collective (as in the sensibility of an age or the culture of an institution) or individual (when it is referred to as a mood).

dasein ("being-there") Heidegger's term for human being: the way of being characteristic of all peoples or a single human being. Dasein, being-there, or being-in-the-world implies an involvement in the world. The world and the human being are co-constituted. The world itself consists of relationships among entities which, in turn, are only defined by their interrelationships.

existence Heidegger's name for dasein's way of being, namely, as the kind of being that embodies an understanding and that manifests in its actions (ways of perceiving, thinking, doing) an implicit interpretation of what it is to be the kind of being it is. This understanding is not fundamentally conceptual or even conscious but is shown in the acts and practices that an individual undertakes. Thus, em-

bodiment an understanding of oneself is to act and be ready to act (comport oneself) in certain characteristic ways. It is a self-understanding and a reaching forward into the world and into the future.

facticity Heidegger's term for the elements found by dasein already present in its world. These are the elements out of which dasein constructs an understanding or interpretation of itself. Although these entities are created by each culture, they are perceived as existing independently of culture.

falling A basic aspect of dasein's way of being in the world. Although dasein is always being-in-the-world, that is, absorbed in and defined by its involvement with the world, falling implies excessive fascination with and self-definition in terms of the world, to the exclusion of an appropriate awareness of one's true nature (the characteristics of being-in-the-world). Thus, in falling, the being of man as embodying a self-interpretation is forgotten.

mitsein ("being-with") A term intended to convey that dasein is always in a shared, public world. The elements of that world with which it is familiar, which it understands and which matter to it, are shared with (and, Heidegger would say, created by) other people. Since these elements are constitutive of dasein, dasein is necessarily always relating to other people through a shared world.

understanding A basic aspect of dasein's way of relating to the world, equivalent to "knowing how" or being capable of doing something in a particular situation. It is understanding of what is possible in a given circumstance (for example, by knowing how a piece of equipment is used), at the level of a skill rather than a conscious set of beliefs.

“Existential psychotherapy” initially referred to the work of a group of therapists who wrote and practiced in the 1940s, 1950s, and 1960s. Trained as psychoanalysts, they believed that many of Freud’s central concepts failed to capture the reality of everyday life and treatment. They objected to what they saw as the mechanistic quality of Freud’s theories and the speculative, nonempirical nature of its key elements. These characteristics of Freudianism were felt to be untrue to actual clinical phenomena and appeared to be barriers to effective treatment. These therapists never denied their debt to Freud, but they also found, in the work of the existentialist philosopher, Martin Heidegger, alternative formulations of the nature of man which seemed to provide what was missing in analysis, namely, an approach and set of concepts for thinking about clinical work which allowed therapists to understand therapeutic processes more immediately and accurately, and to relate to patients as they really were.

Existential psychotherapy is rarely taught systematically, and there are relatively few published English accounts of how it is practiced. At its most “extreme,” existential therapy may seem risky or dangerous, since it appears to require and encourage strong, spontaneous emotional relationships between patient and therapist, and to tolerate, if not foster, regression. In an already complicated and bewildering field of psychotherapies, existentialists introduce a new vocabulary and a new set of concerns (“death anxiety,” “responsibility,” “authenticity,” “existence”) that few practitioners will welcome. Yet many clinical features of existential work have become important parts of psychodynamic, supportive, and, even, cognitive-behavioral therapies. The innovations of the existential therapists overlap considerably with psychoanalytic advances of recent decades. Knowledge of existential ideas and their influence, as well as familiarity with the analysis of man on which they depend, have largely faded from the scene of modern psychiatry and psychotherapy. Yet those ideas bear reexamining. They offer therapeutic approaches that are true to life as it is actually experienced, even though its methods, indications, limitations, and effectiveness have yet to be fully defined.

I. THEORETICAL BASES

A. Heidegger’s Analysis of Human Being

The guiding ideas of existential psychotherapy are found in Heidegger’s *Being and Time*, published in 1927

and translated into English in 1962. The appropriation and application of this work by clinicians, most prominently Eugene Minkowski, Ludwig Binswanger, Erwin Straus, V.E. von Gebattel, Roland Kuhn, and Medard Boss, comprise the founding, classical works of existential therapy. Subsequent workers in the existential tradition have included Viktor Frankl, Martin Buber, Paul Tillich, Edith Weigert, R.D. Laing, Rollo May, Carl Rogers, Irvin Yalom, and Leslie Farber. To understand these clinical works requires some familiarity with Heidegger. A summary of some Heideggerian concepts that have been most important to therapists is therefore necessary.

1. *Being-in-the-World* (“*Dasein*”)

In *Being and Time*, Heidegger’s objective was to describe the essential features of human life. In the philosophic tradition, man as subject or knower was distinguished from an independent, separate, but knowable, reality. Heidegger, by contrast, begins with the observation that there is no subject or knower in our experience and no independent world apart from what is experienced by us. What there is, rather, is a single, unified knower-known. Put differently, in experiencing, feeling, or thinking, we are absorbed by or into what it is we are experiencing, feeling, or thinking about. For example, when we relate to another person in conversation, we are absorbed in our dialogue. We usually do not pay any attention to the specifics of word choice, syntax, gesture, posture, prosody, appearance, and so on which comprise the interaction. We are involved in the dialogue itself and among the entities which the dialogue is about. This being already among the things of the world is captured by Heidegger’s term for human nature, being-in-the-world, or *dasein*.

Usually, our involvement with the world is preconscious and automatic. The mechanics of what we do, whether relating to another person or to things, are out of awareness. When, to take another example, we use “equipment” in the world, we do not think about or rehearse what we do (except perhaps when learning). We *understand* how to use things, and they already matter to us (they have a valence or affective tone; Heidegger called this feature affectedness), even as we are using them, automatically. Heidegger suggests that such knowing-how should not be thought of primarily as internal mental states or events: they are shown or displayed in our acts. We can, at least sometimes, analyze our actions as if we were following explicit rules or beliefs, but, Heidegger emphasizes, this is not what we usually do. In many cases, no conscious reconstruction is even possible. Conscious, thematic, formulated

thoughts, when they do exist, are only possible because of these preexisting, nonverbal skills.

2. *Existence*

People are constituted by and discovered in the actions they pursue in order to achieve short- and long-term goals. They are thus inherently temporal: coming from the past and proceeding into the future. Human nature shows itself through future-directed acts. Actions, including how we use things, how we comport ourselves, and how we relate to other people, embody interpretations of self and world. Actions show what matters to us and what we want, as well as what we believe to be possible (given our appraisals of ourselves and the situations in which we find ourselves). It is not only that we betray ourselves by minor movements or habits, as Freud said, but that, most fundamentally, our natures appear through our comportment (actions). This forward-moving, embodied expression of our self-interpretation Heidegger called existence. In Heideggerian terms, *dasein* exists.

3. *Being-with ("Mitsein")*

When we look more closely at what is inherent in human nature (constitutive of *dasein*), we find that not only are we defined by our actions among the things of the world (our comportment among physical objects), but that we are already, whenever we do or think something, with other people. The entities of the world, what Heidegger called facticity (this book, that chair, the sky, rain), are already shared with others. What I can relate to, others can, too. A chair, for example, was made by someone else and can be sat in by anyone; these features are given along with the physical appearance of the chair itself. What is more, when an individual thinks of the chair as a chair, a piece of wood, or furniture, she is using a family of concepts that have been passed down and learned from other people. Thus, since the world and the individual are co-determined, and since the world is a public, shared world, the individual is constituted or inhabited by other people, even in the contents of his mind.

4. *Authenticity and Falling*

For Freud, it may be said, the essence of neurotic functioning is failure to acknowledge and appropriately express one's feelings, wishes, or impulses, for example, those relating to sexuality or aggression. By contrast, the acknowledgment of one's constitutional or socially created drives or wishes is the key to psychological health. Failure to do this condemns an individual to live in a pale "safety mode" of self-deception.

Heidegger has a similar, and at the same time different, understanding of how life should be lived. For him, the distinction is not between normal and neurotic, but authentic and inauthentic. And just as Freud's normality requires an appropriation of one's previously given, inner reality, so Heidegger's authenticity requires an understanding of what is essential about oneself. But there are two significant differences. First, for Heidegger, because understanding, as a fundamental characteristic of being-in-the-world, is shown in our acts and practices (not in having true inner beliefs), authenticity is shown in styles of behavior or comportment in the world. The second difference is that authenticity is not acknowledgment of sexual or aggressive wishes or drives but an appreciation of *dasein* or being-in-the-world itself, since that is what human nature fundamentally is. In other words, authenticity requires understanding of being-in-the-world: its absorption in things that are factual (entities constituted by our culture, which are nevertheless perceived as necessary and universal). Authenticity is shown by acting with commitment, absorption, and affectedness, despite full awareness of the contingency of the world and our interpretations. Everything, as Wittgenstein says, might have been different. This authenticity resembles love. When an individual loves, it is only a particular individual person who can be the object of her love. Without the loved person the lover feels lost and empty. And yet, she also realizes that no one person could be that special: everyone who loves has her own loved one, and to every lover that loved one is unique. To continue to love, aware of this paradox, is an example of authenticity.

If authenticity is Heidegger's counterpart to psychological health in psychoanalysis, his counterpart to neurosis is falling. It is part of being-in-the-world that individuals are absorbed in their involvement with people and things. But it is always possible for such "thrownness" to lead to inauthentic "falling." In falling, an individual is so absorbed in particular things or relationships that she loses the appropriate appreciation of human nature as being-in-the-world (as Heidegger defines it, in such terms as skillful absorption and facticity). In falling, an individual becomes overly committed to her current situation without acknowledging its contingency, the possibility of alternatives, the impossibility of proof, and the need for commitment and resolute action, despite these features. If authenticity means acting with commitment while also accepting anxiety in the face of human being, falling is trying to avoid anxiety by disregarding what we should appreciate fully, namely, the various aspects of being-in-the-world.

II. DESCRIPTION OF THE TREATMENT

A. From Philosophy to Psychotherapy

In Heidegger, existential psychiatrists found organizing ideas for their clinical work. Their clinical extensions may be grouped under three headings: (1) being-in-the-world and the goals of psychiatric treatment; (2) a model of therapeutic action; and (3) methodological implications of human nature as being-in-the-world. It is apparent that these headings are broad and rather grand. But the philosophical tradition (or Cartesianism) with which the existential approach contrasts has a similar very broad range of clinical implications involving the nature of man and the clinical enterprise (for example, man as a biological object and clinical work as composed of observation, diagnosis, and treatment).

1. *The Goals of Therapy*

The main goal of psychotherapy is to foster human flourishing, and this means, for existential psychotherapy, living authentically. As we have noted, living authentically means absorbed activity in the world, with awareness of its being or nature. The two parts of this definition (absorbed activity and awareness) may be examined separately.

Absorbed, intentional activity involves striving to realize one's goals and to actualize what one values. Thus, a first step in therapy is careful understanding of the "for-the-sake-of-which" an individual acts. This slight change from the traditional emphasis on behavior as arising from instincts, drives, or early patterned experience to behavior as the striving to realize goals and ideals has direct clinical implications. For, from the outset, the clinician asks himself, "What is this patient trying to do? What does she value?" And as the clinician asks himself these questions, the patient becomes more understandable, sympathetic, and human.

Absorbed activity bears a complex relationship to insight. Existentialists emphasize that insight is not the primary goal of therapy. In fact, existential therapists identify excessive self-reflection as an impediment to or avoidance of absorbed involvement, just as the conceptual, conscious mode of contemplating objects derives from and is "inferior" to more basic, skillful absorption.

Absorbed, skillful activity that furthers an individual's goals and realizes her values must, however, involve accurate appraisal of the self and world, if it is to be successful. Such an accurate appraisal requires seeing clearly and moving comfortably within the objects that compose the world. Such accuracy derives, in turn, from focused attention to and involvement with the world—in other words, from being-in-the-world itself. The opposite of such attentiveness and involvement is detached observation, conceptualization, and overgeneralization. Thus, the additional goal of existential therapy is the ability to recognize, appreciate, and use the particular in the service of bringing about one's aims and values.

Accurate appreciation of the nature of being-in-the-world, as such, is the second great goal of existential therapy, the second component of living authentically. Authentic being-in-the-world embodies an appreciation of its own nature, which has several immediate consequences for therapy. First, the goal of therapy is not to eliminate "negative" feelings, such as anxiety or guilt. Anxiety, for example, is an ineliminable part of human nature because, according to Heidegger, any understanding or interpretation we have of human nature is ungrounded and most fundamentally, unjustifiable by reference to an external, eternal, and universal truth. Reasons for whatever we think and do come to an end, and can come to an end fairly quickly, at which point anxiety intervenes.

From another perspective, all our beliefs and what we understand to be our possibilities are taken from a larger set that is given to us by our culture, which constitutes us (factually). Not only are such beliefs and possibilities never subject to ultimate grounding, but they are never, ultimately, mine. Contra Descartes, certainty does not arise from the inside. What is inside has come from outside, and there is no certainty or necessity out there. To limit anxiety, rather than abolish it, we must involve ourselves in absorbed activity, in the living stream, while recognizing that such anxiety is always a lurking possibility.

Guilt is also an ineliminable part of our nature, for similar reasons. Guilt, like anxiety, arises from the fact that we are constituted by the entities that human culture presents to us factually. Because our being comprises these elements, we are indebted to our culture and our forebears, for our entire selves. Of course, despite this dependency, we are still required to act on the basis of the understanding we have.

Our being, then, is not under our own control, in two senses: (1) we do not choose the possibilities or

categories that are presented to us—these are provided by the culture (or world) out of which we are constituted; and (2) as being-in-the-world, we are thrown into absorbed activity but cannot choose which activities (moods, commitments, values) among our possibilities actually absorb us. This unchosen thrownness into absorbed activity is our most basic way of being; yet we nevertheless need to appropriate and acknowledge it as our own.

Existential guilt or indebtedness is connected to guilt as it is experienced everyday. Our ordinary sense of guilt includes the belief or feeling that we have transgressed ethical norms and have neglected our responsibilities to other people, animals, the environment, or God. In guilt, we feel we have been cut loose from the moorings of ethical standards and have behaved irresponsibly. The feeling of guilt reflects the wish to reestablish connection with such ethical norms and standards. But if we understand existential guilt, we realize that we cannot determine ourselves. We are fundamentally determined by our larger culture or world. As Heidegger says, “The self, which as such has to lay the basis for itself, can never get that basis into its power.” Put differently, neurotic guilt is the questing after what is impossible: control in situations where one has no control, achieving perfection one cannot achieve. Wanting the impossible (self-determination) is the basis of guilt.

Living authentically (absorbed, skillful participation and an accurate appreciation of one’s nature as being-in-the-world) bears a close relationship to the correct use of our language. Authentic living implies authentic speaking. Language used correctly is a mode of skillful absorption in the world. But language can also hide or blind us to our real intents and purposes, or the real natures of others. The contrasts here are with speech that is inaccurate, unfelicitous, or distorted by denial, overgeneralization, misplaced emphasis, lack of appropriate nuance, disowning of responsibility, vagueness, and so on. Clinical situations are replete with instances of this—times when a patient speaks in an empty or incomprehensible fashion that leaves the therapist “at a loss for words” and thoughts. In such situations, the patient may not yet be speaking meaningfully at all, not using words as parts of actions that make sense; then the therapist’s goal may be to point out the emptiness of what appears to be meaningful (for example, when guilt presupposes an impossible perfectionism), or give the patient meaningful words to capture his situation. Alternatively, of course, the patient may be speaking meaningfully, but the therapist may fail to recognize it.

In this case, the therapist’s goal is to “get with” (understand) the patient so her truly meaningful act, in speaking, can be completed by the therapist’s comprehension. Existential psychotherapists are particularly inclined to pay careful attention to the specifics of the patient’s language, asking, “What could he mean?” “What is she trying to say or do?” “What do her words imply?” The objective of such close attention is a genuine, active engagement of patient and therapist.

2. A Model of Therapy

The existential approach includes elements that are distinct from those of psychoanalytic or cognitive-behavioral treatments, which emphasize careful, detached observation, diagnosis or formulation by comparison of data to a predetermined set of criteria, and the prescription or administration of treatment. According to Heidegger, such observation and diagnosis do not reveal phenomena; they obscure them. True understanding occurs only through and during active, lived participation. Understanding another person, then, takes place through and during empathic, emotional exchange. The key test of the accuracy or “correctness” of such interplay is its effectiveness in strengthening the connection and emotional resonance between patient and therapist. For the patient, there will be a deepening and amplification of feeling. For the therapist, a similar or complementary reverberation occurs. For both people, success will be experienced as sharing and warmth (in either its positive or negative senses).

The objective of therapy with respect to self-understanding is not to discover or accurately diagnose what is hidden and only known by inference (such as a repressed wish or a hypothesized brain process). Rather, the objective is to enable the patient to see himself more clearly and, therefore, to respond more fully to what is already present in his behavior, but not adequately appreciated. It should be noted that this represents a radical departure from centuries of tradition, often associated with Descartes. In contrast to this tradition, existential therapy emphasizes that what is fundamentally mental is not “subjective” or “in” the head (such as inner images, thoughts, or propositions) but, rather, styles of comportment and patterns of behavior. Fuller appreciation of what is already, immediately present usually includes becoming more aware both of the formative influence of one’s past (facticity) and one’s defining goals, values, and interests (“for-the-sake-of-whichs”). This idea is captured by Wittgenstein in his statement that “If one sees the behavior of a living thing, one sees its soul.” It is also expressed by

Henry James, as noted by Martha Nussbaum: “The effort to really see and really to represent is no idle business in face of the constant force that makes for muddlement.” Our goal is to make ourselves people “on whom nothing is lost.”

Thus, both the methods and the goals of existential therapy are vivid, emotional immersion in the world, particularly the shared world of patient and therapist. How to do this, and how to structure such interactive encounters so they preserve vigorous interchange and still work to the patient’s benefit, need to be discussed.

3. *Methods of Therapy*

So far, our discussion has been highly abstract. But that is precisely the opposite of where existential psychotherapy would like either the patient or therapist to end up. It is in its specific therapeutic methods that existential psychotherapy most clearly shows its adherence to phenomenology, to the aim of disclosing being as it actually is, undistorted by theoretical formulations. The following six characteristics of existential therapy are frequently emphasized: (1) the phenomenological reduction; (2) affective involvement between patient and therapist; (3) exploration of the surface of meaning; (4) the meaningfulness of all behavior; (5) attention to the uses of language; and (6) temporality or life history. All six are derived from the understanding of human nature as being-in-the-world, although some are consistent with other models as well, including psychoanalysis most prominently.

a. Phenomenological Reduction The phenomenological reduction was developed as a philosophical technique by Heidegger’s teacher, Edmund Husserl. It directs philosophers or psychotherapists to focus initially on phenomena—for example, the experiences described by patients—simply as they present themselves to the listener or viewer. The observer is supposed to “bracket,” or put out of consideration, her theoretical knowledge of *what* something is (a hallucination, for example, or a manifestation of schizophrenia). Instead, she is to examine the phenomenon as it presents itself, as it were, without category.

Despite the apparent simplicity of this proposal, at least two fundamental objections should be raised to it. First, according to Heidegger himself, the observer is always already in a world that is constituted by her culture and that includes, not isolated data or category-less entities, but things that are known as particular items (a hammer, a hallucination). In other words,

there is no possibility of approaching phenomena as they are in themselves, free of presuppositions. To do that would contradict the fundamental nature of being-in-the-world; the phenomenological reduction is an empty proposal. The second objection, also based on Heidegger’s analysis of being-in-the-world, is that the attitude of detached, suppositionless observation—what Heidegger called “fascination”—is not the fundamental or basic way of understanding things. Quite the contrary, since the most fundamental and spontaneous way of understanding something is being familiar with it through using it in purposeful activity, detached reflection is artificial and no guarantee of a more authentic relationship to entities.

Yet, beginning with Karl Jaspers, existential psychiatrists made the careful study of phenomenology the foundation of their clinical approach and provided extensive detailed accounts of patients’ subjective experience. Perhaps the resolution of this apparent paradox is that what is to be bracketed is theoretical knowledge, while what is retained and relied on is everyday or ordinary knowledge. Although it is impossible to approach another person with one’s mind emptied of its categories, it may be possible to limit oneself to using only those categories that are widely available in the culture, including to the patient herself.

Phenomenological reduction was not originally used as a therapy; rather, it was a method of investigation that would lead to more accurate generalization and classification. This was how Jaspers, Binswanger, and Minkowski used it in their carefully rendered and detailed case reports. But phenomenological reduction may also have therapeutic effects; there are several ways these might be produced. First, naming an experience often changes it, a point Heidegger emphasized. He said, for example, that “language makes manifest.” Language picks things out and sharpens our focus. One may, for example, think of examples of child abuse or other torture: knowing and naming each part in detail may produce a stronger impact than do more general descriptions. In addition, language brings an experience out of the inner world and into the public world of our common language. Two people may share the same experience through words. Careful reporting and wording of phenomenology is an important tool for placing the therapist where he can share the patient’s experience, minute by minute.

Moreover, phenomenological reduction, though it cannot be totally suppositionless, does remain true to a central Heideggerian theme, namely, the primacy of direct experience and absorption in things themselves,

over abstract, conceptual thought. Heidegger believed, in fact, that it was distance from concrete involvement with life which was the basis of all psychopathology. Thus, a closer approach to or absorption in the details of living can be inherently therapeutic.

b. Affective Involvement Being-in-the-world is active coping with a world of entities that matter to us. Practical, purposeful activity in which entities have emotional valences precedes and is presupposed by all formal, conceptual understanding. If the existential therapist's goal is to form an accurate understanding of what it is like to be his patient, he must develop the same concrete and emotional responses as the patient. Empathy is not a relationship of observing therapist to observed patient. It is sharing the same psychological experience: the therapist must not only understand the patient in terms of diagnostic or other categories, but he must feel what the patient does. This requires affective engagement with the patient.

Although Heidegger included affect among his necessary and constitutive features of being-in-the-world, existential therapists also discovered its importance directly through their work with individual patients. As Eugene Minkowski lived with a delusional depressed man and tried to enter and understand his delusional world, he began to develop intense feelings toward the patient. These were not, however, only the same feelings as the patient's. The patient experienced fear, since he feared his own execution each day. In response to the patient's intractable fear, Minkowski, who was trying to help him, got angry. Other existential therapists have emphasized the importance of genuine respect, fondness, and appreciation which arise in therapists as they work at gaining access to their patients' worlds. Binswanger referred to the curative aspect of love, a position that Edith Weigert also developed. Unlike the dispassionate listener of classical psychoanalytic theory, the existential therapist expects to become emotionally involved with his patient, and he welcomes it.

There are, at least, two ways in which a genuine, emotional relationship may be helpful. First, as in Minkowski's example, people can only influence one another when they matter to one another. In expressing his frustration, Minkowski implicitly challenges the patient's rigidity and challenges him to change. Intense confrontation within an important relationship must lead to change in one or both individuals, or rupture of the relationship.

A second way in which a genuine emotionship may be therapeutic is through love. Through love, the ther-

apist warmly appreciates and values the patient (especially features that she herself undervalues, ignores, or fails to recognize). Thus, the therapist enjoys and applauds the patient's skills, principles, and objectives; the therapist also can see in a positive light aspects of the patient which she insufficiently appreciates (for example, inhibited aggression or "negative," shameful feelings such as anxiety or guilt). The therapist is able to do this because of her genuine liking for the patient, as well as her understanding of the nature of being-in-the-world (which includes thrownness [and, therefore, anxiety], as well as indebtedness [and, therefore, guilt]).

c. Exploring Surface Meanings The existential therapist starts by sharing the patient's experience and then proceeds to explore the surface implications of the meanings of such experiences. In this process, the clinician takes the patient's words, examines them carefully, and tries to form generalizations about them to make manifest their latent (but not hidden!) structure. In this way, she reveals basic characteristics of the patient's thinking.

Minkowski provided the classical example of this procedure. In his close work with a patient with delusional depression, he observed that the patient continued to expect his "final execution" every night, although, of course, this never occurred. Minkowski concluded from this that the patient suffered from "a serious disorder in the general attitude toward the future" and that "The complex idea of time and of life disintegrates, and the patient regresses to a lower level that is potentially in all of us." Minkowski explored *among* the phenomena of the patient's psychosis, searching for the unifying, more general disturbance at the core of the disorder. He did not look for or postulate unconscious processes.

Medard Boss (1963) applied the same procedure in a variety of clinical situations. He took directly observed clinical phenomena at face value and accepted them. The next question for him was not what they revealed about unconscious mental mechanisms or the repressed past. Rather, clinical phenomena were examined as understandable and frequently even admirable behaviors that embodied and displayed aspects of the patient's way of being in the world (which thereby revealed his self-understanding).

Consider Boss's discussion of transference. According to Boss, the existential therapist does not consider "transference" to be a projection or transfer of feelings from one person to another. Nor does treatment involve

working through such a distortion, so that its roots in the past can be clearly separated from the present relationship. Rather, the therapist “admits ‘transference love or hate’ as the genuine interpersonal relationship to the analyst” experienced by the patient. The existential therapist does recognize that the relationship will be “infantile” and that the patient will misperceive the therapist in ways that arose during the patient’s childhood. Yet the therapist still accepts the relationship as genuine and as an important mode of being for the patient. This understanding acceptance, rather than working through of transference distortions, is the mechanism of emotional growth in therapy.

Boss described a similar approach to understanding dreams. He first accepted their surface truth and then looked for more general modes of behavior or self-understanding that they displayed. He recounted a patient’s dream in which lions and tigers escape from their cages in the zoo. The dreamer is frightened and begins to run away. From this dream, Boss extracted a general theme: the patient’s inability to tolerate without fear life’s “vitality,” including danger and aggression. Boss emphasized that the patient’s fearful attitude is shown directly in the dream. To the existential therapist, dreams reveal more vividly aspects of patients’ lives of which they themselves are not usually “adequately and fully aware.” But no unconscious content or mechanisms are invoked. Dreams are an “*uncovering*, an *unveiling*, and never a covering up or a veiling of psychic content.”

d. The Meaningfulness of Behavior Existential analysis of the surface meanings implied by delusions, transference, and dreams is an instance of the more general existentialist principle, shared with psychoanalysis, that all behaviors are meaningful. Meaningful behavior, according to Heidegger, does not require and, in fact, usually lacks, deliberation or even conscious awareness of judgments, motives, or plans. Thus, even acts that appear automatic, reflexive, stereotyped, or driven may be meaningful and reflect a person’s self-understanding. In most ordinary situations, the meaning of behavior can be easily understood: we read the meaning from the behavior in its context. In psychopathology, the task is to decipher and find the general disturbance of existence presented by behavior which is not ordinary.

Boss, for example, observed that the behavior of obsessional patients is constricted: only “‘pure,’ objective and conceptual thinking” is acknowledged and allowed into the patient’s awareness. Intimate contact and emotional involvement are avoided. True involvement (a

truly absorbed and spontaneous being-in-the-world) would expose the obsessional person to “realms of being” which he experiences as filthy, nauseating, dirty, disgusting, or animalistic. Again, the therapist understands such inhibition as arising from childhood experience, but this conceptual understanding is not brought into the therapy and does not form the background for the therapist’s interventions. Rather, the therapist focuses on the patient’s inhibited way of being, the style of comportment that it involves.

Because they assume the meaningfulness of many behaviors that others would not, existential therapists accept and tolerate a range of behavior that is unacceptable to ordinary social convention. Thus, in the case reports of many existentialists, including Minkowski and Boss, we find descriptions of extended periods of time in which the patient was “regressed,” and “childlike.” These therapists accepted such behavior and even participated in it; they believed the behavior reflected a meaningful, though inhibited, mode of being-in-the-world. Such acceptance seemed to have therapeutic effect. One patient told Boss that what was important to her was, “your understanding of my paranoid delusions and hallucinations, your taking them seriously. Your knowledge of their genuine value and meaning enabled me to realize the wholeness of my own self and the oneness of myself and the world.”

e. Uses of Language When a therapist is able to help her patient toward more authentic living, she does so primarily by her use of language. Language can facilitate the active, self-aware, and skillful absorption of being-in-the-world. It may, however, also interfere and distance an individual from the skillful, energetic coping she seeks. In the latter case, language can replace an active life among things and people with a “solipsistic” withdrawal into a world of merely conceptual thinking—a world of thoughts that have no use in one’s life. Similarly, language may strongly encourage or hinder an individual’s empathic attunement and emotional involvement with other people.

The existential therapists’ emphasis on being-in-the-world, including empathic attunement, thus led them to explore how language may be *used* in treatment, which is perhaps unique among psychotherapists. Language is not only a tool for conveying information. It is also a mechanism for expressing one’s feelings or eliciting feeling in another, communicating a value judgment, sharing anxieties or pleasures, demonstrating concern, proving one’s accurate empathic understanding, venting frustration, and accomplishing many other

personal and interpersonal objectives. Sensitivity to and comfortable use of many different ways of speaking are parts of existential therapy, as documented in the writings of Minkowski, Boss, Yalom, Fromm-Reichmann, and others.

Brief, exclamatory remarks (“How awful!” “My God!”) may express an immediate emotional reaction that approaches or complements the patient’s. Impartial and impersonal statements may “translate” patients’ private feelings into feelings that are public, universal, and shareable (“It’s infuriating.” “No one could stand it.”) The use of specific, emotionally charged words (“God,” “peace,” “safety,” the names of important people in a patient’s life) may immediately intensify and deepen a patient’s feeling, as well as her connection to the therapist.

The existentialists did not organize their uses of language or combine them with other treatment elements (such as exploration of surface meanings) into a coherent therapeutic system. Although it seems existential therapists would agree that, as Wittgenstein said, “Uttering a word is like striking a note on the keyboard of the imagination,” only case reports document the therapeutic effects of particular uses of language in existentially oriented work.

f. Life history Human being is temporal: people, in their active, directed being-in-the-world, are always coming from their past experiences and going toward their future goals. Because an individual must adopt her interpretation of herself and her world from the possibilities that are presented factually by her culture (or world), she must always embody an historical dimension that refers, through her behavior, to the past. And because actions are always already understandable as doing something for-the-sake-of-which, she also always manifests her orientation toward the future. In fact, past and future are coordinated: the values and goals that an individual has have been created from elements in the past. To understand someone fully, we therefore usually must know about their past, an insight shared with psychoanalysis but understood somewhat differently by existentialists.

There are many examples of the interplay of appreciating a life history and existential therapeutic practice; some overlap psychoanalytic therapy. First, detailed, comprehensive knowledge of an individual’s past experiences will facilitate the work of empathy—what Martin Buber called “imagining the real.” Second, accurate empathic expressions are more likely to arise from such vivid, vicarious experiences of the patient’s life. Third,

some verbal and nonverbal behaviors may only be understood against the background of the past. Actions may be reenactments, and sometimes only knowledge of the patient’s past will permit the therapist to develop reasonable, intelligible explanations for behaviors that would otherwise seem to be mere symptoms without rational justification. These three examples are familiar to psychoanalytic practitioners.

Perhaps more specific to existential therapy is its emphasis on man’s inherently temporal nature as such. If the goal of therapy is living authentically, and if living authentically comprises an understanding of oneself as being-in-the-world, then it seems that such authentic living must include a clearer and more active appreciation of one’s temporality (one’s being constituted by the past and always projected into the future). Yet despite the importance of temporality as a component of being-in-the-world, existential therapists for the most part have not developed this idea. Keener awareness of the pervasiveness of the past might modify, and perhaps heighten, feelings of anxiety and guilt, which arise inherently from the past and form a structure of being-in-the-world. A therapist’s image of her patient as directed toward future goals and seeking to realize important values may significantly inform her approach to treatment.

III. APPLICATIONS AND EXCLUSIONS

The clinical indications and contraindications for existential approaches have not been systematically established. Historically, existential therapy was developed in work with psychotic patients. Binswanger, Minkowski, and Boss, in their seminal descriptions of existential work, presented patients who suffered from persistent and very troubling delusions and hallucinations. Recent writers in the existentialist tradition have tended to agree that such empathic, “presuppositionless” approaches are particularly suited to engaging and helping patients who are psychotic. If so, it may be because emotional involvement and expression by the therapist can help her to connect with patients who are emotionally withdrawn or who fear and avoid such contact.

Yet there is also evidence that existentialist approaches may have much broader application. Yalom (1980), for example, has described in detail his work with a wide variety of patients who were not psychotic, but who suffered from severe feelings of isolation, loss

of meaning, impairments of the will, or confrontation with death.

The contraindications to these methods have also been based largely on clinical impression, not rigorous study. Patients who may be unable to tolerate strong feelings toward the therapist—for example, individuals who tend to escalate their hopes and expectations for help and care from the therapist, or who become excessively angry when such expectations are disappointed—may find existential approaches countertherapeutic. Such patients may show better outcomes when therapists are less emotionally expressive and involved. However, modifications in technique (for example, “counterprojection” of exaggerated demands or aggressive reactions) may improve the response of such individuals to existential approaches.

IV. EMPIRICAL STUDIES

Empirical outcome studies of existential psychotherapy are lacking. Treatment effectiveness has instead been documented in individual case reports, which are thus not systematically controlled for bias in the selection of reported cases, variations in the treatment provided as “existential” by different practitioners, nonspecific or “placebo” effects, lack of rigorously defined or carefully measured outcomes, and so on. Moreover, the line between specifically existentialist approaches and what might be considered “nonspecific” treatment factors is not easy to draw.

In assessing the evidence in support of existential psychotherapy, it may be helpful to begin with the appreciation that existential treatment elements—including empathy and respect for the patient’s point of view, emotional, expressive relationships between patients and therapists (which will, at times, involve conflict) and attention to degrees of attachment and of separation—are parts of any therapeutic or healing relationship. Of course, other therapies emphasize additional elements as well (for example, transference interpretation in psychoanalysis or skill-building in cognitive-behavioral therapy). But the extensive outcome literatures of these other therapies have documented the importance of such common components within multiple forms of therapy in promoting positive outcomes and, therefore, support indirectly but strongly the importance of existential elements.

Existential therapy seeks to enter and explore the patient’s world from within it, beginning with the phenomenological reduction. The therapist seeks to develop her

understanding of the patient in terms that the patient would agree to and accept—terms that are available not only to the “specialist” with expert training but that are inherent in the very words the patient speaks. This is, in effect, the attempt to share the patient’s perspective, to see it her way, and to share her reactions.

The value of this approach is strongly supported by the extensive literature on the importance of a strong and positive therapeutic alliance. One defining element of the therapeutic alliance, which is associated with improvement in psychotherapy, is agreement on goals and tasks—in other words, a shared perspective on what is “wrong,” what should change, and how. This element has been shown to be crucial across therapeutic modalities and settings: measured at the start of therapy, it is associated with positive outcome. Such agreement between patient and therapist—a true working together and not merely patient “compliance”—must require the therapist to enter the patient’s world, to indicate that she understands what is troubling her and why she seeks help. This working together on shared tasks for common purposes is the essence of both the therapeutic alliance and the phenomenological reduction, as it is applied therapeutically.

In addition, existential psychotherapy emphasizes the therapeutic force of the emotional involvement of patient and therapist. The therapist’s genuine interest in the patient, as well as her respect and valuing of her patient, are key treatment elements. Moreover, the therapist will have and express feelings of liking or affection for the patient, as well as feelings of anger and frustration. These expressions are made in the service of developing an emotional attachment between patient and therapist. The value of this element as well is supported by the literature on the therapeutic alliance. That literature strongly indicates the importance of the patient’s positive regard for the therapist—her perception that the therapist cares and wishes to help—in promoting successful treatment outcome.

These two elements of the existential therapist’s relationship with her patient—sharing common perspectives and the open expression of feeling—have been shown to be important in nontherapeutic relationships as well. For example, the marital and family literature strongly documents the importance of such “healing relationships” marked by respect for individual experience, high levels of connection, tolerance for and ability to resolve conflict, equality, and sharing of responsibility. Such relationships can “treat” the effects of earlier, less facilitating interpersonal interactions on self-esteem and adaptive functioning and can help to prevent the

development of psychopathology. The documented value of such nontherapeutic relationships lends additional empirical support to the existentialist focus on fostering such relationships in the treatment setting.

Recent developments in the neurosciences also support important tenets of existential approaches. For example, much recent work in lower animals and in humans suggests the importance of subcortical and cortical-subcortical brain pathways that subserve the processing of emotional information, automatically and out of conscious awareness. These findings are strongly consistent with the emphasis of existentialist workers that being-in-the-world includes an affective relationship with situations—and other people—which is automatic and which precedes any conscious or cognitive appraisals. The implications of this understanding for psychotherapy have not been systematically worked out. Yet the importance of strong affective exchanges between patient and therapist—both of connection and of conflict—as crucial components of treatment are consistent with the notion that affective interaction, not merely conceptual understanding, is an essential component of treatment. The patient must come to feel situations differently if she is to appraise them and act within them in new, more authentic, and vivid ways.

V. CASE ILLUSTRATIONS

These cases illustrate the central existential task: to apprehend the other's being in the world and by a shared engagement to render such a being in the world both understandable and livable. The basic assumption of this task is the possibility of one person's imagining the real of another, that is, a relatively full acknowledgment of another's experience of individual existence. The aim of existential exactness is this fidelity to the other's existence, which faces within the existential method the problem of reaching what is unconscious to that experience. The therapeutic assumption of such attempts is that a rendering into mutually understandable language reduces the other's isolation and opens the way to productive discourse. Throughout we will have to address whether an existential approach to the conscious, shared, individual elements of experience takes into account not only unconscious factors, but both biology and the larger social context within which experience occurs. Any presentation of one psychotherapeutic approach cannot go forward productively without attention to what may be sidelined or altogether neglected.

The first and most readily usable illustration is engagement with paranoid states. A man of 35 was hospitalized for threatening behavior and persecutory convictions. He refused to take medications or permit access to his family or employer. The initial interviews were centered on making his experience of persecution mutually understandable. The interviewer at first expressed indignation at the behavior the patient reported he had received; further, the interviewer gave examples of similar persecutory behavior he himself had observed. No attempt was made to interpret or "reality test" the patient's statements. Instead, the interviewer wanted to plumb the depth of the patient's experience, and to that end, the interviewer expressed increasing indignation and gave further examples of the injustices of the world. The patient visibly relaxed and in response to the interviewer's growing indignation and examples cautioned the interviewer against becoming paranoid. The two had arrived at some mutuality of concern.

The interviewer, however, did not retreat from his "paranoid" position, remarking that he was older than the patient and had perhaps seen more of the world's injustice. The patient, in turn, did not retreat from his almost anti-paranoid position, speaking of his continuing surprise at injustice and his strong expectations that the world should be a better place. ("Naivete" has often been reported among paranoid cases.) The interviewer expressed admiration for the patient's idealism and also expressed the interviewer's own hopes that such idealism should someday be implemented. They seem to be approaching a position in which they could agree to mildly disagree. Essentially, the interviewer was warning the patient that disappointments in his ideals might throw him into an alienating paranoia. The patient was warning the interviewer that his greater experience might render him disillusioned and cynical.

The patient then began to discuss the events preceding the persecutory experience, even suggesting a behavior of his own that may have contributed to that experience. The paranoid behavior stopped, and the discussions continued and deepened.

Note that the engagement between patient and interviewer quickly encompassed the social context of the patient's immediate experience and later the still earlier experience with family. What had happened was a toning down of each person's position and a new experience for both parties of a common ground in which the whole problem of both paranoid attitudes and their now acceptable disagreements could be explored and discussed out of that common experience.

Much has been left out of this discussion—for example, the usefulness of medication in controlling psychotic phenomena (medication was used in the present case) and, as important, the unconscious sources of both their beliefs: many therapeutic factors operate to bring about positive change. And there are certainly important similarities between, for example, psychoanalytic and existential conceptions of what is helpful. The analytic emphasis on deciphering the meaning inherent in behavior is comparable to the existential appreciation of existence as embodied self-interpretation. But there are also important differences in emphasis. Existential therapy, in particular, emphasizes the affective connections between patient and therapist, and the joining in or sharing of common perceptions and feelings, rather than understanding at a conceptual level, as crucial therapeutic factors.

This emphasis is also illustrated in the second case, a 25-year-old woman who entered treatment because of long and unsuccessful efforts to contain what were difficulties of a different sort. For much of her life she had been regarded as “strange” and came into the therapy when she refused medication and efforts to reach her by other means.

The patient repeatedly writhed. The psychopathological temptation was to see the writhing as diagnostic of catatonia and the patient as a victim of schizophrenia. Instead, an existential approach suggested that writhing might be a form of being-in-the-world, a statement about the patient’s place in the world. (An analytic observer might see the same action as infantile regression, perhaps a conflict between demands on the mother and inhibitions about making those demands). One reason the therapist took an existential approach was his memory of an anecdote about Einstein. Early in the physicist’s career he had found himself writhing when he contemplated Newtonian mechanics. Something discomforted him in that theoretical construction. It has been suggested that it took Einstein almost 20 years to translate those writhings into the differential equations of general relativity. Was the patient, too, experiencing a conflict between what she had been taught to believe and what she herself experienced in the world?

When the patient recited poetry and when she discussed poetry with children, the writhing stopped. The therapist wondered if conventional speech, as opposed to spontaneous remarks or speech close to particular feelings, might prompt the writhing. He therefore tried to avoid conventional speech with the patient and to wait upon spontaneous utterances. The writhing stopped.

It appeared that her yearning for heart-felt contact was of many years’ duration and was only matched by her hesitation to discomfort others by calling attention to artificiality. It also seemed that her desire for honest observations and speech had not always been well received in her family, the parents being divided in their practice and counsel. When the therapist was with the parents, he observed that the father, like the patient, was reluctant to confront the mother’s artificiality.

The existential therapeutic task was therefore to acknowledge and share both the patient’s wish for honesty and her sensitivity to others’ discomfort with honesty, and to do both these tasks in such a way that the therapeutic behavior modeled a comfortable dealing with this familiar conflict. It may be that this last was something that the two parents could not do for one another.

This clinical incident illustrates, and might be seen as, the existential “putting the world between brackets,” that is, approaching the patient without preconceptions, especially pathological preconceptions, whether descriptive or analytic. Yet this fundamental rule of existential work may not be quite right. In fact, the therapist found a useful preconception in the Einstein anecdote. Such a preconception illustrates what may be still more fundamental to the existential task, that is, finding what can be termed thwarted or conflicted modes of being-in-the-world; the last two illustrations are of conflict over idealism and honesty. This points to what are perhaps the central features of existential work—its tendency to depathologize clinical situations and to address patients’ strengths.

The final illustration concerns a woman of 65 who felt her existence had largely ended with the death of her husband. Happily, it had not altogether ended because she sought help in finding what she could not really believe in, an existence of her own. She had been a successful wife and mother to a world-famously successful husband, but she found little in those successes that she felt was her own. Long ago in her adolescence she had heard herself saying “I can write as well as Eudora Welty.” Later this seemed like the memory of a nearly forgotten dream.

It was easy to celebrate what she had done. The children had completed their educations and had careers, marriages, and children of their own. In the case of one son, these goals had been achieved despite appalling difficulties, which called on the patient to guide the young man amidst terrible dangers, to an existence and set of purposes that seemed, of all her children, the most his own. The husband had been revered by these

children and by almost everyone except the patient. She knew how severely anxious he had always been and how much he required her judgment and steadiness to maintain both his face and his fame. She remained overshadowed throughout; only a very few knew what she had done.

She had given herself away, also to a charismatic mother who was the cynosure of all family eyes, to whom the patient had early subordinated herself. Even then she had been the mainstay of the large group of younger children enthralled by the exciting mother. She felt like a shadow in a world for which she was actually central.

It was easy to feel great admiration for what she had always done. It also would have been easy to go on celebrating what she had done and to rest on those laurels. How this challenged all the sexist biases of her male therapist! Why was she not content to have helped such a famous man? By chance, this therapist had seen enough of women's lives to know how extraordinary they often are.

It is the lesson of existential work that the dream of her early life could still be found. The treatment was like a long, quiet argument. The therapist took the part of the faint dream but also shared the almost overwhelming despair, against so many celebrations of the husband and the children's awed memories. The patient found the beginnings of her own rescue in the care of other sick and often dying old people. She began to write about them, all the while reflecting on the dying days of the husband and what felt like her own near demise. The accounts were remarkable, showing forth strong psychological gifts and a capacity for expression that belied the deadly themes. She was making something out of what had felt like almost nothing.

It recalled Proust. At the end of *In Search of Lost Time*, Proust, too, had seen the bankruptcy of his own purposes, his nearly fatal ambition to be part of the itself dying, empty French aristocracy he had worked so hard and long to join. He then made out of the wreckage of those hopes a book which was his own.

It was not enough to do what often rescues an existential despair—to welcome the despair into the therapeutic room, to give the despairing person perhaps the patient's first experience of having desperation welcomed and thereby partly left in that room. It is true the patient had not felt entitled to let her feelings be heard. The job she had was to hear others' despair and support them; she was most unsure that anyone would welcome any other part of her. Yet the need to share de-

spair and honor the other, dependent part of herself sat side by side with a need to have the mother honored, so deeply was she in the mother's thrall, and most of all to have her own independence honored, in the emerging creative sphere.

A turning point seemed to be the obvious pleasure the therapist took in the dawning creativity. For a considerable period the therapist took more pleasure in it than she could. At first she doubted his sincerity—it might all be a therapeutic ploy. Then she wondered how anyone could take her seriously. At this point, she was like a brilliant lawyer giving the jury reason after reason for disbelieving the credibility of a witness. Wisely, the therapist read her early writing efforts with an appreciation for detail that, more than any general support, helped convince her of what she doubted. Deep doubt gave way to a tentative curiosity, and the curiosity to a growing enthusiasm that spread not only to her work but to the person who produced it. Yes, the work was hers, and being hers she might love a little the person who produced it.

The work of apprehending another's being-in-the-world had moved from appreciating what she had done to nurturing what she had not done, what she had long postponed. This meant fidelity to a dream almost forgotten and the capacities that were not so much neglected as pressed into the life of service she had been thrown into. The dream was rendered into mutually understandable language first in therapeutic discourse and then in exacting detail in the writings she made out of that long-deferred dream. The work went not from the manifest to the latent so much as from the latent to the manifest—in the language of analysis from being dreamlike and barely conscious to becoming the largest occupant of her consciousness.

VI. SUMMARY

The central objective of existential therapy is to enable the patient to live authentically: actively absorbed and involved with other people and things, while appreciating and accepting his nature as being-in-the-world. Appreciation of being-in-the-world as the fundamental structure of human being also informs the methods of existential treatment. Existential psychotherapy begins with the therapist seeking to enter the patient's world as it is experienced. This is accomplished by careful attention to the patient's experiential reports, suspension of theoretical presuppositions, and the development and expression of

affective involvement. Surface meanings, rather than unconscious depths, are explored and discussed. Behaviors, even those that appear symptomatic, are assumed to represent important aspects of the patient's past, as well as her values and goals for the future. The use of temporal perspectives—taking account both of the patient's past and the hoped-for future—informs the therapist's overall orientation in treatment.

GLOSSARY

flooding Controlled, prolonged exposure to an intensely fear-evoking stimulus until fear reduces in magnitude.

graded *in vivo* exposure Reduction of fears by working up a hierarchy of fear-evoking stimuli.

implosion Imagining an intensely frightening stimulus until it no longer evokes fear. Implosion often involves embellishing the stimulus by exaggerating its fear-evoking properties.

systematic desensitization A form of imaginal exposure that involves gradually working up a hierarchy of fear-evoking stimuli. Typically combined with relaxation training.

Exposure is a form of therapy commonly used in treating phobias and other anxiety disorders. It involves presenting the person with a harmless but fear-evoking stimuli until the stimuli no longer elicit fear.

I. DESCRIPTION OF TREATMENT

Exposure is used in the treatment of a variety of psychological problems. Most commonly, it is used to treat

excessive fears, which are a central component of many anxiety disorders, such as specific phobia, social phobia, panic disorder and agoraphobia, obsessive–compulsive disorder, and posttraumatic stress disorder. During exposure therapy, the person is presented with a fear-evoking stimuli in a controlled, prolonged fashion, until the fear diminishes. Treatment is collaborative, with the patient and therapist working together to decide how and when exposure will take place. Exposure duration depends on many factors, including the type of feared stimuli and the severity of the person's fears. Typically, an exposure session lasts 20 to 90 minutes, and sessions are repeated until the fear is eliminated. Sessions may be either therapist-assisted or may be completed by the patient as a form of homework assignment.

There are several ways that exposure can be conducted. The person may be exposed to real stimuli or may simply imagine the stimuli. Exposure may be to intensely fear-evoking stimuli, or may be gradual, working up a hierarchy of feared stimuli. These two dimensions—real versus imaginal and intense versus gradual—combine to form the four basic exposure techniques: flooding, implosion, graded *in vivo* exposure, and systematic desensitization.

Flooding involves intense exposure to real stimuli. A person with a dog phobia might be exposed to a large boisterous dog until the person is no longer afraid. The advantage of flooding is that it rapidly reduces phobias; four 2-hour sessions are often all that is required. However, there are several disadvantages. First, flooding requires the person to tolerate a great deal of distress.

Some people, particularly those with severe phobias, are unable to do this. Second, flooding can produce temporary but intense side effects such as irritability and nightmares. Third, flooding is often too difficult for patients to conduct alone, and so this form of treatment does not teach patients a skill that they can readily use on their own. When used, flooding is typically implemented with the support and encouragement of a therapist. It is most often used when there is some pressing need for the person to rapidly overcome his or her fears. If a person had a phobia of hospitals and medical staff, for example, flooding would be used if the person was to be soon admitted to hospital for an urgent operation.

Implosion similarly involves exposing the person to intensely fear-evoking stimuli, but in this case the stimuli are imagined. Often exposure is embellished by having the patient imagine an extremely terrifying form of the stimuli. Implosion is often used in the treatment of posttraumatic stress disorder, where the goal is to reduce the fear and associated distress associated with traumatic memories. A person who developed posttraumatic stress disorder as a result of being held hostage in an airplane hijacking, for example, would be asked to repeatedly imagine the traumatic experience, typically for 30 to 45 minutes per treatment session over several sessions. The narrative of the experience might be spoken into a tape recorder or written down, and the person would be encouraged to repeatedly go over the tape or transcript until the memory of the traumatic event no longer evokes distress.

The advantage of implosion is that by reducing the distress associated with traumatic memories the other symptoms of posttraumatic stress disorder also may abate. Thus, implosion can lead to reductions in reexperiencing symptoms (e.g., nightmares, flashbacks), hyperarousal symptoms (e.g., irritability, increased startle response), and avoidance and numbing symptoms (e.g., avoidance of reminders of the traumatic event). A further advantage is that implosion enables the patient to overcome fears for which live exposure is impossible or impractical. Fear of thunderstorms, for example, can be reduced by having the patient repeatedly imagine such events.

The disadvantages of implosion are the same as those of flooding. Even if a patient is able to complete a course of implosion, it is often necessary to add some form of real-life exposure in order to completely reduce the fear. A hijacking survivor might need to resume traveling on airplanes in order to fully reduce the distress associated with the traumatic memories.

Graded *in vivo* exposure is the method most commonly used to reduce fear. It has two components.

TABLE 1
Graded *in Vivo* Exposure: Hierarchy
for Treating Fear of Public Speaking

<i>Stimulus</i>	<i>SUDS</i> ^a
1. Reading a 1-min prepared speech to a friend.	25
2. Reading a 1-min prepared speech to two colleagues at a business meeting.	35
3. Reading a 3-min prepared speech to two colleagues at a business meeting.	45
4. Reading a 3-min prepared speech to six colleagues at weekly staff meeting.	55
5. Presenting a 3-min prepared speech to two colleagues at a business meeting, relying only on rough notes.	60
6. Presenting a 3-min prepared speech to two colleagues at a business meeting, using no notes.	70
7. Presenting a 3-min prepared speech to six colleagues at weekly staff meeting, relying only on rough notes.	80
8. Presenting a 3-min prepared speech to six colleagues at weekly staff meeting, using no notes.	90

^a Subjective Units of Distress Scale, ranging from 0 (no fear or distress) to 100 (extreme fear or distress).

First, the patient is instructed how to rate his or her fear using a Subjective Units of Distress Scale (SUDS). This measure of fear and distress ranges from 0 to 100, where 0 = none, 50 = moderate, and 100 = extreme. Second, the therapist and patient devise a hierarchy of real fear-evoking stimuli, ranging from stimuli that evoke little or no fear or distress, through to extremely frightening or upsetting stimuli. Table 1 shows an example of a hierarchy used in the treatment of intense public speaking fears, which are a common feature of social phobia. This hierarchy was used to help the patient attain the goal of being able to present a short report at a weekly staff meeting.

Typically there are 8 to 10 stimuli in the hierarchy, separated by SUDS increments of approximately 10 points, so that the stimuli are not too discrepant in the levels of fear or distress they evoke. Patients begin by exposing themselves to items lowest on the hierarchy. Exposure to a given stimulus is repeated until the fear or distress abates. Once fear of this stimuli is reduced, the other stimuli on the hierarchy also become less fear evoking. The patient gradually works up the hierarchy; once the fear associated with one stimuli is diminished, then exposure to the next stimulus is attempted. This continues until all the stimuli on the hierarchy no longer evoke fear or distress.

Sometimes it is necessary to develop more than one hierarchy to reduce all the patient's fears. For a person with generalized social phobia, a patient might work through a public speaking hierarchy, a hierarchy of situations involving one-to-one conversations with a person of the opposite sex, and a hierarchy involving asserting oneself to authority figures. The disadvantage of graded *in vivo* exposure is that it is slower than flooding. The advantage is that it teaches patients a skill for overcoming their phobias in a simple, step-by-step fashion. By progressively working up a hierarchy patients can overcome their phobias gradually, without enduring extreme fear or distress.

Systematic desensitization consists of gradual, imaginal exposure to stimuli organized on a hierarchy. The stimuli in Table 1, for example, could be used in systematic desensitization by having the patient imagine each stimulus. Typically, systematic desensitization is combined with some form of relaxation training. The patient is asked to sit back in a comfortable chair and practice a relaxation exercise. Once a state of deep relaxation is attained, the patient is asked to imagine the least upsetting stimulus on the hierarchy. Exposure duration might be only for a few minutes, alternating relaxation with imaginal exposure until the stimulus image no longer evokes fear or distress. The procedure is then repeated with the next stimulus on the hierarchy. The disadvantages of systematic desensitization are that it is slow, and that it is often necessary to eventually implement some form of live exposure in order to fully reduce the fears. The advantage of systematic desensitization is that it is easily tolerated and is therefore a good place to start with reducing extremely severe fears.

II. CASE ILLUSTRATION

Joseph K. was a 27-year-old man with a 5-year history of panic disorder and agoraphobia. He experienced recurrent, unexpected panic attacks. These typically occurred whenever he experienced cardiac sensations (e.g., rapid heartbeat), which he misinterpreted as a sign of impending heart attack. His catastrophic misinterpretations of these sensations increased his autonomic arousal, thereby escalating the feared symptoms to the point that he panicked. Joseph's agoraphobia was characterized by intense fear of traveling far from home, fear of driving over bridges and through tunnels, and fear of entering supermarkets and shopping malls. A detailed medical evaluation revealed no physical problems, including no cardiac abnormalities.

In order to select the exposure methods to be used in treating Joseph's problems, it was necessary to develop

a formulation or working hypothesis about the causes of his difficulties. The therapist hypothesized that Joseph's primary problem was his fear of cardiac sensations, which arose from the patient's belief that these sensations meant that he was having a heart attack. As a result, Joseph feared and avoided situations in which he had experienced these sensations (e.g., while driving over bridges or standing in supermarket lines), and also feared and avoided situations in which it might be difficult to gain speedy medical attention if he actually had a heart attack (e.g., while traveling far from home). Thus, Joseph's agoraphobic fear and avoidance was hypothesized to be a consequence of his fear of arousal-related sensations.

The therapist shared this formulation with Joseph, who agreed that it was a plausible explanation of his problems. The next step was to use the formulation to select the most appropriate exposure interventions. Interoceptive exposure was selected as the method for reducing Joseph's fear of arousal-related sensations. This involves having the patient deliberately bring on the feared sensations (e.g., running up and down stairs to induce rapid heartbeat). Joseph was very frightened of these sensations, so interoceptive exposure was implemented as a form of graded *in vivo* exposure. A hierarchy of fear-evoking activities was constructed, beginning with mildly feared activities (e.g., walking quickly) through to very frightening activities (e.g., running up a long flight of steps). As Joseph worked up the hierarchy he gradually became less frightened of cardiac sensations, and came to see that the sensations would not cause him to have a heart attack. As this fear abated, he became less disturbed by naturally occurring cardiac sensations, and was less likely to panic when those sensations occurred. Four 60-minute sessions of graded interoceptive exposure were required to eliminate his cardiac fears and panic attacks.

Joseph's agoraphobic fear and avoidance slightly abated as a result of interoceptive exposure, although his agoraphobia was still in need of treatment. In particular, he was still extremely frightened of driving through tunnels, to the point that he was too frightened to attempt any form of real-life exposure to tunnels. As a result, the therapist began with systematic desensitization to treat this problem. Joseph was instructed to repeatedly imagine driving through tunnels. Such exposure went on for 30 minutes in the therapist's office. An audiotape was made of the imagined scenes, where Joseph described in detail the experience driving through various tunnels, including a description of all sensations involved (e.g., sights, sounds, smells, bodily sensations) and thoughts he might have (e.g., catastrophic thoughts). Joseph was

asked to listen to the tape once each day for the following week. During his next treatment session his fear of tunnels had abated to the point that he was ready to commence a course of graded *in vivo* exposure. A hierarchy was constructed. The least fear-evoking stimulus involved driving four times through a short, well-lit tunnel during a time when there would be little traffic on the road. Joseph completed this exercise as a homework assignment until his fear abated. He then gradually worked through more challenging assignments, such as driving through longer tunnels until his fear had abated. His other agoraphobic fears, such as fear of entering shopping malls, were similarly treated with a combination of systematic desensitization and graded *in vivo* exposure.

In all, Joseph received 16 weekly 60-minute sessions of therapy. At the end of therapy he was almost free of symptoms of panic disorder and agoraphobia. He was instructed to use the methods learned during therapy to overcome any other fears that might arise. A series of check-up appointments were scheduled, so that Joseph's progress could be monitored. At the 3- and 6-month check-ups he was symptom-free. However, at the 12-month check-up he reported a return of panic attacks, which arose after his grandfather had suddenly died of a heart attack. The death renewed Joseph's fears of cardiac sensations, thereby leading to the reoccurrence of panic. Three booster sessions of interoceptive exposure were sufficient to reduce the fears and panics.

III. THEORETICAL BASES

The rationale for exposure therapies was originally based on the conditioning models of fear acquisition. An early influential account was O. H. Mowrer's 1960 *two-factor model*, which proposed that fears are acquired by classical conditioning and maintained by operant conditioning. Classical conditioning involves one or more learning experiences that teach the person to associate a particular stimulus (e.g., riding in a car) with an aversive outcome (e.g., a road traffic collision). Clinically, the most important form of operant conditioning is negative reinforcement, where avoidance or escape from fear-evoking stimuli is reinforced by the avoidance or escape from unpleasant states of fear or distress. In turn, avoidance and escape prevent classically conditioned fears from being unlearned.

With subsequent research it became apparent that beliefs and expectations play an important role in both operant and classical conditioning, and theories of fear became correspondingly more complex. According to later models, fear was not directly determined by a

stimulus (e.g., driving in the rain), but by the person's expectation of what the stimulus would lead to (e.g., a road traffic fatality). Expectations are strengthened by full or partial confirmation of one's expectations (e.g., a "near miss" while driving).

The major contemporary theory of fears is E. B. Foa and M. J. Kozak's 1986 emotional processing model. Here, fears are represented in networks (fear structures) stored in long-term memory. The networks contain representations of feared stimuli (e.g., oncoming trucks, driving at night), response information (e.g., palpitations, trembling, subjective fear, escape behaviors), and meaning information (e.g., the concept of danger). In the network the three types of information are linked (e.g., links between oncoming trucks, danger, and fear). Links can be innate or learned. Fear structures are activated by incoming information that matches information stored in the network. Activation of the network evokes fear and motivates avoidance or escape behavior. According to this model, fears are reduced by modifying the fear structure through the incorporation of corrective information (e.g., safety information acquired during behavioral exposure exercises). Although the emotional processing model is considerably more sophisticated than the original two-factor model, both models predict that fears—including phobias—are reduced by the various exposure interventions described in this article.

IV. APPLICATIONS AND EXCLUSIONS

Exposure therapies have been applied to all kinds of disorders in which excessive fears play an important role. Apart from the disorders discussed earlier, exposure therapies have been successfully used in treating obsessive-compulsive disorder. Here, the treatment consists of exposure and response prevention. A person with contamination obsessions and cleaning compulsions, for example, would be exposed to a "dirty" object such as a doorknob, and then asked to refrain from engaging in handwashing compulsions. In this way, the contamination-related distress gradually diminishes, and the obsessions about contamination and associated compulsions similarly abate. Exposure and response prevention are most often used in the form of graded *in vivo* exposure, although flooding is sometimes used.

Other anxiety disorders can be similarly treated with exposure methods. Acute stress disorder, which is in many ways similar to posttraumatic stress disorder, can be successfully treated with implosion or systematic desensitization. Generalized anxiety disorder, for

which excessive worry is a central feature, can be treated by exposing the person, in a prolonged fashion, to their worries. The person might spend 20 minutes each day writing out his or her main worries. The distress associated with the worries gradually abates, and the person correspondingly learns to dismiss the unrealistic concerns.

Exposure therapies should only be implemented by a suitably trained therapist. The therapist should not only be skilled in exposure therapy, but should have a good understanding of psychopathology and psychiatric diagnosis, and should be skilled in the psychotherapeutic interventions commonly used in conjunction with exposure therapy (e.g., cognitive therapy, social skills training, relaxation training). If the patient experiences intense anger or guilt during exposure, as sometimes happens when treating patients with posttraumatic stress disorder, it is often necessary to combine exposure with cognitive therapy. The latter is used to address any dysfunctional beliefs associated with anger or guilt.

The patient should be a willing participant in the process of exposure therapy, with complete control over the nature and timing of any exposure exercises. Exposure may be traumatizing if it is forced on an unwilling patient. Exposure should be used only if the patient is able to tolerate some degree of distress, and is sufficiently motivated to overcome his or her fears. Patients should be told about the side effects of exposure treatment (e.g., transient increases in irritability), so that they can make an informed choice about whether or not to participate in treatment. The therapist needs to consider the patient's other problems before initiating a course of exposure. If a patient had social phobia and alcohol abuse, then one would need to consider whether the distress caused by exposure therapy would cause an increase in alcohol abuse. If this is likely, then the alcohol problem would need to be treated first.

V. EMPIRICAL STUDIES

There have been hundreds of clinical studies of the use of exposure therapy in treating the fears associated with anxiety disorders. Exposure therapies are among

the most effective treatment for fears, with success rates typically ranging from 60 to 80%, depending on the severity and complexity of the disorder. Treatment-related gains have been shown to be maintained at follow-up intervals ranging from 1 to 5 years. Patients who do not fully benefit from exposure may be successfully treated by other psychotherapeutic interventions, such as cognitive therapy.

VI. SUMMARY

Exposure methods are used to help people overcome excessive fears or phobias. Exposure therapy is the treatment of choice for specific phobias, and is an important intervention for use in treating other anxiety disorders. It involves having the person repeatedly expose himself or herself to a feared stimulus until fear abates. Patients play an active role in choosing what they will be exposed to, and when the exposure will occur. For patients who are extremely phobic, the least demanding form of exposure (systematic desensitization) is typically the exposure intervention to be used first. Exposure therapies are often used in combination with other interventions, such as cognitive therapy, social skills training, or relaxation training.

- exposure *in vitro*** Behavioral procedure based on confrontations with anxiety-provoking stimuli in the imagination.
- extinction** Decrements in responding through repetition of unreinforced responding.
- flooding** Exposure to high fear-provoking stimuli.
- habituation** Decline of a response over repeated exposures to fear-provoking stimuli.
- hierarchy** List of fearful situations ranging from no fear (0) to extremely anxious or panicky (100).
- interoceptive stimuli** Bodily sensations such as increased heart rate.
- return of fear** Reappearance of fear after the end of treatment.
- sensitization** Increase in fear responding after repeated exposures to fear-provoking stimuli.

I. DESCRIPTION OF EXPOSURE *IN VIVO*

Exposure *in vivo* therapy is a common behavioral procedure used in many treatments. The purpose of ex-

posure *in vivo* therapy is to diminish avoidance behavior and decrease subjective anxiety. This article will present an overview of the current status of exposure *in vivo* in patients with anxiety disorders. Exposure *in vivo* has also been used in patients with substance abuse disorders and eating disorders, but this so-called cue exposure will not be discussed here.

In 1958 Joseph Wolpe developed a behavioral procedure named systematic desensitization. This was presumably the first behavioral procedure, which entailed systematic and repeated confrontation to anxiety-provoking stimuli. During this procedure, patients were first trained in muscular relaxation. After that, patients were encouraged to move gradually up a hierarchy of anxiety-arousing situations, while remaining relaxed. Systematic desensitization may be applied either *in vitro* (in the imagination) or *in vivo* (in real life), but given the fact that it most often was used *in vitro*, systematic desensitization will not be discussed here.

Traditionally, exposure *in vivo* was limited to external circumscribed situations, objects, or animals. Specific phobics were confronted with, for example, snakes or spiders, heights, or small spaces; social phobics with social encounters; agoraphobics with busy or crowded places away from home; and obsessive-compulsive patients were confronted with dirt. However, exposure can also be applied to feared internal (interoceptive) stimuli such as increased heart rate in the case of panic disorder. Examples of interoceptive stimuli are bodily sensations such as trembling or shaking and dizziness. The bodily sensations can be elicited by climbing up

the stairs (increased heart rate), by pushing against a wall (trembling of the muscles of the arms) and by turning around on a chair (dizziness), or by hyperventilation provocation. Specific bodily sensations related to social anxiety can also be evoked in social phobics who fear that others see that they are trembling, sweating, or blushing. In this case, the primary fear is not the sensation itself—as is the case in panic disorder—but the fear of negative evaluation of the physiological responses by others.

The selection of the exposure stimuli depends on the primary focus of concern of the specific patient with his or her specific complaints. It is of central importance to select those stimuli that are most relevant for the individual patient, that is, those situations or objects that are avoided and elicit anxiety or distress.

The rate at which the exposure can be conducted varies from massed schedules (e.g., treatment sessions within 1 day or 1 week) to spaced schedules (e.g., treatment sessions once a week for several months). A promising new schedule is the expanding-spaced exposure (ESE) sessions, in which the intertrial intervals double between sessions. Exposure according to an expanding-spaced schedule is conducted at day 1, day 2, day 4, day 8, day 16, day 32, and so on.

Another central parameter is the optimal duration of exposure to the phobic stimulus during an exposure session. The usual recommendation for clinical practice is to continue exposure until a marked reduction of fear is established. Mostly, exposure duration of one-and-a-half hours to two hours for one hierarchy item is recommended. Sometimes it is difficult or impossible to realize exposure *in vivo* for such a prolonged period of time (e.g., social encounters usually have a shorter time span). In those cases, repeated exposures (i.e., re-exposures) have shown to be effective.

Escape during exposure therapy is assumed to reduce anxiety and to strengthen avoidance, because the reduction of anxiety reinforces the avoidance behavior. Therefore, patients are instructed to remain in a fearful situation until the fear has been reduced. It seems, however, that escape behavior is not necessarily followed by increases of fear and avoidance. The amount of control patients experience during the exposure probably plays an important role in the reduction of fear and avoidance.

Exposure can be performed in a gradual manner (starting at the bottom of the hierarchy), or very steep in the form of flooding (starting at the top of the hierarchy). It should be noted, however, that flooding could lead to noncompliance and dropping out. On the

other hand, if progress is slow during gradual exposure patients may become disheartened. Despite the relative effectiveness of flooding *in vivo* techniques, exposure tasks are mostly performed using a hierarchy of progressively more anxiety-provoking situations (i.e., graded exposure).

Distraction is expected to interfere with fear reduction. It would impede long-term fear reduction, although it may have a positive effect on short-term reductions of fear because it limits the salience of the feared stimulus. The usual recommendation for clinical practice is to avoid distraction during exposure, if possible. This kind of distraction is also referred to as subtle avoidance behavior, and can include behaviors such as counting, deliberately thinking of something else, or talking to other people in order to distract oneself.

Exposure can be conducted with the aid of a therapist, with the aid of the partner of the patient (spouse-aided therapy), or in a self-directed manner. The therapist is most active in guided mastery treatment. Guided mastery treatment encompasses a range of mastery techniques (e.g., therapist-assisted performance, modeling, graduated tasks, proximal goals, physical support, and mechanical aids).

During self-exposure instructions can be given via a self-help manual, via a computer program (or internet), or via videotapes, or self-exposure can be telephone guided. Finally, an exposure program can also be conducted in a group of patients.

II. THEORETICAL BASES OF EXPOSURE *IN VIVO*

Exposure is not a theory, but merely a description of a common behavioral procedure used in many treatments. Several theories of fear and anxiety reduction explaining therapeutic change in exposure *in vivo* therapy have been formulated and empirically tested. The most important theories will be reviewed.

A. Habituation and Extinction Models

Processes often cited as explanation for the effects of exposure are habituation and extinction.

Habituation refers to a decline in fear responses, particularly the physiological responses, over repeated exposures to fear-provoking stimuli. Habituation is regarded as an unlearned temporary reaction. Habituation is supposed not to be affected by cognitions. The

classical habituation theory predicts that habituation would not occur if (baseline) arousal were high. Then, arousal would further increase and lead to sensitization (i.e., increase in fear responding after repeated exposures to fear-provoking stimuli). However, the literature revealed that, for instance, during exposure to high fear-provoking stimuli (e.g., flooding therapy), a reduction instead of a further increase in psychophysiological and subjective anxiety could be expected. Recent habituation theories have been extended to accommodate these findings. These dual-process theories describe complex interactions between habituation and sensitization, in which habituation can eventually occur after exposure to high fear-provoking stimuli.

Several studies have provided supportive evidence for a role of habituation in exposure therapy. First, in several studies self-reported fear and physiological arousal show a declining trend across exposures consistent with habituation. Second, findings in specific phobias have revealed that physiological habituation is related to improvement, whereas nonhabituation is not. Third, variables independent of habituation (e.g., level of arousal, rate of stimulation, and regularity of presentation) seem to affect habituation and fear reduction in a similar manner.

A major difficulty in the habituation theories is the presumed short-term effect of habituation. The habituation theory would predict a return of fear after a certain time interval without stimulus exposure. Studies, however, show that a considerable proportion of patients report to be free of anxiety during long-lasting periods of time. To account for the long-term effects of exposure, several theorists have made a distinction between short-term and long-term habituation. For example, it was suggested that long-term habituation depends on higher cognitive processes, whereas short-term habituation represents mostly autonomic damping. There are more limitations to the habituation theory. For example, the habituation model cannot adequately explain the persistence of some fearful responding despite repeated exposures.

Extinction refers to decrements in responding through repetition of unreinforced responding. Thus, extinction-based theories suggest that anxiety reduction results from repeated encounters with anxiety-provoking situations without aversive consequences. Unlike habituation, extinction is supposed to be affected by cognitions. In other words, it is assumed to be an active instead of a passive process. The extinction theory presupposes that phobic behavior has been learned and therefore can be unlearned. Several cognitive explanations have been put

forward to explain what is learned during extinction of phobic behavior. For example, it is postulated that what is learned is disconfirmation of outcome expectations, or enhanced self-efficacy, or the fact that the arousal associated with exposure is not dangerous. These cognitive-oriented theories will be discussed in more detail in the following paragraphs.

Still another explanation is that the context determines which meaning a situation becomes. It has been suggested that the joint presence of the stimulus (e.g., palpitations) and the context (e.g., far from home) determine the meaning (e.g., heart attack). The latter theory is in line with evidence that return of fear may be minimized with prolonged exposure sessions to a variety of contexts.

Evidence that is in conflict with the extinction theory in explaining fear and anxiety reduction during exposure comes from “escape” studies. According to the extinction theory, patients have to remain in the fear-provoking situation until anxiety decreases substantially in order to learn that nothing bad happens. Several studies have demonstrated, however, that anxiety reduction can occur, even though patients were allowed to escape from the feared situation before reaching maximum anxiety. In these studies, it is unclear what is learned. The patients did not seem to have the time and chance to learn about the possible feared consequences associated with the feared situation.

B. Cognitive Change Models

In 1993 Jack Rachman explained the success of exposure *in vivo* by the acquisition of fresh, disconfirmatory evidence (e.g. “no heart attack,” “did not lose control”), which weakens the catastrophic cognitions. From this perspective, exposure is viewed as a critical intervention through which catastrophic cognitions may be tested. This is in line with the cognitive-behavioral therapy (CBT) based on the perceived danger theory according to Aaron Beck and colleagues. Within this model exposure (i.e., behavioral experiments) is generally regarded as a necessity for testing the validity of dysfunctional thoughts next to other strategies such as Socratic questioning of probabilities.

So far, it remains to be shown whether exposure changes cognitions and thereby lessens anxiety, or whether cognitions are less likely to arise when anxiety diminishes. The traditional outcome (pre- versus post-test) studies do not reveal whether cognitive change occurs as a function of exposure therapy. To answer these questions, process-oriented studies are required. Process

studies require repeated measurements of relevant variables during the treatment process.

Several process studies have been performed into the cognitive processes of exposure *in vivo*. In these process studies, thoughts are generally collected by means of *in vivo* assessment (e.g., thoughts are reported into a tape recorder) during exposure, or using thought-listings (i.e., free report of all thoughts on paper) directly following exposure. In general, inconsistent findings are reported in these process studies designed to measure the relationship between cognitive change and improvement during *in vivo* exposure in phobic patients. However, the production techniques used to measure cognitive change show some flaws, for example, the inability to recall all thoughts (thought-listings), and social discomfort with publicly talking to themselves (*in vivo* assessment). Furthermore, the *in vivo* assessment may distract the patients from being engaged in the exposure situation with possible consequences for treatment outcome. Finally, the thought-listing procedure is, generally, utilized following the exposure sessions, and therefore cannot reveal the process during treatment.

More consistent results were found in a process study using a short self-report questionnaire to measure the frequency of thoughts during exposure *in vivo*. Results showed that cognitive change (decrease in frequency of negative self-statements) was achieved by exposure *in vivo* therapy. However, cognitive change per se was not related to a positive treatment outcome. The results suggested that the magnitude of the frequency ratings of negative self-statements at the start, during, and at the end of exposure therapy was the most critical factor. The most improved patients reported overall less negative thoughts.

C. The Self-Efficacy Theory

According to the self-efficacy theory of Albert Bandura, published in 1977, therapeutic change can be brought about by experiences of mastery arising from successful performance. Bandura has proposed that phobic behavior is influenced more by self-efficacy judgments than by outcome expectations. He argues that a person's self-efficacy can be improved by those psychological procedures, which enhance the level and the strength of the self-efficacy. Implicitly, he states that an exposure procedure is not a necessary condition to obtain therapeutic change. Self-efficacy can be improved by various treatment procedures. Field mastery experiences are, however, considered a critical ingredient of treatment of phobic disorders. Thus, in the self-

efficacy theory, the psychological mechanism of change is a cognitive one, whereas the most effective psychological procedure is a behavioral one (performance-based). According to Bandura, perceived self-efficacy through performance successes depend on various personal and situational factors, for example, difficulty of the task, amount of effort subjects expend, and the temporal pattern of their successes and failures. The model posits a central role to information processing. It states that subjects process, weight, and integrate information about their capabilities, and they regulate their behavior and effort accordingly. Strong relationships have been found between perceptions of self-efficacy and changes in phobic behavior by different treatments (including exposure therapy) for various phobias. On the other hand, there is also some evidence that seems in conflict with the self-efficacy theory. Some studies found that although self-efficacy predicted self-reported change, it did not have a significant relationship with behavioral or physiological change.

More recently, Bandura extended the self-efficacy theory by stating that phobic anxiety derives from both low self-efficacy for performing overtly, and from low self-efficacy for exercising control over scary thoughts. Overall, self-efficacy seems a powerful measure in predicting dysfunctional behavior. The self-efficacy mechanism has received considerable support from research in describing the relationship between what subjects think they can manage and what they can manage both before and after treatments for phobic complaints.

D. The Match–Mismatch Model

Rachman and colleagues have suggested that anxiety expectancies might play a mediating role in exposure therapy. They found that phobics typically overpredict the amount of fear they expect to experience in a threatening situation.

A number of researchers investigated the overprediction of fear in a series of laboratory studies, in which they asked the subjects to rate their predicted fear before they were exposed to a threatening situation, and to indicate their reported fear just after the exposure trial. Subjects overpredicted their fear when the predicted fear was higher than the reported fear. On the other hand, subjects underpredicted their fear when the predicted fear was lower than the reported fear. A match was defined as no discrepancy or a very small discrepancy between predicted and reported fear. Subjects participated in several trials to observe whether their predictions changed over time. Accord-

ing to Rachman, fearful subjects tend to overpredict their fear during exposure to a fearful situation. Further, the match–mismatch model states that inaccurate fear predictions are followed by adjustments of these predictions. For example, when a subject underpredicts a fearful event, it is likely that he or she adapts his or her prediction in the form of an increase of predicted fear for future events. On the other hand, when overpredictions are followed by disconfirmations, future predictions will be lowered. The model also states that other variables, like anticipatory fear and avoidance behavior, are influenced by inaccurate predictions. Increases in these variables are expected after underpredictions, and decreases are expected after overpredictions of fear. Furthermore, it is assumed that underpredictions have stronger and more long-lasting effects on fear expectations, avoidance, and anticipatory anxiety than overpredictions, which are assumed to have moderate effects on reductions of these variables. For example, one underprediction of fear can lead to a substantial rise in fear expectations. Overpredictions, on the other hand, need several disconfirmations to become more accurate, but have a less dramatic influence on the decrease of expectations. In addition, it is assumed that predictions of fear become more accurate with practice. Lastly, during exposure, it is assumed that the fear reduction process is not influenced by inaccurate predictions; reports of fear tend to decrease, regardless of the accuracy of earlier predictions. Thus, the model assumes that a second process is responsible for the process of habituation/extinction.

Reviewing the empirical evidence for the match–mismatch model it can be concluded that the studies report strong relations between inaccurate predictions and future predictions in subclinical and clinical patients. So far, it is unclear whether mismatches of fear influence the habituation or extinction process. In sum, overpredictions of fear lead to avoidance behavior and anticipatory anxiety because subjects expect to be more fearful during exposure than should actually be the case. Subjects, thereby, reduce the chance of disconfirmation of the predictions. The effects of exposure are assumed to be due to repeated disconfirmations, because predictions become more accurate with repeated exposures. During exposure, it is expected that underpredictions have far more influence than overpredictions. The underlying mechanisms of overpredictions are as yet not clear.

Most support for the match–mismatch model derives from studies performed in a laboratory setting with relatively mild phobic subjects. A recent study investigated whether the results of the laboratory studies

could be replicated in a clinically relevant situation, namely exposure *in vivo* therapy, with a clinical group of agoraphobic patients. Many of the findings of the laboratory studies were replicated. However, although patients tended to overpredict their fear, they did not show a tendency to become more accurate in the course of exposure therapy.

E. Emotional Processing

Emotional processing is defined as the modification of memory structures that underlie emotions. This model of anxiety reduction is partly based on Peter Lang's model of bioinformational processing and Jack Rachman's work on the concept of emotional processing.

According to Lang emotion is represented in memory structures as action tendencies that contain (1) information about the feared stimulus situation; (2) information about verbal, physiological, and overt behavioral responses; and (3) interpretative information about the meaning of the stimulus and response elements of the structure. Treatment should aim at activating all aspects of the prototype fear image stored in memory, so that the information can be processed and a new prototype can be formed that contains less fearful or nonfearful response to the stimulus information. Because emotion is considered an action set, it is assumed that it generates physiological output.

Rachman suggested indices of satisfactory and unsatisfactory emotional processing, and concrete factors that are expected to impede and promote emotional processing. In his view, satisfactory emotional processing leads to evidence that subjective distress and disturbed behavior decline, and to evidence of a return of normal (routine) behavior.

Foa and Kozak offered a framework about the mechanisms of therapeutic change and specified indicators of emotional processing. They suggested that the fear structure is a program to escape from danger. The fear structure is distinguished from a normal information structure by excessive response elements (e.g., avoidance and physiological arousal), and by the meaning of the stimuli and responses. The fear structures can be modified during exposure therapy when two conditions are satisfied: (1) the fear structure must be activated; and (2) new information must be incorporated. Exposure to information consistent with the fear structure would be expected to strengthen fear, whereas information incompatible with the fear structure would reduce fear.

It is assumed that measurable physiological activity and self-reports reflect the fear structure during fear

evocation. Especially, physiological activity is considered as an index that information is processed: Fear activation cannot occur without preparatory changes in physiological activity. That is, within a fear structure defined as a program to escape or avoid, fear will produce physiological activity regardless of whether one actually avoids the fearful object or not. The following responses occurring in patients who improve with exposure-based treatments are seen as indicators of emotional processing: (1) activation of psychophysiological responses and subjective fear responses during exposure, (2) decrease of these responses within exposure sessions (within-sessions habituation), and (3) decrease in initial reactions to feared stimuli across sessions (across-sessions habituation). Activation of the fear structure can be complicated by, for example, cognitive avoidance or other distractions, as was also mentioned by Rachman. Incomplete emotional processing can occur when the duration of exposure is not long enough for habituation to occur. Finally, initial high arousal would interfere with anxiety reduction (habituation).

This model is generally supported by research findings. It should be noted, however, that the model also faces several difficulties. For example, the emotional processing theory cannot explain controlled escape exposure.

III. EMPIRICAL STUDIES

Empirical outcome studies have proved that exposure *in vivo* is an effective treatment in reducing phobic complaints in specific phobias, in social phobias, in agoraphobia with or without panic disorder, and in hypochondriasis. Studies have shown that exposure to anxiety-provoking situations also has a positive effect on frequency and intensity of panic attacks in agoraphobics. Obsessive–compulsive disorder patients benefit from exposure *in vivo* treatment with the addition of response prevention (i.e., the prevention of behaviors that reduce fear).

A. Parameters of Exposure *in Vivo*

Wolpe explained the relative effectiveness of systematic desensitization by the fact that it would be impossible to feel anxious and relaxed at the same time; he called this reciprocal inhibition. Research, however, has demonstrated that the addition of relaxation to the exposure element is not essential for improvement. In the eighties, Lars Göran Öst introduced “applied relax-

ation”. The purpose of applied relaxation is to teach the patients to monitor and recognize the early signs of tension and to apply a relaxation technique when confronted *in vivo* with phobic situations. It has not been proven that the addition of applied relaxation enhances the effects of mere exposure *in vivo*.

Massed exposure sessions are expected to be related to higher dropout rates, more return of fear, and more stressfulness in comparison to spaced sessions. However, research into the optimal format of exposure does not provide firm evidence to justify this expectation. For example, in agoraphobics massed exposure was generally more or as effective as spaced exposure in reducing avoidance behavior and self-reported anxiety. Furthermore, the dropout rate, relapse rate, and stressfulness were comparable for patients who received spaced or massed sessions. In addition, for specific phobics and for obsessive–compulsive patients, no differential effect was found between spaced and massed exposure in relapse rate or dropout rate. As to the ESE sessions, in which the intertrial intervals double between sessions, research showed that the ESE sessions led to no clear return of fear, whereas a massed condition (four exposure trials within 1 day) did lead to return of fear 1 month after the end of treatment.

Another central parameter is the optimal duration of exposure to the phobic stimulus during an exposure session. Several studies have consistently indicated that long continuous sessions (prolonged exposure) are more effective than shorter or interrupted sessions. However, some studies on escape behavior during exposure have shed a different light on this issue.

Several studies compared endurance conditions with escape conditions. During the endurance condition, patients stayed in the fearful situations until the anxiety markedly decreased, whereas in the escape condition patients were allowed to leave the exposure situation at high fear levels. In general, results revealed no differences in effectiveness between the treatment conditions on measures of fear and avoidance. It is assumed that the option of escaping during exposure may serve to increase the patients’ sense of control, which would in return lead to a reduction of their fears. This form of escape is also referred to as controlled escape. Thus, the amount of control patients experience during the exposure probably plays an important role in the reduction of fear and avoidance.

Another parameter is the amount of arousal patients experience in relation to improvement by exposure. Some studies indicate that patients who were most aroused before treatment (mostly measured by heart

rate) were also most likely to be improved after exposure therapy. Other studies showed that patients with relatively high heart rate demonstrated the most return of fear at follow-up as compared to patients with relatively low heart rate levels. Still other studies found no relationship between heart rate and return of fear or found inconsistent results.

The results with respect to distraction versus attention-focused exposure on fear reduction and improvement are inconclusive. Either no differences are found in the amount of fear reduction between distracted and focused exposure, or the fear levels during distracted exposure remained stable whereas during focused exposure fear ratings increased. With respect to return of fear, results showed that distracted exposure led to return of fear, or the distracted exposure condition experienced more fear reduction at follow-up compared to the focused exposure condition.

The results of the studies on agoraphobia and obsessive-compulsive disorder indicated that the participation of the spouse in the exposure treatment did not enhance the treatment effects. Further, results with respect to the comparative effectiveness of therapist controlled versus self-exposure are inconclusive. However, in six out of eight studies, guided mastery was substantially and significantly more effective than mere exposure. In all these studies the duration of the treatment conditions was equal, and both conditions were therapist-assisted.

B. Long-Term Efficacy of Exposure *in Vivo* Therapy

Despite the effectiveness of exposure therapies on group level, the results show that not all patients benefit equally at posttreatment from exposure therapy or maintain their gains at follow-up. A proportion of phobic patients, about 25 to 30%, either fail to respond, or show only modest improvement after a standard exposure treatment and therefore need more treatment, or do not maintain their gains in the long run. The efficacy figures, however, tend to differ somewhat among the studies on the same disorders and also among the same phobic disorders over studies.

In general, exposure techniques have led to long-term improvement in about 75% of obsessive-compulsives. Also, the long-term efficacy of exposure treatment for agoraphobics has been well established. About 75 to 80% of the patients are rated as “improved” or “much improved” at the end of treatment. Furthermore, posttreatment effects of exposure therapy are maintained during the follow-up period in panic and agoraphobic patients.

Results from a recent study investigating the long-term effectiveness of exposure *in vivo* revealed that of the 93 treated panic disorder patients with agoraphobia, 67.4% continued remission up to 7 years.

The efficacy figures of *in vivo* exposure therapy for social phobic patients are less encouraging. For example, one study reported that 47% of the social phobics needed more treatment at the end of exposure treatment.

In sum, although, exposure *in vivo* therapy is effective for most patients, the efficacy is limited; some patients show only moderate clinical improvement or do not maintain their gains. It is not clear why some patient(s) (groups) benefit more from *in vivo* exposure than others.

C. Exposure *in Vivo* Therapy versus Cognitive Therapy

One of the theoretical problems in the comparison of the effectiveness of exposure *in vivo* therapy and cognitive therapy is that cognitive restructuring without any form of exposure is rare in cognitive therapy. The use of exposure exercises called “behavioral experiments” or “hypothesis testing” is seen as clinically important aspects to test the validity of the beliefs.

In specific phobias, cognitive therapy was generally less effective than *in vivo* exposure. Several studies found cognitive therapy and exposure *in vivo* therapy with the addition of response prevention about equally effective in obsessive-compulsives. Similarly, cognitive therapy is as effective as exposure *in vivo* therapy alone for social phobic complaints. In general, studies find that cognitive therapy alone is of limited value for agoraphobia as compared to exposure *in vivo*. More recently developed cognitive approaches focusing on catastrophic cognitions are effective with respect to reduction of panic attacks in patients with panic disorder with no or limited avoidance, but less effective than exposure *in vivo* in severe agoraphobic patients. However, these cognitive restructuring packages contain an “exposure” component (i.e., behavioral experiments). Finally, exposure *in vivo* was as effective as cognitive therapy in hypochondriasis.

Overall, the literature suggests that cognitive therapy does not enhance the effects of exposure *in vivo*. For example, results of several studies showed that exposure with and without cognitive modification was equally effective in social phobia. Similarly, studies with acrophobics revealed that exposure with self-statement training was as effective as exposure alone. Further, a number of studies found cognitive-behavioral packages not more effective than exposure *in vivo* for panic disorder with agoraphobia. In addition, in obsessive-compulsive disorder,

cognitive therapy did not enhance the effects of exposure *in vivo*. Possibly these findings can be explained by the fact that cognitive changes also naturally accompany exposure *in vivo*.

IV. SUMMARY

Exposure *in vivo* therapy is a behavioral procedure in which patients are confronted in real life with those situations or objects that they fear and/or avoid. The purpose of *in vivo* exposure is to reduce subjective anxiety and avoidance behavior. There are many variations in the way exposure is conducted. The efficacy of these varied procedures differs somewhat between the disorders. Research has shown that exposure *in vivo* therapy is an effective strategy for most phobic patients. About 70 to 80% of the phobic and obsessive-compulsive patients who complete treatment benefit from exposure *in vivo* therapy and maintain their gains in the long run. On the basis of the efficacy studies that have been conducted, a task force of experts in the field judged exposure *in vivo* as one of the few well-established psychotherapies.

Several theories on fear and anxiety reduction during exposure *in vivo* therapy have been formulated and empirically tested. Most theories assume that some kind of cognitive change is essential for improvement by exposure. However, it is still unknown what is exactly modified. Are dysfunctional thoughts modified as suggested by several cognitive models? Does the confidence of the ability to perform successfully change as suggested by the self-efficacy theory? Are the fear predictions becoming more accurate as suggested by the match-mismatch model? Or does the fear memory alter as suggested by the emotional processing theory? It is un-

likely that one process can explain fear reduction during exposure therapy. Different processes may change different responses in different patients.

GLOSSARY

extinction burst A temporary increase in the rate or intensity of a behavior on extinction.

extinction-induced aggression Aggressive behaviors that occur following the introduction of extinction to a target behavior. These behaviors have no other identifiable causes.

intermittent schedule of reinforcement An arrangement under which not every occurrence of a behavior is reinforced, although some occurrences are reinforced.

planned ignoring Deliberate withholding of attention, including verbal exchanges and physical interaction, for a brief period following inappropriate behavior.

respondent extinction A procedure in which respondent conditioned behaviors are weakened by breaking the pairing between a conditional stimulus (CS) and an unconditional stimulus (US), either by presenting the CS alone or by presenting the CS and US independently of one another.

resurgence The appearance of behaviors that were previously extinguished when extinction is introduced for a more recently reinforced response.

spontaneous recovery The reappearance of behavior substantially weakened by extinction following a period of time despite no resumption of reinforcement.

The term extinction is used to refer to two different kinds of response-weakening operations, respondent extinction and operant extinction. In one, respondent conditioned behaviors are weakened by breaking the pairing between a conditional stimulus (CS) and an unconditional stimulus (US), either by presenting the CS alone or by presenting the CS and US independently of one another. Although respondent extinction can be a component of the treatment of some behavioral problems (e.g., phobias, sexual fetishes), operant extinction is a more widely used procedure and only it will be covered further here.

I. DESCRIPTION OF TREATMENT

Operant extinction is a procedure in which reinforcement of a previously reinforced behavior is discontinued. Reinforcement occurs when a behavior is strengthened by its consequences. When such consequences no longer occur, the behavior eventually weakens and occurs rarely, if at all. This is operant extinction (hereafter called "extinction"). During extinction, emission or omission of the response in question produces neither a negative nor a positive reinforcer.

Therapeutic applications of extinction involve four steps:

1. The behavior to be reduced must be defined and a system for accurately quantifying the behavior must be

selected. This step is a prerequisite to treating any behavioral problem.

2. The events that follow and maintain the behavior, that is, its reinforcing consequences, must be determined. Isolating the consequences that reinforce a behavior, and the situations under which those consequences are evident, is termed functional assessment. Functional assessment is often, although not necessarily, accomplished through direct observation and interviews with care providers. It must be done prior to the use of extinction.

3. Conditions must be arranged so that the consequences that previously served as reinforcers no longer follow the inappropriate behavior. Moreover, the behavior must not be followed by new reinforcing consequences. The exact procedures required to arrange extinction depend on the nature of the reinforcing consequences and the situations in which they occur.

4. As with any treatment, the effects of extinction must be evaluated carefully. If necessary, the procedure should be modified to produce the desired effects. Although extinction is simple in principle, in practice it often is difficult to arrange and initial attempts frequently are unsuccessful. Moreover, extinction sometimes produces undesired and unacceptable changes in behavior that may require termination of the procedure.

The most common application of extinction is to behaviors that are maintained by positively reinforcing consequences that are delivered by other people, such as social attention. By definition, positively reinforcing consequences (or positive reinforcers) are stimuli that strengthen a behavior by being added to an individual's environment. That is, they are not present in the absence of a particular behavior, but are produced (or increased in intensity) by its occurrence. For example, the self-injurious behavior of some people with developmental disabilities is maintained, although unintentionally, by the attention of caregivers. That is, when the person hurts himself or herself, attention is immediately forthcoming, and this is why the behavior occurs. If it is possible for a therapist, or some other invested party, to determine that this is the mechanism responsible for the self-injury, and to convince caregivers to stop attending to the self-injury, then extinction would be arranged and the behavior should eventually disappear. Because responding may persist for a substantial period when extinction is arranged, and may even increase in intensity, the procedure would be used in such a case only if the self-injurious behaviors did not pose significant risk to the client.

Planned ignoring is a procedure related to extinction that is often used as an intervention for reducing inap-

propriate behavior in children. Planned ignoring involves the deliberate withholding of attention, including verbal exchanges and physical contact, for a brief period (typically no more than 1 or 2 minutes) following inappropriate behavior. This procedure involves extinction if the inappropriate behavior historically was maintained by events that are withheld during the period of planned ignoring and the behavior actually occurs during this period.

Arranging conditions such that the event that previously served as the positive reinforcer is presented independently of the previously reinforced behavior is another procedure for arranging extinction. If, for example, a baby's screaming is positively reinforced by parental attention—the parents attend to the baby only when it screams—extinction could be arranged by having the parents attend to the baby regardless of whether or not it was screaming. Although this procedure might be effective in reducing screaming, it probably would be less effective than simply ignoring the behavior.

Presenting the reinforcer independently of responding is rarely used clinically to reduce responding maintained by positive reinforcement. An exception is a procedure commonly (but inaccurately) termed noncontingent reinforcement (NCR), which has recently generated researchers' interest as a treatment for high-rate problem behaviors maintained by positive reinforcement (e.g., attention) in people with developmental disabilities. NCR usually involves presenting the stimulus that historically maintained a troublesome behavior under a fixed-time (FT) schedule. Under an FT schedule, something is done to an individual every time a specified time passes, regardless of the individual's behavior during that period. When NCR is arranged, the interval initially is very short (e.g., 5 seconds) and is gradually increased over time, typically to a terminal value of around 5 minutes. For example, if functional assessment reveals that a client's self-injurious behavior is maintained by caregivers' attention, NCR might involve having caregivers attend to the client almost continuously, regardless of whether or not self-injury occurred. Over time, the frequency of attending to the client would be gradually reduced, perhaps to a brief interval of attention every 5 minutes. Such procedures have been demonstrated to be effective in reducing troublesome behaviors in controlled settings for relatively short periods, but their value in the long-term management of inappropriate responding in everyday settings is unknown. When NCR is effective, extinction and satiation (a reduction in the reinforcing effectiveness of a stimulus because of repeated exposure to that stimulus) appear to be its mechanisms of action.

In some cases, troublesome behaviors are maintained by automatic and positively reinforcing sensory consequences. It may appear that extinction cannot be arranged when this occurs, but that is not necessarily so. A procedure called sensory extinction, in which sensory consequences are altered or removed, may be effective in reducing inappropriate behaviors maintained by automatic reinforcement. For example, in the first published study in which this procedure was used, Arnold Rincover successfully reduced plate spinning in a client with developmental disabilities. Rincover proposed that the behavior, which occupied a great deal of the client's time and was disruptive, was maintained by the auditory stimulation produced by the moving plate contacting the top of the client's desk. Covering the top of the desk with carpeting eliminated the noise produced by spinning the plate and, over time, virtually eliminated the behavior.

Extinction can be arranged for behaviors maintained by negative, as well as positive, reinforcement. Behaviors maintained by negative reinforcement are strengthened because they eliminate a stimulus (or reduce its intensity), in which case they are escape responses, or because they prevent the occurrence of an otherwise forthcoming stimulus, in which case they are avoidance responses. A child who has tantrums soon after being placed in a bathtub because, historically, doing so ended baths is engaging in escape responding. A child who pleads to a sympathetic grandparent at bedtime "I'm too tired for a bath, Gram, can I just sleep now?" because, historically, doing so prevented the parents from bathing the child, is engaging in avoidance responding.

Effective extinction for escape responding can be arranged by maintaining the stimulus once escaped regardless of whether the behavior that once controlled that stimulus occurs or not. The child in our example will eventually stop having tantrums in the tub if such behavior is ineffective in terminating baths.

Extinction often is not a useful strategy for reducing avoidance responding. In this case, extinction can be construed as failing to present the stimulus that once was avoided, regardless of whether or not the avoidance response occurs. In our example, the parents might decide simply to forgo bathing their child when the grandparent was present, regardless of the child's behavior. Under such conditions, the historical avoidance response, although no longer effective in controlling baths, might persist indefinitely. In large part, this is because it would be difficult for the child to ascertain that conditions have changed. Successful avoidance responses prevent something from happening—the child did not have to take a bath after pleading with Gram—and that same some-

thing does not happen when extinction is arranged in this way—the child still does not have to take a bath, although this is not because of pleading.

Arranging extinction in a different way, that is, by presenting the once-avoided object or event regardless of whether or not the historical avoidance response occurs, makes extinction easy to discern and is likely to weaken the response rather quickly. In our example, forcing the child to take a bath regardless of whether or not pleading occurred probably would eliminate the behavior fairly quickly.

In general, extinction is likely to be effective in reducing troublesome behavior if five conditions are met:

1. Reinforcers that historically strengthened the behavior are accurately identified.
2. Reinforcement of the troublesome behavior never occurs.
3. Extinction is arranged for a sufficient period to reduce the behavior to acceptable levels, probably indefinitely.
4. Conditions of extinction are explained clearly and accurately to verbal individuals who are exposed to those conditions.
5. Arrangements are made so that the reinforcers that once maintained inappropriate behavior are available dependent on appropriate behavior, unless the reinforcers themselves pose problems.

II. THEORETICAL BASES

Like punishment and reinforcement, extinction is a term that describes a particular relation among behavior and other environmental events. There is no "theory" of extinction as the term is commonly used. As discussed in the article "Operant Conditioning," it may eventually be possible to disclose the physiological changes responsible for the behavioral effects of extinction. For the most part, however, behavior analysts have been content to describe relations among behavior and other environmental events and to ascertain the variables that modulate those relations.

From the beginning of his career early in the 20th century to his death in 1992, the eminent psychologist B. F. Skinner claimed that the effects of consequences on behavior are not permanent. If the reinforcers that initially established and maintained an operant response no longer follow such behavior, then the behavior eventually weakens and rarely occurs. Skinner used the term

“extinction” to refer to the discontinuation of reinforcement for a previously reinforced response, and the term has persisted. Many laboratory studies of nonhumans, and a smaller number of basic (i.e., not clinical) studies with humans have investigated the effects of extinction and documented the general effectiveness of the procedure in reducing operant responding. Those studies also have isolated the variables that influence responding during extinction.

Early clinical applications of extinction involved procedures that were close parallels of those used in basic laboratory studies and, like those laboratory procedures, were effective in reducing behavior. Over the years, extinction has been arranged in various ways in clinical settings, but all of these variations share a common feature: Reinforcement is no longer available for a response that historically was reinforced. It is consistent with the principles of operant conditioning that responding will decline when this occurs, and theoreticians expect this to happen. Moreover, as explained in the following section, it characteristically does.

III. APPLICATIONS AND EXCLUSIONS

Operant behavior in any human being is sensitive to extinction; therefore, the procedure may be appropriate for reducing a given behavior in clients regardless of their diagnosis or presenting problems. Extinction is appropriate for reducing specific target behaviors—it is not sufficient for dealing with the confluence of signs and symptoms that commonly occur in people with psychiatric labels. For instance, extinction might be useful in reducing a particular operant behavior in a person diagnosed as schizophrenic, but it would not be appropriate for dealing with the full spectrum of problems characteristic of the disorder (e.g., hallucinations, flat affect, thought disorders). Therefore, extinction often is part of a treatment package, not a stand-alone treatment, for people with psychiatric disorders.

In the literature, extinction has been used most often with children or persons with developmental disabilities. This is not because the procedure is effective only in such individuals. Instead, behaviors that are good candidates for treatment with extinction probably appear especially often in these populations, and it is often relatively easy to control their environments so that troublesome behaviors are extinguished.

There is nothing intrinsic to extinction that makes it unacceptable to particular ethnic or racial groups, al-

though cultural practices and personal preferences should be considered in considering a specific extinction procedure. For example, some parents will object to ever withholding attention from their child, even if the goal is to reduce an inappropriate behavior. Obviously, such parents would not be good candidates for using extinction. There also are factors that limit the use of extinction in general; these factors are discussed in the next section.

IV. EMPIRICAL STUDIES

In principle, extinction can be applied to any operant behavior over which control of its consequences can be arranged. Published studies have documented the use of extinction to control a wide variety of undesired behavior, including crying, whining, tantrums, food refusal, stealing, night waking, self-injurious behavior, self-stimulatory behavior, and disruptive classroom behavior. The effects of extinction are long-lasting and use of the procedure typically is not constrained by the legal and ethical considerations raised by punishment. These are points in its favor.

Even though extinction can be used to reduce a variety of behaviors in a wide range of individuals, extinction has characteristics that limit its utility. One limitation is that it may not be possible to arrange conditions so that the consequences that historically reinforced an inappropriate behavior are no longer available. For example, a middle-school student's swearing may be maintained by the laughter of peers. Trying to arrange the world so that the peers stopped laughing following jokes would be, at best, difficult. More likely, it would be impossible. Similarly, nicotine is a powerful positive reinforcer that plays a major role in the maintenance of cigarette smoking. There is presently no way to eliminate nicotine as a consequence of smoking, although some pharmacological technique for producing such an effect may eventually be developed. Drugs such as naltrexone block the physiological, subjective, and positively reinforcing effects of heroin, and have potential for the treatment of heroin abusers. Their primary mechanism of action is extinction. Scientists eventually may develop drugs that block the reinforcing effects of nicotine. The problem with such drugs, of course, is that cigarette smokers may refuse to take them. Escape from or avoidance of extinction is not unusual.

The most common reason that attempts to reduce behavior with extinction fails is inconsistent application of the procedure. That is, reinforcement typically is not available, but occasionally it does occur. The result is that

the troublesome behavior is maintained under an intermittent schedule. For instance, parents taking away a toddler's bottle may ignore requests for the bottle on many occasions, then give in to a midnight crying fit and provide a bottle "just this one time so we can sleep." The result is that asking for the bottle has been reinforced under an intermittent schedule and, therefore, has become more resistant to extinction. The rate and pattern of responding in extinction is strongly influenced by how reinforcement was arranged prior to extinction. As a rule, the more intermittently reinforcement occurred prior to extinction, the longer behavior persists when extinction is arranged. Inconsistent use of extinction is apt to constitute an intermittent schedule that reduces the effectiveness of subsequent, consistently arranged, extinction. Effective clinicians recommend the use of extinction only when they are relatively sure that the procedure can be implemented consistently over long periods.

Keeping extinction in effect over long periods sometimes is rendered difficult by a behavioral phenomenon known as extinction-induced bursting. Extinction-induced bursting refers to a transient increase in the rate of responding that often occurs soon after extinction is implemented. For instance, a child whose requests for a bottle are unsuccessful is apt to increase the rate of asking over the short run. This may be intolerable for the parents, who eventually "give in." The intensity as well as the rate of behavior may increase briefly during extinction, which can also cause problems. So, too, can the increase in variability of responding that characteristically occurs during responding. For instance, an increase in the intensity of self-injurious behavior, or a change in its form, might pose an unacceptable risk of serious harm to the client. Although such effects rarely limit the use of extinction, they can occur and therapists must be alert for them. Therapists must also understand that extinction also often induces negative emotional responding and may induce aggressive responding. Such behaviors may be unacceptable in some circumstances.

Resurgence, which refers to the reappearance of behaviors that have been previously extinguished when extinction is arranged for a current behavior, potentially could cause problems in therapeutic settings. For example, a preschool student may have historically gained attention from teachers by crying, which was successfully treated by extinction. At a later date, "whining" produced the same reinforcer, and was treated successfully in the same way. Most recently, the child has begun to secure attention by making "animal sounds." Extinction has been introduced for this latest problem behavior,

which has begun to decrease in frequency. As it does so, however, it is possible that whining, and subsequently crying, will occur more often than before extinction was arranged for making animal sounds. If so, resurgence has occurred.

Although resurgence conceivably could create problems in therapeutic settings, this is unlikely to occur. Perhaps the primary significance of resurgence is that its existence emphasizes that responses weakened by extinction are not absent from an individual's repertoire, even though those responses have not been observed for a substantial period. A change in stimulus conditions, a substantial increase in motivation for the reinforcer in question, or verbal mediation may lead to the reappearance of an extinguished response. In fact, the passage of a substantial period of time during which the response that is undergoing extinction is not emitted may be sufficient for the response to recur. This phenomenon sometimes is called spontaneous recovery. If a response that has been exposed to extinction is reinforced, the troublesome behavior can rapidly be reestablished. In essence, extinction controls troublesome behavior only so long as the procedure is consistently in effect.

Verbal mediation is another variable that may also limit an individual's sensitivity to ongoing extinction. Human behavior can be controlled by rules, which are descriptions of relations among responses and stimuli (objects and events). If a rule describes a relation between a particular kind of behavior and its consequences that is contrary to the relation that actually obtains in a person's world, then following that rule will limit the sensitivity of the person's behavior to actual environmental events. As an example, consider a college student participating in an experiment who is told before the experiment begins to "press the e key fast to earn points exchangeable for money." This individual is likely to do so, even if pressing the key slowly produces far more points and, in the absence of the verbal instruction, the student would readily learn to press slowly. The verbal rule probably would also reduce the student's sensitivity to extinction. That is, if conditions were first arranged so that pressing the "e" fast produced points (reinforcement), then they were changed so that no points were available (extinction), substantially more responding would occur during extinction if the person were given the rule at the start of the experiment than if this were not done.

Like people in contrived experimental settings, people exposed to therapeutic applications of extinction can generate, or be given, rules that reduce their sensi-

tivity to the procedure. Therapists need to be aware of this possibility and to take steps to ensure that the extinction procedure is adequately explained, which would tend to foster rules and rule-governed behavior consistent with therapeutic objectives. Therapists also need to be aware that inappropriate rules can interfere with the effectiveness of extinction, and take steps to prevent this from occurring.

V. CASE ILLUSTRATION

Extinction is an easy procedure to understand, although it is often a difficult procedure to implement consistently. As a case in point, consider the parents of a preschooler who sought help in dealing with their child's persistent demands for attention at bedtime. During consultation with a psychologist, it became apparent that each night after his father or mother took the boy to bed at 9, he made repeated requests that, if granted, increased the time spent with his parents.

For example, he might ask to go to the bathroom, to have a drink of water, or to have another story read. Many such requests occurred in sequence, and it was not unusual for the parents to spend over 2 hours in attempting to get the child asleep. Typically he fell asleep while listening to the last in a long sequence of stories. Occasionally, when his parents were very tired, they allowed the boy to sleep in their bed. On these occasions, few demands were made and everyone got a longer night's sleep. This arrangement did not suit the parents, however. Neither did the lengthy bedtime routine, which left them frustrated and exhausted.

The psychologist asked the couple to record how long it took them to get the child into bed and asleep each night for a week, then suggested a simple intervention using extinction combined with some environmental arrangements. Specifically, a modified bedtime routine was recommended, in which the parents were instructed to approach the child each night at 8:30 and say, "It's getting time for bed; go to the potty and have a drink, then we'll go to your bed and read two stories. After that, we'll all go to sleep." The psychologist recommended that the parents guide the child through these activities, using verbal or physical redirection as necessary, to minimize dawdling (i.e., avoidance of the undesired activity of going to bed). After story reading was over, the parents were to tell the child goodnight,

to remind him to remain in his bed, and then to kiss him and leave the room and not return. The psychologist cautioned the parents to expect temper tantrums (e.g., yelling out or throwing toys) and other misbehaviors. In the event the child left his room, the parents were to return him to his bed with little discussion. The parents were instructed to ignore crying and demands by the child for attention, and were warned that such behaviors could occur for relatively long time periods (e.g., 2 hours). The psychologist also warned the parents that the boy might engage in some aggressive behaviors during the procedure. Again, they were instructed to minimize interactions with the boy when dealing with such behaviors, and to return him to bed with as little interaction as possible.

The parents, somewhat discouraged, returned to the psychologist after 1 week. Each night the child had cried himself to sleep, and on the third night the boy began throwing toys around his room. On the fourth evening, he had torn the ear of his favorite cuddly bunny and had cried and screamed for 3 hours before sleeping. On a positive note, on the evening before returning to the therapist's office, the boy had cried for only 30 minutes before sleeping. And, according to the parents, the crying was less intense. The psychologist praised the parents for their diligence and consistency, and encouraged them to try the intervention for another week.

When the parents visited the psychologist the following week, the boy was following the bedtime routine without protest. The parents reported satisfaction with the outcome of the intervention, but indicated that implementation of the procedure was emotionally and physically draining and that they often were tempted to abandon it and give in to the child's demands. Had they done so on even a single occasion, their subsequent task would have become considerably harder. For extinction to work, it must be implemented with utter consistency.

VI. SUMMARY

Operant extinction is a procedure in which reinforcement of a previously reinforced behavior is discontinued. Published studies have demonstrated that the procedure, which is conceptually sound and logically simple, is effective in reducing a wide range of troublesome operant behaviors in a variety of clients. Although extinction is a useful and generally accepted response-

reduction procedure, it can be difficult to arrange consistently. Moreover, troublesome behavior may persist for a substantial time, and even briefly increase in rate and intensity, under extinction. These and other considerations occasionally preclude the use of extinction to deal with particular behavioral problems.

GLOSSARY

adaptive resolution A state that occurs as a result of complete information processing; learning takes place, information is stored with appropriate affect and is available to guide future action.

desensitization Elimination or reduction of anxiety elicited by specific environmental or internal stimuli.

dysfunctionally stored information A situation that occurs as a result of incomplete processing; information is stored in a memory network with a highly negative emotional charge and isolated from more adaptive information.

information processing The process by which new perceptual information is sorted, connected with associated memory networks, encoded, and stored in memory.

information processing system A physiologically based system that is geared to process information to a state of adaptive resolution.

memory networks Neurobiological associations of related memories, thoughts, images, emotions, and sensations.

post-traumatic stress disorder An anxiety disorder that can occur following exposure to a traumatic event. Symptom criteria include intrusive memories, avoidance of reminders, emotional numbing, physiological hyperarousal, and functional impairment.

reprocessing The process of forging new associative links between dysfunctionally stored information and adaptive in-

formation, resulting in complete information processing and adaptive resolution.

stabilization State of equilibrium maintained by the client prior to reprocessing of distressing events; includes safety, affect regulation, and impulse control.

state-dependent learning Information that is learned in a specific physiological state and is most accurately recalled when the individual is in the same or similar physiological state and is most accurately recalled when the individual is in the same or similar physiological state.

Eye Movement Desensitization and Reprocessing (EMDR) is an eight-phase treatment approach that facilitates resolution of distressing historical events, desensitization of present triggering stimuli, and acquisition of desired behaviors. While originally designed to alleviate the distress associated with traumatic memories, EMDR is now implemented within comprehensive treatment plans to address a range of experientially based complaints. This entry provides an overview of the treatment process, its conceptual underpinnings, the studies of treatment efficacy, and EMDR's various clinical applications.

I. DESCRIPTION OF TREATMENT

Eye Movement Desensitization and Reprocessing (EMDR) is an integrative psychotherapy treatment that synthesizes elements of many orientations, in-

cluding psychodynamic, cognitive-behavioral, body-based, person-centered, and interactional therapies, and that incorporates several unique elements, including eye movements or other bilateral stimulation. EMDR appears to expedite the accessing and processing of disturbing memories and an attendant learning process. It focuses directly on all the perceptual components of memory (cognitive, affective, somatic) and creates new links with the adaptive information contained in other memory networks. This reprocessing results in an adaptive resolution, as indicated by the desensitization of triggers, elimination of emotional distress, elicitation of insight, reformulation of associated beliefs, relief of accompanying physiological arousal, and enhancement of personal growth and functional behaviors.

A. The Information Processing System

The physiologically based information processing system can be compared to other body systems such as digestion in which the body extracts nutrients for health and survival. The information processing system sorts perceptions of experience and stores memories in an accessible and useful form. Information processing is essential for learning and involves the forging of associations with experiences previously stored in memory. The strong negative affect or dissociation induced by a traumatic event may impair information processing, inhibiting associative links with adaptive information in other memory networks. The memory is then dysfunctionally stored without appropriate associative connections and with negative emotion and physical sensations intact. When triggered by similar situations the memory is reexperienced, rather than simply recalled as an historical event. A prime example involves the intrusive thoughts, emotional disturbance, and negative self-referencing cognitions of post-traumatic stress disorder (PTSD).

B. The Eight Phases of Treatment

During EMDR, the unprocessed dysfunctionally stored material is linked to more adaptive material, and new associations are made. The client attends to emotionally disturbing material in multiple brief doses while simultaneously focusing on an external stimulus (e.g., therapist-directed eye movements, hand-tapping, bilateral tones). EMDR's three-pronged protocol ensures that all past, present, and future aspects of the problem are

thoroughly addressed. Current conditions that elicit distress are processed to eliminate sensitivity, and a template for appropriate future action is incorporated to enhance positive behaviors and skill acquisition.

Contrary to a common misconception, EMDR is not a simple by-the-book procedure dominated by the use of repeated eye movements, but rather an integrated therapy incorporating aspects of many traditional psychotherapeutic orientations. EMDR structures these elements in a unique combination to enhance information processing. It utilizes an eight-phase approach, with each phase augmenting and consolidating positive treatment effects. In addition, specific protocols guide the application of EMDR to a variety of clinical complaints.

1. Phase One: Client History and Treatment Planning

During Phase One the therapist takes a full history, assesses the client's readiness for EMDR, and develops a treatment plan. The therapist evaluates aspects such as diagnosis, comorbidity, suicidality, dissociation, existing support system, life stability, presence of current stressors, physical health, secondary gain issues, and substance use. Although acquisition of a full history and evaluation of the overall clinical picture are standard psychotherapy procedures, they have an additional purpose in EMDR and are used to identify suitable targets for treatment.

Targets are chosen according to theories about information processing. It is assumed that (a) processing may be accompanied by intense emotions; (b) processing of memory networks may activate related prior incidents; (c) if related early events are not processed, treatment may be incomplete and possibly ineffective; (d) treatment effects are likely to generalize to similar events, but not to unrelated incidents; and (e) processing should include a focus on past events, present stimuli, and future situations or behaviors. Therefore, treatment targets can include affect management resources, recent distressing events, current situations that stimulate emotional disturbance, historical incidents, and the development of specific skills and behaviors.

Targets are prioritized for sequential processing and evaluated according to patterns of generalization within memory networks. Treatment effects tend to generalize from memory to memory when features are similar. Only one representative event from a cluster of similar experiences (e.g., several related instances of molestation by the same perpetrator) may need to be treated. Such generalization of treatment effects should not be expected if the client reports a variety of dissim-

ilar events and triggers, necessitating that each of these be reprocessed separately.

When appropriate, events are selected for processing in chronological order, beginning with the earliest. It is assumed that a later related event will contain elements that are connected to the earlier incident and that it will not be adequately processed until such elements are resolved. For example, “Trina” was the first person on the scene after a car had crashed on a deserted road and rolled into a river. She rescued the passengers who were still alive. Afterward, she blamed herself for the deaths of those who had not survived. While processing this with EMDR, she realized how similar this was to the drowning death of a younger sibling when she was 5 years old: Her parents had blamed her for the tragedy. The emotional content of the childhood event was fueling her emotional response to the current incident. After EMDR was used to target the issues of responsibility for her sibling’s death, the distress related to the current accident resolved rapidly. (*Note:* Trina’s story and subsequent clinical vignettes are based on actual clients, with names and minor details changed to protect confidentiality.)

2. Phase Two: Preparation

Phase Two involves establishing the therapeutic relationship, setting reasonable levels of expectation, educating the client about his or her symptoms and about EMDR, and ensuring that the client demonstrates adequate stabilization. Stabilization is a state of equilibrium achieved prior to the processing of distressing material and includes safety, affect management skills, and self-control. Clients with histories of childhood trauma/neglect often have deficits in affect regulation and impulse control and may require substantial preparation. Similarly, avoidance behavior exhibited by anxiety-disordered clients must be addressed before serious attempts at reprocessing can begin.

Client strengths are developed by combining relaxation, imagery, and EMDR in interventions that assist the client in acquiring new skills and resources. For example, EMDR is commonly used to enhance “safe place” visualizations. Such self-calming techniques are an important element of treatment and are used to “close” incomplete sessions, as well as to maintain client stability between and during sessions. During Phase Two, the client is prepared to “just notice whatever happens” and to maintain a balanced observation/participation position. This is encouraged by the use of helpful metaphors (e.g., to imagine being on a

train and to think of the disturbance they may be experiencing as merely passing scenery).

Many of the procedural elements in subsequent phases of EMDR treatment incorporate elements to enhance stabilization. For example, during the desensitization phase, frequent brief exposures to the distressing experience encourage a sense of psychological mastery and stability and may counter the avoidance reaction that accompanies and maintains the pathology. The client receives supportive statements from the clinician in a safe context, fostering positive counterconditioning.

3. Phase Three: Assessment

In the third phase, the client and therapist select a specific memory to address during the session and identify the associated mental image, beliefs, emotions, and physical sensation, taking baseline response measures. The assessment phase contains steps designed to fully activate the dysfunctional memory network. First, the representative and/or most salient mental image of the event is identified. Next, the therapist helps the client to identify the current negative belief about him/herself that is related to the target memory (e.g., “I’m powerless” or “I am worthless”). It is formulated in the present tense to activate the disturbing information and to assist clients in recognizing the impact of the past event on current self-concept. This is the first step in recognizing the irrationality of their cognitive interpretation of themselves in relation to the event. While the words “I was powerless” may be an appropriate description of the past event, the words “I *am* powerless” are considered an irrational cognition because the person is not *currently* powerless. The words verbalize the current belief and affect experienced by the client when the dysfunctionally stored memory is accessed.

After this, the therapist helps the client to identify a desired positive belief that expresses a sense of empowerment or value in relation to the past event, such as “I’m competent” or “I’m lovable.” The client rates how accurate this positive belief feels on the Validity of Cognition Scale (VOC), where 1 represents “completely false” and 7 represents “completely true.” This is not an intellectual assessment of accuracy but rather a felt sense of how true the cognition feels when paired with the target incident. The VOC rating provides both client and clinician with a baseline with which to assess a given session’s progress, thereby further promoting client treatment adherence. It also increases clients’ awareness of their cognitive distortion and offers a “light at the end of the tunnel,” thereby encouraging

and motivating them to stick with the treatment. This process forges preliminary associative links between the state-dependent memories and the emotionally corrective information contained in the positive cognition and may expedite information processing.

In the fourth step, the image and the negative belief are paired to facilitate access to the stored memory of the trauma. The client identifies the emotions that are elicited by the memory and rates his or her level of distress on the Subjective Unit of Disturbance (SUD) Scale, where 0 is “calm” and 10 is “the worst possible distress.” Explicitly labeling the emotion allows the clinician to (a) offer the appropriate verbal support, (b) anticipate any beliefs about emotions that might block processing and that therefore need to be addressed, and (c) establish a response baseline. It also allows both client and therapist to recognize changes in the type of emotion experienced during the session. Next, the client identifies and locates the body sensations that accompany the disturbance. During EMDR, clients are encouraged to concentrate for prescribed periods of time on the physical sensations associated with their traumatic imagery. This focus may allow them to identify the purely sensory effects (e.g., physical pain) of the trauma and to separate them from the cognitively laden affective interpretations (e.g., I am helpless) of these sensations.

4. Phase Four: Desensitization

During the desensitization phase of EMDR, adaptive processing (i.e., learning) takes place. The client is instructed to focus on the visual image, the identified negative belief, and body sensations, and then to “Let whatever happens, happen.” He or she maintains this internal focus while simultaneously moving the eyes from side to side for 20 or more seconds (depending on nonverbal cues), following the therapist’s fingers as they move across the visual field. Other bilateral stimuli (e.g., hand-tapping, aural stimulation) can be used instead of eye movements. After the set of eye movements, the client is told “Blank out (or “Let go of”) the material, and take a deep breath,” and then is asked “What do you get now?” Depending on what emerges (image, thought, sensation, or emotion), the clinician then directs the client’s attention to the appropriate target for the next set of eye movements. This cycle of alternating focused attention and client feedback is repeated many times according to specified procedural guidelines that address various aspects of the memory network and is typically accompanied by shifts in affect, physiological states, and cognitive insights.

Because EMDR uses a nondirective free association method, some clients spend very little time being exposed to the details of the presenting problem. They may rapidly and spontaneously access a succession of related thoughts, images, emotions, sensations, and memories. These associations to the various components of the targeted memory network and other related networks are indicative of the active reprocessing of dysfunctionally stored material. For example, having started with a memory of his mother beating him, “John” recalled many incidents of his mother’s cruelty, her vicious criticisms, humiliating him in front of his friends, laughing at him. He progressed through a range of intense emotions (anger, fear, sadness, shame), with accompanying physiological shifts. John experienced a number of insights, including the realization that he frequently repeated his mother’s harsh criticisms in his own internal dialogue. Throughout the session the therapist remained almost entirely silent, gently asking, “What do you get now” and encouraging John to “Just notice” and to “Stay with that.” If John’s processing had stalled, the therapist would have used specialized interventions worded and timed in a specific manner to reactivate processing.

5. Phase Five: Cognitive Installation

As negative imagery, beliefs, and emotions become diffuse and less valid, positive ones become stronger and more salient. This transformation appears to result from a shift in how the memory is stored with new associations to more adaptive information. The fifth phase occurs after the targeted issue is resolved and the accessed memory spontaneously arises without distress. This phase allows for the expression and consolidation of the client’s cognitive insights. For many clients it is characterized by a profound change in self-concept that entails an integration of self-acceptance and new positive and realistic self-perceptions. In this phase, the original target is paired with the most enhancing positive cognition during sets of eye movements. This could be the belief designated to replace the original negative self-belief or a more therapeutically beneficial belief that emerged during the desensitization phase. The focus is on incorporating and increasing the strength of the positive cognition until strong confidence in the belief is apparent (e.g., VOC of 6 or 7). For example, while a rape victim may enter therapy “knowing” that she is not to blame, the installation phase is not considered complete until she truly “feels” the truth of this self-evaluation.

6. Phase Six: Body Scan

In Phase Six, the clinician asks clients, while focusing on the image and positive cognition, to notice if there is any tension or unusual sensation in the body. Because dysfunctionally stored information is experienced physiologically, processing is not considered complete until the client can bring the previously disturbing memory into consciousness without feeling any significant body tension. Any residual negative sensations detected by the body scan are targeted with eye movements until the tension is relieved. Such body sensations can be linked to unprocessed aspects of the memory network. For instance: After an apparently complete EMDR session targeting a car accident, "Sam" reported a strange feeling in his foot during the body scan phase. This sensation was targeted with EMDR and resulted in him recollecting a forgotten aspect of the accident. His foot had been stuck for a brief period after the collision, and he had felt trapped and frightened. After processing this with EMDR, the foot sensation disappeared, and SUD and VOC ratings were consolidated at optimal levels.

7. Phase Seven: Closure

In this phase, the therapist determines whether the psychological material has been adequately processed and, if not, assists clients with the self-calming interventions developed in Phase Two. The client is told by the therapist that other material might emerge after the session and is asked to maintain a journal to record any disturbance that arises, such as nightmares or flashbacks, or related material such as insights, memories, emotions, and dreams. The form that this journal takes parallels the assessment stage of treatment (Phase Three) and identifies possible targets for future sessions. This process of recognizing and recording patterns of reaction extends treatment effects to real-life disturbing events and encourages a sense of self-mastery and observation, thus facilitating between-session stabilization.

8. Phase Eight: Reevaluation

Reevaluation takes place at the beginning of every EMDR session following the first. In this phase, the therapist determines whether the treatment gains from the previous session have been maintained by eliciting the previously processed targets and assessing the current emotional, cognitive, and physiological responses. The clinician reviews the client's journal to evaluate the degree to which treatment effects have generalized or need further attention, and to identify new issues that

need to be addressed. For example, after processing the molestation by her grandfather, "Lisa" began thinking about her grandmother who had refused to believe that he was an offender. This new material became a treatment target.

In addition to relying on behavioral reports, the therapist is encouraged to use various standardized self-report measures, such as the Impact of Event Scale or the Beck Depression Inventory, to monitor changes in specific symptoms. The goal of EMDR therapy is to produce the most substantial treatment effects possible in the shortest period of time, while simultaneously maintaining client function and preventing emotional overload. Therefore, thorough ongoing evaluation of reprocessing, stability, behavioral change, and integration within the larger social system is essential. The eight phases of treatment may be completed in a few sessions or over a period of months, depending on the needs of the client and/or the seriousness of the pathology.

II. THEORETICAL BASES

A. The Adaptive Information Processing Model

The Adaptive (or Accelerated) Information Processing (AIP) model which guides EMDR practice assumes that humans possess a physiologically based information processing system, which, under normal circumstances, naturally responds to and resolves everyday minor disturbances. Information is normally processed to an adaptive state where connections to appropriate associations are made, emotional distress is relieved, experiences are used constructively, and learning takes place. Information is understood to be stored in a system of memory networks, which are neurobiological structures containing related memories, thoughts, images, emotions, and sensations. For example, "George" was shocked and angry when his employer criticized him and his work product. George mentally reviewed this interaction by accessing stored information about the quality of his work, his employer's stressors, and his own competence. This allowed him to assess the situation and to make decisions about his course of action. He dismissed the personal negative comments because they were discordant with information about his abilities. Such connections are made during waking state and perhaps through the information processing mechanisms of rapid eye movement (REM) sleep.

After a traumatic event, persons who were high functioning prior to the incident generally assimilate the perceptual experience and reestablish themselves. For others, an incident of sufficiently high negative valence can result in little integration with existing positive or more adaptive information stored in networks. The AIP model proposes that pathology results when experiences are not adequately processed and the memories are dysfunctionally stored with the perceived distressing affects and physical sensations. The traumatic memory network becomes effectively isolated, and no new learning takes place.

PTSD is not the only mental disorder known to have an etiological event; phobias, panic disorders, depression, dissociation, and personality disorders are sometimes related to precipitating incidents. Deficit experiences, such as neglect, rejection, or humiliation, that occur during developmental windows can function as “small-t traumas.” With frequent repetition of such events, the memory network becomes predominant, organizing similar experiences in associated channels of information and precipitating a continued pattern of behavior, cognition, and related identity structures. Such persons often develop rigid defenses, a limited sense of self, impaired interpersonal function, and affect dysregulation.

Because of the lack of adequate assimilation of these events into the larger associative network, similar experiences in the present, including a variety of triggers implicit in the memory network, can elicit these dysfunctional affects and negative appraisals. It is further hypothesized that the inadequately processed information is stored in a “state-dependent” fashion. The information is easily activated when the individual experiences affect or a physiological state similar to that of the memory network. Feeling afraid, for example, activates fear-related information, while feeling depressed activates information about hopelessness and helplessness. The flashbacks of PTSD often contain immediate sensory information: the smell of the rapist’s breath, the feel of his rough hands on bare skin. Sometimes the material that is activated is primarily affective, such as fear or shame.

B. Reprocessing Information

The AIP model proposes that pathology arises when the information associated with seminal events is inadequately processed. Consequently, these disorders should respond to treatment that enhances reprocessing of the dysfunctionally stored information. The goal

of EMDR therapy is to stimulate information processing by accessing the dysfunctionally held information and forging new connections with more adaptive information. It is assumed that when appropriately stimulated and maintained in dynamic form, the inherent healing processes of the information processing system will result in a positive resolution, manifest in affective, cognitive, and behavioral changes and comprehensive learning.

The AIP model has four principles that describe and predict the effects of adaptive processing.

1. Direct, Nonintrusive, Physiological Engagement with the Stored Pathological Elements Is Possible

The dysfunctional storage of disturbing memory elements is viewed as the physiological basis of the pathology. Rather than targeting the client’s reaction to the earlier event, EMDR focuses on the memory components (image, affect, cognition, sensations). The treatment protocol is designed to specifically access components of the memory in such a fashion that the material is available for complete reprocessing.

2. The Information Processing System Is Intrinsic and Adaptive

The system appears to be configured to process information and restore mental health analogous to the way the body frequently recovers from physical injuries. This belief is the basis of EMDR’s client-centered model, which assumes that if the information processing system is appropriately stimulated, the client’s cognitions and affect will move to an adaptive level with minimal therapist intrusion.

3. As the Embedded Information Is Processed, Identity Constructs Change

Pathological personality characteristics are understood to be entrenched in dysfunctionally stored information. Therefore, it is assumed that when this information is adequately processed, there is a concomitant shift in clients’ sense of self-worth and efficacy, with structural alterations in related personality characteristics, evident in changes in self concept, interactions with others, and behaviors.

4. Reprocessing Results in Rapid Changes

EMDR facilitates therapeutic effects through the adaptive connection of associated neurophysiological networks in the information processing system. Recent findings in neurobiology support the notion that treat-

ment outcomes can be rapid, regardless of the amount of time since the original distressing event.

C. Mechanisms of Action

Although it is apparent that EMDR expedites information processing, the exact mechanisms by which this occurs are unknown. Speculation about the role of eye movements abounds. A wide variety of primary research studies dating from the 1960s through the present have indicated a correlation between eye movements and shifts in cognitive content and attribution. Several hypotheses attempt to explain how they may contribute to information processing within the EMDR procedures: (1) eye movements disrupt the function of the visuospatial sketchpad and interfere with working memory; (2) they elicit an orienting response that stimulates an instinctive interest–excitement affect creating new associative links with the dysfunctionally stored information; (3) they evoke a relaxation response, or a new set of physiological states and responses, creating new associative links with the dysfunctionally stored information; (4) they activate neurological processes that mimic REM sleep-type function and its information processing mechanisms; and (5) they act as a distractor that titrates the emotional overload and encourages client engagement.

Although it is assumed that all aspects of the EMDR structured procedures and protocols contribute to its effect, two other possible mechanisms of action currently under investigation are its use of repeated brief client-directed exposure and free association. In addition to the primary research on physiological mechanisms, clinical observations have contributed to the present treatment structure. For instance, it appears that developing the ability to mentally delimit and control disturbing internal stimuli may provide clients with a sense of mastery and decrease distress about their symptoms. Use of short doses may also counter the avoidance reaction that is likely to accompany and maintain the pathology. Most importantly, information processing appears to be facilitated by repeatedly eliciting related information after each exposure. The free association component appears to activate the entire memory network and to forge connections with other associated networks. This results in the complete reprocessing of the dysfunctionally stored information. The nondirective free association method used in EMDR allows for the therapeutic focus to shift from the original targeted event to other related past experiences and is very different from exposure therapies that em-

ploy a chronological, concentrated focus on the traumatic event.

The findings of dismantling research are limited by methodological problems. Although component studies with clinically diagnosed PTSD subjects provide preliminary indications that an eye movement condition is more effective than control conditions, such studies have typically used small samples (e.g., 7 to 9 persons per condition) with inadequate power, and selected inappropriate controls. Truncated procedures are common; one study for example, provided only 145 seconds of treatment. The results of such studies are inconclusive and comprehensive research is required.

III. EMPIRICAL STUDIES

A. Posttraumatic Stress Disorder

Because of its claims of rapid effective treatment, EMDR has been subjected to many empirical tests and to much scientific scrutiny. It has been extensively researched in the treatment of PTSD. All but one of the research studies that used civilian participants found EMDR to be efficacious in the treatment of PTSD, and the one combat veteran study that provided a full course of treatment also revealed EMDR to be efficacious. Generally, these studies found substantial clinical effectiveness, reporting a decrease in PTSD diagnosis for 70 to 90% of the civilian participants after three or four sessions and in 78% of combat veteran participants after 12 sessions. There have been several other combat veteran EMDR studies, but these addressed only one or two memories in this multiply traumatized population, and thus their findings regarding efficacy are equivocal. Nevertheless, the effect sizes achieved in these studies were similar to those achieved in cognitive-behavioral therapy (CBT) studies with combat veterans.

In all but one controlled study, EMDR appeared to be equivalent in treatment outcome to CBT comparison conditions and was reported to require fewer direct treatment and/or homework hours. There are reports that EMDR may be better tolerated by clients than traditional exposure, perhaps because it typically results in a rapid in-session decrease in anxiety (as measured by SUD ratings). When EMDR was compared to other treatments such as relaxation therapy, standard mental health treatment in an HMO, and active listening, it was found to be superior on numerous measures. Two of these studies compared EMDR in actual field settings

to treatments that are commonly provided, and thus maximized the external validity of the results.

In future studies with PTSD populations, it is recommended that exposure therapy, cognitive therapy, Selective Serotonin Reuptake Inhibitors, and EMDR be compared with one another, with special attention paid to efficacy, effectiveness, efficiency, attrition, as well as clinician and client preference (e.g., tolerance and comfort) for the type of therapy being used.

B. Diverse Clinical Applications

In large-scale studies of EMDR treatment with trauma populations, direct internal comparisons were made for those with and without PTSD diagnosis. The equivalent findings on numerous affective and cognitive measures lend credence to the notion that EMDR can be effectively used to process disturbing experiences that may contribute to a variety of clinical complaints. Although positive reports have been published on the application of EMDR to the treatment of (1) personality disorders, (2) dissociative disorders, (3) various anxiety disorders, and (4) somatoform disorders, controlled research is needed to confirm the efficacy of these applications. Some of the findings are promising. For example, although body dysmorphic disorder is known to be relatively intractable to treatment, researchers in one case series study reported that five of seven patients treated with EMDR no longer met diagnostic criteria after one to three sessions.

The evidence for the effectiveness of EMDR with phobias and panic disorder is inconclusive. Many of the research studies investigating the use of EMDR with these disorders have been compromised by the incomplete application of the eight-phase approach. An analysis of procedural fidelity in the phobia studies determined that low adherence to EMDR protocol was associated with poor clinical outcome.

IV. SUMMARY

EMDR is an integrative psychotherapy approach implemented within comprehensive treatment plans to address a range of experientially based complaints. It is formulated to expedite the accessing and processing of disturbing memories by forging new links between the perceptual components of memory and adaptive information contained in other memory networks. Complete reprocessing is evident in the desensitization of

triggers, elimination of emotional distress, elicitation of insight, reformulation of associated beliefs, relief of accompanying physiological arousal, and acquisition of desired behaviors.

During EMDR the client focuses on an external stimulus (e.g., therapist-directed eye movements, hand-tapping, aural stimulation) while simultaneously attending, in brief sequential doses, to emotionally disturbing material that is elicited through free association. Structured procedures based on memory association patterns enhance information processing and are embedded in a comprehensive eight-phase approach. Specific protocols ensure that all past, present, and future aspects of the clinical picture are thoroughly addressed.

The Adaptive Information Processing model posits a physiologically based information processing system that has a tendency to move toward health by processing information to a state of adaptive resolution. Various mental disorders are viewed as caused by information from traumatic events which are inadequately processed. The negative affects and cognitions contained in the memory network are frequently elicited by current life stimuli, thus precipitating maladaptive behaviors and self-concepts. Consequently, such characteristics and disorders should respond to treatment that enhances reprocessing of the dysfunctionally stored information.

Currently, EMDR has been found efficacious in the treatment of PTSD. Civilian participants have shown a 70 to 90% decrease in PTSD diagnosis and a substantial improvement in reported symptoms after three or four sessions. The only combat veteran study that provided a full course of treatment also revealed EMDR to be efficacious with a 78% decrease in PTSD diagnosis after 12 sessions. In all but one controlled study, EMDR appeared to be equivalent in treatment outcome to CBT comparison conditions and was reported to require fewer direct treatment and/or homework hours. Although there are numerous anecdotal and case study reports documenting EMDR's effectiveness in the treatment of other disorders, controlled studies are lacking or inconclusive, and future research is required to establish the parameters of EMDR's usefulness with these populations.

GLOSSARY

fading Systematic process of removing prompts.

prompt Stimulus used to increase the likelihood the target response will occur at the appropriate time.

stimulus prompt Antecedent stimulus added, removed, or otherwise altered to increase the likelihood the target response will occur.

response prompt Response emitted by the individual conducting training to increase the likelihood the target response will occur.

I. DESCRIPTION OF FADING

Interventions used in applied practice take a variety of forms depending on such variables as the presenting problem and the theoretical orientation of the practitioner. One strategy that is used for a variety of presenting problems and across orientations is teaching the client a new skill or behavior. For example, a practitioner working with a client who is “shy” might teach the client to maintain eye contact with others and to initiate conversations. Initially the practitioner likely will have to remind the client to emit these new behav-

iors, however the hope is that, over time, the client will need less frequent reminders and will begin to emit the newly learned skills in a variety of situations. The process of gradually decreasing reminders—often referred to as prompts—such that the client emits the target response independently is called fading. Several fading procedures exist, and the specific procedure used depends on the strategy of prompting that was used to teach a new behavior. Thus, this article begins with a discussion of prompting strategies. Next, specific fading strategies are presented. Examples are used throughout to facilitate understanding of fading procedures in applied settings.

Individuals typically are taught new responses through the use of prompts. For example, when a person who is not proficient in computer use purchases a computer, that person might ask a colleague to help assemble the computer. The colleague might verbally prompt the individual through the steps of assembly. Alternatively, the individual might simply follow the instructions included with the computer. Such prompts—behaviors emitted by the trainer to guide specific responses—are called response prompts. The second type of prompt that might be used is a stimulus prompt. Stimulus prompts involve changing some aspect of the situation that should evoke the desired behavior. Continuing with the computer example, computer companies often color code connections such that connector cables are the same color as the relevant computer port. In this case, the company is adding something—color codes—to the existing items—connection cables and ports—to increase the likelihood

the user will correctly assemble the machine. Regardless of the type of prompting used, response prompts or stimulus prompts, the eventual goal of most instructional programs is to have individuals emit the correct response without the use of prompts. To accomplish this goal, the prompts must be gradually faded. Fading involves systematically removing prompts over time.

II. THEORETICAL BASES

The process of fading is derived from the behavior analytic literature. Fading procedures have been used with nonhumans as well as humans however it most often is seen in programs designed to teach individual's new skills. Fading incorporates several principles of operant conditioning including the use of reinforcement and stimulus control. Reinforcement is defined as the response-contingent delivery (or removal) of a stimulus that increases the likelihood the behavior will occur again in the future. As is discussed later, reinforcement must continue to occur following correct responding throughout all steps of a fading procedure. Stimulus control also is relevant to fading procedures. Stimulus control develops when a response is more likely to occur in the presence of a particular stimulus (e.g., a prompt) than in its absence because the response has been followed by reinforcement most often in the presence—but not absence—of that stimulus. The ultimate goal of a fading procedure is to bring the target response under stimulus control of the naturally occurring cue—the event that the instructor hopes will naturally evoke the target response.

III. USING FADING

Teaching a new behavior is most often accomplished through the use of response prompts. When using response prompts, the practitioner uses some sort of cue to evoke a behavior. Cues might be relatively simple, such as looking in a certain direction, or making a gesture, or more invasive, such as touching the learner's shoulder or physically guiding the learner to move in a certain way.

A. Fading Response Prompts

When a new response is taught through the use of response prompts, fading is accomplished through one of three procedures: time delay, least-to-most prompts, and

most-to-least prompts. Time delay involves allowing the natural cue to occur, and then waiting several seconds before prompting. For example, when teaching deep breathing to an individual with anxiety, the natural cue to use deep breathing would be the occurrence of any anxiety producing stimuli, perhaps the approach of an individual of the opposite gender. In training sessions, when such a person approached the client, the practitioner would wait for several seconds before prompting the individual to begin deep breathing—the goal being to see if the client would initiate deep breathing independently. Over time, the practitioner would gradually delay the prompt for even longer durations.

Like time delay, least-to-most prompt fading is a procedure that provides the learner with an opportunity to independently emit the correct response prior to prompting. The difference between the two concerns is the variety of prompts that might be used in training: time delay typically involves only using one type of prompt (e.g., a verbal prompt), least-to-most prompting allows the trainer to use the most intensive level of prompting needed to help the learner exhibit the correct behavior. When using least-to-most prompting, the trainer begins with the least intrusive type of prompt possible and gradually increases the intrusiveness of the prompt until the learner emits the correct response. Consider again the individual learning deep breathing. The natural cue to use deep breathing is the occurrence of an anxiety-producing event (e.g., approach of an individual of the opposite gender). If the anxiety-producing stimulus has been present for certain amount of time (e.g., 5 sec), and the client has not initiated deep breathing, the practitioner would prompt the client using the least intrusive level of prompting (e.g., a gesture, such as holding up the hand). If this prompt does not result in deep breathing, the practitioner would use a more intrusive prompt, such as verbally reminding the client to use deep breathing. If the client still did not begin to use the breathing exercise, the practitioner might place a hand on the client's shoulder—using a still more intrusive level of prompting.

The third commonly used prompt fading procedure is graduated guidance. Graduated guidance involves using the most intrusive level of prompting needed to prompt a response to occur, and then immediately removing the prompt when the individual is responding independently. For example, when teaching a child to ride a bicycle, a parent might walk closely behind the child, steadying the child whenever necessary. The parent might steady the child by placing a hand on the child's shoulder or, if needed, by actually holding the

handlebars and steering the bike for the child. Foxx and Azrin discuss in their 1973 work two procedures to be used in graduated guidance: shadowing and spatial fading. Shadowing involves closely following the learner's physical movements with your own body. For example, a parent teaching a child to ride a bicycle might walk next to the child and hold the child's hands directly above the child's shoulders, ready to steady the child if need be. Over time, the parent gradually moves the hands and body further away from the child. Spatial fading is used when the trainer gradually moves a physical prompt. Continuing the bicycle example, the parent might begin teaching the child by holding onto the handlebars with one hand to steer the bike, and steadying the child with the other hand. Over time, the parent might have the child steer the bicycle but continue to steady the child. Gradually the parent would provide the child with less and less physical support until the parent was walking beside the child, but not providing any support unless necessary. The parent would then move further away from the child, until the child was riding independently.

In contrast to the other types of prompt fading, most-to-least prompt fading does not initially provide the learner with an opportunity to respond independently. Most-to-least prompt fading is often used with individuals with severe cognitive disabilities. This type of prompt fading involves using the most intrusive level of prompting initially and then gradually reducing the level of guidance provided. For example, if an individual was being taught to make the bed, the trainer might initially use hand-over-hand guidance to have the individual make the bed. The trainer would gradually fade the physical prompt by decreasing the amount of physical pressure used to have the person make the bed. Over time, the trainer might fade to gestural prompts (e.g., pointing toward the pillows), and then to verbal prompts. Eventually, the sight of the unmade bed alone should evoke the response of making the bed.

B. Fading Stimulus Prompts

When the natural cue was changed to evoke behavior, stimulus prompts must gradually be faded. For example, if the behavior being trained is recycling, the natural cues should include items to be recycled (e.g., paper, pop can). Stimulus prompts that might be used in such a situation include signs telling people to recycle or placing multiple recycling vesicles in the building. The eventual goal is to transfer control of the response—recycling—from the prompt (e.g., signs) to the natural cue (e.g., used paper), such that individuals

s	Z
s	Z
z	s
Z	s
s	Z

FIGURE 1 Example of stimulus fading procedure to teach an individual to discriminate between the letters “Z” and “S.”

will search for and use a recycling container on coming in contact with an item that can be recycled. Fading stimulus prompts involves either stimulus fading or stimulus shaping.

Stimulus fading often is used to teach an individual to discriminate between similar items. Consider the example of teaching students to discriminate between two similarly shaped letters, Z and S. One way that the discrimination might be taught is by increasing the size of one letter relative to the other. An example is shown in the top line of Figure 1. In this example, the correct response (stating, Z) is more likely to occur because the letter Z is much larger than S. Over time, the difference in size between the letters would be reduced until both letters were the same height (see Figure 1). Another use of stimulus fading occurs when additional prompts were added. For example, when children are learning addition or subtraction, teachers often use objects to represent the numbers the children are to add or subtract. To illustrate: if a worksheet instructs a child to add “4 + 3,” the worksheet might have a group of four apples next to a group of three apples (see Figure 2). Over time, the teacher could reduce the salience of the additional objects (e.g., apples) by making them smaller in size (see Figure 2).

The second method of fading stimulus prompts is stimulus shaping. Stimulus shaping is the procedure used when the shape of the prompt is changed and then is gradually made to look like the prompt the trainer wants to evoke behavior. Such a training procedure might be used to teach an individual who does not read to recognize the word “walk” (as might be seen on a pedestrian crossing traffic signal). The initial prompt used should be something that the learner recognizes,

5 + 2 = _____	
5 + 2 = _____	
5 + 2 = _____	
5 + 2 = _____	
5 + 2 = _____	
5 + 2 = _____	

FIGURE 2 Example of stimulus fading by decreasing the size of the additional prompt.

in this case a picture of a person walking with a line through it. Over time, the prompt is gradually be changed to the natural prompt (in this case, the word “walk”). More important, the shape of the prompt must be changed slowly, so that the learner is likely to continue to respond correctly. Parents often use stimulus shaping when teaching a child to independently ride a bicycle. The child typically begins to ride with the assistance of training wheels. When the parent sees that the child is able to maintain balance relatively well, the parent may remove one training wheel, leaving the other in place. Eventually the parent removes that training wheel as well, and the child is riding a bicycle without the assistance of any additional prompts.

C. Considerations in the Use of Fading

When individuals are learning a new response, prompting is most often used. Over time, the learner must come to emit the correct response without prompting. The removal of prompts is called fading and can involve either fading response prompts or fading stimulus prompts, and the specific type of fading depends on the prompting strategy used to teach new behaviors.

Regardless of the prompting (and hence fading) strategy used, several caveats are in order. Considerations include the criterion for completion of training, selection of a reinforcer, the starting point for training, and the steps of fading. First, the instructor must determine what the goal of training is. That is, what is the stimulus that will evoke behavior when fading is completed. Ideally,

the stimulus will occur naturally in the environment, so that responding will be maintained. For example, for a “shy” individual learning to maintain eye contact, fading might be considered complete if eye contact was maintained only after initiated by another person. However, if the majority of people the individual came in contact with did not initiate eye contact, the client’s newly learned skill would likely not maintain. In this case, the final cue for eye contact might be simply the presence of another person within 3 ft of the client (with the exception of certain situations, such as in elevators).

Once the goal of training is determined, it is important to select a reinforcer. The reinforcer must be something that the individual enjoys and that will serve to reward and maintain responding. When working with adults who are typically developing the reinforcer often is simply the ability to emit the target response. For example, for a “shy person,” simply maintaining eye contact for some duration may be reinforcing in and of itself. When working with children, individuals with disabilities, nonhumans, or adults for whom the target behavior is not likely to be especially rewarding in and of itself (e.g., coming to work on time, calculating a tip rapidly, without the use of a pencil and paper), it is critical to determine an effective reinforcer. Ideally the reinforcer should be one that is likely to occur in the individual’s natural environment. For example, a natural reinforcer for rapid calculations of a tip might be admiration from others, or avoidance of “odd looks” from restaurant staff. Once a reinforcer is identified, it should be used consistently in the training program. The reinforcer should be delivered following each instance of the target response, throughout training and fading.

The third step to complete prior to beginning a prompting and fading procedure is identification of a starting point. The stimulus used for initiation of training should be something that will reliably evoke the target behavior. Continuing with the “shy” individual, the initial prompt might be a verbal cue such as “look at me.” Alternatively, it may be necessary to use several types of prompts to ensure the behavior will occur when training begins. For example, a parent teaching a child to clean the child’s bedroom might make a chart with pictures showing what needs to be done and in what order. The parent also might need to remain in the room and verbally prompt the child through each step. Regardless of the level of prompting or number of prompts used initially, it is critical that the initial prompts reliably occasion the target behavior. Once the behavior occurs immediately following the initial prompt for several consecutive trials, prompt fading can commence.

The fourth consideration prior to beginning a prompting and fading procedure is to determine when fading will begin and how rapidly fading will progress, based on the learner's performance. For example, the instructor might determine that fading will begin when the learner has correctly emitted the target response following prompt presentation for three consecutive trials. Further, prompts will be successively removed when the learner has correctly emitted the target response following that level of prompting for three consecutive trials. Second, the instructor should measure the learner's response in some way, so as to ensure that the fading procedure is working effectively and efficiently. The goal is to enable the learner to respond without prompts, however if fading is too rapid, the learner may cease to respond. Alternatively, if fading is conducted too slowly, the individual may become "prompt dependent." That is, the learner may not learn to exhibit the desired behavior without the prompt. Careful evaluation of the learner's progress will ensure that fading is accomplished at the desired rate. More important, as fading progresses, the goal is for removal of cues to be gradual enough that few errors occur. If an error occurs, it may be necessary to back up to the previous prompting level for several training sessions. Alternatively, frequent errors might signal two potential problems, either fading is occurring too rapidly, or the reinforcer for correct performance is no longer effective. In the case of the first problem, the instructor should return to the level of prompting at which no or very few errors occurred. Once the individual is again reliably emitting the correct response, fading should again commence, however the steps of fading need to be smaller or occur more gradually. In the case of the second problem, an ineffective reinforcer, the instructor must identify another reward that will increase the likelihood of correct responding.

IV. EMPIRICAL STUDIES

Fading has been used to decrease the use of prompts for a variety of behaviors. In 1990, Mary Ann Demchak

published a comprehensive review of the use of stimulus and response prompt-fading procedures when providing instructions to individuals with severe disabilities. Both types of prompt fading also have been used to facilitate language acquisition, as evidenced by a review published by Sebastian Striefel and Charles Owens in 1980. Response prompts have been used to teach many behaviors including social skills and reading comprehension. In 1988, Phillip Moore provided a comprehensive review of the utility of fading procedures in teaching reading comprehension.

Fading of stimulus prompts also has been widely used. To illustrate, in 1984 Elsie Labbe and Donald Williamson published a comprehensive review of interventions using stimulus fading to treat elective mutism. Also, Rebecca Kneedler and Daniel Hallihan published a review of studies using fading to increase on-task behavior of children in academic settings in 1981.

GLOSSARY

reframe Changing the conceptual and emotional perspective of a problem such that the meanings of the behaviors associated with the problem are viewed in a way that allows modifying the behavior easier for the client.

task A therapeutic directive that forces the entire family or selected family members to interact differently from the pattern thought to be associated with the presenting problem. Tasks occur in-session or as homework to be done between sessions.

Family therapy is a perspective of interpreting and modifying behavior. This perspective is implemented as psychotherapy in several diverse ways each according to a different set of theoretical tenets, where each tenet or cluster of tenets forms a separate model of family therapy. Although implementation varies, the multiple methods of doing family therapy derive from a single assumption: Presenting problems originate from inadequate, inappropriate, or dysfunctional interper-

sonal relationships, and therefore should be subsequently altered using techniques that in some manner modify interpersonal relationships. The various approaches of family therapy can be trichotomized based on their respective therapeutic assumptions and techniques; they are ahistorical, historical, or experiential. Each classification approach represents a general orientation toward ameliorating the problem, and within each type, various models reside.

Models within the ahistorical classification attempt to remove the presenting problem by altering family interaction sequences. Advocates of this orientation assume that current interaction processes may be unrelated to the etiology of the presenting problem, but certainly contribute to its maintenance. In general, the goal of therapy is to remove the presenting problem by changing attribution or behavioral patterns. Models within this group include strategic, structural, Mental Research Institute (MRI) narrative, behavioral, solution focused, and psychoeducational.

Historical models have psychoanalytic psychodynamic roots. Therapy tends to be longer and the therapist is generally less active in the session than in either of the other two classifications. Emphasis is on early family dynamics as templates that influence all subsequent intimate relationships. Also important is individual growth and individuation within the family. Models within this group include object relations and Bowenian.

Experiential models emphasize personal growth, experiencing and monitoring internal processes, and the development of self within the context of the

family. In addition, therapists are encouraged to share their internal processes in response to the session. Therapy within this classification is usually associated with a person (e.g., Carl Whitaker) rather than a model. Of the three types, the ahistorical approach probably best describes how contemporary family therapy is practiced and forms the basis for this article.

I. DESCRIPTION OF TREATMENT

Family therapy is any attempt to modify salient environmental features, most importantly interpersonal contacts or beliefs about those contacts, which alter interaction patterns, allowing the presenting problem to be unnecessary. Notice that family therapy does not necessarily exclude nonfamily members, nor does it necessitate that all family members be present in therapy. Problems are assumed to be embedded in behavioral patterns, and patterns are determined by context. Family therapy, then, exists to alter context. From this viewpoint, the job of the therapist is to alter the context driven behavior.

A. Initial Contact and First Session

Like other forms of psychotherapy, during the first session the objective is to join with the client and assess the problem. However, unlike other forms of psychotherapy, family therapy also begins by attempting to alter the family's perspective. Almost immediately an effort is made to dilute the idea that the presenting problem associated with an individual is encased within that person; instead an attempt is made to modify beliefs so that the problem is perceived to be a by-product of the situation that characterizes the system (i.e., environment) housing the individual. In effect, an initial objective is to have the problem viewed differently by the family. Family therapy then, especially initially, occurs through social negotiation. It involves determining what the family wants, how they see the problem, how they want it fixed relative to the assumptions and orientation of the family therapist, and how well the therapist can pull the problem away from an individual and distribute it to the system. Once this has commenced, the therapist then allows the presenting problem to be unnecessary by altering the family structure, which simultaneously alters interaction patterns, relationships, and beliefs about the family. Alternatively, the therapist modifies the beliefs about the relationship, which simultaneously alters patterns of interaction, and the family structure. Simply said, the

therapist enters the family at the relationship level, not at the level of a particular individual, and alters interaction associated with the various relationships.

1. Initial Contact

Everyone relevant to the presenting problem is asked to attend the initial session. This includes all adults in the household, and all siblings. Each individual brings unique information about the family beliefs and the presenting problem. Subsequent sessions require various combinations of family members as dictated by the therapist needs.

In the interpersonal model, therapy is directed toward the relevant behavioral pattern, not the person. As such, only those family members (or relevant members of the system) are needed that provide the leverage to alter the interactions that require changing. Stated differently, the therapist needs in therapy those subsystems that have the ability to change the relationship. This needed configuration changes from moment to moment within a session, and across sessions. It is not unusual to shuffle people in and out of the therapy room if doing so generates leverage, or if the act of excluding someone mimics metaphorically the desired changes.

Conversely, sometimes the needed individuals will not, or cannot attend therapy. Although not optimal, since therapy is with the relationship, it is assumed that the intervention will ripple through the system.

2. First Session

In family therapy at least three features about the presenting problem are examined: (1) timing, (2) function, and (3) who. Each provides an important clue to discerning relevant contextual information associated with the problem.

a. Timing. General timing questions provide a timeline for understanding the evolution of the problem. The therapist seeks answers to the following questions. Why is this problem occurring now? What has occurred recently, or if not recently, how long ago? What was going on in the family when this started? Why was the behavior not present yesterday or last week? What is occurring now that makes the behavior necessary for the individual? Were there changes in the family or larger environment when the problems started? Were there job changes, separations, fights, and so on before the onset? These questions can be asked directly or indirectly. An indirect question would be something like, "Give me a picture of the family, and how it has changed over the past year," or "Describe the family's everyday routine for the past 6 months."

b. Function. General function questions provide a framework that examines the utility of the behavior associated with the problem. The therapist, asking each individual to describe the presenting problem, wants to know, “What is the result of the behavior?” Similarly, the therapist is curious about, “What gets accomplished, and what does not get accomplished when the behavior occurs?” Accomplished here means any personal or interpersonal activity that should occur in a functional family. These include, for example, developmental changes, relationships, work, or individual activities.

c. Who. These questions provide necessary information about the people involved with the problem. For example, when the problem occurs, who directly reacts to the behavior, and then what happens? Reaction means attention, action, or general response. Consider John, the biter. When John bites Jane (the sister), who reacts, how do they react, does John get more or less attention (than before the bite), do bites occur most often when mom and dad are fighting, or have they increased since mom and dad separated? This is the type of sequence information necessary to conceptualize how the presenting problem ripples among the network of family members.

Although this example illustrates a short-term (hours or minutes) behavioral sequence, the thinking is equally applicable to sequences that cycle over a period of days. The child who regularly threatens suicide illustrates this extended perspective. For example, the child threatens suicide, mom calls the crisis unit, everyone converges to the scene, and mom and child have a very different relationship for some extended, yet temporary, period. “Who” questions generate information about which people are needed in therapy or else, at minimum, who must be considered relevant when tasks are assigned.

B. Belief Structure

Depending on the specific model of family therapy, each emphasizes to a lesser or greater extent the role of beliefs and cognitions in maintaining the behavior patterns associated with the presenting problems. Consequently, the therapist seeks to simultaneously change the presenting problem, either directly or indirectly, and the cognitive perspective that necessitates the dysfunctional interactions within the environment. In family therapy, this cognitive perspective is a belief structure maintained by the family, with slight variations held among the individual family members. This family level cognitive perspective acts as a filter, determining the meaning of events, which in turn, dictate reactions to the events. De-

pending on the family's history and culture, events are interpreted according to beliefs held by the family. The beliefs, or myths, may be functional or dysfunctional. They may be functional in their ability to keep the family intact, and yet to the world outside the family, be dysfunctional in the type of behavior that the beliefs produce. Treating an individual within the interactional perspective assumes that he or she has a cognitive perspective that influences the perception of environmental input, and determines that individual's behavioral reaction. Consequently, family therapy seeks to alter the belief as well as the behavior. However, depending on the family therapy orientation used, the therapist may seek to change the belief either directly, or through a change in the presenting problem. In other words, it is held that you can change the behavior and assume that it will allow the belief to be less valid, and subsequently unnecessary; or you can attempt to change both simultaneously. Either way, the presenting problem must change, and its underlying belief structure must be altered enough to allow the dysfunctional behavior to be unnecessary.

C. Implementing Treatment: Dimensions of Family Therapy

It is assumed that the therapeutic process begins at first contact, and from that moment on, the distinction between assessment and prescribed change is blurred as these interdependent features continuously address the presenting problem. Instead of thinking of therapy changing over time (e.g., phases), it is better to think of therapy as containing three interdependent dimensions occurring simultaneously over the period of treatment. These dimensions are assessment, instilling doubt, and pattern change.

1. Assessment

Assessment includes determining relevant behavioral patterns and belief systems in the family. Assessment occurs throughout treatment; the therapist's concept of the problem is continuously updated using information gathered via questions and responses to tasks. Assessment is in two areas: interaction patterns and belief structures. Assessing behavioral interaction patterns include questions about who does what and when, and who responds to whom, when, and how?

Assessing the family belief structure involves the following types of questions:

1. How does the family think, in the sense of a singular unit; what themes are present?

2. Where are the family alignments and coalitions?
3. What is the language of the family, and how does it reflect their beliefs?

The therapist also examines the family beliefs and myths about causality; these usually have one or more of the following themes: genetic influence (i.e., bad seed), vaguely defined biochemical imbalance, some supernatural influence (e.g., god, devil), influence of peers, or a bad parent (typically the one not present in therapy). These beliefs are typically associated with an assumed cure; for example, if the assumed problem is peer influence, then new friends would alleviate the problem. Finally, part of the assessment includes appraising the development stage of the family. This includes considering the age of the children and their parent(s). Parents of a young child face a very different set of problems than do parents of a preadolescent, an adolescent, or a young adult living at home. At each stage of development, individuals within the family have expectations that influence their behavior. Collectively, these expectations influence the expression of the presenting problem. Each stage of the parenting process is made more complex by the impact of the marital relationship. Single parents handle parenting situations differently than married parents, and happily married couples handle parenting problems differently than unhappily married couples.

In family therapy, the therapist should be cognizant of how the family arrangement and stage influence the patterns that maintain the presenting problem, and how each can affect treatment success or failure. No single recommendation can be made for each possible combination of family stage by family composition by marital status by parenting skill, and so on. Instead it is much better to examine each family as a unique composite, having its own history and belief system. By observing this belief system as expressed through behavioral patterns, the proper therapeutic intervention becomes evident for each particular family, irrespective of developmental stage.

2. *Instilling Doubt*

Simultaneous to assessment, the therapist begins the process of subtly casting doubt on the validity of the family's current belief system about the presenting problem. Seldom will the family acknowledge that marital or family interaction patterns produce the presenting problem, or even that the problem lies outside of the identified patient. Typically, the therapist addresses the interactional and contextual dynamics surrounding the presenting problem. This occurs in several ways; for ex-

ample, perspective altering questions, reframes, and directives for in-session interaction.

This process begins immediately in the first session and continues unabated throughout the treatment period. Initially it serves to alter the presenting perspective to allow change in dysfunctional patterns, and later serves to concretize the new ideas about how behavior occurs.

3. *Pattern Change*

Implicit or explicit requests for change in the behavior patterns that are associated with the presenting problem characterize this dimension of therapy. Using the removal of the presenting problem as the goal, decisions are made about what needs to be changed, and how to shift the belief structure to allow the desired behavior to occur. Although the presenting problem is the defining reason for being in therapy, short-term goals for smaller, less volatile behavior coax the individual or family toward more desirable behavioral patterns along with an altered family belief structure. This implies that as assessment is occurring and doubt is cast upon the existing beliefs, opportunities are offered for behavior change.

These opportunities occur both in and out of session. In-session opportunities occur when verbal statements by the therapist prompt a slightly different perspective (e.g., using a reframe) or when requested tasks force the family to interact differently. Out-of-session opportunities occur when behavior tasks are implemented. These requested tasks may include parents negotiating curfew times, or having the parents decide on consequences for misbehavior. The requested task forces new interactions around the presenting problem. When any task is, or is not completed, the response to the task by each individual provides additional information used by the assessment dimension.

a. Tasks: In-Session versus Out-of-Session. Requesting change via tasks is a hallmark of family therapy. Tasks, or requests for specific behaviors, can occur either in- or out-of-session. In-session tasks consist of directing the interaction among family members. This can consist of interaction between family subunits, or among members as a whole. Out-of-session tasks usually are thought of as homework assignments. Irrespective of family therapy orientation, most therapists use both types.

In-session task. The in-session task has three functions: (1) It allows the therapist to see relevant interaction, (2) it allows the therapist to alter relevant interaction, and (3) it allows the family to experience new patterns of interaction. Observing interaction in a session is extremely

beneficial in determining what is occurring in the family and how it needs to be changed. Assuming that the in-session behavior is isomorphic to the out-of-session behavior, the therapist is confident that what is seen reflects what happens in the home.

These tasks can be as simple as asking the husband and wife to talk about relevant issues, or as complex as having a family meeting on some topic. Each task, irrespective of complexity, generates relevant interaction needed for continuous assessment.

Another value of the in-session task is that it provides the therapist with the opportunity for the intended family interaction pattern to fail. For the therapist, there are therapeutic benefits in observing the family fail at the assigned task. Specifically, observing a failed task provides information about the pattern structure, provides immediate opportunity for therapist to comment on the process, and provides an opportunity to challenge the belief system.

Some families benefit more than other families from in-session compared to out-of-session tasks. Because in-session tasks generate new interactions among the family during the session, they are especially useful with families characterized as chaotic, that is, where most family members have infrequent, or volatile contact with other family members. This also includes families in which the lifestyle increases the likelihood that the family will come for only one or two sessions. Finally, in-session tasks may be necessary for families that fail, for whatever reason, to complete out-of-session tasks. These families should be given in-session tasks to determine what interactional components contribute to out-of-session failures.

Out-of-session tasks. Tasks that request specific changes in behavioral interactions outside of therapy have the singular function of altering, however slightly, familial interactions that are consistent with removing the presenting problem. Out-of-session tasks require interactions that need time, opportunity, or situations that are outside of the therapy session. These might include positive interaction opportunities (e.g., trip to the park), or need several days or weeks to complete (e.g., parent monitoring of child behavior). Moreover, if the task fails, the out-of-session task allows the therapist to determine the sequencing of behaviors associated with failure.

Like in-session tasks, failure to complete out-of-session tasks is seen as a source of information within the assessment dimension of therapy. In turn, the failure information is used to devise and re-assign another, slightly modified task. This next task accounts for the previous failure by modifying important ingredients in the interaction, which if successful, takes the pattern

closer to the objective. If the task again fails, even with the modifications, then the therapist has more information about what is interfering with change. When successful, tasks simply allow the perspective shift to manifest itself behaviorally. The task, in effect, demonstrates that behaviors can change in accordance with the precepts of therapy. In some cases, no tasks need to be given, and in others, the therapist gives a task at each session. Whether or not to assign a task depends on what the therapist determines the family needs, and since the needs of families vary, so should task assignment.

D. Subsequent Sessions

Subsequent sessions build on the initial session—shifting perspective and changing behavior. Each therapeutic maneuver either sets up or implements small changes that are consistent with eliminating the presenting problem. These small behaviors are, in fact, short-term goals; in turn, success in these short-term goals inexorably lead to changes in the presenting problem. Changes, as defined here, refer to not only interaction patterns, but also shifts in the client belief structure. Remember, the shift in perspective refers to a method of allowing the individual or family to see behavior in a slightly different way. Specifically, efforts are directed toward changing the behavior via interactional tasks while concomitantly asking questions about, or indirectly making reference to, the beliefs that underlie those interactions.

In general, there are no precepts about what to do in any given session other than always to guide the client to change. Each therapeutic maneuver should be goal directed; each should attempt to alter pattern, perspective, or both in relation to short-term goals. In turn, each short-term goal must be directly related to the long-term goal of removing the presenting problem. For example, a short-term goal might be getting the mother and father to view the son in a slightly different way; to view the child, not as a “sick” kid, but as a son reacting to a chaotic home life. A series of small moves such as this eventually allow the parents to take more responsibility for the environment that shapes the child’s behavior.

E. Termination

Because the object of all ahistorical family therapy models is to remove the presenting problem, once that objective has been met therapy ends. By maintaining a very specific objective, such as removing the presenting problem, all parties involved work toward a common goal, and everyone is aware of the changes that have

been made, or need to be made, in order for therapy to be successful. Therapy should be as brief as possible, typically lasting from 6 to 20 sessions.

II. THEORETICAL BASIS

A clear and consistent message implicit in traditional psychotherapy is that the individual with the presenting problem has a core deficit. The identified client may be lacking social skills, has aberrant thinking, is developmentally arrested or unable to resolve internal conflicts, or has some flawed biochemical process. Irrespective of etiology, the problem is within the individual and all effort focuses on treating the assumed structural deficit within the individual. Conversely, family therapy is an interpersonal model of psychotherapy; it focuses on treating the relationships between members of a delimited environment. Unlike the individual deficit model, family therapy assumes that a presenting problem reflects the inadequate quality or inappropriate structure of interpersonal relationships in which the individual resides. Moreover, family therapy assumes, *a priori*, that the individual expressing a symptom for the system is no more or less likely than any other family member to be psychologically vulnerable. Simply put, the identified patient is fulfilling a role within the larger system.

Each model in family therapy posits different theoretical tenets for the processes that generate the problematic behavior. Some assume a dysfunctional multigenerational process (e.g., lack of individuation), while others assume that psychological remnants from early attachment figures stifle the ability to maintain later relationships, and still others assume that inappropriate reinforcement or punishment creates a chaotic environment that produces aberrant behavior in children. Although each model has different assumptions about the presenting problem, a single conceptual thread binds them together—the identified patient represents the cumulative inability of the immediate environment, usually the family, to functionally adapt to exogenous or endogenous changes that naturally occur as a system evolves over time. Furthermore, although the family produces the symptom, the identified patient is simply selected as the carrier; this implies that any sibling could do just as good a job if drafted for duty.

Most of the assumptions held by family therapists derive from global theories that have no direct link to psychotherapy but instead focus on natural or biological systems. Many of the central ideas draw from general system theory, initially forward by the biologist Ludwig von

Bertalanffy in the early 1930s. Lesser known theories (at least in the social sciences), such as information theory and cybernetics, also influenced the seminal writers in this area. Given the fluidity inherent in these dynamic systems models, it is not surprising that family therapists assume that, unlike many traditional psychotherapy models, change can occur spontaneously, that etiology is impossible to know, or that defense mechanisms and client resistance have no conceptual foundations. In effect, families are evolving systems, embedded in other systems and that the function of the therapist is to perturb the system enough to alter the processes that characterize the system. Exactly how the therapist induces this perturbation forms the unique underpinnings of each of the various models of family therapy.

III. APPLICATIONS AND EXCLUSIONS

Because family therapy does not attempt to modify a person but rather the behaviors exhibited by a system, it is generally applicable to most of the problems seen by mental health practitioners. With children and adolescents, it has been applied to problems ranging from conduct disorder to anxiety and depression. In adults, it has been applied to relationship problems, as an adjunct to the treatment for schizophrenia, depression and anxiety, modifying family reactions to medical illness, and drug and alcohol abuse.

Most of the couples and families treated with family therapy, at least as described in the scientific literature, have been predominantly upper-lower and middle class, and white. In the past decade, greater emphasis has been made to apply these techniques to more diverse groups such as Asian and Hispanic populations. Because family therapy did not evolve from a psychological perspective but rather from a general systems orientation, most of the assumptions that form family therapy are equally applicable across family types and cultures. For example, Salvador Minuchin developed structural family therapy in the early 1960s at a facility that dealt with young delinquents, mostly black and Puerto Rican.

IV. EMPIRICAL STUDIES

A number of studies provide evidence that family therapy is generally as effective as other forms of psychotherapy for the types of problems noted in the previous section. It is clearly the treatment of choice for relationship problems; this was established almost two

decades ago and has subsequently been confirmed through multiple studies. William Pinsof and Lyman Wynn edited a book in 1995 that provides an excellent overview of family therapy outcome studies.

V. CASE ILLUSTRATION

This synopsis reviews the case of a 10-year-old girl that presented with uncontrollable head shaking and humming. The condition had been occurring for about 1 year, and the parents were told that the disorder was caused by a biochemical imbalance in the brain. The child and her family were referred to the Marriage and Family Therapy Clinic after several thorough neurological examinations found no physical reason for the condition. The humming and head shaking, although reported to be uncontrollable, did not occur at school, during therapy sessions, or in situations that the child enjoyed. It occurred primarily at night, starting within minutes after the child went to bed. The humming usually increased slowly until it got the attention of the parents, who would then check on the girl, reassure her, and then leave the bedroom. This cycle continued until the child fell asleep. This case was assigned to an M.S.-level family therapist, and I was the supervisor.

After reviewing the videotape of the initial session, and assuming no physical disorder could explain the selective head shaking and humming, I further assumed that the family was inadvertently reinforcing the behavior of the child, and the child was unable to engage the parents with less drastic measures. I decided to discourage this reinforcement without focusing on the child or blaming parents. I used an MRI-type approach that involved having the parents "evaluate" the behavior without explanation. The intent was to simply reorganize the patterns of interaction between the girl and the response of her parents to her behavior. The therapist was instructed to commence the second session by asking about the symptoms during the previous week, what the parents did in response, and so on; most of emphasis was on getting the child to talk about the uncontrollability of the behavior. Near the end of the session, the therapist asked the following questions (these had been developed prior to the session) to the girl (with the parents present):

1. "Do you shake your head from left to right or from right to left?"
2. "Do you hum a low note, a high note, or a medium note?"
3. "Do you shake your head faster as the note gets higher?"

After each question, the therapist allowed the girl to respond, but typically, the girl would look puzzled and simply waited for the therapist to talk again. Finally, the therapist made the following statement: "I looked up biochemical imbalances in some books and I found out there are two types: the controllable type and the uncontrollable type. If, in fact, you do have a biochemical imbalance, you have the controllable type." And then the therapist said, "Ask me how I know that (pause). I know because you choose when you do it. You don't do it at school and you don't do it when I'm here. And I bet there are many, many other times when you don't shake your head and hum, right? Let's check that out right now. Shake your head and hum right now." (Note: It did not matter whether she moved her head or not, either behavior showed control.) After a long pause, the therapist said, "That confirms everything I've read. In your case it's very controllable."

The therapist then asked the young girl to step out to the waiting area and gave the following instructions to the parents. "Do you want to get rid of the head-shaking and humming, which she can control?" Of course, the parents said yes, and then the therapist gave each parent a set of 10 (3 × 5) cards, numbered consecutively from 1 to 10. The therapist then said, "Each of you has a card, numbered from 1 to 10, with 10 being high. Before I tell you what to do with these cards, I need your complete assurance that you will do exactly what I say. Are you willing?" The parents nodded affirmatively. Next the therapist said, "If you do this every single time it's appropriate, she will stop, very soon." After more assurances by the parents, the therapist said, "One thing about this type of behavior is that kids can sometimes do it better and sometimes do it worse. Since it's controllable, we've found by using this method, it effectively reduces the incidence—if it's used correctly. Many parents are distressed enough by the behavior to follow through. Do you think you are?"

After repeated assurances by the parents, the therapist then gave the following instructions: "Every time she does the behavior, it's your job to evaluate how well she does it. Go to where she is; turning the light on if she's in bed. Watch for 5 to 10 seconds to evaluate. Dad holds up his card with his rating. Mom then rates. Finally, dad adds the two ratings up, then divides by two, to get a single rating. Dad, in his very best fatherly tone, tells (child's name) her rating on this episode of the behavior. Then both parents calmly turn around and walk away, saying nothing more about the behavior. Do this every single time, but only one time per episode." Mom was assigned to keep track of the number of times they forget to do this.

At the following session (1 week later), the parents reported that during the first rating (while the child was in her bed) the girl stopped the head shaking and humming after several seconds of the parents observing and asked the parents what they were doing. They did not respond but simply completed the task as directed. During the second and third episodes, she stopped when the parents walked into the room. The fourth episode occurred in public; when the girl began her head movement and humming, the mom pulled out her set of cards and the girl stopped immediately. The following week no episodes occurred, and again at a 1-month follow-up, no additional episodes had occurred. The family was seen for a total of four sessions.

This case illustrates the use of an out-of-session task assigned to alter interaction around a problem behavior expressed by the child. The task and assignment method (i.e., specific oral instructions) allowed the family to view the distressful behavior as controllable. Each parent was assigned a unique part of the task, and as a unit, they engaged in behavior that modified the typical response to the presenting problem, thereby forcing new interaction patterns for the family.

VI. SUMMARY

Although multiple, disparate models of family therapy exist, all presuppose that the presenting problem is embedded and maintained in behavioral patterns that originated from inadequate, inappropriate, or dysfunctional interpersonal relationships. Consequently, the psychotherapy techniques used by a family therapist attempt to modify salient environmental features, most

importantly interpersonal contacts or beliefs about those contacts, which alter interaction patterns, allowing the presenting problem to be unnecessary. These techniques include in-task and out-of-session behavioral tasks, reframes, and perspective-altering questions. Therapy is typically brief (less than 20 sessions) and ends when the presenting problem or behavior has stopped or is no longer considered distressful.

(2) a commitment to equality and social justice for all people; and (3) the assumption that both personal and social change are necessary to support feminist therapy goals.

GLOSSARY

consciousness-raising Activities that increase awareness about how oppressions such as sexism, racism, heterosexism, and ageism influence the lives of individuals.

feminist analysis and gender role analysis Techniques used to examine how inequality, injustice, and power imbalances may limit individual potential. Gender analysis involves examining restrictive gender role beliefs and behaviors, weighing their costs and benefits, and constructing alternatives to prescriptive gender roles.

the personal is political Personal issues are not individual concerns alone, but are shaped by cultural forces and have implications for political and social change.

Feminist therapy integrates feminist analysis with a variety of psychotherapy systems to support egalitarian psychotherapy practice and goals as well as social change. Of central importance to this approach are (1) efforts to address the connections between variables such as race, culture, class, sexual orientation, and gender;

I. DESCRIPTION OF TREATMENT

Psychotherapy was first described as “feminist” during the early 1970s. Feminist therapy was not founded by or connected to any specific person, theoretical position, or set of techniques; its origins are embedded in the diverse social change goals and activities of the women’s movement. Feminist practitioners integrate knowledge about psychotherapy methods, social structures, multiple intersecting oppressions, activism, feminism, multiculturalism, and the diversity of women’s and men’s lives. Feminist therapy can be best defined as an umbrella or philosophical framework for organizing a therapist’s assumptions and psychotherapy techniques. Important features include emphases on (1) consciousness-raising and activism; (2) egalitarian therapist–client relationships and goals; (3) diversity and the multiple meanings of gender; and (4) a sociocultural perspective that addresses relationships among the personal problems, social forces, and various “isms” (e.g., racism, heterosexism, sexism, ageism). Feminist therapists are informed by a wide range of personality and psychotherapy theories, eschewing only those techniques that support inequality or narrow life options.

In contrast to traditional psychological approaches that may emphasize internal attributes and pathologies, feminist therapists view problems from a complex biopsychosocial framework, highlighting the ways in which social realities shape, constrict, and limit choices. Intrapyschic explanations of distress may decontextualize problems, promote narrow thinking, or support victim blaming. If therapists define problems primarily as a set of symptoms, they may also tend to emphasize symptom removal, which may not result in genuine change or renewal, but may merely call on individuals to resolve issues by accepting the very circumstances that contributed to their problems.

From a feminist perspective, many psychological symptoms represent efforts to cope with negative conditions, and thus, reflect communication and survival mechanisms. These behaviors, which frequently play important short-term adaptive roles, often become increasingly uncomfortable and counterproductive over time, and may eventually exhaust a person's resources. The feminist therapist helps the client understand how these forms of coping, such as anxiety and depression, can be redirected in productive and empowering ways. The therapist's frame of reference is not how symptoms are signs of pathology that must be removed but rather, what symptoms convey about a person's circumstances, strengths, and coping skills.

The feminist therapist emphasizes egalitarian practice and shared responsibility, and views the client as competent and as an expert on his or her own life and circumstances. Due to the training of therapists, however, the relationship may approach equality but is not likely to be fully equal. From a feminist perspective, open therapist–client discussions of power and the positive and negative uses of power facilitate the client's ability to deal with unequal power both within and outside of psychotherapy. Believing that all human interactions are infused with values, feminist therapists often make their values explicit, and encourage clients to take an active role in clarifying their own values and preferences.

During the 1970s, feminist therapists provided leadership within mental health professions by promoting informed consent and highlighting the value of clearly negotiated, collaborative therapeutic contracts. Informed consent assists therapists and clients in evaluating progress regularly, minimizes the risk that therapists will abuse power or manipulate clients, and enables clients to assume optimal levels of responsibility for their own direction in psychotherapy.

The goals of feminist therapy emphasize personal awareness of biological, personal, relational, cultural,

and sociocultural factors. Clients are encouraged to consider the role of both internal and external contributors to their problems and explore denied or distorted aspects of their experiences in order to discover hidden or submerged sources of strength. This consciousness-raising and clarification process may decrease clients' self-blame and help clients transform indirect forms of influence (e.g., symptoms) into direct, constructive, assertive expressions that support health. Clients may also explore ways in which restrictive environments may limit their freedom or may punish them for stepping outside of prescribed roles. In order to help clients deal with external and internal resistance to creative change, therapists often encourage clients to weigh the costs and benefits of change, and to consider how they may cope with negative reactions to their positive change efforts. Feminist therapists, recognizing that individual change alone will not lead to extensive systemic change, also attempt to devote some time to social action and advocacy. When appropriate, clients are also encouraged to become involved in social change or volunteer work that contributes to social justice.

As feminist therapists pursue the goals outlined above, they incorporate techniques from a variety of psychotherapy approaches. Some techniques are identified as hallmarks of feminist therapy, such as gender-role analysis, feminist analysis, self-disclosure, group work, and social change activities. Gender-role analysis, a component of assessment, involves exploring the impact of gender and related identity statuses (e.g., age, sexual orientation, race) on psychological well-being, and using this information to make new decisions about gender roles. Laura Brown summarized comprehensive gender role analysis as including the (1) exploration of gender in light of personal values, family dynamics, life stage, cultural/ethnic background, and current environment; (2) discussion of the rewards and penalties for gender role conformity or noncompliance in the past and present; (3) clarification of how the client–therapist relationship mirrors gender issues or provides insight about the client's gender roles; and (4) exploration of the client's history related to victimization and oppression. A victimization history may include information about interpersonal violence, sexual harassment, assault and abuse, racism, sexism, heterosexism, and other related injustices that have contributed to the person's gender-related rules. The goals are to clarify how gender-related messages were absorbed by the individual, what functional and negative forces they have played in the individual's life, and how the client can use this information to choose emotional,

cognitive, and behavioral responses that enhance health.

Feminist analysis and power analysis refer to various methods for helping clients understand how unequal access to power and resources can influence personal choices and distress. Therapists and clients explore how inequities or institutional and cultural barriers may limit or complicate self-definitions, achievements, and well-being. To facilitate this process, therapists may provide information about dynamics or statistics associated with problems related to the unequal distribution of power (e.g., family violence, divorce, traditional marriage, sexual abuse). They also use open-ended questions to explore these dynamics and how clients can develop positive, personal approaches to power and relationships that empower themselves and others. Bibliotherapy, therapist self-disclosure, and psychoeducational groups may also be incorporated into feminist analysis.

Both gender-role and feminist analysis help clients reframe problems and develop new lenses for understanding issues, which often lead to renewed self-esteem. Rather than viewing themselves as deficient and needy individuals who must experience psychological overhaul, clients learn to define themselves as capable individuals who will benefit by redirecting their energy toward new goals.

Self-disclosure and group work are sometimes used to build connections between diverse groups of women, demystify the psychotherapy process, and decrease power differentials in psychotherapy. Therapist self-disclosure may decrease a client's feelings of isolation, and help the client connect abstract concepts about social structure and gender role conflicts to real-life issues. Through carefully timed and appropriate self-disclosure, the feminist therapist may serve as a coping model whose human qualities facilitate client empowerment. As noted by the Feminist Therapy Institute "Ethical Guidelines for Feminist Therapists," all self-disclosure must be used "with purpose and discretion and in the interest of the client." Group work, including consciousness-raising, support and therapy groups, psychoeducational groups, and seminars may also decrease feelings of isolation between clients and foster self-trust and social support. The sharing of life stories supports the mutual disclosure of gender role conflicts and everyday inequities, and often facilitates increased awareness of gender issues and solidarity among members. Members learn to use power effectively by providing support to each other, practicing new skills, and taking interpersonal risks in a safe environment. Groups also decrease

power imbalances between therapists and clients because members are not only receiving, but also giving emotional and practical support.

II. THEORETICAL BASES

During the first decade of feminist therapy practice, practitioners tended to be most concerned with responding effectively and immediately to the extensive gender-related problems that had been ignored, marginalized, or distorted by the lenses of mental health professions that had been dominated by androcentric theories and practices. The feminist critique of the mental health professions focused primarily on four overlapping issues: (1) personality theories and research that supported biased models of therapy; (2) double standards of mental health that overvalued attributes described as "masculine" and devalued attributes labeled as "feminine"; (3) diagnostic practices that contributed to labeling clients without regard to contextual, situational contributors to distress; and (4) psychotherapy relationships in which an all-powerful therapist defined reality for the client.

In the late 1960s, Naomi Weisstein declared that "psychology has nothing to say about what women are really like, what they need and what they want, essentially, because psychology does not know." A study conducted by Inge Broverman and colleagues during the early 1970s also revealed that mental health professionals' views of healthy men and women were influenced by gender stereotypes. In addition, Phyllis Chesler's influential book, *Women and Madness*, compared the therapy relationship to that of a patriarch and patient, noting that this relationship mirrored women's roles in patriarchal families where women were rewarded for submitting to an all-knowing father figure. Chesler argued that the band of "normal" behavior for women was extremely narrow and that women were diagnosed for both underconforming and overconforming to limiting mandates.

These powerful critiques, along with the activism of the women's movement, contributed to an initial emphasis on providing immediate, practical, respectful therapeutic options to women, as well as changing the systems in which therapy occurs. Following the establishment of basic principles, feminist therapists focused on developing theory that supports ethical practice, and one outcome was the Feminist Therapy Institute's "Ethical Guidelines for Feminist Therapists." These principles are not designed to replace other codes, but

to enhance feminist practice by enumerating positive, proactive responsibilities regarding cultural diversities and oppressions, power differentials, overlapping relationships, therapist accountability, and social change responsibilities of feminist therapists.

Rather than articulating one feminist theory of practice, feminist therapists have tended to propose criteria for evaluating theories applied to women's lives. For example, Hannah Lerman indicated that feminist personality theories should (1) view women positively and centrally, (2) avoid confining concepts, (3) encompass the diversity and complexity of women's lives, and (4) attend to the inextricable connections between the internal and external worlds. The feminist theory working group of the 1993 National Conference on Education and Training in Feminist Practice proposed that feminist theories should (1) support social transformation and the development of feminist consciousness; (2) emerge from and speak to the lived experiences of clients who exist in changing social worlds; (3) address power imbalances related to gender and diversity; (4) give voice to and authorize the world views of oppressed persons; (5) recognize that psychological constructs, including feminist constructs, are not based on universal "truths," but vary across time and culture; and (6) de-center the experiences of dominant groups, whose behaviors are often defined as healthy, correct, or normal. Several feminist psychological theories have also provided important foundations for the work of many feminist therapists. These include Sandra Bem's gender schema theory, Carol Gilligan's work on the relational qualities of women's ethics, and the self-in-relation model of Jean Baker Miller and colleagues at the Stone Center at Wellesley College.

The work of feminist therapists is informed by a wide range of sociological, philosophical, political, feminist, and psychological theories, and these feminist philosophical theories posit a variety of overlapping and sometimes competing views of the meanings and nature of sex and gender, the causes and consequences of gender oppression, the implications of gender-related inequity, and solutions to gender-related oppression. Feminist theories bear diverse labels such as liberal feminism, cultural feminism, radical feminism, women of color feminisms, lesbian feminism, global feminism, socialist feminism, postmodern feminism, and third wave feminism. Although feminist therapists generally agree on basic principles of practice, their unique orientations to feminism may have profound impacts on their interpretation of feminist therapy principles and choice of psychological and social interventions. One's feminist theoretical perspective influ-

ences the degree to which the therapist believes that (1) gender is socially constructed or an aspect of one's essential nature; (2) self-disclosure serves as a useful support for empowerment; (3) traditional diagnosis can or cannot be integrated with an egalitarian stance with clients; and (4) social change activity is an essential role of feminist therapists.

Judith Worell and Pam Remer developed a five-step decision-making model to help feminist therapists assess the compatibility of specific psychological theories and feminist therapy principles and, when necessary, transform incomplete or biased theories. The decision-making sequence starts with the identification of a theory's historical development and theoretical concepts, its views of clients' problems, its use of language and labels, the functions and roles of diagnosis and assessment, the role of clients and therapists, and techniques. Therapists then identify limitations, consider ways to restructure the theory, and incorporate aspects of other theories to construct more inclusive, egalitarian approaches.

III. APPLICATIONS

As a philosophical approach that can be integrated with a wide range of psychological theories, feminist therapy is applied to a broad range of psychological problems, including those problems that are often defined as "feminist" (e.g., sexual and domestic violence, sexual harassment), as well as problems that are influenced by biological factors (e.g., bipolar disorder, schizophrenia, anxiety, depression). Approaches to dealing with the following issues have received the most extensive attention in the feminist therapy literature: achievement and career issues, eating disorders, addictions, relationship issues, sexual assault and abuse, sexual harassment, family and domestic violence, trauma-related problems, depression, anxiety, and dissociative disorders.

Some early feminist therapists opposed the use of prescription medications because some practitioners' indiscriminate and singular use of some biological interventions represented forms of superficial treatment, social control, or led to addiction (e.g., the prescription of valium to homemakers in order to ease anxieties related to dissatisfying roles). At present, however, most contemporary feminist therapists operate from a biopsychosocial model that highlights social contributions to distress but also recognizes multiple contributions to psychological problems, including biochemical imbalances. Feminist psychopharmacology, an aspect of feminist psychiatry and therapy, is characterized by

the integration of feminist principles with attention to biases in medical diagnosis and research, vigilance about gendered prescribing practices, rejection of mind-body dualisms, and respect for the client's choices and treatment preferences. Phyllis Chesler, an early critic of the medical control of women through biological interventions, has recently argued that although clients are still often overmedicated or wrongfully medicated, medical advances have increased the quality of life of many. A sociocultural framework remains crucial for ensuring that clients experience an integrated approach that addresses the full range of internal and external contributors to distress.

Feminist therapy was originally developed by, practiced by, and applied to work with women. However, there has been increased recognition of the ways in which men's traditional roles and socialization can also be restrictive. Feminist therapy may be used to help men redefine masculinity according to values other than power, prestige, and privilege. Feminist therapy may also help men integrate relationship and achievement needs; increase men's capacity for intimacy, emotional expression, and self-disclosure; create mutually rewarding and collaborative relationships; and learn noncoercive problem-solving methods. In order to affirm men's contributions to justice and egalitarianism while also preserving the uniqueness of women's experiences as therapists and clients, some feminist therapists refer to the feminist activities of male therapists as profeminist therapy. Profeminist approaches are applicable to a wide range of men's problems including depression, anger management, interpersonal violence, anxiety issues, addiction, achievement concerns, and relationship and family problems.

Feminist therapy is appropriate for working with a variety of diversities, such as ethnicity, multicultural themes, class issues, life stage issues, sexual orientation, and physical disability. A substantial feminist therapy literature has emerged on the counseling needs of women of color, lesbians, and bisexual women. Authors such as Oliva Espin, Lillian Comas-Diaz, Beverly Greene, and Karen Wyche have also articulated feminist therapy approaches relevant to diverse groups of women of color, including immigrant women and lesbians of color.

IV. EMPIRICAL STUDIES

Some of the earliest studies relevant to feminist therapy examined the impact of consciousness-raising groups on participants, and in general, found that participation in these groups was associated with increased

endorsement of feminist attitudes and expanded concepts about women's potential. During the late 1970s, Marilyn Johnson's comparison of a small sample of clients who participated in feminist or conventional therapy found that these two groups reported similar types of problems, similar levels of satisfaction, and similar levels of change. Diane Kravetz, Steven Finn, and Jeanne Marecek compared the experiences of consciousness-raising group members who had sought feminist or conventional therapy and found that women who defined themselves as feminist reported higher levels of satisfaction when the therapist was feminist.

Another group of studies examined reactions of potential clients to videotaped, audiotaped, or written depictions of nonsexist, liberal feminist, and radical feminist therapy. Gail Hackett and Carolyn Zerbe Enns found that feminist respondents, including male participants with profeminist values, showed more positive reactions to all versions of counseling than individuals who did not endorse feminist values. Research participants were able to accurately identify counselors with a feminist orientation and generally expressed positive attitudes toward feminist therapists. Respondents also rated liberal and radical feminist counselors as emphasizing similar goals, but viewed radical feminist counselors as communicating these goals more strongly than liberal feminist therapists.

Recent survey studies have explored shared values and perspectives of feminist therapists and how these values may differentiate their work from therapists who do not define themselves as feminist. Judith Worell, Redonna Chandler, and colleagues found that self-identified feminist or woman-centered therapists were significantly more likely than nonfeminist therapists to endorse the following behaviors: affirming the client, adopting a gender-role perspective, valuing woman-centered activism, using therapist self-disclosure, and displaying an egalitarian stance. In 2000, Bonnie Moradi and colleagues compared the reported behaviors of feminist therapists and those who did not identify themselves as feminist. A factor analysis of feminist therapy behaviors revealed three major themes: (1) an emphasis on gender role analysis and the personal is political, (2) empowerment through respecting individual differences and focusing on strengths, and (3) valuing behaviors such as assertiveness and autonomy. When examining the five top-ranked behaviors of feminist therapists, this study found no significant differences between feminist therapists and other therapists with regard to displaying empathy and unconditional positive regard toward clients. However, feminist therapists were significantly more likely to describe their top

five behaviors with both male and female clients as consistent with the following: (1) paying attention to clients' experiences of discrimination, (2) adopting a collaborative role with clients, (3) reframing problems to include an emphasis on socialization, and (4) enhancing self-esteem by emphasizing clients' unique and positive qualities. Marcia Hill and Mary Ballou's 1998 survey of 35 feminist therapists also revealed the following themes: (1) attention to power differences, overlapping relationships, and therapist accountability; (2) an emphasis on the sociocultural causes of distress; (3) the valuing of women's experience; (4) application of an integrated analysis of the multifaceted and interlocking aspects of oppression; and (5) an emphasis on social change. These findings show the repeated endorsement of two key groupings of feminist therapy principles: the personal is political, and egalitarianism.

A final group of studies examined whether actual clients have viewed their therapists as displaying feminist therapy behaviors. Studies conducted by Judith Worell, Redonna Chandler, Anne Cummings, Niva Piran, and colleagues showed that clients view feminist therapists as displaying the qualities and behaviors that feminist therapists endorse (e.g., empowerment, reducing power differentials, exploring gender-role issues). Noting that traditional measures of symptom reduction are not consistent with feminist therapy outcomes, this group of researchers has also developed measures of feminist empowerment and have found that feminist therapy clients report outcomes consistent with feminist empowerment (e.g., resilience, developing coping skills for dealing with barriers).

Given the fact that feminist therapy is usually defined as a philosophical approach rather than as a highly standardized, technique-oriented approach to therapy, the examination of the processes and outcomes of feminist therapy is complex. Nevertheless, it is essential for researchers to study the process and outcome variables associated with distinctive techniques such as gender-role analysis, feminist social and power analysis, and feminist self-disclosure. It is also important to examine outcomes related to feminist therapy for specific types of problems (e.g., sexual assault, career counseling) as well as how the theoretical diversity of feminist therapists is reflected in actual feminist therapy behaviors.

V. CASE ILLUSTRATION

Briana, a 21-year-old college student, reported difficulty concentrating on courses, conflicts with her boyfriend and parents, depressed feelings, anxiety, and

nightmares. Other issues included difficulties trusting others, feelings of inadequacy, dysfunctional eating, and alcohol use. During initial sessions, Briana's therapist also asked questions about family and relationship interaction patterns, paying special attention to "shoulds" and beliefs that appeared related to gender dynamics in her family, friendships, and school experiences. When the therapist (Jean) inquired about the presence of past trauma or victimization, which is one aspect of gender-role analysis, Briana reluctantly revealed being the target of sexualized comments during her high school and college years and an unwanted sexual experience during her second year in college. After inquiring further about these experiences, Jean hypothesized that Briana coped with these unresolved events by minimizing the significance of these events. Her use of alcohol, eating issues, and her anxieties represented survival skills related to Briana's efforts to cope with events that might be too overwhelming to acknowledge. Although Briana's descriptions of unwanted sexual encounters were consistent with legal definitions of sexual harassment and rape, she did not label these experiences with these terms. She merely noted that she had been stupid and gullible, and that in accordance with her family's subtle "shoulds," she had learned to avoid thinking about these issues in order to "get over it and move on." After focusing briefly on the costs and benefits of this belief, Briana stated that she did not want to think about these experiences while she was trying to cope with pressing everyday demands.

Respecting Briana's ability to assess her most immediate needs, subsequent sessions focused on helping her deal more effectively and assertively with interpersonal and academic tasks. Jean and Briana identified and practiced concrete strategies for negotiating conflicts with her boyfriend and parents, dealing with anxiety and concentration problems, and decreasing her use of alcohol. Briana developed new communication skills, cognitive behavioral tools, coping imagery, and relaxation to deal with the immediate problems. Although Briana became more confident about everyday coping, she admitted that she continued to have nightmares, did not enjoy physically intimate contact with her boyfriend, and still used alcohol or food to submerge depressed feelings.

In response to the therapist's tentative hypothesis that her negative sexual experiences might be related to these issues, Briana expressed willingness to explore this material. The therapist briefly disclosed that her own sexual assault as a college student had drained her energy and productivity for some time, but that working through her reactions had freed her to deal more

effectively with life tasks and direct her anger in productive directions. While acknowledging that Briana's experience was unique, she noted that the research literature reveals that many women have long-term reactions to unwanted sexual behavior, and proposed that exploring this material might be a constructive experience.

Before talking specifically about her unwanted sexual experiences, Jean and Briana identified how she might use the new skills she had learned to deal with uncomfortable emotions that could emerge during their next phase of exploration. Briana described her memories about the painful sexual experience of the past year, which had involved a friend forcing her to have sex following an evening at a party and a bar. She had coped by defining it as a bad experience, and had stifled painful emotions because she believed that family and friends would not believe her or would blame her for being "seductive." As Briana described the assault, she cried and expressed feelings of sadness and anger. Jean supported her expression, framing it as a new type of response-ability and a chance to refocus her intense feelings from depression to more direct expression of her feelings.

Building on earlier gender-role analysis activities, Jean encouraged Briana to draw potential connections between her thoughts about the sexual violation and messages and myths she had learned from family, media, and friends. These included (1) "It was my fault because I was dressed in a sexy outfit"; (2) "It was my fault because I had two beers and could not resist like I should have"; (3) "He was a good friend and wouldn't do anything to hurt me, so I must have sent the wrong signals"; and (4) "It's a sign of weakness to be overwhelmed by this." An exploration of the myths that supported these beliefs (feminist analysis) helped Briana understand how the cultural "smog" she had been exposed to had affected her self-statements. Further examination also focused on how her status as an African-American woman contributed to her realistic fears about how others would react to potential disclosure about harassment and sexual violation. They discussed how myths associated with confining images of African-American women's sexuality as Sapphires and Jezebels contribute to beliefs that Black women are promiscuous, sexually voracious, dominant, and incapable of being raped. Thus, Briana may have been affected by these beliefs, perhaps nonconsciously, and did not believe she could expect empathy from others. Paying attention to personal trauma is not unique to feminist therapy; however, efforts to place victimization within a larger social context by exploring myths and social attitudes, as well as efforts to redirect self-

blame associated with these myths are important features of feminist therapy.

Jean also recommended several books that (1) identify the dynamics of acquaintance rape and gender harassment on college campuses (*I Never Called It Rape*, by Robin Warshaw), (2) discuss the acquaintance rape of women of color as well as cultural beliefs that support acquaintance rape in American culture (*A Woman Scorned*, by Peggy Sanday), and (3) describe healing after rape (*After Silence*, an autobiographical account by Nancy Venable Raine). After writing about her experience for a homework assignment and reading these materials, Briana developed a new framework for conceptualizing the personal violations, and began to use the terms rape and sexual harassment to describe her victimization. The books affirmed and validated her experience, and provided additional permission to deal more specifically with the consequences of harassment and rape.

Counseling sessions also focused on (1) finding effective ways of expressing feelings related to personal violation and anger, and translating this anger into positive directions; (2) talking with intimate others about her experiences of violation; and (3) learning to initiate intimate contact on her own terms. Briana's therapist referred her to a support group for sexual assault survivors, and in this setting she was able to work through additional feelings in a supportive environment, overcome feelings of isolation, and experience empowerment through connections with others. She also became more aware of the many ways in which media promote rape and how fears about rape often constrict women's lives. Briana enrolled in a psychology of women course in order to gain more understanding of gender dynamics, and as an extension of her emerging interest in activism and supporting others, she enrolled in crisis training at a rape crisis hotline. She also joined several student activist groups on campus, including Sisters for Sisters, a group designed to provide support for women of color on campus.

VI. SUMMARY

Some form of unequal power, victimization, or abuse often underlies the concerns that clients bring to therapy. Many clients have experienced abuse or unequal power over an extended period of time, and may enter therapy with intense feelings of guilt, isolation, and self-denigration. These clients often use denial or minimization as methods for coping with the long-term, insidious effects of unequal power and abuse and may have difficulty

identifying and naming the problems they are experiencing. As clients disclose personal information, the therapist and client examine how these issues are influenced by the contexts in which they live, confront personal myths that support internalization, and identify ways in which symptoms serve as survival mechanisms. Working through these problems is often difficult because they have become entrenched and solidified by many years of restrictive socialization and unequal power.

As clients experience new levels of awareness, they often express previously suppressed feelings of anger, pain, grief, or disappointment. Clients also explore sources of strength, capacity, and personal power, which help them develop new coping and behavioral skills for caring for themselves and interacting with others. Finally, creating new support systems that support individual changes reinforces positive progress and also helps individuals think more globally about the implications of their experience for social change in general.

main variations of flooding and the theoretical basis for the intervention. Finally, a review of the effectiveness of this intervention with anxiety symptoms as well as a discussion of contraindications are provided.

GLOSSARY

- conditioned response** Response to conditioned stimulus; similar to response to unconditioned stimulus.
- conditioned stimulus** Stimulus that elicits similar response as unconditioned stimulus after repeated pairings.
- exposure** General term for many therapeutic techniques in which clients are presented with feared stimuli or situations in order to reduce anxiety symptoms.
- neutral stimulus** Stimulus that produces no response prior to repeated pairings with unconditioned stimulus; becomes conditioned stimulus.
- operant conditioning** Type of learning; responses that are reinforced will be repeated, whereas responses that are punished will not be repeated.
- respondent conditioning** Type of learning; repeated pairing of unconditioned and neutral stimuli will result in neutral stimulus becoming conditioned stimulus and eliciting conditioned response.
- unconditioned stimulus** Stimulus that elicits response without training.

Flooding is an intervention developed for the treatment of anxiety symptoms. This article will discuss the

I. DESCRIPTION

Due to the many variations of flooding, it is difficult to provide a concise and universal definition of the technique. Traditionally, flooding has been defined as a technique that involves prolonged exposure to feared stimuli or situations at full intensity, in an attempt to extinguish anxious responses. In other words, from the beginning of treatment, the client is exposed to stimuli that evoke maximal anxiety. In addition, the client is exposed to these stimuli for prolonged periods of time, until anxiety has begun to dissipate. Flooding typically is conducted *in vivo*, with live presentation of anxiety-provoking stimuli. The duration of each session varies depending on the client's presentation, with a typical session lasting anywhere from 90 to 180 minutes. The length of the session is not predetermined but instead is dictated by the client's level of anxiety. In addition, the number of sessions is not fixed but instead is based on the client's anxiety level. Research suggests that significant symptom reduction generally occurs following 10 to 15 hours of exposure. Throughout the flooding procedure, anxiety symptoms should be consistently monitored via physiological assessment or client subjective

ratings of distress. Sessions typically are spaced close in time (e.g., daily or several times per week) rather than scheduled at weekly intervals.

This general definition of flooding belies the many variations of the technique that have been reported in the literature. Overall, many central features, including the method and intensity of stimuli presentation, as well as the use of response prevention techniques, may vary while still being considered flooding. Rather than consider flooding one technique, it may more properly be considered a collection of techniques that are designed to expose clients to anxiety-inducing stimuli with the purpose of reducing anxious responses. A description of the variations of flooding is required to fully understand this collection of techniques.

A. *In Vivo* versus Imaginal Flooding

Clients may be exposed to actual feared stimuli (*in vivo* flooding) or may be asked to picture feared stimuli (imaginal flooding). Deciding which procedure to employ requires clinicians to consider practical matters as well as prior research. Overall, studies have found that *in vivo* exposure is superior to imaginal exposure in reducing anxiety symptoms. In particular, for simple phobias, anxiety reduction is clearly enhanced with *in vivo* exposure. However, *in vivo* stimuli presentation has been found only marginally superior to imaginal exposure for obsessive-compulsive symptoms.

Logistically, setting up *in vivo* exposure situations may be difficult when the fear involves remote or unpredictable stimuli (e.g., fear of earthquakes). Further, it may be impossible to arrange *in vivo* exposure to existential fears (e.g., fear of dying). Finally, due to the anxiety-inducing nature of treatment, clients may be more reluctant to engage in live exposure situations, at least initially. However, imaginal exposure also has its difficulties. First, not all clients are capable of evoking anxiety-inducing images in sufficient detail or for sufficient periods of time, which may necessitate time-consuming imagery training. Second, clinicians never will be able to fully ensure treatment adherence with imaginal exposure, as such procedures are assessed only via self-report. In other words, it is impossible for clinicians to accurately assess the clarity and duration of imagery, as well as whether the client is avoiding focusing on the anxiety-invoking image.

B. Graduated versus Intensive Stimuli Presentation

Clients may be exposed to stimuli in a graduated fashion, beginning with a stimulus that induces little

anxiety, or in an intensive fashion, beginning with a stimulus that is maximally anxiety-provoking. The decision on which format to follow should be based on prior research and practical concerns. Research has demonstrated that either format is effective in reducing overall anxiety symptoms, both immediately following treatment and after a short interval. However, one study found that intensive exposure appears more effective in the long run: 5 years posttreatment, 76% of the intensive exposure group and 35% of the graduated exposure group remained free of anxiety symptoms for the treated stimulus. Surprisingly, in comparison to reports from the intensive exposure group, clients who received graduated exposure reported that the procedure was more distressing overall.

Despite research supporting effectiveness of the intensive approach, a decision to utilize this format must be tempered by the acceptability of the approach to clients. Studies have found that the graduated approach produces fewer clients leaving treatment prematurely. The intensive approach, due to its high anxiety-provoking format, may be intimidating to clients, at least initially.

C. Response Prevention versus Exposure Alone

Typically, flooding involves both exposure to a feared stimulus and a response prevention component. In other words, once exposed to the stimulus, clients are prevented from responding with escape or avoidance behaviors. It was believed that allowing clients to avoid focusing on the anxiety or to escape the flooding situation prior to anxiety reduction would only increase anxiety symptoms. Prevention of escape or avoidance behaviors was once considered the hallmark of flooding procedures. However, more recent research has suggested that exposure alone may be as effective as exposure with response prevention.

Studies on the role of avoidance behaviors have examined the use of distraction techniques (e.g., playing video games, spelling tasks) or medications (e.g., anxiolytics) during flooding procedures. Cognitive distraction techniques allow clients to avoid focusing on their feelings of anxiety. Anxiolytics, which are designed to reduce anxiety symptoms, may prevent anxiety induction and allow clients to avoid focusing on feelings of anxiety during flooding. Research has found that distraction provides more rapid decrease in both subjective reports of anxiety and in avoidance responses immediately following treatment and at short-term follow-up. In addition, research has found that concurrent use of anxiolytic medications and flooding was effective in reducing

subjective reports of anxiety symptoms, particularly early in treatment.

Studies on the role of escape behavior have found that flooding is effective in reducing overall levels of anxiety even if clients are allowed to terminate flooding sessions when their anxiety reaches unduly high levels. In other words, research has found that keeping a client in the session until anxiety decreases (within-session reduction of anxiety) is not necessary for successful treatment outcomes. In addition, clients allowed to escape the anxiety-inducing situation reported more perceived control and less overall fear during the flooding session than clients who were told to remain in the situation.

Taken together, these studies suggest that long periods of unavoidable or inescapable anxiety are not essential for anxiety reduction. In addition, it appears that clients may find exposure alone without a response prevention component to be more acceptable and less distressing.

D. Summary of Variations

Given the many variations of flooding, clinicians must, in collaboration with clients, make difficult decisions as to which method to employ. Research has not provided a clear answer regarding which variation works best with which client. In general, *in vivo* flooding with intensive presentations of stimuli appears to be most effective with the majority of clients. Requiring clients to remain in high-anxiety situations for long periods of time, once considered the hallmark of flooding, no longer appears necessary.

Once a clinician and client agree on the preferred flooding method, many unanswered questions remain regarding the optimal presentation of the technique. Although most researchers agree that massed sessions are more effective than spaced sessions, optimal frequency of sessions has not been determined. In addition, debates are ongoing over the necessity of clinician-directed individual sessions. Research supports the idea that flooding is as effective with group sessions as it is with individual sessions. In addition, research has found that self-directed flooding may be as effective as therapist-directed flooding, albeit somewhat less rapid.

II. THEORETICAL BASES

To understand how flooding is believed to work, acquisition and maintenance of fear or anxiety first must be considered. Orval H. Mowrer developed a two-factor theory that incorporates both respondent and operant

conditioning principles. He posited that fear originally is learned through respondent conditioning but maintained through operant conditioning. A person learns to fear a previously neutral stimulus when it is paired over time with an aversive unconditioned stimulus. Once this conditioned stimulus elicits fear, the person will engage in escape or avoidance behavior in an attempt to reduce fear or anxiety. Successful reduction in fear or anxiety reinforces escape or avoidance behaviors, increasing the likelihood that they will be repeated in the future.

Based on the two-factor model, flooding is believed to work to reduce anxiety by the process of extinction. Extinction is defined as repeatedly presenting a conditioned stimulus without an unconditioned stimulus; over time, the conditioned response will diminish. During flooding, the person experiences no aversive event with the presentation of the feared stimulus. Repeated and continual presentation of the conditioned stimulus without the unconditioned stimulus results in extinction of the fear response over time.

Traditionally, theorists have touted the necessity for both within-session and between-session extinction for flooding to be effective. In other words, it was believed that successful flooding entailed diminishment of anxiety both within a single flooding session and across several sessions. As previously indicated, research has not consistently supported this belief, as some studies have found that within-session reduction of anxiety is not necessary for successful outcomes. However, it should be noted that the majority of studies support the view that the combination of within- and between-session extinction increases the likelihood of positive treatment outcomes.

Although extinction is the predominant theory regarding the mechanisms of flooding, Edna Foa and Michael Kozak offered an alternative view based on emotional processing theory. Briefly, this theory stated that anxiety-provoking stimuli reactivate a fear memory from some earlier trauma. During treatment, incompatible information is presented to the client, in that the client is exposed to feared stimuli without negative outcomes. This information is incorporated into the fear memory, so that a new memory is formed. In other words, Foa and Kozak posited that it is the processing and incorporation of corrective information that is the mechanism for reducing anxiety or fear during flooding, rather than simple extinction. Their model includes a cognitive component that is not discussed in the extinction literature.

One final issue should be noted regarding the theoretical bases of flooding. Flooding frequently has been confused with other anxiety-reduction techniques, such as

systematic desensitization and implosion. Although there is much procedural overlap among these techniques, there are some significant theoretical differences.

Systematic desensitization is a behavioral technique that involves short periods of exposure to feared stimuli, which are presented in a graduated or hierarchical fashion. As previously discussed, flooding may utilize either a graduated or intensive presentation of anxiety-inducing stimuli. Therefore, the major difference between flooding and systematic desensitization lies not in procedural differences but in the theoretical mechanisms believed to underlie the techniques' effectiveness. In systematic desensitization, clients are taught a competing response (i.e., progressive muscle relaxation), so that feelings of anxiety experienced while undergoing treatment may be minimized. Joseph Wolpe, the developer of systematic desensitization, advocated the theory of reciprocal inhibition, the idea that it is impossible for a person to feel both anxious and relaxed at the same time. He concluded that anxiety could be reduced by inducing a relaxed state and then slowly introducing anxiety-invoking stimuli; due to reciprocal inhibition, the relaxed state would inhibit the anxious responses. As previously discussed, flooding is presumed to operate due to extinction processes rather than reciprocal inhibition.

Implosion is a technique developed by Thomas Stampfl and Donald Levis, based on psychodynamic theory. In flooding, no attempt is made by the clinician to construct scenarios that elaborate or expand on the situations described by the client. Implosion, on the other hand, involves exploring clients' childhood memories and developing hypothesized cues based on repressed childhood trauma. Hypothesized cues may involve Oedipal situations, death wish impulses, and fears of castration, to name a few. Implosion imaginably exposes clients to horrific situations, including bodily injury, world annihilation, universal condemnation, and abandonment, in an attempt to induce maximal levels of anxiety. Psychodynamic theory underlying implosion requires use of hypothesized cues, whereas the behavioral theory behind flooding generally eschews these hypothesized cues for cues based on current symptom presentation.

III. EMPIRICAL SUPPORT

Flooding was introduced to the psychological literature via animal studies. In one early study, rats were conditioned to avoid electric shock in one half of a cage

by moving to the other side of the cage when a buzzer sounded. After conditioning, the buzzer was continually sounded while the rats were prevented from emitting the avoidance response by the presence of a barrier in the middle of the cage. After several long trials of continuous stimulus presentation along with response prevention, the rats no longer exhibited the avoidance response in the presence of the buzzer when the barrier was removed. Human studies quickly followed, including numerous case reports in which adult subjects were successfully treated via flooding for examination panic, snake phobia, and spider phobia.

Since that time, many studies have been done establishing the effectiveness of flooding for the treatment of anxiety symptoms. Flooding has been found effective in treating adults with the following anxiety disorders: obsessive-compulsive disorder, simple phobias, social phobia, agoraphobia, posttraumatic stress disorder, and panic disorder. For example, in a 1993 meta-analysis, George Clum, Gretchen Clum, and Rebecca Surls found that flooding was the treatment of choice for panic disorder, showing better results than other psychological techniques (such as systematic desensitization) or medications. In a 1995 review, Melinda Stanley and Samuel Turner concluded that flooding was the treatment of choice for obsessive-compulsive disorder, resulting in greater reduction of anxiety symptoms, decreased drop-out rates, and decreased relapse rates over time than other psychological techniques or pharmacological treatments. Across all anxiety disorders, flooding has been found to be effective in the 60 to 75% range. Longitudinal studies have reported that symptom improvement may last up to 9 years.

There have been few studies examining efficacy of flooding with children. Research that has been conducted has demonstrated that flooding is effective in treating childhood obsessive-compulsive disorder, posttraumatic stress disorder, specific phobias, and panic attacks. Results should be interpreted with caution, as prior research has focused solely on case studies. To date, no large-scale group study examining long-term outcome has been conducted with children.

Research has not supported a common belief among clinicians that flooding inevitably retraumatizes clients or further exacerbates problems. It is true that brief exacerbation of anxiety symptoms may occur throughout treatment as the client is exposed to feared stimuli or situations. Overall, however, studies have found that negative side effects of flooding are extremely rare. In one survey of practitioners, only 9 out of 3493 clients undergoing flooding techniques experienced any negative

effects. The complications that did occur were serious, however, and included exacerbation of vegetative depressive symptoms, increased suicidal ideation, relapse of alcoholism, and precipitation of panic disorder. It is likely that comorbidity with other Axis I disorders increases the risk of negative outcome of flooding. Therefore, flooding may not be the treatment of choice if, in addition to anxiety symptoms, the client is diagnosed with Major Depressive Disorder or Substance Abuse/Dependence. There are no known studies that have demonstrated an increased risk of physical problems due to flooding. However, it is possible that intense exposure to anxiety-inducing stimuli may aggravate medical conditions such as high blood pressure and asthma. Therefore, clinicians should require clients with physical ailments or on medications to obtain medical clearance prior to implementing flooding techniques.

IV. SUMMARY

Overall, flooding has been found effective in reducing anxiety symptoms with both children and adults. In addition, flooding techniques are relatively brief and results may be long lasting, making flooding an extremely cost-effective treatment. As previously reported, flooding has been found to be effective in the 60 to 75% range across all anxiety disorders.

Although flooding is the treatment of choice for many anxiety symptoms, it should not be the first treatment employed when anxiety is due to a skill deficit. In that case, the deficit should be remedied by skill-building techniques prior to assessing the need for anxiety-reducing therapies. Flooding may not be successful in cases where the client is in the process of seeking compensation for trauma (e.g., via a lawsuit, worker's compensation). In a case where compensation is dependent on continued demonstration of symptoms, the client may sabotage treatment efforts, making it unlikely that any therapy technique would be effective.

Despite positive research results, flooding may not be frequently employed by clinicians for two main reasons. First, there is a widely held belief that flooding results in negative side effects. Although rare, it is true that serious negative side effects have occurred during flooding, including the exacerbation of existing Axis I symptoms. To prevent this, clinicians should not employ flooding as a first-line treatment with clients with comorbid Major Depression or Substance Abuse/Dependence diagnoses.

In addition, clinicians should carefully monitor clients throughout treatment to assess for exacerbation of any comorbid symptoms.

A second reason that flooding may not be frequently employed is the belief that the technique is not acceptable to clients. To address client concerns, all reasonable treatment options as well as the research supporting each option should be presented to clients prior to implementing a treatment plan. The theoretical rationale for flooding should be clearly explained to clients, and clients should be warned that brief exacerbation of anxiety symptoms is to be expected. Clinicians should debunk myths about flooding and reassure clients that they will be allowed to leave the situation if needed. Not only is it unethical to prevent clients from withdrawing from treatment, research has not supported the idea that preventing escape or avoidance responses is necessary for successful outcomes. Finally, clinicians should fully inform clients about the many variations of flooding. It is likely that the options of imaginal and graduated presentations of stimuli would be more acceptable to clients, at least initially. When employed with informed and cooperative clients, flooding may be one of the most effective techniques a clinician has to treat anxiety symptoms.

I. DESCRIPTION

A psychotherapy formulation links descriptive diagnosis to treatment. It contains inferences representing the therapist's best explanation of the causes, triggers, and maintaining influences of a patient's problems. As the result of two trends, formulation has become more important in recent years. First, the predominance of brief psychotherapy has required therapists to determine a treatment focus early. Second, the current nosology of mental disorders is almost exclusively descriptive rather than etiological in nature, leaving a gap between diagnosis and treatment that formulation is meant to fill. A formulation is a "work in progress" that changes as it is tested and as more information about a patient is revealed. As an organizational tool, a formulation helps the therapist categorize information about a patient; in particular, it can bring disparate pieces of information into a coherent whole. The specific categories used will depend on the formulation approach of the therapist, but may include symptoms and problems; events that precipitate symptom or problem onset; concepts of self and others; maladaptive interpersonal behavior patterns; methods for controlling ideas and affect; strengths and resources, wishes and fears; biological or constitutional influences; environmental circumstances; and developmental factors.

A formulation is useful to the extent that it accurately guides the therapist's interventions and facilitates a favorable outcome. A well-developed formulation enables the therapist to maintain a focus in treatment, to

GLOSSARY

- central relationship pattern* Repeated and maladaptive ways of initiating and maintaining important interpersonal relationships, presumed to be based on early interpersonal experiences and innate dispositions.
- core beliefs* Organizing beliefs or schemas about the self, others, and the world that are presumed to precipitate and maintain psychological problems.
- functional analysis* Causal relationships among a patient's problematic behavior, goals, affects, and cognition.
- states of mind* Recurrent and distinct complexes of affect, cognition, experience, and behavioral propensities.

Case formulation is a core psychotherapy skill that posits hypotheses about the causes, precipitants, and maintaining influences of a person's psychological, interpersonal, and behavioral problems. A formulation helps organize information about a person. It serves as a blueprint guiding treatment, as a marker and predictor of change, and as a structure facilitating the therapist's understanding of and empathy for the patient's intrapsychic, interpersonal, cultural, and behavioral world.

construct language effectively, and to anticipate events in therapy so as to respond more effectively if those events occur. Therapy goals are embedded explicitly or implicitly in a formulation. Therefore, the formulation enables the patient and therapist to track progress and to identify and correct missteps. A key advantage of a formulation is that it helps the therapist to understand and therefore to empathize with a patient.

Ideally, a clinician should aspire to four goals when constructing a case formulation. First, the formulation should paint a distinct portrait of a unique individual; it should not describe a person or a patient in general. At the same time, it should remain consistent with current scientific knowledge about personality, psychopathology, development, and interpersonal relationships. Second, as a fundamentally practical tool, a formulation should be parsimonious and just comprehensive enough to explain the patient adequately for the purposes of the therapy. The formulation should not contain excessive or extraneous information or be so complicated that it fails as a practical guide to treatment. Utility is a key objective. Third, a formulation should strike the right balance between observation and inference. Low-level inferences are usually best for effective therapy. These are inferences that are tightly linked to readily observable behavior, but go beyond those observations to a construction of their meaning and consequences. Inferences that go “too deep” may lack sufficient empirical foundation and may not be meaningful or helpful to patients. A fourth characteristic of an ideal formulation is objectivity. A formulation should be about the patient and not the therapist. Psychologists have documented many biases in clinical judgment that therapists are prone to commit. For example, a therapist may assume that a patient is either too much like the therapist or too different. Psychoanalysts have long cautioned about the risk of therapists imposing their own psychological needs, characteristics, or problems on patients rather than seeing those patients more objectively.

A few practical details about case formulation may be helpful. First, a formulation should be written down, referred to during treatment, and revised when necessary; otherwise, the therapist is like a builder without the benefit of blueprints. Second, a case formulation should be constructed systematically early in therapy. Typically, a formulation can be constructed after the first one or two sessions, and certainly within the first five sessions. Research suggests that formulations constructed early in therapy predict topics discussed much later in long-term therapy. With practice, a formulation can be constructed within a matter of a

few minutes using notes and memories from early sessions. Efficient and high-quality work is facilitated by having an *a priori* set of formulation categories or “bins” in mind that one “fills in” based on information provided by the patient and others. The formulation systems described later in this article provide examples. Research has shown that a formulation is more likely to be reliable and accurate when the therapist is guided by a structured and systematic formulation method.

Some therapists avoid formulations for fear that they may limit the therapist’s openness to new experiences of the patient, may lead to a rigid view of the patient, or may place the therapist in an unsalutary dominant, powerful role. On the contrary, a well-constructed and well-implemented formulation should facilitate openness to the patient, and should help the therapist develop and communicate empathic understanding in the context of a collaborative, mutually respectful relationship. As an expert in interpersonal communication and psychological problem solving, the psychotherapist should avail himself or herself of the “tools of the trade” to facilitate the work.

Therapists sometimes wonder whether and how a formulation should be shared with patients. In a sense, the entire therapy can be viewed as the construction, revision, and imparting of the formulation. Yet the question remains as to how explicitly the written formulation should be shared in a single session or intervention. Opinions are divided on this question. Some, such as Anthony Ryle who developed cognitive analytic therapy, recommend that the entire formulation be shared with the patient and serve as an explicit center point guiding the therapy. Others believe that sharing the entire formulation in one intervention is unwise because it may overwhelm a patient, may be too much to assimilate at once, may be used by the patient in nontherapeutic ways, or may be less therapeutic than letting the patient arrive at the formulation on his or her own terms. Instead, these practitioners advise that the therapist select portions of the formulation and offer them in succinct interventions that are timed to match the current topic under discussion and the emotional state of the patient. Whichever approach one chooses, the intervention should enhance the therapeutic alliance rather than detract from it. Further, one should not offer the entire formulation until one is reasonably confident of its accuracy.

II. HISTORY AND INFLUENCES

The modern psychotherapy case formulation can be traced to the medical examination and case history,

which are rooted in Hippocratic and Galenic medicine. Hippocratic physicians emphasized viewing the individual as a whole in arriving at a diagnosis, and encouraged the patient's active involvement in his or her cure. In contrast to their forebearers' beliefs in polytheism and mythological causes of disease, they based conclusions on observation, reason, and the belief that only natural forces are at play in disease. Hippocratic case reports provided many observable details about physical functioning, then drew inferences from these observations before prescribing treatment. Galen's contribution to modern medicine was his emphasis on experimentation and a focus on physical structure and function as the foundation of disease.

Consistent with the tradition of Hippocrates and Galen, psychotherapy case formulations depend on close observation as a basis for inference. In accord with the holistic ethos of Hippocrates, a formulation should consider the patient from multiple dimensions, including the biological, psychological, and social. Also consistent with the Hippocratic view, psychotherapists view active patient involvement in treatment as essential for success. Galenic influences are seen in inferences about psychological structure, including concepts such as the id, ego, and superego, and more cognitive concepts such as self-representations, faulty reasoning processes, and maladaptive core beliefs about the self, others, and the world.

The content of a case formulation is influenced by multiple factors. Chief among these is the therapist's world view, that is, the basic axiomatic tenets that guide the therapist's assumptions about people, the world, and the future. The therapist's world view, in turn, influences and is influenced by the therapist's opinions on the nature of psychopathology, and his or her approach to psychotherapy and how it works. A third influence is recent case formulation research. It is to these three influences that I now turn.

A. Nature of Psychopathology

What the therapist defines as adaptive or maladaptive behavior will affect how problems are defined and conceptualized in a case formulation. Views of psychopathology fall into two general classes: categorical and dimensional. Those favoring the categorical view believe that mental disorders are syndromal and are qualitatively distinct from each other and from nonpsychopathological states. The dimensionalist view is that psychopathology lies along a set of continua from normal to abnormal. The difference between normal and abnormal behavior is viewed as one of degree rather than of quality.

The therapist's stance on the categorical–dimensional debate can affect the formulation in a number of ways. First, it may affect the terminology appearing in the formulation. Dimensionalists tend to think in terms of a relatively small set of dimensions, such as the five-factor model of personality. The categoricalists use a broader range of terms, including those in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)*, which is categorical in nature. On the other hand, categoricalists may be more prone to stigmatize patients by reifying what is actually a theoretical construct. For example, being told one “has” a personality disorder may inadvertently damage self-esteem and confirm pathogenic beliefs rather than be therapeutic. Finally, some argue that the categorical approach is easier to use than the dimensional approach because many clinical decisions are categorical in nature (e.g., treat or not, use intervention A or B). Ease of use is an important consideration because a case formulation must often be developed quickly.

A therapist's criteria for defining normality are also central to the task of case formulation. Common criteria include personal distress, behavior that causes distress in others, capacity to adapt to stress, deviation from an ideal of normality, personality inflexibility, and irrationality. These criteria provide a context and reference point for understanding patients and for setting therapy goals.

B. The Therapist's Approach to Psychotherapy and How It Works

One's approach to psychotherapy provides a framework for conceptualizing patients. Psychoanalysis has had a pervasive effect on views of personality and psychopathology, as well as on our understanding of the psychiatric interview. Before Freud, the psychiatric interview was viewed simply as an opportunity for the patient to report his or her symptoms. Now, we recognize the interview as a vehicle through which the patient's problems express themselves; that is, interpersonal problems outside of therapy may be enacted within the therapy.

Like psychoanalysis, cognitive therapy has provided a lexicon for case formulation, and sets of standardized formulations of psychopathology, particularly for depression, anxiety, substance abuse, and personality disorders. These formulations emphasize cognitive patterns, schemas, faulty reasoning processes, and core beliefs, each specific to particular disorders.

Behavior therapy has typically not emphasized diagnosis or formulation, but nevertheless has affected the case formulation process through its emphasis on

symptoms, a skepticism toward mental representations, and a focus on empiricism. Behaviorists strive to understand the topography of symptomatology, including stimulus-response connections, behavioral chains, and contingencies of reinforcement. Behaviorists have also focused on the role that environmental conditions play in maladaptive behavior. Consequently, behavioral formulations include analyses of the environment and how it might be changed to help an individual.

Phenomenological and humanistic psychotherapies have also influenced the case formulation process. Like behavior therapy, they traditionally have rejected case formulation, although on grounds that it can position the therapist in a superior, more knowing relation to the patient and foster an unhealthy dependency. The contributions of humanistic thought to case formulation are an emphasis on the person instead of a disorder, a focus on the here-and-now experiencing of the therapist and patient, and the view of the patient and therapist as equals, both focused on enabling the patient to achieve greater self-awareness and congruence within the self. Humanistic psychology's holistic approach to the person, following from the Hippocratic tradition mentioned earlier, is also an influence.

C. Case Formulation Research

A final influence on the case formulation process is that it has come under much greater scientific scrutiny in the last several decades. The key questions asked are the following: Can case formulations be constructed reliably and validly? To what extent do formulation-based interventions predict psychotherapy outcome and processes? What does the formulation add to outcome? Can a formulation be used to understand psychopathological states?

In 1966 Philip F. Seitz, a Chicago psychoanalyst, reported a 3-year effort to study the extent to which analysts agree in formulating the same clinical material. Each of six analysts independently reviewed either detailed process notes or a set of dreams from a single case. Each analyst wrote an essay-style narrative addressing the precipitating situation, focal conflict, and defense mechanisms at play in the case. The group distributed the formulations, giving each member the opportunity to revise his work based on the formulation of others, then met weekly to review their findings. The results were largely disappointing in that consensus was reached on relatively few cases.

The primary contribution of Seitz and his colleagues' work is that it has alerted the community of psy-

chotherapy researchers to the "consensus problem." If psychotherapy research aspired to be a scientific enterprise, progress had to be made in the consistency with which clinicians describe a patient's problems and way of managing them. Another contribution of Seitz was his delineation of why the clinicians failed to agree. One key problem was that group members made inferences at overly deep levels that seemed to stray too far from the clinical material, for example, making references to "phallic-Oedipal rivalry" and "castration fears." Seitz also noted that the group relied too much on intuitive impressions and did not systematically and critically check their interpretations.

Seitz's paper achieved its stated goal and sparked research efforts to improve methods of case formulation. In the following decades, at least 15 formal methods for constructing case formulations were developed and empirically tested. Most of these methods share several characteristics: They focus on relationship interactions expressed in psychotherapy sessions; they identify core relationship conflicts based on the frequency with which patterns are conveyed in therapy; they rely on clinical judgment rather than rating scales; they include provisions for testing the reliability and validity of the method; they emphasize relatively low-level inferences; the formulation task is broken down into components; and they reveal a trend toward psychotherapy integration. The following section describes some of these methods.

III. STRUCTURED FORMULATION METHODS

A. Core Conflictual Relationship Theme

The first of the structured formulation methods, the Core Conflictual Relationship Theme (CCRT), was introduced by Lester Luborsky in 1976. The CCRT is based on Freud's concept of transference, which states that innate characteristics and early interpersonal experiences predispose a person to initiate and conduct close relationships in particular ways and in repeated fashion later in life. The goal of the CCRT is to reliably and accurately identify a patient's central relationship pattern. The CCRT focuses on narratives a patient tells in therapy, identifying three key components within those narratives: an individual's wishes, expected responses of others, and responses of the self. The CCRT is applicable in everyday clinical use as well as in research. In day-to-day clinical use, therapists may note the relationship

components as they arise in therapy, then infer a CCRT later. In the research context, trained judges first extract relationship episodes from therapy transcripts; a second set of judges then identifies each of the three key relationship components just mentioned. The CCRT is operationally defined as the most frequently observed wish, response of other, and response of self, regardless of whether these components occur sequentially in the separate narratives. Based on a mixed group of patients in multiple studies, the most frequent CCRT is a wish to be close and accepting, a response from others of rejection and opposition, and a response of the self marked by disappointment, depression, and anger. Due to its complexity, Luborsky does not recommend that therapists offer patients the entire CCRT in a single intervention, but rather select portions that are most likely to be accepted by patients in the current context of the therapy. He also recommends that therapists link the CCRT to symptoms; focus primarily on wishes and responses from others because these are the most reliably identified components; and focus on negative components of the CCRT but in a manner that enhances the therapeutic alliance.

The CCRT is the most frequently researched of the structured case formulation methods. Luborsky and his colleagues found adequate to good reliability in identifying the three components, but particularly the wish of self and response of other. Other CCRT-related research findings are that about four narratives are typically told in a therapy session; interventions based on a patient's CCRT predict psychotherapy outcome; gaining mastery of the CCRT is associated with successful outcome in therapy; CCRTs derived from dreams are similar to those derived from waking life; narratives told outside of a session are similar to those told in sessions; CCRTs show consistency across the life span and across the course of psychotherapy, although successful treatment is correlated with a decrease in the pervasiveness of the CCRT (i.e., the extent to which it characterizes multiple relationships); greater pervasiveness of the CCRT is associated with greater psychopathology; and symptom onset seems closely related to central interpersonal conflicts of patients as measured by the CCRT.

B. Configurational Analysis

Configurational Analysis (CA), developed by Mardi J. Horowitz, is similar to the CCRT in its focus on identifying a central relationship pattern, but adds important elements. These are inferences about a patient's states of mind; the assumption of multiple rather than single relationship patterns; and defensive control processes.

States of mind are recurrent and distinct complexes of affect, cognition, experience, and behavioral propensities. They can be described in simple adjectival terms, such as "depressed and helpless" or "angry and bitter"; in motivational terms (a wished-for or feared state); or according to the degree of affect modulation characterizing the state. According to Horowitz, states of mind are organized by mental representations that guide interpersonal relationships and concepts about the self and others. These representations can be depicted in configurations of role relationship models that describe wished-for, "dreaded," and either adaptive or maladaptive compromise relationship patterns, views of self and others, and states of mind. CA also includes a system for formulating an individual's defensive control processes, which are habitual ways of controlling ideas and affect so as to maintain a well-modulated state of mind.

The formulation steps in CA move from description to increasing degrees of inference. They are to (1) describe clinically relevant phenomena; (2) identify the patient's repertoire of states of mind; (3) identify self, other, and relationship schemas; and (4) identify defensive control processes. Finally, the therapist plans goals and interventions specific to each of these categories.

Research on CA has shown a similar level of reliability as that shown by the CCRT, although the studies are fewer as are subjects per study. Convergent validity for CA as well as for CCRT is suggested by the high level of similarity between formulations independently constructed with each system. Horowitz and colleagues have also provided evidence that states of mind can be reliably coded. In a series of quantitative single-case studies of individuals responding to psychosocial trauma, Horowitz and colleagues found evidence of recurring emotionally significant states; showed that state shifts are related to whether or not a patient is discussing a conflict-laden topic; and showed that increased signs of defensive control processes occur when conflictual or unresolved themes are being discussed in therapy. A series of single-case studies have also shown convergences between clinically derived case formulations and quantitatively derived formulations.

C. Plan Formulation Method

The Plan Formulation Method (PFM), developed by John Curtis and George Silberschatz, follows earlier formulation work by Joseph Caston and is based on Joseph Weiss's control mastery theory of psychotherapy. Control mastery theory assumes that psychopathology results from pathogenic beliefs stemming from traumatic

events that are usually experienced in childhood. Weiss believes that patients develop an unconscious plan to disconfirm these beliefs. The plan may involve testing the therapist through behavioral or verbal challenges or expressions of anger. The therapist must understand the purpose of these events in order to best help the patient.

The goal of PFM is to identify, categorize, and test the key elements of control mastery theory. Five components comprise a plan formulation: the patient's goals for therapy; the obstructions (pathogenic beliefs) that may interfere with achieving the goals; the traumas that produced the pathogenic beliefs; insights necessary to help the patient achieve the goals; and tests the therapist might expect from the patient as the patient attempts to disconfirm a set of pathogenic beliefs. For regular clinical use, these components can be inferred from the early sessions of psychotherapy. For research purposes, coders follow a five-step process. First, three or four judges who are versed in control mastery theory review transcripts from early psychotherapy hours and create a list of "real" and plausible "alternative" items for each formulation component. Second, a master list of goals, obstructions, traumas, insights, and tests is compiled and randomly ordered within each component. Third, the judges review the master list and rank order each item according to its relevance to the patient. Fourth, mean ratings are obtained and rank ordered; those items ranking below the median are discarded. Fifth, the group meets and consensually finalizes the most relevant items for each formulation category. The final formulation contains a description of the patient and his or her current life circumstances followed by the patient's presenting symptoms and problems. Then, the goals, obstructions, tests, insights, and traumas are listed.

The reliability of the PFM is excellent, although adherence among the clinical judges to an explicit conception of psychotherapy appears essential. One interesting study showed that two independent research teams, one working from the control master perspective and the other working from an object relations standpoint, independently developed highly reliable plan formulations, but the two formulations correlated poorly with each other. Several studies have been published showing that the degree of therapist's adherence to the plan formulation predicts patient progress and outcome in psychotherapy. Patients appear to deepen their level of experiencing subsequent to plan-compatible interventions as compared to plan-incompatible interventions. Other studies show that achieving goals and insights, as listed in the formulation, correlates with standard psychotherapy outcome measures.

D. Other Primarily Dynamic or Integrative Methods

The CCRT, CA, and PFM are representatives of psychodynamic-based structured formulation methods. Another in this class is Thomas Schacht and colleagues' Cyclical Maladaptive Patterns (CMP) approach, which helps organize interpersonal information about a patient. This method has four major components: acts of self, expectancies of others' responses, acts of others toward the self, and acts of the self toward the self. Recently, the CMP has been integrated with Lorna Benjamin's Structural Analysis of Social Behavior, a system for organizing interpersonal behaviors.

Another dynamic formulation method is J. Christopher Perry's Idiographic Conflict Formulation Method, which draws from Erik Erikson's psychosocial model of development. It places a particular emphasis on a patient's defensive structure. In addition, Anthony Ryle has developed a formulation method based on his cognitive analytic therapy, which integrates dynamic and cognitive therapy. Franz Caspar's Plan Analysis is atheoretical in nature and can be applied to behavioral, dynamic, cognitive, or other forms of psychotherapy. Case formulation methods have also been developed for cognitive-behavioral therapy and behavior therapy. Two examples are now described.

E. Cognitive-Behavioral Case Formulation

Jacqueline Persons is one of several cognitive-behavioral (CB) therapists who have developed case formulation methods, but hers may be the best known. The method draws extensively from Aaron Beck's cognitive therapy, which holds that psychological symptoms and problems result from the activation of maladaptive core beliefs under conditions of stressful life events. The CB case formulation approach also draws from behavior therapy, which emphasizes measurement to track change and the identification of causal, functional relationships among behaviors that lead to problematic behaviors. According to Persons, a CB formulation must contribute to treatment outcome for it to be valuable.

Persons identifies seven steps in CB case formulation. First, the therapist compiles a problem list. She recommends 5 to 10 items that should include psychological symptoms, problems in adaptation, and other problems in living. Second, the formulation should include hypotheses about the patient's core beliefs about the self, others, and the world. These beliefs are assumed to

maintain the patient's problems. Third, the formulation includes precipitants and activating situations that trigger a maladaptive core belief. Next, the therapist formulates a working hypothesis. It is the heart of the formulation and links the preceding components. Step five of the CB formulation states the origins of the maladaptive core beliefs. This section could include two or three key incidents in the individual's past. Step six states a treatment plan. Finally, the CB case formulation includes predicted obstacles to treatment. These may include statements regarding how the patient's core beliefs may undermine the therapy.

Persons has reported data showing average to good levels of agreement among clinicians independently constructing CBT-based formulations. The utility of CBT formulations has been preliminarily assessed by exploring the contribution that individualized formulations have on treatment outcome. Early evidence is equivocal. A study by Persons found that a group of depressed patients treated by her with individualized CBT guided by a CBT case formulation had similar outcomes to patients treated in a much larger study in which similar patients were treated with a standardized CBT protocol. Persons noted, however, that many of her patients had comorbid diagnoses that would have ruled them out for the comparative study.

F. Behavioral Case Formulation

As noted, behavior therapists emphasize a detailed analysis and evaluation of behavior. They use the term "functional analysis" to describe the clinician's assessment of causal relationships among a patient's problematic behavior, goals, affect, and cognition. Although the emphasis is on readily observable behavior including how the environment affects behavior, many behavior therapists also attend to an individual's thoughts and affect, considering these to be important mediating variables leading to behavior problems or solutions. Behavior therapists distinguish between ultimate outcomes and instrumental outcomes. The former reflect global, multidimensional, end-point solutions, such as resolution of a depressive episode. The latter refers to sets of tools that can facilitate achieving the ultimate outcome. For example, a depressive episode may be resolved through increasing social contacts, improving social skills so as to increase social reinforcements, exercise, changing self-beliefs, or decreasing negative automatic thoughts.

Many behaviorists view their work fundamentally as a problem-solving endeavor, and the role of the case formulation is to delineate problems, then generate, imple-

ment, and evaluate solutions. Arthur Nezu and colleagues have articulated a four-step case formulation process centering on a problem-solving approach. Step one is to identify the problem. Nezu advocates a comprehensive, systematic approach in order to reduce clinical judgment error. Problems may occur either within the individual or the environment. Within the person, problems may occur in the behavioral, cognitive, affective, or biological realms. Problem behaviors reflect deficits (e.g., lack of social skills) or excesses (e.g., obsessive-compulsivity). Problematic cognition may reflect deficiencies (e.g., failure to appreciate the responses of others to one's actions) or distortions (e.g., arbitrarily inferring lack of self-worth based on a single mistake). Environmentally, problems may be identified in the physical realm (e.g., housing, financial) or social realm (e.g., dangerous neighborhood, nature of social support). A behavior therapist may also view problems from a temporal standpoint (present to past) and with regard to the source of information (factual and well-substantiated versus the perceptions and assessments of a patient). Step two is to generate solution alternatives. Here, the clinician may encourage brainstorming for solutions. This involves producing numerous possible solutions and suspending judgment as to their quality until after the list is completed. Step three is to plan treatment. The key question the clinician tries to answer is, "What treatment strategies and tactics will best implement the solution alternatives selected in step two?" The clinician must determine how amenable the target problem is to treatment; whether the therapist is capable of providing the treatment and if not, whether the treatment is available elsewhere; and whether reaching the selected instrumental objective to solve a target problem will achieve the ultimate objective. Step four is solution implementation and verification. This step involves putting the planned solution into effect, assessing the consequences of the plan, and evaluating its effectiveness.

To date, no studies have been published showing the reliability of the method just described or similar methods, although they have been called for. Some behaviorists assert that a hypothesis-testing approach in which early interventions and their outcomes are assessed, and altered as needed, is more important than initial agreement.

IV. SUMMARY

Formulation is a basic psychotherapy skill that involves generating and testing hypotheses about the

causes of and factors perpetuating a patient's problems. The formulation guides treatment and is revised as necessary. Several reliable, structured methods of case formulation have been developed and empirically tested.

each behavior in the chain, there is a discriminative stimulus and a response. Also called a behavioral chain or a chain of behaviors.

GLOSSARY

- conditioned reinforcer** A previously neutral stimulus that becomes a reinforcer after it is paired a number of times with an established reinforcer.
- continuous reinforcement** A schedule of reinforcement in which the reinforcer is delivered after every response.
- discriminative stimulus** A stimulus that is present when a particular response is followed by a reinforcer.
- fading** Gradual removal of a prompt as the behavior occurs in the presence of the discriminative stimulus.
- intermittent reinforcement** A schedule of reinforcement in which the reinforcer is not delivered after every response.
- prompt** A stimulus delivered by the trainer following the discriminative stimulus that increases the likelihood that a person will engage in the correct behavior in the presence of the discriminative stimulus.
- reinforcer** A stimulus that increases the future probability of a behavior when it is delivered contingent on the occurrence of the behavior.
- response** One instance of a particular behavior.
- stimulus control** A behavior is under the stimulus control of a particular discriminative stimulus when it occurs in the presence of that discriminative stimulus.
- stimulus-response chain** A behavior that consists of two or more component behaviors that occur in sequence. For

I. DESCRIPTION OF TREATMENT

Forward chaining is a procedure that is used to teach a chain of behaviors (a stimulus-response chain). In forward chaining, you first conduct a task analysis to identify each component of the stimulus-response chain. Then you use prompting and fading to teach the first component of the chain. Once the learner can engage in the first component behavior without prompts, you teach the second component behavior in conjunction with the first component. Once the learner can engage in the first two components of the chain of behaviors without prompts, you teach the third component in conjunction with the first two components. This process continues until the learner can engage in the entire chain of behaviors at the appropriate time without prompts.

Forward chaining, similar to backward chaining, is used with beginning learners (young children) or learners with limited repertoires (for example, individuals with mental retardation). Forward chaining is used when more efficient training strategies, such as instructions or modeling, cannot be used with learners with limited intellectual abilities.

A common example of forward chaining involves teaching a young child to recite the alphabet. A parent typically divides the alphabet into four strings of letters

and uses verbal prompts to teach the child to recite the first string of letters (ABCDEFGH). The child recites the string of letters after the parent's prompt, and the parent provides praise. Once the child can recite this first string of letters without help, the parent adds the second string of letters (HIJKLMN), and the child repeats the first two strings together with praise from the parent. When the child can recite the first two strings of letters without help, the parent adds the third string of letters (OPQRSTU) and the child repeats the first three strings together with praise from the parent. Finally, when the child can recite the first three strings of letters without any help, the parent adds the fourth string (VWXYZ), and the child recites the entire alphabet with praise from the parent. In this case, each of the four strings of letters is a response and the four responses are chained together until the child recites the whole alphabet.

The process of conducting forward chaining is described next.

A. Conduct a Task Analysis

Because each component behavior in a behavioral chain is taught in sequence, the first step in conducting forward chaining is to conduct a task analysis to identify each component behavior. A task analysis identifies each discriminative stimulus (S^D) and response (R) in the chain of behavior from start to finish. Consider the following task analysis of a four-component behavioral chain in which a person with mental retardation stuffs brochures into envelopes as part of her job in a sheltered workshop. In this chain of behaviors, the person (1) first picks up a brochure from a pile of brochures on the table, (2) then picks up an envelope from a pile of envelopes on the table, (3) then stuffs the brochure in the envelope, and finally, (4) puts the envelope containing the brochure into a bin. In a task analysis, each of the stimulus and response components would be identified as follows.

S^D_1 : Pile of envelopes, pile of brochures, and a bin on the table in front of the learner

R₁: Pick up a brochure

S^D_2 : Brochure in hand and pile of envelopes and bin on the table

R₂: Pick up envelope

S^D_3 : Brochure in one hand, envelope in the other hand, and bin on the table

R₃: Insert brochure into the envelope

S^D_4 : Envelope containing a brochure in hand and bin on the table

R₄: Put the envelope containing the brochure into the bin

As can be seen in this task analysis of a stimulus-response chain, the chain of behaviors is initiated when the first S^D (S^D_1) is present, and each response in the chain creates the S^D for the next response in the chain. For example, the first response (R₁-pick up envelope) creates the second S^D (S^D_2 -envelope in hand), the second response (pick up envelope) creates the third S^D (envelope in hand), and so on. The learner cannot engage in each subsequent response until the previous response has occurred and created the S^D for the subsequent response.

A task analysis can be conducted in three different ways. First, you can observe a competent person engaging in the chain of behaviors and write down the sequence of stimulus-response components. Second, you can ask an expert who performs the behavior competently to identify all of the stimulus-response components. Finally, you can engage in the behavior yourself and write down all of the stimulus-response components.

Once you have conducted the task analysis, you can then conduct the forward chaining procedure.

B. Conduct Forward Chaining

To begin forward chaining, you present the first S^D , prompt the first response, and provide a reinforcer such as praise. You then fade the prompts over trials until the learner can engage in the first response without any prompts when the first S^D is present.

From the previous example, you have the learner sit at a table containing a pile of envelopes, a pile of brochures, and a bin (the first S^D), prompt the learner to pick up a brochure (first response), and provide praise (a reinforcer). The prompt might involve physically guiding the learner's hand to pick up the brochure (physical prompt), showing the learner how to pick up the brochure (modeling prompt), pointing to a brochure on the pile of brochures (gestural prompt), or telling the learner to pick up a brochure (verbal prompt). You repeat the trial a number of times and gradually remove the prompt (fade the prompt) until the learner engages in the first response in the presence of the first S^D without prompting.

S^D_1 ----> R₁----> praise

After the learner consistently engages in the first response when the first S^D is present, you add the second component of the chain. To do this, you present the first S^D and the client will engage in the first response (because the first response is under the stimulus control of the first S^D). The first response creates the second S^D . At

this time, you then prompt the second response and provide a reinforcer. In this way, the learner is engaging in the first two component responses in sequence; the first is unprompted because it was previously learned, and the second is prompted after the first response creates the S^D for the second response. Over trials, you fade the prompts until the learner is engaging in the first and second responses in the chain without any prompts.

From this example, you have the learner sit at a table with a pile of brochures, a pile of envelopes, and a bin (first S^D) and the learner will pick up a brochure (first response). Once the brochure is in hand (second S^D), you prompt the learner to pick up the envelope (second response) and provide praise (a reinforcer). Over trials you will fade the prompts until the learner can engage in the first two components of the chain without any prompts.

$$\begin{array}{l} S^D_1 \text{----} \rightarrow R_1 \\ S^D_2 \text{----} \rightarrow R_2 \text{----} \rightarrow \text{praise} \end{array}$$

At this point, you use prompting and fading to teach the third component of the chain. To teach the third component of the chain you present the first S^D (every trial starts with the presentation of the first S^D), and the client will engage in the first two responses in the chain without prompts. The second response creates the third S^D . Following the second response, you prompt the third response and provide praise. Over trials, fade the prompts for the third response until the learner makes the first three responses in the chain without any prompts.

From this example, have the learner sit at the table with the pile of brochures, envelopes, and a bin (first S^D). The learner will then pick up a brochure (first response) and pick up an envelope (second response) without any prompts. Once the learner has engaged in the first two responses and has a brochure and envelope in hand (third S^D), prompt the learner to insert the brochure into the envelope (third response) and provide praise. Fade the prompts over trials until the learner is engaging in the first three responses without any prompting.

$$\begin{array}{l} S^D_1 \text{----} \rightarrow R_1 \\ S^D_2 \text{----} \rightarrow R_2 \\ S^D_3 \text{----} \rightarrow R_3 \text{----} \rightarrow \text{praise} \end{array}$$

Now the first three components of the chain have been learned and it is time to teach the last component of the chain. To teach the fourth response in the chain, have the learner sit at the table with the piles of brochures and envelopes and a bin (first S^D) and the learner will engage in the first three responses without

any prompts. The third response creates the fourth S^D . After the third response, prompt the learner to engage in the fourth response and provide praise. Over trials fade the prompts until the learner is engaging in all four responses without any prompts.

From this example, have the learner sit at the table with the piles of brochures, envelopes, and the bin (first S^D) and the learner will pick up a brochure, pick up an envelope, and insert the brochure in the envelope (first three responses). When the envelope containing the brochure is in the learner's hand (fourth S^D), prompt the learner to put it into the bin (fourth response) and provide praise. Over trials, gradually withdraw the prompts until the learner is engaging in all four responses without any prompts. The learner has now learned the entire chain of behaviors.

$$\begin{array}{l} S^D_1 \text{----} \rightarrow R_1 \\ S^D_2 \text{----} \rightarrow R_2 \\ S^D_3 \text{----} \rightarrow R_3 \\ S^D_4 \text{----} \rightarrow R_4 \text{----} \rightarrow \text{praise} \end{array}$$

Following forward chaining (or any other chaining procedure), the learner should engage in the complete chain of behaviors without any prompts when the first S^D is present. Although the learner can now engage in the chain of behaviors without assistance, it is important to continue providing a reinforcer, at least intermittently, following the completion of the chain of behaviors. During training, a continuous reinforcement schedule is used, and every response is followed by a reinforcer. Once the learner is engaging in the chain of behaviors without any prompts, the schedule of reinforcement can be thinned so that the behavior is maintained with intermittent reinforcement.

In the previous example, the learner gets praised for every correct response during training. Once the learner can complete the entire chain of behaviors without prompts, the trainer continues to provide praise every time the learner completes the chain of behaviors. After the learner successfully completes the chain of behaviors a number of times without any prompts, the trainer can start to use an intermittent reinforcement schedule and provide praise after the learner completes the chain every second time, then every third time, and so on until many responses are required for reinforcement.

II. THEORETICAL BASES

Forward chaining is based on the behavioral principles of stimulus control and conditioned reinforcement.

Stimulus control is present when a response occurs in the presence of an S^D . Stimulus control develops because the response has been reinforced in the presence of the S^D in the past. In forward chaining, you prompt the first response in the presence of the first S^D and reinforce the response. As a result, over a number of trials, the first response is then more likely to occur without prompting when the first S^D is present. The first S^D now has stimulus control over the first response. Next you prompt the second response in the presence of the second S^D and reinforce the response. Over a number of trials the second response will occur when the second S^D is present without any prompts. The second S^D now has stimulus control over the second response, and the first two responses in the chain will occur together. This process continues in forward chaining until each S^D develops stimulus control over each response in the chain of behaviors and all of the responses in the chain occur in sequence.

The second principle involved in forward chaining is conditioned reinforcement. In conditioned reinforcement, a neutral stimulus becomes a conditioned reinforcer when it is paired a number of times with an established reinforcer. In forward chaining, the S^D that is produced by each response becomes a conditioned reinforcer because each response is followed by the delivery of praise from the trainer. As a result, the outcome of each response in the chain (the S^D produced by each response) becomes a conditioned reinforcer and serves to maintain each of the individual responses in the chain of behaviors. This is particularly important in a long chain of behaviors where the reinforcer may occur a long time after the occurrence of the early responses in the chain. Conditioned reinforcement for each response in the chain is also important after the learner has learned the chain of behaviors and intermittent reinforcement is used to maintain the chain of behaviors.

III. EMPIRICAL STUDIES

Forward chaining is one of the three chaining procedures (along with backward chaining and total task presentation) described in major behavior modification textbooks, applied behavior analysis textbooks, and learning textbooks.

A number of studies have evaluated forward chaining procedures for teaching chains of behaviors to individuals with developmental disabilities. For example, Wilson and his colleagues in 1984 used forward chaining procedures to teach family-style dining skills to individuals with profound mental retardation living in an

institution. The authors first conducted a task analysis of the chain of behaviors involved in family-style dining. The components of the chain of behaviors involved in family style dining included the following:

1. Hold bowl with both hands
2. Place bowl within 1 in, from plate
3. Grasp serving spoon
4. Grasp bowl with one hand without hand in food while spoon is in bowl
5. Serve food to plate
6. Replace spoon
7. Grasp bowl with both hands
8. Pick up bowl
9. Place in neighbor's hand or place within 6 in. of neighbor's plate.

After developing the task analysis of the behavioral chain, the authors used forward chaining procedures to teach the mealtime behaviors. Starting with the first response in the chain, the authors used prompting and fading until the learner engaged in the response without prompts. Then they taught the second response in conjunction with the first using prompting and fading procedures. The authors proceeded in this fashion until the learner could engage in the entire chain of behaviors without any assistance.

Another example of the use of forward chaining is the 1982 study by Tom Thompson and colleagues in which the authors taught laundry skills to individuals with developmental disabilities. The authors first conducted a task analysis of the chain of behavior involved in doing laundry and identified 47 responses that they grouped into seven major components. The authors then used prompting and fading to teach the first of the seven laundry components, then the first and second, then the first three, and so on until the individuals were engaging in all seven components without any prompts.

IV. SUMMARY

Forward chaining is one of three procedures used to teach a chain of behaviors. A chain of behaviors involves individual stimulus and response components that occur together in a sequence. Forward chaining is a procedure that is typically used with individuals with disabilities or extremely limited abilities. The first step in forward chaining is to conduct a task analysis that identifies each S^D and response in the chain of behaviors. To conduct forward chaining you use prompting and fading to teach the first component behavior in the

chain. Once the learner engages in the first response without prompts, you teach the second response in conjunction with the first using prompting and fading. Once the learner engages in the first two responses in the chain without assistance, you use prompting and fading to teach the third response in conjunction with the first two. This process continues until the learner can engage in the entire chain of behaviors without assistance. Praise or other reinforcers are delivered on a continuous reinforcement schedule for every correct response during training. Once the learner competently engages in the chain of behaviors without assistance, an intermittent schedule of reinforcement can be used to maintain the behavior.

events, structures, and motivations in which there is an active and motivated effort to keep from consciousness certain material.

GLOSSARY

countertransference The feelings and responses that the therapist has towards the patient.

discontinuities A momentary impairment or sudden modification of thought, affect, memory, sensation, self-control, etc., in which unconscious motivations may or may not be expressed.

free association The effort to speak the contents of one's mind free of conscious control, aimed towards social appropriateness, coherence, etc.

fundamental rule The requirements that the patient report or, in the more modern iteration, attempt to report all of his or her associations without editing them and without an effort to make them socially appropriate to express a certain idea or to conform to conventions of coherence and reasonableness.

parapraxis Unintentional lapses in behavior or thinking which are believed to be compromise formations resulting from a conflict between the actor's conscious goals and intentions and unconscious urges seeking expression.

transference The tendency to unwittingly construct and create, through an active but unconscious process, the pattern of imagined and real past relationships with an important person in the present.

unconscious The quality of a mental structure not being available for conscious examination and a system of mental

I. HISTORICAL BACKGROUND

“The technique of free association, considered by many people the most important contribution made by psychoanalysis, the methodological key to its results” as Sigmund Freud stated in 1931, remains central to psychoanalysis and psychoanalytic psychotherapy. Although it has a history in literature and philosophy dating to classical antiquity, free association as an investigative and psychotherapeutic method was Freud's invention in the 1890s. It derived from the cathartic “chimney sweeping” use of unrestricted speech, under hypnosis, by one of the patients of Freud's senior colleague, Josef Breuer. Freud gradually modified the method of free association, discarding massage and hypnosis that were its earlier companions, eventually following the patient's lead rather than introducing a subject of his own. Focusing on the patient's introspections, with the requirement that the patient speak without critical judgment, he created a systematic means to infer unconscious thoughts and feelings. The approach was consonant with his general conviction about the determinism of mental life and the importance of unconscious influences. Going far beyond the original aim of reducing traumatic experiences by abreaction, he turned the new method into a vehicle

for deciphering the language of dreams, parapraxes (Freudian slips), and symptoms and for elucidating inferred unconscious conflicts and the history of their development in the patient's life.

II. DESCRIPTION

An important difference between the method of free association and a directed discussion of problems, is that the free associations provide a basis for inferences of unconscious aspects of the patient's mental life. Discontinuities in the patient's mental functions—impairments of thought, affect, memory, sensation, desire, sense of self, self-control, and personal relationships—can be accounted for in large part by unconscious influences. The free associations are “understood” by recognition of sequences, patterns, and a variety of attributes and characteristics that permit them to be “interpreted.”

Here is an example of free association. A young man, wondering about his own psychoanalytic treatment, thought: What good is a treatment that only uses words? Not taking the question seriously, he went about his business (actually, some early spring work in the garden) and found himself, a few minutes later recalling the well-known lines from “Daffodills”:

*For oft when on my couch I lie,
In vacant or in pensive mood,
They flash upon that inward eye,
Which is the bliss of solitude.*

At that point he recognized that he had returned to his original thought. He was pleased to see that the poet's name, Wordsworth, repeated his original question, and he took the sequence as something of an answer. He was not then aware that the couch in the poem had eliminated the problematic analyst and afforded him the privacy of solitude, which likely reflected some less friendly feelings about psychoanalysis. Both the young man's understanding of “Wordsworth” and the added idea that there was a hostile side to his unconscious thoughts about psychoanalysis constitute inferences about his unconscious motivations.

The term “free association” is used in a number of different ways. In all of these the word “free” connotes a relative freedom from conscious control. So, the activity of free association (i.e., the expression of a sequence of thoughts, feelings, wishes, sensations, images, fantasies, and memories) produces the free as-

sociations (or, more simply, the associations). The method of free association involves two persons, patient and analyst (or therapist). It is an integral part of the psychoanalytic situation. The analyst's first aim is to promote greater freedom of association, that is, relatively greater autonomy from unconscious interferences (resistances) to expression. Together patient and analyst engage in an attempt to understand and modify the patient's mental life, through the consequent process of free association (or analytic process, therapeutic process). Accordingly, the concept of free association touches on all the concepts that are implied in therapeutic process. Transference and countertransference, for example, can be recognized as patterns of association. Their unconscious existence can be inferred from those patterns.

The “fundamental rule” of psychoanalysis was originally stated as the requirement that the patient report all of his or her associations, without editing them, saying whatever came to mind. In his original work on free association, Freud used the associations to interpret to the patient the nature of his or her unconscious motivations, which sometimes brought dramatic relief to patients. This approach led to his study of dreams, which he published in 1900. Inevitably, in the interests of expanded treatment potential, modifications in the analyst's aims have brought about a more complex concept of the analyst's role and activity.

The fundamental rule is now usually presented in a somewhat less authoritarian way. The patient is expected to try to say whatever comes to mind, and part of the attention of the analytic pair is directed toward an understanding of the difficulties in following the rule. To make sense of this “rule” and of the psychoanalytic method, one must understand that the activity of free association is interspersed with an attempt to recognize meaning in the associations, through the interpretive efforts of both the analyst and the patient. The therapeutic method, whose central feature is the understanding of the associations, goes beyond the study of the patient's words to the interpretation of actions and interactions within the psychoanalytic (psychotherapeutic) situation, that is, between the analyst (therapist) and the patient. The analyst's associations and actions (principally, the action of words) are now seen as an integral part of the analytic method.

The stance of the analyst or therapist—his or her attitude to the task and to the patient—is an essential part of the method of free association. A fundamental component of that stance is a commitment on the analyst's part to provide a setting of safety for the patient's free as-

sociation and to channel his or her energies, as much as possible, into understanding the associations and the interactions of the analytic process. Necessarily, the analyst's stance must be a blend of subjectivity and objectivity, of compassion and dispassion, involvement and separateness, although what may be an ideal mixture, for any analyst or for any patient, at any particular time, remains a matter of uncertainty and debate. Variations among analysts on these matters continue to provide fruitful avenues of research into therapeutic effectiveness. Savo Spacal, for example, in 1990, demonstrated differences between Freud's use of free association and that of the relational schools, which, as he saw it, had reduced the introspective emphasis and substituted interpretation of interaction. In practice, the two forms operate together, variably, in most psychoanalytic work.

III. CONCLUSION

These considerations make it hard to define limits for the method of free association. To attempt to distinguish associations from dreams and transferences, for example, seems wholly arbitrary. But even interpretations, whether made by the analyst or by the patient, cannot be reliably distinguished from the associative

flow. It is sufficient to know that the data of free association and the events of the therapeutic process can be understood from a variety of useful perspectives, some of which may pay little regard to associative sequences and patterns, while others attend closely to them.

Functional analysis is an approach that guides treatment decisions. This article provides information about the approach, focusing on the theory from which it developed, and its clinical application. This article also introduces some of the well-validated treatments that make use of functional analysis and provides a clinical example of the process.

GLOSSARY

conditioned stimulus A stimulus that acquires some aversive or appetitive psychological functions as a result of respondent conditioning processes.

discriminative stimulus (S^D) A stimulus (or context) that increases the probability of a given response as a result of a history of reinforcement in the presence of that stimulus and extinction in its absence.

establishing operations (EOs) Operations that have two primary effects on operant responding. First, EOs make a given response more probable. Second, EOs make a reinforcer associated with that response more effective. For example, if a rat has been reinforced for lever pressing with food, food deprivation would be an EO. The establishing operation has sometimes been referred to as a fourth term in the three-term contingency analysis.

reinforcing stimulus (S^R) A stimulus that follows a response and alters the future probability of that response. Reinforcing stimuli increase the probability of response, and punishing stimuli decrease the future probability of response.

three-term contingency A description of the functional relationship between (1) antecedent stimulation, (2) responding, and (3) the consequences produced by that response.

I. DESCRIPTION OF TREATMENT

Functional analysis is not a treatment per se. Rather, it is an analytic strategy that directs intervention. In the most abstract sense, the term functional analysis is borrowed from mathematics and describes some relationship between variables in which changes in one variable alter the value of another variable. In psychology, functional analysis refers to the exploration of how certain stimuli and responses mutually fluctuate. The process includes monitoring a target behavior over time and manipulating antecedents and consequences methodically to determine the features of the environment that predict and influence the behavior of interest. Although functional analysis has historically been most identified with operant conditioning, operant and respondent conditioning processes do not occur in isolation of one another. Rather, these are densely interrelated conditioning processes. Especially in attempting to understand complex clinical phenomena, functional analysis must include an assessment of both respondent and operant contingencies and their interactions.

Functional analysis in psychotherapy is the link between pretreatment assessment data and the design of individualized treatment plans. Elements of the analysis affect decisions about which variables should be targeted in treatment. Such treatment focuses on the variable or variables whose modification is likely to cause the greatest reduction in the problem behavior and/or increases in behaviors that enhance the client's quality of life. Because certain behaviors are reasonably well correlated, research may guide the functional analysis. For example, if someone reported a fear of panic attacks, research suggests a variety of situations that are likely to be avoided (e.g., shopping malls, buses), and those would be assessed directly. However, because functional analysis is linked to a tradition of examining the effects of antecedent and consequent events on the patterns of behavior in individual subjects, the focus has been on individualized assessment of these variables.

Functional analysis used for treatment purposes involves several steps:

- A. Assessment of problem behaviors, including intensity, frequency, duration, and variability
- B. Assessment of relevant antecedents, including establishing operations, discriminative stimuli, and conditioned and unconditioned aversive and appetitive stimuli
- C. Assessment of consequences, including reinforcing and punishing consequences
- D. Treatment by intervening on identified antecedents and/or consequences.

A. Assessment of Problem Behavior

Where direct observation of problem behaviors is possible, it is preferable to indirect assessment. However, in the treatment of adult outpatient cases, such direct observation is often impossible or impractical. In such instances, assessment of the problem behavior is accomplished through questions like, "What is going on in your life that concerns you?" Details about the range of the problem can be obtained through questions about affect, overt behaviors, somatic sensations, and thoughts that are related to the problem. Questions that illuminate duration, intensity, and variability might include: "On a scale of 1 to 10, how depressed did you feel?" "How long did that continue?" or "Can you tell me about the worst your problem has ever been and also times when it seemed to improve?" Terms like anxious and depressed are used very loosely in lay vocabulary. For treatment purposes, we want a more particular description of the

problem behavior. We may obtain this by asking questions such as "When you say you feel depressed, what, in particular, does that mean to you?" Examples may be provided based on research demonstrating the co-occurrence of some behaviors. For example, in an interview with a client complaining of depression, we might ask about sleep, mood, and appetite concerns.

B. Assessment of Antecedents

Questions such as "Has this ever happened at any other time in your life?," "What else is going on when this occurs?," and "Does this same thing happen in different places or at other times?" can be used to assess the antecedents influencing behavior. It may also be useful to ask about situations in which the client's difficulty is least likely to occur, or is least severe. In summary, it is necessary to ask questions that provide the therapist with some sense of the variability in the problem behavior. Identification of most and least problematic contexts can form the basis for hypotheses about relevant discriminative stimuli as well as conditioned appetitive and aversive stimuli.

For example, a client might describe anxiety in social situations that is exacerbated by an evaluative component in the social interaction. In this example, social interaction is the context (S^D) in which escape is reinforced by the termination of the aversive stimulus (e.g., the social interaction, aversive thoughts, emotional, and bodily states associated with such interactions). Adding an evaluative component to such an interaction would constitute an establishing operation (EO), because it would alter the probability of escape and the reinforcing value of that escape.

C. Identification of Consequences

Consequences can sometimes be identified by asking questions such as "What happens after this?" and "How do you feel when this is over?" Sometimes there are social consequences for symptoms. For example, others in the household may pay more attention to the client when the client show signs of depression, or they may temporarily take over household tasks. This sort of consequence can be assessed through questions like "What are the reactions of other people when you get depressed?" Whenever possible behavior, antecedents, and consequences should be assessed using direct observation. When direct observation is not possible, using multiple sources of information, such as family, friends, and co-workers, can be helpful.

D. Treatment Process

An intervention is devised based on the functional analysis. Appropriate interventions could be aimed at a variety of components identified in the analysis. Some interventions aim at altering the presence of the actual antecedent and consequent stimuli that maintain the behavior. For example, a heroin addict might be relocated to a setting that had few or no drug dealers. This would result in the removal of both S^Ds (drug dealers) for drug seeking, and heroin, which is the reinforcer for drug seeking. Other interventions are aimed at altering the psychological functions of the antecedents and consequences, rather than their actual presence. The same addict might be given methadone to eliminate the reinforcing properties of the opiates. Opiate deprivation is an EO for drug seeking, because it makes drug seeking more probable and increases the reinforcing properties of opiates. Because methadone blocks abstinence syndrome, it also alters the motivational (EO) effects of opiate deprivation and therefore alters the probability of drug seeking.

Other means of altering the psychological functions of antecedent stimuli might be to reduce or eliminate the effects of appetitive or aversive conditioning. In the earlier social anxiety example, this might involve systematic exposure to social interactions, which would result in lessened fear and avoidance in the presence of social situations. In the addiction example, we might systematically expose the addict to drug cues, thereby reducing the conditioned appetitive functions.

Finally, the problem behavior can be targeted directly by, for example, increasing the probability of some incompatible behavior. Often, these interventions are combined. Thus, in the social anxiety example, the therapist would likely give considerable social reinforcement to the client as the client approached feared social situations. This intervention might result in both strengthening of the approach operant and extinction of conditioned fear. Having been conceptualized in terms of basic behavioral principles, the treatment is implemented, and an assessment of change is made. If the outcome is acceptable, the process is complete. If the outcome is unacceptable, the next step is to recycle to conceptualization stages. More assessment may be needed, or other controlling variables may be manipulated.

These cases consist of relatively simple examples; however, functional analysis need not be limited to a narrow range of behaviors, antecedents, or consequences. Extraordinarily complex human problems can be examined without violating the fundamental pre-

ises of functional analysis. Some of the process will be illustrated with the following case.

E. Case Example

Mary is a 20-year-old African-American female who was seven months pregnant with her third child at the time of the interview. She was referred for psychological treatment by her gynecologist, who described her as “difficult,” “angry,” and “indifferent.” His immediate concern was her drug use. Excerpts from the initial interview with Mary are used to illustrate assessment components in a functional analysis in an outpatient clinic setting.

Therapist directly assesses problem behavior: Mary, your doctor referred you here, because he was worried about you and your children. It would be good to take a few minutes to talk about this. Help me understand what is going on. First, tell me about the drug use and then we can talk about anything that you think will help me understand what it is like for you. Your doctor tells me that you have been smoking marijuana about once a week, drinking alcohol several times a month; and that you have smoked crack cocaine twice since becoming pregnant.

Client: Yeah, that's about right. So what?

Therapist attempts to get the client to discuss range of the drug problem: So what? You tell me. What does that mean to you?

Client: I don't care.

Therapist continues to assess range: You don't care about your health, or your baby's?

Client: Not really.

Therapist attempting to elicit other problems and prioritize: Wow, that is a pretty powerful statement. Things must be really bad.

Client: Not any different than usual. I have never had a happy day in my whole life. Never. There is nothing for me to live for. I am sad all day.

Therapist attempting to find out about duration and variability: You have never had a happy day, what about a happy moment?

Client: I guess that I have had a few short minutes but I don't really remember them.

Therapist assesses problem severity: Have you ever thought about ending it all, about suicide?

Client: Every day. I think of it every day. I've tried twice by taking a bunch of pills, but it didn't work. My boyfriend killed himself.

Therapist asking about boyfriend's suicide as potentially important antecedent: When did that happen?

Client: Three months ago. His family blames me. We were fighting and talking about breaking up. He told me that he was going to do it. I didn't believe him. I hung up on him, and two hours later I found out he was dead.

Therapist: How did you find out?

Client: His friend walked over to my apartment and told me.

Therapist assesses response to painful antecedent: What did you do?

Client: I took my kids to my mom's and went to get high.

Therapist attempting to clarify response: You got high, how?

Client: I smoked a blunt (marijuana). I drank some beer too, just two. I don't like the taste of alcohol.

Therapist attempting to assess consequences: You don't like the taste but you drink anyway. What does it do for you?

Client: Same thing it does for everybody, helps keep my mind off things.

Therapist assessing consequences: Did it help you keep your mind off your boyfriend's suicide?

Client: For a little while.

Therapist asking about other antecedents: When you are getting high what other things are you trying not to think about?

Client: Men. I hate men.

Therapist clarifying range and context: All men?

Client: All men. My boyfriend was the only halfway decent one that I ever met. They think differently than women. They think backwards. I hate them.

Therapist assessing variability: You say that you hate men; do you feel anything else?

Client: My cousin starting molesting me when I was six. He kept doing it until I moved out. I told my uncle but he did not believe me. I told my stepdad and he didn't believe me. You cannot trust a man. Do we have to talk about them? I wanted a female to talk to so we wouldn't have to talk about them.

Therapist eliciting other problems: I understand that it is very hard to talk about these things. I am only trying to figure out what all of your concerns are. What do you think is the hardest thing for you right now?

Client: Being depressed. I just watch TV all day long. Usually I watch game shows but I am not very good at them.

Therapist asking about context: Is there anytime when you do not feel depressed?

Client: Not really.

Therapist assessing antecedents: Is anyone else around?

Client: My baby. He will be one next week. He is wild sometimes.

Therapist assessing social environment as relevant context: One year olds aren't great to talk to. Do you have any friends?

Client: My mama. That's it. She is the only one who cares about me.

Therapist assessing consequences: Is there anything, besides getting high, that seems to make things better?

Client: Watching television helps a little. Sometimes I clean the house, even if it does not need it. It keeps my mind off stuff.

Therapist asking about context and consequences: What about doing something out of the house, like work or school?

Client: I can't get a job. I can't pay a babysitter. Besides, nobody wants to hire me. I went to college for one semester, after my baby was born. I got mostly A's. I got twelve credits, but I cannot go back because it would be too hard with three babies. People tell me that I can't do it.

Therapist clarifying nature of problem: Do you think that you can't do it? You had good grades before and you already had two kids.

Client: I don't know, someday. I have to get them to school first.

Therapist assessing consequences: Sounds frustrating. It sounds like you want to go to school but feel like you can't. What about a job?

Client: I really don't want that.

Therapist clarifying consequences: So, you get out of having to work because you have kids and are pregnant. Is there anything else that these problems get you?

Client: I don't know, maybe.

Therapist assessing consequences: Like what?

Client: My mom helps me out. I like that. I am still a kid, you know.

Therapist: Is there anything else that you have to say that will help me understand things better?

Client: No.

Therapist reasserts interest in understanding client's problems and the need for more assessment: Ok, see you next week. I will keep asking more of these questions to try and get it. Thanks for talking with me.

In this excerpt from an intake interview several potentially important components of the client's problem and its context were revealed (see Table 1). From them a tentative case conceptualization can be formulated. As identified by the client's physician, drug use during

TABLE 1
Components and Treatment Implications of Functional Analysis of Behavior

<i>Antecedents</i>	<i>Behaviors</i>	<i>Consequences</i>
Social isolation	Drug use during pregnancy	Drugs produce positive intoxicating effects
Low levels of physical activity	Depressed mood	Drug use makes temporary avoidance
Hx of sexual abuse & other negative experiences with men	Hopeless thought patterns	of negative cognition and mood possible
Death of boyfriend	Avoidance of negative mood and cognitions using unproductive activity such as drug use, TV	Drug use reduces social isolation
Social punishment for boyfriend's suicide	Generalized avoidance of men	
<i>Potential intervention on antecedents</i>		<i>Potential intervention of consequences</i>
Increase general and especially social activity		Reinforce any increases in general and especially social activity
Exposure-based treatment to cues related to loss of boyfriend, including both external cues as well as associated cognition, emotion, and bodily states		Reinforce client's willingness to engage in exposure-based treatment efforts
Exposure-based treatment with respect to sexual-abuse cues, including both external and interoceptive cues		Antidipsotropic medications to replace reinforcing effects of alcohol with punishing effects (poor choice given client circumstances and problem severity)
Antidepressant medication to alter negative mood states that precipitate maladaptive avoidance		

pregnancy is this young woman's most pressing behavior problem. Relevant antecedents appear to be depressed mood, guilt, boredom, and perhaps relief from decidedly fatalistic thinking. Given the client's circumstances, these are not unexpected reactions. In behavior analytic terms, drug use is maintained by negative reinforcement. That is, aversive mood and thinking are removed as consequences of drug use. In another part of the interview, the client revealed that the instances of drug use were also some of her only social interactions apart from interactions with her mother and children. This further bolsters the notion that drug use is maintained by negative reinforcement. Drug use not only reduces aversive mood and cognition, it also reduces social isolation and increases a general low level of activity.

Intervention on the consequences of drug use is unlikely to be helpful. The reinforcing effects of alcohol could be eliminated by administering an antidipsotropic drug, like antabuse, that would produce a potent punisher for drinking. Given the pregnancy, however, this would be unacceptable. No such pharmacological interventions are available for marijuana or cocaine. In addition, the client would be left with no good alternative strategies to cope with her rather bleak existence and resulting aversive mood states. Intervention on problematic antecedent mood states might include antidepressant drugs, although this pharmacological intervention might

reduce aversive mood states, it would not address the clients impoverished life circumstances.

A more hopeful intervention could focus on increasing the client's general activity level, with a special emphasis on healthy social interactions. Because this client grew up in a very active religious community, the possibility of becoming engaged in social, worship, and volunteer activities with her church could be explored. Reentry into school could also be examined as a possibility. Initially, any increase in physical and/or appropriate social activity ought to be reinforced. Behavioral activation has several advantages. First, behavioral activation has been repeatedly demonstrated to have a positive impact on negative mood and cognition. Second, these activities would be incompatible with drug use. Third, the young woman would likely broaden her social support system. And finally, the resulting social support system might provide reinforcement that could maintain this ongoing stream of healthy behavior.

This client revealed a variety of other difficulties that may bear further exploration and direct treatment. For example, her history of sexual abuse may have precipitated a host of potential difficulties. She may have difficulties with intimate relations and issues of trust with men. Although not revealed in this interview, possible posttraumatic stress disorder symptoms, like sleep disturbance, flashbacks, and hypervigilance are possible

and ought to be directly assessed. The same functional analytic strategy would be applied to these difficulties.

II. THEORETICAL BASES

Although the concept of functional analysis can be identified with a variety of schools of thought, it is most commonly associated with the behavioral tradition. The core position suggests that if we want to understand behavior, we must understand the context, both historical and current, that produced and maintain the behavior of interest. Advocates of this position have sometimes maintained that environmental events are the real determinants of behavior. A somewhat softer position, called functional contextualism, holds that behavior may be understood in terms of its functional relation to environmental events and that such a method of understanding leads quite naturally to effective interventions, because the analysis points to manipulable aspects of context. Stated in this way, the position does not exclude other methods of understanding behavior, it simply claims this one as an effective strategy for the prediction and influence of behavior.

III. EMPIRICAL STUDIES

As previously stated, functional analysis is not a treatment, instead it is an analytic strategy that provides a basis for treatment. As such, there are not studies of functional analysis per se. However, functional analyses are components of many well-validated treatments. Functional analysis as a component in treatment development is most clearly and explicitly described in journals such as the *Journal of Applied Behavior Analysis* and *Behavior Modification* that tend to have a behavior analytic focus. Within them, one may find hundreds of studies treating a diversity of behavior problems, such as tic disorders, infant feeding problems, trichotillomania, and self-injurious behavior, as well as a wide variety of behavior deficits among populations with both developmental disabilities and normal development such as daily living skills, job skills, communication skills, academic skills, and social skills, among others.

Although less explicit in the published journal articles, functional analysis exists as a key component in a wide variety of empirically supported behavioral and cognitive-behavioral treatments. For example Michael Kozak and Edna Foa's treatment manual for obses-

sive-compulsive disorder, David Barlow and Michelle Craske's anxiety and panic manual, and Stewart Agras and Robin Apple's eating disorders manual all contain careful assessment of antecedents, behaviors, and the outcomes of those behaviors. Although early behavioral treatments were focused on external antecedents and consequences, more recent advances such as Barlow and Craske's panic treatment include a wide variety of interoceptive antecedents that are directly targeted in treatment. In these instances, negative mood, cognition, and bodily states can be thought of as both problematic behavior and as antecedents for other problematic behaviors. Using panic disorder as an example, someone may have a panic attack at a shopping mall and begin avoiding shopping malls. Panic as a response pattern is problematic and can be analyzed in terms of its functional relation to external events, such as the shopping mall. However, individuals with panic also begin to avoid activities that will precipitate early indicants of autonomic arousal, such as avoiding exercise to avoid increased heart rate. Thus, avoiding exercise can be understood distally in terms of the shopping mall, but more proximally in terms of bodily states associated with panic attacks at the mall.

IV. SUMMARY

Functional analysis is a theory-driven approach to understanding behavior in terms of its context. It involves the organization of our understanding of behavior into three primary categories, including (1) antecedents, both remote and proximal, and also including internal and external cues; (2) the behavior of interest; and (3) consequences of that behavior. The analysis proceeds on the assumption that manipulation of antecedents and/or consequences can produce changes in relevant patterns of behavior. Identification of antecedents includes both discriminative stimuli and conditioned aversive and appetitive stimuli. Assessment of the behavior of interest involves examination of frequency, intensity, duration, and variability in the problem behavior. Identification of consequences includes assessment of potentially reinforcing and punishing consequences for the behavior of interest. Having gathered this information, a case formulation is made in terms of the well-established behavioral principles of operant and respondent conditioning and the interaction of these two conditioning processes. A wide variety of interventions have emerged from this functional perspective on behavior, including very

straightforward interventions involving reinforcement of appropriate classroom behaviors to the treatment of complex adult clinical problems like panic disorder with agoraphobia.

perception, language, and even truth and reality vary according to our past.

therapy rationale An explanation given to clients about the causes and cures for their problems. The rationale reflects the theory and types of techniques used during treatment and varies with the type of therapy being done.

GLOSSARY

Beck Depression Inventory A standardized measure of depression that is used to assess a client's progress during treatment.

behavior therapy A type of psychotherapy that is based on learning principles, is usually time limited, and is symptom focused.

cognitive-behavior therapy A variety of behavior therapy aimed at detecting and changing faulty beliefs, attitudes, or thoughts that are hypothesized to be responsible for the symptoms.

internal validity Refers to whether an outcome of a therapy treatment can be confidently attributed to the treatment itself and not some extraneous factor.

major depressive disorder A mood disorder characterized by sadness, despair, loss of energy, sleep and appetite disturbance.

radical behaviorism The psychology of B. F. Skinner that accounts for our external actions, private feelings, and beliefs in terms of the types of past experiences that shape us. The most fundamental type of past experience involves the contingencies of reinforcement (nontechnically referred to as rewards and punishments) that we experienced throughout our life span. This historical account of behavior leads to a contextual approach in which meaning,

Functional analytic psychotherapy (FAP) is a form of behavior therapy that emphasizes use of the therapist–client relationship for providing powerful *in vivo* learning opportunities. Based on the radical behaviorism of B. F. Skinner, FAP produces change through the natural and curative contingencies of reinforcement that occur within a close, emotional, and involving therapist–client relationship.

I. DESCRIPTION OF TREATMENT

Psychologists Robert J. Kohlenberg and Mavis Tsai noticed that some of their clients treated with conventional cognitive-behavior therapy techniques showed dramatic and pervasive improvements that far exceeded treatment goals. In their search for an explanation as to why this happened with some clients, they noticed that the dramatic improvements occurred in those clients with whom they had particularly intense and involved therapist–client relationships. These intense relationships were not created purposely as part

of the therapy but seemed to emerge spontaneously from time to time. As a result of these observations, Kohlenberg and Tsai used behavioral concepts (a) to theoretically account for the hypothesized connection between dramatic improvement and an intense therapist–client relationship, and (b) to delineate the steps therapists can take to facilitate intense and curative relationships. The result was FAP, a new type of behavioral therapy in which the therapist–client relationship is at the core of the change process. In particular, the FAP therapist focuses on the special opportunities for therapeutic change that occur when the client's daily life problems are manifested within the therapeutic relationship.

In 1994, Kohlenberg and Tsai detailed how FAP, a powerful treatment by itself, is also an integrative approach that can be combined with almost any other type of therapy to improve outcome. It should also be pointed out that FAP emphasis on the therapist–client relationship, based on behavioral theory, has some unexpected similarities to the Freudian concept of transference.

A. *In Vivo* Learning Opportunities

Functional analytic psychotherapy underscores the importance of *in vivo* learning opportunities—the actual occurrences of the client's daily life problems in interactions with the therapist. The well-accepted notion that learning is accelerated when done *in vivo* can be illustrated by the accelerated learning that occurs when learning to drive a car while actually driving with an instructor, as opposed to classroom instruction.

In vivo occurrences of the client's problems are “real” and are distinguished from the “role playing” or “behavioral rehearsal” that are sometimes used in behavior therapy. Examples include: (a) A woman, depressed mainly because she has no friends, avoids eye contact during the therapy session, answers questions by talking at length in an unfocused and tangential manner, has one “crisis” after another, and gets angry at the therapist for not having all the answers; (b) An unhappy man whose main problem is that he avoids getting into love relationships, always decides ahead of time what he is going to talk about during the therapy hour, watches the clock during the session so he can end precisely on time, states that he only can come to therapy every other week because of tight finances (he makes a relatively large income), and cancels the next session after making an important self-disclosure.

In these examples, the client is seeking treatment for certain daily life problems and then acts in the same

problematic way within the therapist–client relationship. In FAP, these *in vivo* occurrences of the client's problems are referred to as clinically relevant behaviors, type 1 (CRB1s). On the other hand, clinically relevant behaviors, type 2 (CRB2s) are actual improvements that occur in-session. For example, if the woman in the earlier example subsequently increases her eye contact with the therapist and is more accepting of the therapist's limitations, these are CRB2s. In order to do FAP, it is crucial that the therapist has an understanding of CRBs, be able to recognize them when they occur, and know how to nurture the development of CRB2s.

B. Doing FAP

Functional analytic psychotherapy employs several therapeutic strategies. The three primary ones are: (a) watch for CRBs, (b) evoke CRBs, and (c) reinforce CRB2s.

Strategy 1: *Watch for CRBs*. This strategy is the most important one because it alone will lead to more intense and effective treatment. A therapist who is skilled at observing instances of clinically relevant behavior also is more likely to naturally encourage clients to give up self-defeating patterns in the here and now, and foster more productive approaches to life.

Strategy 2: *Evoke CRBs*. Because the occurrence of CRBs are required to do FAP, how can this be facilitated by a therapist? Client problems reenacted during role playing, as pointed out earlier, are not the same as naturally occurring CRBs. Further, feigning evocative situations, such as coming late to a session or getting angry at the client, are not recommended. Such disingenuous behaviors are incongruent with the close and honest relationship called for in FAP.

As it turns out, the structure of most therapy sessions naturally evokes CRB. For example, all therapists set appointments and require fees for treatment. These procedures can evoke CRBs relating to the client making and keeping commitments, being punctual or being too compulsive, feeling like they are so worthless that they need to pay someone to listen to them, and so on. Similarly, the universal therapist request to the client to be open and to express both positive and negative feelings could evoke the client's problems in forming close relationships. CRBs are ubiquitous in all therapies but frequently are overlooked by therapists who are not trained to see them.

Strategy 3: *Reinforce CRB2s*. Reinforcement is the technical term that means the therapist should nurture and strengthen in-session improvements. It is best to rely on the therapist's natural reactions for this process rather

then to gratuitously use phrases such as “that’s terrific” or “great,” which may be viewed by the client as insincere. Therapists who are skilled in FAP are aware of CRB2s as they occur and are genuinely and spontaneously reinforcing. One way that therapists can become more naturally reinforcing of improvements in their clients is by doing good deeds for others in their own personal lives.

On the other hand, therapists who are not aware of CRBs may inadvertently punish CRB2s (improvements). For example, consider a case in which a woman was seeking help for depression that was related to her lack of assertiveness with her husband. The therapist attempted to teach her to be assertive by using role playing, a common behavior therapy procedure. The client expressed discomfort with role playing and asked if there were another way to approach the problem. The therapist then suggested to the client that by resisting the role playing she was being avoidant, and he pressured her to do the role playing anyway. The FAP analysis of this incident is that the client’s expression of her reluctance to do the role play was a CRB2 because she was being assertive with the therapist—the very real-life skill that the therapist was attempting to teach. The therapist, on the other hand, did not nurture and strengthen this assertiveness and may even have unintentionally punished it by accusing her of being avoidant and insisting that she do the role play. If the therapist had been aware that a CRB2 were occurring (as called for in Strategy 1), he would have recognized the *in vivo* therapeutic opportunity and nurtured the assertiveness by pointing out to the client how useful it is for her to express her feelings, and to find other ways to approach the problem besides role playing.

C. Using FAP to Improve Cognitive Therapy for Depression

Cognitive-behavior therapy (CBT) for depression, developed in 1979 by Dr. Aaron Beck and his colleagues, has been shown to be an effective treatment for major depression. As with any treatment for depression, however, there is room for improvement. In particular, some clients are resistant to the methods and rationale of cognitive therapy, and outcome is endangered by what is known as a rationale–client mismatch. Examples of mismatches include clients who experience that their feelings rule no matter what thoughts they have, who are looking for a more intense and interpersonal therapy, and those that want to understand how their problems are related to their family histories. In an attempt to more effectively address the diverse

needs of clients, reduce mismatches, and yet retain the value that cognitive therapy has for many clients, a combined FAP and cognitive therapy (CT) treatment was developed. The new treatment is referred to as FAP enhanced cognitive therapy (FECT).

FECT contains two enhancements to standard CBT. The first is an expanded rationale for the causes and treatment of depression. The expanded rationale includes several possible causes for depression in addition to the cognitive therapy hypothesis that depression results from dysfunctional thoughts and beliefs. For example, clients are told that depression can be related to losses that need to be grieved, to family of origin or historical issues, to a dearth of experiences that bring a sense of mastery and pleasure, to anger turned inward, to not having intimacy skills. This expanded rationale allows for better treatment–client matching.

The second enhancement is using the therapy–client relationship as an *in vivo* opportunity to learn new patterns in thinking and to create better relationships. Clients are told that.

It will be helpful for us to focus on our interaction if you have issues or difficulties that come up with me which also come up with other people in your life (such as co-workers, acquaintances, supervisors, friends, spouses). When one expresses one’s thoughts, feelings, and desires in an authentic, caring and assertive way, one is less likely to be depressed.

II. THEORETICAL BASES

FAP stems from the psychology known as radical behaviorism proposed by Psychologist B. F. Skinner. Many readers may erroneously associate Skinner with a narrow theory used for explaining lever pressing by rats in experimental chambers. In fact, Skinner attempted to show how contingencies of reinforcement enter into the understanding of fundamental human processes such as perception, sense of self, identity, beliefs, language, poetry, happiness, personality, love, and creativity.

As a means of illustrating how radical behaviorism works, consider how it views thoughts, beliefs, or cognition. Cognitive theory (often considered the nemesis of radical behaviorism) posits that a person’s thoughts, beliefs, or attitudes determine how they react to events in the world. Known as the A->B->C paradigm, it is shown in Figure 1 (a). The radical behavioral position, in contrast, posits that one’s thoughts in some cases may determine a person’s subsequent reactions as shown in

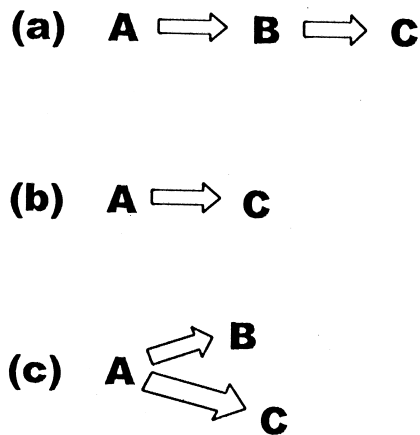

FIGURE 1 Some cognition-behavior relationships according to the FECT expanded rationale. A = Antecedent Event; B = Belief/Cognition; C = Consequence (emotional reaction). Figure (a) represents the standard cognitive model; (b) represents a situation in which there is no cognition; (c) represents a situation in which cognition precedes but is not causally related to the reaction.

Figure 1 (a), but in other cases thoughts may occur that have no influence on reactions (Figure 1 [c]). In fact, one may even have reactions without any preceding thoughts (Figure 1 [b]). The radical behavioral position is that different paradigms apply depending on our history of reinforcement. Using an example from our daily lives, we all have had thoughts in the form of a self-promise, such as “I will not eat that fattening cream pie” when offered a piece. At times we will confirm paradigm 1 (a), the cognitive hypothesis, by not eating the pie. At other times, however, we will have the thought but eat the pie anyways (paradigm 1 (c)), thus disconfirming cognitive theory. Then, of course, at times we will have the experience of just eating the pie without any preceding thoughts (Figure 1 [b]) which is also inconsistent with cognitive theory. An advantage to the radical behavioral view is that it accommodates all these possibilities. Because the radical behavioral view accommodates a wider range of how people experience the relationship between their thoughts and subsequent actions, it was used as part of the expanded rationale to enhance cognitive therapy.

Another implication of radical behaviorism as applied to therapy is that people act the way they do because of the contingencies of reinforcement they have experienced in past relationships, and more broadly, in our culture. Based on this theory, it follows that clinical improvements or psychotherapeutic change also involve contingencies of reinforcement that occur in

the relationship between client and therapist. A well-known aspect of reinforcement is that the closer in time and place the behavior is to its consequences, the greater the effect of those consequences. Treatment effects will be stronger, therefore, if clients’ problem behaviors and improvements occur during the session, where they are closest in time and place to the available reinforcement. In other words, FAP places great emphasis on the therapist being aware of the therapist–client interaction and on client CRBs because the most significant therapeutic change results from contingencies that occur during the session within the therapist–client relationship.

Functional analytic psychotherapy theory does not say that other types of interventions (e.g., giving advice, using homework, cognitive therapy, social skills training) are not effective. Rather, the FAP position is simply that *in vivo* interventions are more powerful and increase the likelihood of positive therapy outcome.

III. EMPIRICAL STUDIES

Kohlenberg and Tsai present a number of case studies in their 1991 book, *Functional Analytic Psychotherapy*, that supports their hypothesis that an *in vivo* focus during therapy leads to significant clinical improvement. In 1994, they published a case study of a 35-year-old depressed man who started a course of standard cognitive therapy. Although he showed an initial improvement as measured by the Beck Depression Inventory, he failed to make further progress until the therapist began using FAP Enhanced Cognitive Therapy (FECT) in Session 7 of the 13-week treatment. The patient also reported that his interpersonal relationships improved as a result of FECT. In another case study published in 1999, R. H. Paul and associates reported benefits of using FAP as an addition to other treatment for a pedophile. In a group therapy for depressed adolescents, Scott Lawrence and Scott Gaynor at the University of South Carolina, Greensboro, reported at the annual meeting of the Association for Behavior Analysis in 2000 that FAP improved treatment outcome.

Also in 2000, Robert Kohlenberg, Mavis Tsai, Chauncey Parker, Jonathan Kanter, and Madelon Bolling completed a National Institute of Mental Health treatment development study using FECT for clients with major depression. The study demonstrated that experienced cognitive therapists could learn how to competently do FECT. The results also showed that FECT improved treatment outcomes and interpersonal

relationships. Other studies using FAP are currently underway—at the University of Nevada-Reno, William Follette is studying patients who are dependent on tranquilizers, and Steve Hayes, Elizabeth Gifford, and Barbara Kohlenberg are studying the treatment of nicotine dependence.

Although the empirical findings are favorable, FAP is a new treatment, and the types of empirical studies conducted thus far reflect its early stage in the treatment development process. Threats to internal validity have not been dealt with unequivocally. To advance to the next stage of empirical support, Robert Kohlenberg and colleagues are conducting a randomized clinical trial in which patients are randomly assigned to receive either CT or FECT for major depression. The outcome of this study will add important evidence that will be useful in assessing the utility of FAP.

IV. SUMMARY

Functional analytic psychotherapy posits that the therapist–client relationship is a social environment with the potential to evoke and change actual instances of the client's problematic behavior. FAP underscores the importance of *in vivo* learning opportunities, the actual occurrences of the client's daily life problems in therapist–client interactions. Change is produced through the natural and curative contingencies of rein-

forcement that occur within a close, intense, and emotional therapeutic relationship.

GLOSSARY

antecedent The preceding factor or stimulus that may cue the occurrence of the observable behaviors (an antecedent for tantrums in young children is being told “no”).

applied behavior analysis Field of inquiry that studies variables influencing observable behaviors by use of a systematic experimental design. This term is oftentimes used interchangeably with behavior therapy and behavior modification.

augmentative communication system An alternative communication designed for those impaired in verbal communication. Systems may vary from simple photographs, to picture symbols, to computerized devices programmed specifically for an individual.

consequence The event or stimulus, occurring after a behavior, that influences the future likelihood of the behavior. A consequence may be a reinforcer (thus increase the likelihood of the behavior to occur) or a punisher (decrease the likelihood of the behavior).

extinction Commonly called systematic ignoring; a behavior procedure by which reinforcement of an earlier reinforced behavior is withheld with the goal of reducing the behavior.

punisher A consequence presented contingent on a particular behavior that results in the decrease of the behavior.

reinforcement A process in which the consequence of a behavior results in an increased frequency of the behavior.

reinforcers A contingent consequence of a behavior that results in an increased frequency and long-term maintenance of that behavior.

self-injurious behaviors Behaviors self-inflicted by an individual that have the potential to be harmful (hand biting, head banging, face slapping).

single-subject design A research design often utilized in behavior treatment whereby measurements of a behavior are repeated under same and different conditions to determine the effects. Studies using this research design may have one to a handful of subjects.

stereotypical behaviors Repetitive, seemingly nonpurposeful movements, also often referred to as self-stimulatory behavior (hand flapping, body rocking, finger posturing).

Functional communication training (FCT) is a treatment approach often implemented to attenuate challenging behaviors, most often in individuals with developmental and communication disabilities. The specific FCT procedures for an individual are determined by the findings of a functional assessment and analysis of the challenging behaviors to be treated. FCT is typically one component of a multicomponent treatment package. This article provides a description of this treatment approach, the theoretical underpinning, and a summary of empirical findings to date.

I. DESCRIPTION OF TREATMENT

The premise for the treatments that fall under this domain is that challenging, problematic behaviors may act as an unconventional but effective form of communication. Hence, the goal of FCT is to teach an alternative, more adaptive behavior that will serve the same function or purpose for the individual with the assumption this will in turn attenuate the occurrence of the challenging behavior. This treatment is a popular approach as one component to addressing the often-occurring challenging behaviors in individuals with developmental disabilities, communication delays, and other groups whose ability to communicate effectively is thwarted (hearing impaired, traumatic brain injury). FCT has been successfully implemented in treatment of such behaviors such as aggression, self-injurious behaviors, disruption, severe tantrums, and stereotypical behaviors. Common communicative functions these challenging behaviors have typically found to serve are (a) to escape or avoid a situation, (b) to gain attention or comfort, (c) to obtain access to a preferred tangible item or reinforcer, (d) and to gain sensory reinforcement. There are likely many more communicative purposes behaviors serve, but

these are the ones most researched. Determining first what communicative functions challenging behaviors serve is critical to the implementation of FCT. Hence, a specific type of assessment precedes successful FCT. A functional assessment and analysis is conducted during which the function or purpose of the behavior is hypothesized. Subsequent to the functional assessment, the type of communicative behavior to be taught may be chosen (to end an activity, to obtain assistance, to request a preferred activity, to gain sensory input). Based on developmental and communication levels of the individual, the communicative behavior may be verbal, a manual sign, use of pictures, or other augmentative communication systems (electronic devices). To be effective, the alternative behavior response to replace the challenging behavior needs to be less effortful, more efficient, and consistent in obtaining the same end or the same need met for the individual. Steps in using treatments based on this paradigm are outlined below

1. Following a functional assessment and a determination of the function of the problem behavior, a replacement behavior is chosen. Table 1 provides examples of responses that might be taught based on

TABLE 1
Examples of Responses That Might Be Taught

<i>Challenging behavior maintained by</i>	<i>Teach</i>	<i>Examples</i>
Escape—to get out of or avoid a situation	Appropriate escape responses	<ol style="list-style-type: none"> 1. Verbalize “I need a break.” 2. Manual sign “Finish.” 3. Push some items away
Attention—to gain someone’s attention	Appropriate attention gaining response	<ol style="list-style-type: none"> 1. Raise hand 2. Ring a bell 3. Press communication device programmed to say “Hey look at me.” 4. Shake a rattle
Tangibles	Appropriate request for tangibles	<ol style="list-style-type: none"> 1. Verbalization of “I want...” 2. Use of picture communication symbols to show an adult what is wanted 3. To lead an adult to what is wanted. 4. To manually sign “toy” if that is what is wanted.
Sensory feedback	Appropriate requests for sensory activities	<ol style="list-style-type: none"> 1. Teach child to point to a bin of tactile, sensory items.

the hypothesized purpose or function of the challenging behavior.

2. The training of these replacement behaviors may initially take place out of the setting where the challenging behavior is likely to occur.

3. Once the individual has the chosen behavior in his repertoire, he is prompted to use that communication while often ignoring or interrupting the challenging behavior. For example, if an individual hits himself when given a difficult task, he may be prompted to request a break.

4. When individuals are consistently using the communication, replacement behavior in lieu of the challenging behavior, the addition of requests (in the case of escape situation) or increasing the delay for a response (in the case of receiving assistance) are typically systematically added. Differential reinforcement is often part of this step whereby the individual receives additional reinforcement for complying with requests and for the absences of the challenging behavior.

The replacement communication behavior chosen is dependent on findings from the functional assessment conducted prior to treatment planning. If it is determined the individual is attempting to escape or avoid a situation, then a likely communication to be taught would involve an indication of wanting a break, asking to leave, or of simply disliking an aspect of the situation. The communication behavior chosen to be taught depends on a number of variables. First, the skills of the individual obviously have to be determined. For individuals with no verbal skills, a non-verbal mode of communication will need to be chosen. Again, based on the developmental level of the individuals, the communication behavior could range from a sign, to pointing to a picture, or to using some other augmentative communication device. Augmentative communication devices now available include an array of sophisticated electronic devices that are individually programmed to support an individual in his or her communication needs. For example, the device may be programmed to “verbalize” the individual’s favorite cereal when the key with a picture of that cereal box is pressed. Although the goal may be for the individual to use verbal communication, for purposes of FCT in decreasing a challenging behavior, a lower-level communication behavior is typically chosen. To illustrate this point, a child may have recently begun using phrases and short, simple sentences to make requests. This child however, when upset, uses no words. Hence, a possible replacement

communication behavior may be a single word such as “help” to signal the child needs assistance from an adult in the setting.

A major advantage of this treatment is that a new, appropriate behavior is being taught versus the simple suppression of the challenging behavior. It may also be considered a more proactive approach instead of simply reacting when a challenging behavior is observed. Further, for individuals with limited skills to be independent and exert control and make choices, this approach builds more independence and choice making. Also of great importance is the increased likelihood of the effects of this treatment to maintain over time and to generalize to new situations. That is, the treatment will be effective over time and in new settings where not initially trained. For example, the individual will communicate the need to get out of a situation or to gain attention in a new classroom.

II. THEORETICAL BASES

Functional communication training is a set of treatment procedures borne out of the applied behavior analysis tradition. Numerous treatments for behavior and emotional problems have emerged from this field. Functional communication training as well as functional assessment and functional analysis share the basic principles of operant learning theory. The shared tenets based on this theory include the “ABC” model that assumes overt, observable behavior (the B) depends on the antecedents (the A) and the consequences (the C) of the behavior. Behaviors such as aggression, self-injury, tantrums, and disruptions are certainly challenging; however, for the individual engaging in them, they may not be maladaptive at all. The consequences for these behaviors may be positive reinforcement or negative reinforcement. In the case of positive reinforcement, the individual is given a reinforcer contingent on the behaviors. For example, a child may be given a preferred toy or adult attention. An example of the challenging behavior being negatively reinforced is the behavior results in the individual being allowed to get out of doing something (i.e., escaping, avoiding, or delaying a situation or task that is aversive). In other words, problematic behaviors may result in the individual obtaining attention or comfort from another, being allowed out of a situation they find uncomfortable or stressful, or acquiring a favorite item. Hence, on the contrary, these behaviors labeled as problematic or challenging may be quite

adaptive for individuals, effectively providing them control over their environment and access to desired reinforcers or outcomes. FCT is based on what has been described as the “communication hypothesis” of challenging behaviors. Carr and Durand in a 1985 seminal article first hypothesized that behaviors serve to communicate for an individual that may have limited effective means to communicate his or her needs or preferences. The individual may in fact have language, but for many possible reasons, the challenging behaviors may have been reinforced more often than language or communication efforts. For example, in young children, a child biting certainly will gain more immediate attention than a soft, poorly articulated request. Hence, the essence of this treatment approach is to teach or strengthen alternative communication skills to serve as a replacement for the challenging behavior.

A. Functional Assessment and Functional Analysis

Essential to the FCT approach is the first conducting a functional assessment and functional analysis. It is universally accepted in the field of applied behavior analysis that a functional assessment is quintessential to appropriately design behavior treatments. In a 1999 edited book, by Alan Repp and Robert Horner, the importance of effectively conducting a functional analysis to then develop effective behavior treatments of all types is stressed. In the case of FCT, the comprehensive assessment informs the choice of specific FCT procedures for a particular individual. As with FCT, functional assessment practices have been the focus of tremendous investigative efforts in the past two decades. Functional assessments are intended to identify the relative “functions” of the identified challenging behavior for a particular individual. Since Brian Iwata and his colleagues published their 1982 article on the functional analysis of self-injury, the importance of conducting functional assessments and analyses to appropriately design functionally derived interventions is widely acknowledged.

Functional assessments may include a range of indirect and direct assessment practices. Indirect assessments may include structured interviews with individuals knowledgeable about the identified client and a behavior motivation checklist developed to ascertain the possible function or purpose of a target behavior for a specific individual. Direct assessment may

include naturalistic observations or analogue observations. With naturalistic observations, the individual is observed in a typical setting (school, home, and other community setting) with the intent of observing the challenging behavior, and thus infer the function for that individual given the consequences the behavior rendered. As illustrative, did the child gain the teacher’s attention by hitting a classmate? Alternatively, was the child allowed to “escape” the situation for the same behavior by being sent out of the room (and away from the stack of worksheets)? The term functional analysis is typically reserved to describe specific analogue observations, which are often employed as part of a functional assessment. Analogue, meaning analogous to a situation, observations are intended to simulate likely real-life scenarios in which the challenging behaviors likely occur. Hence the goal of a functional analysis is to identify environmental variables that may be maintaining or controlling certain challenging behaviors. In the functional analysis observations, the systematic manipulation of variables in an analogue setting allow for data-based development of hypotheses regarding the function of a particular observed behavior.

To get an idea of what a functional analysis entails, commonly used functional analysis conditions and procedures first published by Brian Iwata are briefly described.

B. Social Attention

This condition is designed to approximate a common type of reinforcement contingency that may maintain a challenging behavior. In the natural environment, many challenging behaviors may in turn result in attention from caregivers, teachers, and peers. Verbal attention, nurturance, and comfort may be the consequence of an individual engaging in a challenging behavior, thus inadvertently maintaining the behavior as a form of positive reinforcement. In this analogue observation, attention is delivered contingent on the challenging behavior.

C. Demand

This session is designed to assess whether a challenging behavior is maintained by negative reinforcement as a result of being allowed to escape or avoid demanding or stressful situations. In this condition, demands or requests are issued, and the individual is

allowed to escape contingent on the challenging behavior under assessment.

D. Preferred Tangible Removal

This session serves to determine if the challenging behavior is a means to gain access to preferred activities or items. In this condition, preferred items may be removed and then returned contingent on the identified challenging behavior.

E. Alone

This analogue condition assesses whether a behavior is maintained by sensory reinforcement. The individual is observed without stimulation/activities and receives no attention.

These types of observations usually are conducted after other earlier described assessment procedures have been completed. The functional analysis observations are the most controlled observations and may be thought of as “testing out” the hypothesized purpose of challenging behaviors for an individual. The approach may not always be feasible in all settings. Nonetheless, gathering as much precise data about the function of a problematic behavior is of great importance. Accurate hypotheses about the purpose or function of a particular challenging behavior are essential in the design of effect in FCT procedures.

III. EMPIRICAL STUDIES

Since the first FCT studies were published in the mid-1980s, there has been much enthusiasm surrounding this promising approach. This enthusiasm was generated for several reasons. The treatment approach moved away from the reliance of consequence and earlier punishment procedures that had evoked controversy in the field. The treatment also resulted in often dramatic decreases in challenging behaviors and had more inherent likelihood of being maintained over time. Edward Carr and V. Mark Durand first reported in 1985 on four individuals with developmental disabilities. Aggression, self-injurious behavior, and tantrums were successfully treated with FCT. Subsequent to this first report, a plethora of investigations emerged very quickly in the behavior treatment literature. Most commonly, functional communication training has been implemented to decrease excessive

behaviors. In the research literature, behaviors studied have included most commonly aggression, self-injurious behaviors, tantrums, and disruptive behaviors such as throwing. The studies have been almost entirely single-subject design, hence each study includes only a small number of subjects. Thus, the generalization of the application of specific FCT procedures to populations different than the specific characteristics of the subject studies is yet to be understood.

In recent years, there has been considerable FCT research designed to examine the underlying behavioral mechanisms to explain the powerful effects of the treatment. It appears that FCT is only useful in combination with components. That is, FCT is only effective when the problematic behavior is simultaneously placed on extinction or even perhaps punished. FCT is also more likely to be effective if there are more opportunities for the new replacement behavior to be evoked and then reinforced.

IV. SUMMARY

The past 15 years have seen a truly remarkable impact of the functional communication or functional equivalence training approach to the amelioration of challenging, interfering behaviors. This approach has been primarily applied to individuals with developmental disorders and those with noted limitations in communication skills (young children). Since the introduction of this treatment approach, a plethora of empirical reports in the literature have supported the efficacy of this approach as one component in a multi-component treatment package. This approach is not only widely accepted in intensive treatment settings but has been instituted as an intervention in children's behavior support plan as part of their individual education plan in the special education system.

GLOSSARY

core cognitive error Relates to gamblers' erroneous cognitions related to randomness and predictability.

pathological gambling Individuals gamble because they maintain the unrealistic hope that they will recover their losses if they continue to gamble.

randomness No event can influence another, thus resulting in the unpredictability of events.

I. DESCRIPTION OF TREATMENT

The legalization of new forms of gambling is increasing in most Western countries. This trend has created a situation in which more and more people will develop serious gambling problems, for which they will need to seek professional help. Pathological gambling was officially recognized in 1980 with the publication of the *DSM-III*. It is now acknowledged that the prevalence of pathological gambling is related to the availability of gambling opportunities, legal or illegal. Current prevalence rates of this disorder

vary from 1 to 2% in the United States and Canada.

The cognitive approach to the treatment of pathological gambling is based on experimental work demonstrating a wide range of cognitive errors made by gamblers in relation to gambling. The core cognitive error lies in the gamblers' notions concerning randomness and predictability. Essentially, gamblers fail to recognize the random nature of games of chance and believe that they can predict the outcome of the game and win through the use of skills or strategies. This misconception of randomness leads gamblers to develop what has been referred to as the "illusion of control," and false beliefs in their ability to predict the outcome of a game. The basic assumption of cognitive theories is that gamblers will dramatically decrease their gambling activity if their erroneous perceptions about randomness can be corrected.

Our treatment program focuses on erroneous perceptions about randomness and makes it the most important target for change. Two components are crucial in this treatment: the cognitive correction of erroneous perceptions and relapse prevention. Because cognitive therapy usually integrates behavioral as well as cognitive strategies for change, specific behavioral interventions are included in the treatment package. This specific treatment is administered on an individual basis, over an average of 12 weekly sessions lasting 60 min each.

A. Evaluation of Pathological Gamblers

A thorough evaluation of each individual's gambling problem must be conducted to determine how best to implement the therapeutic intervention. Before treatment begins, therefore, the nature and severity of the gambling problems must be evaluated. Although the South Oaks Gambling Screen (SOGS) is not made for diagnosis, this brief questionnaire developed by Henry Lesieur and Sheila Blume is a pertinent, easy to use, and widely recognized evaluative instrument. This instrument is frequently administered over the phone, before the first treatment session takes place. To date, the *DSM-IV* criteria for pathological gambling remain the most accepted instrument for the diagnosis of pathological gambling. Thus, to achieve a complete and comprehensive evaluation, our group developed a semistructured interview that includes the *DSM-IV* criteria and obtains additional information about historical gambling habits, social functioning, suicidal thoughts, concomitant excessive behaviors, and so on.

Ambivalence toward abstinence or controlled gambling is the gambler's worst enemy and must be addressed during the first stage of evaluation. The motivational level of individuals with a gambling problem should therefore be assessed before they undertake any treatment. Our team of therapists have made use of a motivational scale allowing them to decide which treatment target should be prioritized. A high level of motivation, such as 7 out of 10, could indicate a lower level of denial from the client, and a better likelihood of treatment adherence. In contrast, a low score on the motivational scale indicates that treatment adherence may be a problem and should be addressed first. Ambivalence about conquering the desire to gamble must necessarily be dealt with if the treatment is to succeed. Thus, addressing motivational issues is the very first step, before even considering targeting erroneous perceptions about gambling.

To further test the gambler's motivation to cease gambling, the therapist and client also engage in discussion about the positive and negative aspects of gambling during this evaluation phase. A better consciousness of the positive and negative aspects of ceasing gambling is also an issue. During this discussion, the therapist obtains information about the client's gambling behavior and identifies the client's goals regarding treatment.

To keep track of their gambling activities, clients are asked to complete a daily monitoring sheet. With the help of this monitoring sheet, the therapist can start

every clinical session with a discussion about the client's progress or relapse throughout the course of the therapy.

The next treatment target involves the correction of the client's erroneous perceptions about the role of randomness in games of chance. Most gamblers are either not aware that their perception of these games is inaccurate, or they simply deny that they believe these games can be predicted, controlled, and won. Increasing awareness of their gambling activities and the erroneous perceptions associated with them is an essential first step if gamblers are to overcome their urge to gamble and work their way toward abstinence. Given that relapse rates among gamblers are high, and that gamblers tend to be ambivalent about conquering their habit, or deny that they even have a problem, abstinence is the ultimate goal in therapy. A study currently underway at Laval University is evaluating the efficacy of controlled gambling versus abstinence, with the gambler's characteristics as predictors of success for either goal; until these results are known, however, abstinence should remain the main goal of therapy.

Cognitive treatment for pathological gambling is not based on simply providing information concerning actual probabilities and the true random nature of games of chance. Rather, the main goal of this treatment is to enable gamblers to become aware of their own misconceptions about gambling and challenge their unrealistic beliefs about the predictability of games of chance. Thus, an evaluation of the gambler's misconceptions is a crucial step that must be taken before therapy can be initiated. To do this, clients are invited to describe the evolution of their gambling habits. As mentioned previously, the main cognitive error of the pathological gambler is to make links between events that are in reality absolutely random. Gamblers will perceive patterns and signs about the patterns of numbers in a game that they believe allow them to predict the outcome. The basic misconception, which is specific to gambling, is expressed through a number of erroneous perceptions about gambling and games of chance. Examples of such misconceptions are: "I won three times in a row, that's my lucky day today," "Since I won yesterday and the day before, I can't lose today," "After winning the jackpot, I must continue gambling because I don't want to break my lucky streak," "When little numbers come up on the wheel, it means that a big one is coming." To identify these erroneous perceptions and to increase gamblers' awareness of them, a careful analysis of a gambling episode is carried out.

B. Detailed Analysis of a Gambling Session

An innovative way of assessing the gamblers' erroneous thoughts is through a detailed analysis of a gambling session. For this analysis, clients are invited to describe in detail what they were thinking about before, during, and after a gambling session. By asking gamblers what they were doing and thinking at each stage of a memorable gambling session, the therapist will gain access to the illusions and cognitive errors of clients. The following questions are examples of what the therapist may ask the client:

Before: "What were you doing when the idea of gambling popped into your head? What were you thinking at that precise moment, or what were you saying to yourself?" "Once you decided to go, what did you do? What was going through your mind?" "On your way to the casino, what were you thinking?" "Once you arrived there, what did you do and why? How did you choose your slot machine or roulette wheel? Did you start gambling right away? What were you thinking then?"

During: "What was your first bet? Why?" "Because gamblers have their own specific ways of gambling, how were you playing? What were you thinking at that precise moment? Why?" "Tell me more about what you were doing and thinking while you were playing the game." "Pretend I don't know the game, what would you recommend if I were to play? Why?" "Do you pay attention to what is happening on your slot machine or bingo table? Why?" "Once you lost the \$60, what did you do? What were you saying to yourself? Why didn't you quit at that time?" "When you went to the bank machine, what were you saying to yourself?" "When you came back to the game, what did you do? Why?" "Do you sometimes change your slot machine for another? Why?"

After: "Once you lost everything, what did you do? and why?" "On your way home, what were you thinking? What did you do after?"

The information gathered at the "during" phase of the analysis will identify the gambler's obvious misconceptions about randomness. This process also allows clients to discover some of their own errors in perception. Gamblers will often spontaneously describe strategies that assume that there is more predictability present than is in fact the case. Inevitably, gamblers wrongly use information to predict an event that is independent of all other

events, and is essentially unpredictable beyond its chance probability. The therapist's attitude during this analysis should be one of curiosity and a certain naiveté concerning gambling, rather than a confrontational or challenging approach. This will usually lead to cognitive dissonance within clients, as they attempt to clarify and justify their beliefs and behaviors; this dissonance can be useful in the therapeutic phase. The ultimate goal of this procedure is to make clients doubt the validity and reliability of the predictors they rely on while gambling (behavior, feelings, thoughts). Progressively, clients will learn to free themselves of their erroneous thoughts and regain control over their choices and lives.

C. Cognitive Treatment

In the next phase of therapy, clients are invited to give their definition of the concept of chance or randomness. At this point, games of skill are discussed in contrast to games of chance, as gamblers often mistakenly believe that games of chance can be influenced by the application of skills that will improve their chances of winning. This example of the illusion of control explains why people tend to bet more money as they become more familiar with a game, firmly believing that they have developed specific skills that can be used profitably. During this stage of treatment, information is provided to highlight the fact that games of chance essentially exist for business reasons, and that therefore the sole purpose of these games is to make a profit. At this point, clients may become ready to discuss their misconceptions about randomness and all the pitfalls that surround this misconception. Literature detailing the frequent misconceptions about gambling may then be provided to the gamblers.

D. Increasing Awareness toward the Notion of Randomness

The crucial concept of randomness, or independence between events, is addressed as a priority in the treatment. The explanation and demonstration of the fundamental concept of randomness is the heart of the treatment program. The concept of randomness is essentially that no event can influence another, which results in the absolute unpredictability of events. Because games of chance are random, the events they involve cannot be influenced, and in reality no strategy has the capacity to control the outcome of the game. The therapist will illustrate the concept of randomness by referring to the client's own gambling strategies, helping

them to realize that these strategies arise from the mistaken linking of independent events. The therapist should always remain focused on any verbalizations made by the client relating to the attempt to predict the outcome of a game by linking unrelated events. Clients will gradually realize that their beliefs are erroneous, and more importantly that these beliefs are based on the association of irrelevant events, that are actually unrelated to their chances of winning.

A useful way to illustrate how erroneous links can be made between unrelated events is to toss a coin. First, therapists might ask the gambler to predict whether the next toss will result in heads or tails and to explain their choice. Most gamblers will say that their choice is based on a 50/50 probability of each possible outcome, which is indeed correct. This exercise is carried out a few times to demonstrate that predicting heads or tails is simple, and that the outcome of each toss is independent from every previous toss. At this point, clients will generally agree with the therapist. Then, to demonstrate the presence of erroneous perceptions during gambling, a simple test can be performed. The therapist tosses a coin six times without showing the results to the client. The therapist then writes down six consecutive heads, no matter what really happened, and covers these results with a piece of paper. Once again, the gambler is asked to predict the outcome of the next toss. After the choice has been made, the six "previous" outcomes are revealed, and the gambler is asked if he or she would like to change his or her prediction before the coin is tossed again. Whether the gambler changes the prediction or not, he or she will certainly examine the series of previous outcomes. The therapist can then point out that although the client knew that every outcome of a coin toss would be independent, the gambler examined past outcomes even though they were perfectly useless in the prediction of the next result. This simple exercise has proven to be very helpful for demonstrating how this tendency to link irrelevant events is very powerful. The concept of randomness is then explained in detail and illustrated by examples of specific types of games the client has played.

E. Cognitive Restructuring Exercise Sheet

In the next part of treatment, clients are asked to identify their own erroneous perceptions about gambling and to write them down. This can be achieved through an additional analysis of a specific gambling session, or through a variety of methods, that is, asking

gamblers to describe what they typically say to themselves when they gamble; by simulating a game and having clients describe how they choose their bets; or by asking them to imagine a gambling session and describing out loud what they are thinking using the "thinking out loud" method for gambling.

During the therapy program, pathological gamblers will monitor their own verbalizations when they are thinking about gambling, when they have the urge to gamble, or when they actually gamble, if they are not able to remain abstinent. The client's tasks are to (a) to identify erroneous perceptions, (b) to evaluate and challenge the adequacy of these perceptions, (c) to replace these inadequate perceptions by adequate verbalizations, and (d) to assess the strength of their beliefs in their new, realistic perceptions. The following is an example of how such cognitive restructuring might be achieved with clients who have just relapsed and lost a large sum of money:

Therapist: "What happened before you decided to gamble?"

Gambler: "I had just received an unexpected amount of money."

Therapist: "What did that mean to you at that moment?"

Gambler: "I saw it as an opportunity to make it grow a little."

Therapist: "To make it grow..."

Gambler: "Yes, since I had lost so many times recently, I felt it was going to be my turn to win."

Therapist: "Do you usually listen to such a feeling?"

Gambler: "Yes, all the time!"

Therapist: "Does it ever happen that you lose, even when you have this feeling?"

Gambler: "I understand what you mean by that question..."

Therapist: "This feeling seems to get you into a lot of trouble. Since you listen to it, would you rate this feeling as a good or bad predictor of winning?"

Gambler: "I never thought of being critical about my feelings. I guess I should be..."

The successful resolution of this phase is normally required before further issues can be addressed. If the illusion of predictability in gambling events remains, relapse is likely to occur. This is the most important target of the treatment. Of course, other erroneous thoughts, superstitions, or intuitions also stem from the basic error of linking independent events. The belief that a specific watch can bring luck and that a specific feeling can predict the outcome of a game are good examples of this phenome-

non. However, other erroneous thoughts must also be addressed even if they are not linked to misconception about randomness. For example, many gamblers will say to themselves that “I have nothing to lose by continuing to gamble” or “This time, I will control myself,” or “I will gamble only \$20.00, that won’t do me any harm,” or “I want to win a last time before I quit gambling. I must not quit as a loser.” Obviously, all these thoughts must be addressed if a treatment is to be maximized.

When they are in the process of modifying their habits, gamblers usually find it helpful to use a cognitive restructuring exercise sheet. When they are confronted with a high-risk situation, clients must ask themselves what they are thinking, identify what their misconceptions are, and correct them with realistic thoughts. Finally, clients must choose what they want to do. Gambling is a choice as long as the gamblers are fully aware of their thoughts, beliefs, and misconceptions. Furthermore, our clinical experience and empirical data support the proposal that other therapeutic components such as behavioral strategies can be helpful within such a cognitive therapy to diminish the risk of a relapse. However, these behavioral interventions must follow, not precede, the cognitive correction of erroneous perceptions if therapeutic gains are to be maintained.

F. Behavioral Strategies and Relapse Prevention

Clients undergoing treatment for pathological gambling often struggle with many high-risk situations that may reduce their resistance to gambling. Cognitive correction will help clients to develop a more realistic perception of gambling that will help them to refrain from participating in these activities. However, social, professional, or financial difficulties may compromise their abstinence goal and put them in a state of vulnerability. Behavioral interventions can forestall many problems and raise the efficiency of a cognitive treatment.

A basic relapse prevention strategy is to ask clients to list the high-risk situations that may confront them following treatment. The purpose of this exercise is to make clients aware of what triggers their desire to gamble. There are five main categories of high-risk situations: (a) exposure to gambling situations, (b) financial problems, (c) emotional or relational problems, (d) lack of employment, and (e) alcohol and drug consumption. These difficulties can be prioritized, and strategies for dealing with these situations can then be generated through the use of problem-solving training or social skills training.

1. *Exposure to gambling situations:* Exposure to a gambling situation is by far the most difficult test of the gambler’s ability to remain abstinent, and the one in which relapse is most likely to occur. Thus, therapist and client must discuss the possible consequences associated with high-risk gambling situations. Avoiding these situations becomes an alternative, and clients are strongly encouraged to find strategies that will enable them to avoid exposure to gambling. For example, on their way home from work, clients may choose alternatives route that do not require them to drive past a gambling establishment. Or, a client may choose only to frequent bars that do not have video lottery terminals.

2. *Financial problems:* Because excessive gambling involves important financial loss, gamblers must find ways to stabilize their financial situation. It will therefore be useful for the therapist to know how much money has been lost in gambling activities, what the client’s weekly earnings and expenses are, as well as the amount of the client’s gambling-related debts. Given this information, the therapist can help clients find money-managing strategies such as asking a family member to take care of their finances for a period of time. During the high-risk period immediately following therapy, many gamblers find it helpful to carry a small amount of money or no money at all on their person. This behavioral strategy serves to restrict access to money and discourage excessive gambling behavior. Along with cognitive therapy, some clients may benefit from the advice of a financial counselor, to help resolve financial problems and maintain their motivation to abstain from gambling.

3. *Emotional and relational problems:* If needed, the therapist might explain how emotional or relational difficulties are linked to gambling problems and discuss ways in which the client can resolve these difficulties. Social skills training is useful, for example, when gamblers have difficulty saying “no” to an invitation to gamble. Social skills training can teach clients how to refuse such invitations. For others, gambling activities might conceal difficulties with establishing social contacts or maintaining friendships. Learning how to develop new, mutually rewarding social ties might in these cases aid clients in abstaining from gambling.

4. *Lack of occupation:* Gamblers are encouraged to look for new activities to occupy the time they formerly spent gambling. Activities they enjoyed prior to the onset of their gambling problem are often the key to safely occupying their new spare time. Scheduling specific activities is a good way to avoid the feelings of emptiness and boredom that are so frequently associated with relapse. Behaviors that improve the quality and closeness of

clients' relationships are emphasized. In fact, because pathological gamblers tend to isolate themselves, they often abandon activities involving their spouses or children. Simply encouraging clients to go to the park and play with the people they love can be very beneficial.

5. *Alcohol and drug consumption:* For many gamblers, alcohol or drug consumption contributes to losing control and leads to excessive gambling. If this appears to be an issue, it should be evaluated immediately. Even if there is no substance dependency, but some substance abuse is occurring, the client will have to address this issue because it can contribute to the maintenance of excessive gambling.

G. Relapse Prevention

Relapse prevention is a major theme throughout therapy. When clients have successfully modified their cognitive errors and gambling behaviors, the therapist introduces a relapse prevention strategy. First, the therapist asks clients to describe what a relapse would mean to them, and then to outline the events, thoughts, or situations that could trigger such a relapse. A discussion about past relapses can be helpful. The therapist employs other strategies to prevent relapse such as a gradual tapering-off of therapy or increasing time between consultations. This tapering-off strategy encourages clients to perform their cognitive exercises after the end of the therapy, to use available resources, and to promote the idea of participating in self-help groups such as Gamblers Anonymous. Finally, the therapist outlines what clients can do in emergency situations, or when they experience the overwhelming urge to gamble. They are instructed to: (a) stay calm, (b) remember their commitment, (c) carefully analyze the situation that has produced the relapse or increased their desire to gamble, and (d) ask for help.

II. THEORETICAL BASIS

The central assumption of cognitive approaches to the treatment of pathological gambling is that individuals gamble because they maintain the unrealistic hope that they will recover their losses if they continue to gamble. It is assumed that their erroneous beliefs about gambling, the nature of predictability, and their own special skills and knowledge concerning the prediction of gambling outcomes conspire to maintain the gambling far beyond any reasonable limits. It follows that the correction of these erroneous perceptions weakens the belief that gambling losses can be recouped.

Gambling takes place when an item of value, usually money, is staked on the outcome of an event that is entirely unpredictable. In gambling, the primary task of gamblers is to use available information at their disposal to try and predict the outcome of an event that is essentially unpredictable. Most gamblers behave as if the act of gambling actually involves some element of personal skill, the exercise of which might influence the outcome of the game. In the mind of the gambler, skill can be superimposed on chance. This phenomenon, described as an illusion of control, refers to the belief that the outcome of a chance event can be influenced or controlled to some degree by one's skill or ability.

Most gamblers fail to correctly perceive or understand that there is no relationship between their behavior and the outcome of a chance event, and that no matter how hard they try, they have no ability to exert any influence or control over the final outcome. There is an abundance of experimental and anecdotal evidence demonstrating the existence of this illusion of control among gamblers.

James Henslin conducted an observational study of gamblers in the casinos of Las Vegas. He described a characteristic behavior displayed by some gamblers: when "craps" players wished to obtain a high number on the roll of a dice, they threw the dice rapidly and forcefully, while when they desired a low number, they threw them slowly and lightly. In this case, the illusion of control can be seen through the player's attempt to "control" which numbers come up through the use of a specific type of wrist motion when throwing the dice.

In our laboratories, we have verified the central role that illusions of control and erroneous perceptions have in the overall process of gambling. In one experiment, we invited two groups of gamblers to participate in a session of roulette. The two groups were exposed to the same conditions as those found in a casino, with one exception: the "active gamblers" were allocated the responsibility of throwing the roulette ball themselves, while for the "passive gamblers" in another group, the dealer performed this task. In reality, the numbered slot where the ball finally came to rest was left to chance regardless of whether the gambler or the dealer threw the ball onto the roulette wheel. However, the results of the experiment clearly demonstrated that participants who threw the ball themselves placed higher bets and overestimated their chances of winning to a greater extent than did the passive gamblers.

As intelligent beings, we like to impose order and causality on the events that happen around us. We are not used to, and feel a degree of discomfort in, relying

on chance as an accurate and plausible explanation for events. Chance is a concept we are most likely to invoke when confronted with events that are totally unusual, unpredictable, coincidental, or unexpected. However, scientific studies have convincingly revealed that few people fully understand the concept of randomness. People do poorly in generating a random sequence of numbers. People have an excessive tendency to avoid repetition, and because of this, when asked to produce something random, they produce too many variations in sequences or patterns. For example, few individuals will believe that the following sequence of heads (H) and tails (T) was randomly generated: H-T-H-T-H-T-H-T. The same is true when playing the 6/49 lottery. Few will have the courage to select 20, 21, 22, 23, 24, and 25 as their choice of numbers despite this series having the same probability of coming up as any other combination.

We have noted that this cognitive tendency reflects the fact that people in general find it difficult to take into account the independence of events. This cognitive tendency or trap is, in our opinion, one of the most important elements in understanding the psychology of the gambler, and ultimately, the pathological gambler. Let's take another example. When we ask gamblers to generate sequences of "heads and tails," we observe that more than 70 to 80% of people rely on the outcome of past events in predicting the next one. Yet, we also know very well that in each toss of the coin, "heads" or "tails" has, and will always have, a one in two chance of appearing. How does this error in thinking often manifest itself? A detailed analysis indicates that the principal error committed is in the desire to have an equal proportion of "heads" and "tails" in a sequence; the gambler attempts to move away from any form of apparent pattern and avoids long sequences of the same event. This has been shown empirically by the tendency of people to prefer a selection of "heads" after a run of six or seven "tails." The outcome of the next toss is still one in two for heads independent of whatever pattern or sequence of heads or tails came before it.

What happens in the minds of problem gamblers when they are in the midst of gambling? How do gamblers interpret the probabilities and outcomes of a game to conclude that, despite the presence of repeated losses, taking continued greater financial risks is justifiable? Several observations made in our experimental and clinical work leads us to the conclusion that gamblers' cognitive activity is distorted in many respects, and that these distortions bias the individual's perception of reality. To understand and solve the puzzle of cognitive dis-

tortions, we must examine the cognitive activity of gamblers during play; for this purpose, the "thinking out loud" method is extremely useful. In this method, gamblers are requested to clearly verbalize all the thoughts that go through their minds about the game itself, even if these statements seem unimportant or irrelevant to them. This verbalization of internal dialogue is recorded onto audiocassette and then analyzed by an experienced psychologist. The researcher then evaluates and categorizes the cognitive content of the audiocassette into two classifications: "rational and adequate" or "irrational and erroneous," according to whether the elements verbalized seem to consider accurately chance as the primary determinant of the outcome. With the assistance of the thinking out loud method, we studied slot machine players. The results showed that more than 75% of the verbalizations made by the players were irrational, inadequate, or erroneous; that is, they did not reflect reality in that they clearly ignored or denied chance as the determining element of the game. It should be noted that this is a particularly large percentage considering that slot machines involve little subtlety and no opportunities to apply personal skill of any kind.

These results have been independently confirmed in several other studies carried out around the world, among different types of gamblers, using various types of games. In addition, we have observed that the erroneous perceptions of gamblers share a common factor: Gamblers consistently commit the error of associating previous independent events in predicting the outcome of the game.

III. EMPIRICAL STUDIES

Although the prevalence estimates of pathological gambling range between 1 and 2% of the population, the number of gamblers who will seek professional treatment is only a small percentage of the population. Relatively few effective interventions have been developed and validated. Most published papers dealing with the treatment of pathological gamblers have either been uncontrolled case studies, or consisted of small samples, thus making it difficult to reach any conclusions about the efficacy of the interventions in question. Their most useful function might be as a source of valuable hypotheses concerning treatment efficacy that can then be evaluated more rigorously. This article is based on studies that have employed a randomization procedure to allocate gamblers to treatment and control groups. A review of the literature reveals that few studies appear to

exist, originating in Australia, Canada, and Spain. We review these studies, according to the countries where the interventions were developed and evaluated.

A. Australia

Nathaniel McConaghy, Alex Blaszczynski, and their colleagues, in Sydney, have conducted several controlled studies of imaginal desensitization (ID), which is based on a conceptual model of compulsive behavior. According to their theory, if an individual does not perform a given compulsive behavior when in the presence of conditioned stimuli (which could be environmental or cognitive), tension and arousal will increase and will be relieved only when the compulsive behavior is carried out. Imaginal desensitization (ID) was developed as a means of giving individuals control over their compulsive behavior by reducing their level of arousal and tension in the presence of the conditioned stimuli, so that the urge to complete the behavior sequence is no longer experienced.

In 1983, these researchers compared the efficacy of ID for pathological gambling to electric aversion therapy. ID consisted of inducing a relaxed state in the presence of several imaginal gambling-related episodes. Electric aversion therapy consisted of delivering an aversive stimulus to inhibit the excitation produced by undesired gambling stimuli and interrupt the compulsion to gamble, which otherwise would be acted on. The key findings were a significant difference in the number of ID participants attaining cessation or a marked reduction of their gambling and urges, compared to participants in the electric aversion condition. They further conducted an additional trial to evaluate the efficacy of ID. Twenty pathological gamblers were randomly allocated to ID and imaginal relaxation, a treatment similar to ID but that does not instruct the individual to visualize gambling situations but rather being in the presence of relaxing situations. Results indicated no differences at either follow-up assessment point, with 30% of both groups reporting either abstinence or controlled gambling. Similar results were reported for gambling urges.

B. Spain

Enrique Echeburua and his colleagues compared three different active treatments for pathological gambling to a wait-list control group. The active treatments consisted of exposure–response prevention, group cognitive restructuring, and a combination of these two types of treatment. Exposure–response prevention is a behavioral treatment in which participants are trained to

manage money, avoid gambling situations, and encouraged to remain present in high-risk gambling situations but refrain from gambling. The cognitive treatment challenged the “illusion of control” and other memory biases within a group format. The combined treatment included both treatments. These three treatments differ from each other that one half of the participants in each type of treatment received it in a group format, and the other one half received it in an individual format. Although the three treatment groups showed higher rates of abstinence at 6-month posttreatment than did the control group, there was no difference between the combined group and the control group. The individual treatment was found to be superior to the group or combined treatment at the 12-month posttreatment assessment, but there were no group differences between the active treatments for any of the other dependent variables at 12 months. The control group, however, did show considerable improvement at 6 months on most of the gambling-dependent variables, which suggests that natural recovery or spontaneous remission played an important role in the outcome of this study. This finding underscores the need for including non-active control groups in gambling research studies.

In a follow-up to this study, 69 problem slot machine gamblers were treated with stimulus control and *in vivo* exposure with response prevention and then randomly assigned participants to one of three treatments: individual relapse prevention (RP), group RP, and no treatment control. The RP conditions trained participants to identify high-risk gambling situations and to develop effective coping strategies for these situations. Exposure to gambling-related stimuli was also included as a component of RP. All 69 participants stopped gambling following the exposure–response prevention phase of the study, a precondition to enter the relapse prevention phase. The results showed no significant differences between the two RP groups and the no-treatment control group until 3 months posttreatment. At that point, and continuing until the 12-month follow-up point, the two active RP groups were achieving significantly higher rates of abstinence than the control group.

C. Canada

A treatment developed by Robert Ladouceur and his team was among the first to target cognitive errors, such as the independence of events, in the treatment of pathological gambling. Assuming that this fundamental error is the basis of the progression of nonproblematic to problematic gambling behavior, the target of the treatment was to help gamblers realize this cognitive

error and provide them with the means of correcting their perceptions. Using a single-case experimental design, this treatment program included four components. The combination of cognitive correction, problem-solving training, social skills training, and relapse prevention resulted in positive treatment outcomes. Following treatment, participants no longer met *DSM-III-R* criteria for pathological gambling. These results were maintained at a 9-month follow-up.

Three ensuing studies further investigated the efficacy of this procedure through the use of controlled designs. The efficacy of cognitive-behavioral treatment was compared to a wait-list control group. Participants were randomly assigned to a control group or to an individual treatment consisting of cognitive correction of core erroneous gambling cognitions, problem-solving training, social skills training if indicated (about one half of the sample) and relapse prevention. The treated group was found to improve on all key dependent variables compared to the control group, as well as on measures of gambling behavior (frequency, hours spent gambling, and amount of money spent gambling). Clinically significant changes indicated that the majority of the treated participants no longer met the *DSM-III-R* criteria neither at the end of treatment nor at the 12-month follow-up.

Because the cognitive correction was accompanied by two behavioral procedures (problem solving and social skills training), these positive outcomes may not have solely been the result of the cognitive intervention but may also have been due to the positive effects of the behavioral intervention. To investigate this possibility, a preliminary study of the treatment of five pathological gamblers was examined using a multiple-baseline, across-participants design. Cognitive correction targeted gamblers' erroneous perceptions of randomness was the only therapeutic intervention used. Following treatment, four participants reported a clinically significant decrease in their desire to gamble, an increase in their perception of control, and no longer met *DSM-IV* criteria for pathological gambling. Therapeutic gains were maintained at a 6-month follow-up assessment. These results suggest that a cognitive therapy targeting misconceptions about randomness is a promising treatment for pathological gambling.

In a related study, Ladouceur and his colleagues compared the efficacy of this purely cognitive treatment to a wait-list control group. Patients (mainly video lottery players) were randomly assigned to an individual treatment consisting of the cognitive correction of core erroneous gambling cognitions, followed by relapse prevention. The treated group was found to improve on all key dependent variables compared to the control group,

as well as on measures of gambling behavior (frequency, hours spent gambling, and amount of money spent gambling). Thirty of the 35 treated participants (85.7%) attained the criteria for clinically significant change compared to 4 of 29 participants (13.8%) in the control group. More important, all 35 treated participants scored 4 or less on *DSM-IV* criteria for pathological gambling. These therapeutic gains were maintained at a 6- and 12-month follow-ups.

This latter study was recently replicated, but therapy was delivered in a group rather than an individual format (4–5 individuals per group). Results from this study confirmed previous results: Over 85% of the treated gamblers were no longer considered pathological gamblers (*DSM-IV*) at the end of treatment. In addition, participants had a greater perception of control over their gambling problem, as well as an increased self-efficacy in high-risk gambling situations.

These studies show that the central component of the treatment was highly specific, and based on a theoretical understanding of cognition in gambling, which may explain the magnitude of therapeutic gains. Research on the psychology of gambling suggests that gamblers' core cognitive error lies within their beliefs about randomness, and in their belief that they can control the outcome of random events (the illusion of control). It follows that if the gambler's erroneous perceptions and understanding of randomness can be corrected, then the motivation to gamble decreases dramatically.

IV. SUMMARY

Effective treatments are now available to help pathological gamblers. The rationale of the interventions is grounded in empirical studies that have clarified the psychology of gambling. Clinical research should now address the important issue of which patients should receive which treatment.

foreground As distinguished from background, that aspect of experience that is the focus of attention at any given point.
Gestalt A German word that has no direct translation in English. “Configuration,” “structure,” and “whole” are used as translations, but none of these capture the complete meaning. “Figure” and “Gestalt” are often used interchangeably.
organismic self-regulation The process whereby homeostasis is maintained via the figure formation/destruction process.

GLOSSARY

background As distinguished from figure or foreground, that which is not uppermost in awareness. Provides the context and is the source from which figures emerge and become prominent in awareness.

closure The result of the natural movement toward the completion of perceptual or experiential units.

contact The experience at the self/environment boundary that leads to assimilation and growth. Good quality contact involves awareness and excitement.

contact boundary The dynamic relationship at the meeting point of self/other, or self/environment. Where experience occurs, and the focus of therapeutic intervention.

creative adjustment A person’s best adaptation to dealing with feelings and needs in response to environmental inadequacy in meeting the needs, or competing environmental requirements.

figure What stands out from the background as a focus of interest and attention. Generally related to a need or desire.

figure formation/destruction process The process whereby a figure of interest emerges, becomes a focus of attention and is acted upon, resulting in the dissolving of that figure.

Gestalt therapy has roots in psychoanalysis, Gestalt psychology, Reichian character analysis, and the work of the early phenomenologists. It was developed in the 1940s primarily by Frederick Perls, Laura Perls, and Paul Goodman. Gestalt therapy is humanistic, holistic, and experiential. It is a process-oriented and relational approach based on a theory of healthy functioning. The focus in therapy is on disruption of the natural process of self-regulation. The goal of treatment is the restoration of awareness, which allows for increased choice and flexibility in all aspects of living.

I. DESCRIPTION OF TREATMENT

A. Philosophical Foundations

Gestalt therapy method is guided by three philosophical foundations. The first of these is field theory, a concept that comes from physics. The “field” is a dy-

namic interrelated system, each part of which influences every other part. Nothing exists in isolation. Gestalt therapy is a field theoretical and process-oriented approach, which means the therapist attends to the total field including content and subject matter, as well as the here-and-now process occurring in the moment. This involves things such as the patient's tone of voice, style of communication and interaction, facial expression, physical gestures, posture, breathing, sensation, and affect. The therapeutic field also includes the patient's history and current situation, the therapeutic relationship, feelings experienced by the patient and the therapist, and their mutual impact on one another.

The second philosophical foundation is phenomenology. The Gestalt therapist attempts to bracket off preconceived biases, beliefs, theories, and interpretations, and attend as much as possible to what is actually understandable through the senses, with the focus on the patient's subjective experience. The therapeutic stance is one of meeting the patient where he is, and the therapist describing what she observes, rather than explaining or interpreting. The patient is encouraged to do the same. The therapist also brings her own feelings, sensations, and awareness into the interaction with the patient when useful for the treatment.

The third philosophical foundation is dialogue. A dialogic stance requires that the therapist be "present," confirm the patient, and be available for an I-Thou way of relating. Presence is the therapist bringing all of himself to the encounter in the here and now. Confirmation involves seeing and accepting patients for all they are and all they are capable of being. The I-Thou mode of relating has the qualities of immediacy, directness, presence, and mutuality. These qualities create a therapeutic relationship that is not hierarchical, and a meeting between patient and therapist that is in and of itself healing.

B. Goal of Treatment/Theory of Change

In Gestalt therapy, the goal is increased awareness. Although the patient presents specific symptoms such as anxiety, depression, stress-related physical complaints, relationship difficulties, or character/personality issues, the Gestalt therapist does not focus only on symptoms or behavior change. Rather, Gestalt therapy provides a holistic perspective where symptoms and problematic behaviors are seen as the person's best attempt to deal with conflicting needs, or needs conflict-

ing with environmental requirements. Psychological problems, symptoms, and difficulties in interpersonal relationships result from what were originally creative adjustments that have become rigid, reflexive, and unaware, restricting the experience of self, and possibilities. By focusing on moment-to-moment process in the therapy session, the Gestalt therapist works with how the person creates and maintains her particular experience of self and other, and how this experience impacts the current situation.

Change then occurs spontaneously, as a result of this increased awareness. Gestalt therapy's change theory is paradoxical in the sense that change occurs not as a result of attempting to change (one part of the self trying to control and dominate another part) but as a result of the patient attending to, investing more fully in, and living more completely the actual current experience—what is. Doing this enables new responses to emerge that better fit current needs. Increased awareness leads to choice and opens up new options for behavior and interaction.

As aspects of the personality that have been disowned are re-identified with, an expanded sense of self is also restored. For example, the patient increases her capacity to experience and express grief, anger, or tenderness, which expands her ability to live authentically, and to connect more with other people. Gestalt therapy does not focus directly on problem solving, but rather on what limits the patient's capacity for creative solutions. As the saying goes "Give a person a fish and he eats for a day; teach a person to fish and he eats for a lifetime." A Gestalt therapist is interested primarily in the latter.

C. Therapy Method

By attending to observable behaviors that indicate blocked awareness and interruptions to acting on needs, desires, or interests, Gestalt therapy captures the essence of a person's existential position in the world, which impacts all aspects of self-experience and relationships. For example, the patient speaks softly, apologizes frequently, becomes slightly tearful but cannot cry, changes the subject, or shuts down if strong feelings threaten to emerge. Can she become aware of how she clamps down on herself? What makes this shutting down necessary? How might holding back, or not allowing herself to take up space be a theme in this patient's life? How many areas of her experience and relationships are impacted by it? How is it related to her presenting symptoms of anxiety or depression, or the dissatisfactions in her life?

The therapy process enables increased awareness of these blocks and how they are maintained, and also looks at why they were initially developed. For example, if the experience or expression of sadness has been criticized, punished, or even ignored by the parent, the child learns to cut off either the feeling, or its expression to others, or both. If a child's needs have been met with resentment, criticism, or disgust, the child's creative adjustment is to learn to block awareness of needs, or to learn to avoid showing or expressing them to others.

Through focused attention, the patient can become aware of how he blocks feelings/expression, for example, tightening muscles to hold back tears, internal messages such as "Don't be weak," or "Men don't cry." And the patient will discover the etiology—what made this necessary in his development. Symptoms then resolve as the patient reconnects with his authentic self and experience. For example, anxiety may result from a fear that certain "unacceptable" needs or feelings will surface in a particular situation. Depression may result from holding in anger or grief, poor self-esteem from directing frustration or criticism toward the self that needs to be expressed to another. Relationship problems may result from an inability to open up and reveal feelings, or difficulty needing another person.

Gestalt therapy's method is experimental and experiential. Experiments can be diagnostic as well as serving to highlight current experience and uncover new possibilities. For example, an unassuming person who does not make eye contact and qualifies most of what she says, complains that people do not listen to her or take her seriously. In therapy she might be asked to experiment with lecturing the therapist on the proper way to do something that is in her area of expertise. She might then show and experience the side of herself that is a knowledgeable expert. She may begin to speak more directly and forcefully. In this process she can get more in touch with this aspect of herself, as well as increasing her awareness of her reluctance to show this aspect of herself to others, or her anxiety in doing so. Conversely, the patient may speak to the therapist as if she is not an expert, when in fact she is. Her language might be filled with reflexive use of qualifying phrases. She might speak without conviction. In either scenario, the patient can see and understand how she contributes to others not giving her the respect she desires.

The patient also learns what made this way of being necessary. She could have been told "Children should be seen and not heard," or one of her parents might have become angry or silently disapproving if she ex-

pressed an opinion of her own. She might have been told she was stupid or wrong. Prior to therapy, she may not have remembered these incidents, she may have dismissed them, or minimized their impact. She may not even have been aware that she presented herself as timid and unsure of herself, or why it was important to do so. With the new awareness, she regains the possibility of a wider range in experience and behavior.

Gestalt therapy uses experimentation to increase awareness. Meaning for the patient then comes from experienced awareness rather than being imposed by the therapist's interpretation. The therapist tries to have no goal, agenda, or desired outcome in proposing an experiment, other than to observe and work with what happens next. An experiment can also be used to highlight an aspect of the patient's way of communicating. For example, a person who qualifies much of what he says by use of words like "Maybe," "Possibly," or "I guess," could experiment with either exaggerating the use of qualifying words, or cutting them out entirely and adding after every sentence "and I mean that." The therapist encourages the patient to pay attention to his experience as he does an experiment, and to express any reluctance in doing it.

Experiments can also enrich what a person is saying, and transform it from "talking about" to a lively present encounter. For example, the patient might imagine the person she is talking about is present in the room, and express her feelings directly to that person. This use of the empty chair or two chair experiment can also be effective in highlighting an internal conflict. The patient might imagine a part of herself in the empty chair and create a dialogue between the conflicting aspects of herself, such as the part that wants to be more creative and take more risks and the part that is more logical and conservative. This type of experiment can also explore an area of impasse or stuckness, for example, suggesting the patient develop a dialogue between the part of herself that wants to leave her marriage and the part that wants to stay.

To give an example of some of the above concepts, a patient who learned to stifle her feelings and needs, and to nurture herself with food comes to treatment depressed, with a poor self-concept, complaining that she has "tried everything" to control her eating and has been unsuccessful. Turning to food to meet emotional needs was at one time her creative adjustment, the best option available given the needs she had and the lack of available gratification possibilities—in this case a mother who was stern and unaffectionate and sent the patient to her room if she was "too emotional."

The Gestalt therapist observes this patient's responses in the moment, and helps to facilitate her awareness of them. For example, the therapist notices that the patient speaks more quietly and holds her breath when she talks about a hurtful or frustrating experience. The therapist can either make an observation ("It looks like you're tightening your jaw" or "I notice you holding your breath") or ask the patient to attend to what she is currently aware of ("What is your experience right now as you tell me this?"). The patient becomes aware that she is trying to control herself. The therapist attends to her need to control herself. He also attends to what she is controlling—verbalizing feelings, showing anger or tears. Through this process the patient becomes aware that there is also a part of her that would like to express itself and feels held back. Both aspects are explored.

The working through process involves the patient becoming aware of the importance of holding back feelings to prevent reexperiencing the rejection she felt from her mother, or the anger she felt toward her mother when she had feelings or needs. She might remember a forgotten traumatic experience. She might also discover that she expects the therapist to have a similar response. This patient learned over time to identify with her "nonfeeling, nonneeding" self. Her eating behavior may be one of the only remaining vestiges of her "feeling, needing" self. In therapy, she can also experiment with giving voice to the part of her that wants to eat, and re-identify with her needs and desires, instead of only wanting to suppress these needs. For example, she might realize that while part of her wants to stop overeating, part of her—out of her awareness—also wants to continue eating as a way to take care of feelings and to comfort herself. This part might say something like "Don't take food away from me, it's all I have." Change becomes possible as she invests more fully in being where she is—feeling those needs she translates into a desire for food—and may take the form of learning to nurture herself in other ways, or to get her needs met in relationship with others.

II. THEORETICAL BASES

Many central concepts of Gestalt therapy theory are based on laws of perception discovered and studied by Gestalt psychologists in the early 1900s. Gestalt therapy applies these laws more broadly to all aspects of experience and psychological functioning. Importantly, these Gestalt psychologists discovered that we are not simply passive recipients of perceptual stimuli, but that

we are active in organizing our perceptual field. Laws discovered by the Gestalt psychologists include the natural tendency to perceive a figure against a background as a way of organizing experience, and a natural tendency toward completion or closure.

Gestalt therapy takes its theory of healthy functioning from a biological concept called organismic self-regulation. This describes the organism's process of taking in from the environment what is needed (food, oxygen) and expelling into the environment that which is not required (waste products, carbon dioxide) in order to maintain balance or homeostasis. Applied to psychological functioning, this theory says that in health, people will naturally go to the environment to get emotional and psychological needs met—the need to be listened to, need for support, sex, physical comfort, social contact—and will discharge as needed by talking, expressing feelings, crying, touching, doing, and creating. Gestalt therapy theory does not see the individual as separate from the environment but rather considers the individual/environment field.

According to Gestalt therapy theory, such self-regulation occurs via the figure formation/destruction process. This process is central to any human functioning and as such is a core characteristic of people. In all functioning there is an ongoing process of the formation of a figure of interest and the eventual gratification and dissolution of this need or interest. This cycle has several stages: (1) awareness, (2) clarification of need/interest (3) scanning self-environment, (4) action, (5) contacting, (6) assimilating, and (7) withdrawing. For example, I am on my way to my favorite restaurant for lunch and see an old friend across the street. I become aware of sensations of excitement and increased energy (stage 1). I recognize my interest in talking to my friend (stage 2). I understand that walking across the street will facilitate meeting this need (stage 3). I walk across the street (stage 4). I say hello, and give my friend a hug, and we talk (stage 5). As we say goodbye I tell my friend and acknowledge to myself what this meeting meant to me (stage 6). I walk back across the street with a feeling of satisfaction, resolve to see my old friend more often, and my focus shifts to what I want to eat for lunch (stage 7).

In healthy functioning, a person will maintain balance by intake and discharge as required for the satisfaction of emotional and psychological needs by this continuous process of figure formation/destruction. Assuming there is no interference in this process (a disruption that causes the person to misperceive her needs, or an environment that is hostile to the needs, or both) what becomes figural or foreground is based on

the most pressing need at any given moment. After a need is met, this figure recedes (closure) and is replaced by whatever is next in the hierarchy of needs.

When there is a disjuncture between needs and what is available in (or required by) the environment, a person adapts. A creative adjustment is the best possible accommodation she can make at the time, given her experience, perceptions, and limitations. Over time, these creative adjustments may become obsolete, rigid, and maintained out of awareness, limiting a person's potential for satisfaction and growth. Psychotherapy involves looking at and understanding how the natural self-regulatory process has become disrupted, preventing closure on units of experience.

Disruption can occur at any stage of the figure formation/destruction process, and diminish a person's experience of himself and his ability for contact. A person who is experiencing disruption interferes with his own development of a strong and clear figure (stage 1 and 2) or with the ability to maintain the excitement and energy necessary for action (stages 3 and 4) or to move into satisfying contact (stage 5), which allows for assimilation (stage 6) and closure (stage 7). Either the interference with the development of a strong figure, or the blocking of excitement and action can interfere with good-quality contact. A Gestalt therapist is trained to observe both where in the cycle the disruption occurs and how it occurs. Often the focus is on how the disruption dilutes or distorts interpersonal contact.

In health, a person will perceive, experience, identify with, and act on needs and desires. Healthy functioning requires the ability to readily identify "This is me" or "This is for me," versus "This is not me" or "This is not for me." When disturbances exist in perceiving, experiencing, identifying with, and acting on needs, this loss of functioning is observable by the trained therapist at the contact boundary, which refers to the dynamic relationship at the point where the person and environment meet and interact.

The following five processes are the "how" of any disruption of contact. These processes can occur at any stage of the figure formation/destruction process. It is via these processes, maintained rigidly and out of the person's awareness, that the experience of self and the ability for contact that includes satisfaction of needs and closure is diminished.

Introjecting is experiencing something in the environment as if it is part of the self. An introject is an idea that has been "swallowed whole" without the "chewing" necessary to assimilate it and make it truly a part of the self. Introjecting is particularly problematic if it is a person's primary way of dealing with the world and

relationships (such as doing things for others and ignoring one's own needs out of a sense of duty or obligation) or when the introject is destructive (such as a parental introject "You're good for nothing").

Projecting is disowning a feeling, behavior, attitude, or trait of one's own and attributing it to another, or the environment. For example, a person who is not able to be angry—due to an introject—may inaccurately perceive another person as angry at him.

Retroreflecting is when energy or action that could be directed toward the environment circles back and is directed at oneself. Retroreflecting is of two types. In the first type a person directs toward herself a feeling or action meant for someone or something in the environment. For example, the person who is unable to experience anger toward another person—again due to an introject—might end up blaming herself. Any unaware suppression or shutting down is also accomplished by this type of retroreflecting. The second type of retroreflecting is doing for/to oneself what you would like another person to do for/to you. For example, a person might soothe herself, buy herself gifts, or hug herself instead of getting this need met by interacting with another.

Confluence is the attempt to deny the existence of a self/environment boundary. Confluence requires a lack of discrimination and articulation of points of difference or otherness. While there is the possibility of a "healthy" confluence during which two people feel so joined that they seem "as one" (such as at the moment of orgasm) and there is momentary dissolving of the boundary, prolonged attempts to maintain confluence prevent satisfying contact.

Deflecting is behavior that dilutes or reduces the intensity of contact. Examples are avoiding eye contact, laughing off what one says, circumlocution, and understating one's true feelings. There is disagreement among Gestalt therapy theorists as to whether this is to be considered a separate self-regulatory boundary process, or whether it is the behavioral manifestation of the others—that is a result of introjects, retroreflection, projection, or desire to maintain confluence.

III. APPLICATIONS AND EXCLUSIONS

Because Gestalt therapy is not an adjustment therapy and strives to be value-free, with a focus on understanding each unique individual and the individual's subjective experience as opposed to an "objective" standard for psychological health, there is no popula-

tion that would be excluded from treatment. The phenomenological and field theoretical stance, whereby the therapist is striving to understand the patient's subjective experience rather than impose his own, make this orientation valuable for different cultures and minority groups. The Gestalt therapist does not claim to know what is right for the patient, nor does he desire any particular outcome, as the only goal is increased awareness for the patient that leads to more choice.

Gestalt therapy can be used with all patient populations (children, adolescent, adult, geriatric, physically/mentally challenged, prison inmates, inpatient and outpatient psychiatric patients) as well as in a variety of modalities (individual, couples, family, group, and organization). It is applicable for a wide array of problems (such as eating disorders, substance abuse, affective disorders, personality disorders, PTSD, adjustment disorders, loss, and grief). It is an approach that can be used in both long- and short-term therapeutic work. Of course not every therapist is equally effective with all patient populations, modalities, and diagnoses. The experienced and well-trained Gestalt therapist would be aware of personal limitations and areas of expertise and refer those patients who fall outside of these limits to other practitioners, just as a responsible therapist of any orientation would.

IV. EMPIRICAL STUDIES

Research on the effectiveness of Gestalt therapy is scant, and primarily confined to specific aspects of the approach. Most research has been focused on one technique that comes from Gestalt therapy method—the empty chair (or two chair) experiment. It is important to note that use of this or any other single technique does not actually constitute a Gestalt therapy approach, without application of the three philosophical principles described in the treatment section. Although no single technique can be said to represent the essence of the Gestalt therapy approach, a technique has the advantage of being easily defined and thus accessible to the manipulations of empirical research.

The majority of research used the empty chair technique. Subjects were asked to have a dialogue with either a part of themselves, or with someone else relevant to the issues they were grappling with. Most of the studies that used the empty chair technique found it to be more effective than other forms of therapy or control groups. It was also found to be more effective in reducing anger and producing positive attitudes than either

intellectual analysis or emotional discharge. It was more effective than empathic reflection or focusing for creating a greater depth of experience. For resolving “unfinished business,” it was more effective than an attention-placebo condition.

In one study, K.M. Clark and L.S. Greenberg found the empty chair technique to be more effective than either a cognitive decision-making task or a waiting list control group for resolving decisional conflict. During the process of using this technique, the original decision the person had wished to make often unfolded into a deeper related decision.

In summary, studies have shown this technique to result in an increase in affect, depth of experience, and the resolution of related emotional issues. Results have included a decreased sense of decisional conflict, reduced anger, increased positive attitude, lower systolic blood pressure, and the resolution of “unfinished business.”

Two studies found no benefit in using the empty chair technique for resolving grief issues or dealing with mild depression. In a study conducted by N.P. Field and M.J. Horowitz, the intervention consisted of placing subjects in a room alone and asking them to talk to their deceased spouses for 5 minutes through the direction of a taped recording. Nothing like this would ever be done in an actual Gestalt psychotherapy, which requires a focus on moment-to-moment process and the presence of the therapist. This technique was not found to be effective in reducing symptomatology 6 months later. Another study found the empty chair technique to be no more effective than time for decreasing mild depression. The researchers stated that the lack of positive results may have been due to the short duration of treatment, gravitation toward the mean over time, or experimenter bias.

Focused expressive therapy (FEP) was used in several research studies. FEP borrows from Gestalt therapy method and uses such procedures as directed fantasy, two chair dialogues, and awareness exercises. It emphasizes the importance of emotional insight and the magnification of internal experiences, but it also includes a high level of authoritative guidance and confrontation that is inconsistent with a Gestalt therapy approach. FEP was not found to be as effective as either cognitive group therapy or self-directed therapy. However, the description given for self-directed therapy was actually more similar to Gestalt therapy as it is practiced, than the more authoritarian FEP method used to represent Gestalt therapy in this study.

Few studies looked at a more complete Gestalt therapy approach. Most of these yielded positive results

such as an increase in levels of self-actualization, and more positive attitudes toward body image. Gestalt therapy was found to increase internal locus of control and the assumption of personal responsibility in prison inmates. A Gestalt therapy approach resulted in more behavior change than empathic reflection. Gestalt therapy was found to help Vietnam veterans with symptoms of PTSD. In couples therapy it was effective in replacing power struggles with self-definition, limit setting, and intimacy, resulting in greater clarity, acceptance, and understanding.

V. CASE ILLUSTRATION

The following case example will illustrate the treatment process and application of the theoretical concepts that have been presented. The therapist in this case was Stephen Zahm.

Kim, a 44-year-old successful professional woman was referred by her physician due to recurrent periods of depression. She had been depressed off and on for much of her life. The bouts of depression had worsened recently in both duration and severity. She had not been able to tolerate antidepressant medications, and two previous experiences with therapy, both brief, had not yielded lasting improvement.

Kim presented as a smart, attractive, stylishly dressed woman. Her wit and humor were evident in spite of her somewhat depressed affect. Her facility with language, keen observations, and easy manner made it clear why she had achieved success professionally. During the initial session Kim asked perceptive questions about my experience, my therapy orientation, and how I thought therapy could help her. She had been disappointed in her previous therapy experiences. When asked what she hoped to get from therapy she answered "Not just a Band-Aid, I'd like to get to the bottom of what this depression is about."

Kim described herself as "an overeducated over-achiever," who had been successful in school and in her profession. She worked long hours, but wondered what the point of all her hard work was, as she took little enjoyment from her accomplishments. Kim saw her life as lacking in meaning, with little that gave her pleasure. She said she felt "down" a lot, woke up in the morning dreading the day ahead, and said she was just "going through the motions" of social interaction.

Kim described her relationship with her husband Bill as "pleasant enough" but lacking a sense of emotional connection or passion. She reported little inter-

est in sex herself, and stated that their infrequent lovemaking was "more for him." She said "it's like I'm dead inside, or just numb." Kim reported that most of her friends were work acquaintances, and that she had only one "good friend," but didn't really confide in her. Kim and her husband had no children. Kim and I agreed to meet for weekly individual psychotherapy sessions, and to track whether she felt the sessions were useful and whether she was getting what she needed.

In describing her history, Kim reported that her parents had divorced when she was eight. Her father abandoned the family, moving to another state to avoid paying child support. Kim, the oldest of three, became responsible for helping her mother with her younger siblings and doing household chores so that her mother could go back to work to support the family. Kim also became her mother's confidant, and emotional support. She reported that she never really "got to be a kid" after that, and that her mother "never had time" for her. Kim's mother had died about 8 months prior to our first meeting. She minimized her feelings about her mother's death, saying she thought she had "dealt with it."

Kim's therapy themes emerged right away in her relationship with me. In our initial sessions, her fear of showing or revealing vulnerable feelings to me stood out. For example, when Kim talked about her mother's death she would reflexively shut down. I noticed her retroreflections and deflections including choking back tears, changing the topic, and looking away. I pointed these out in an attempt to sharpen this figure, to clarify what was most important to her at that point. I observed that while she had strong feelings about this loss, it was also important to her not to show these feelings or talk about them to me right then.

This process helped Kim focus on her reluctance to open up and share vulnerable feelings. The theme of having a variety of "softer" feelings (sadness, loss, emptiness) and the reluctance to express them to me was something we worked with over the course of the therapy. The essential components involved introjects such as "Be strong" and "Don't show weakness," and the belief that no one would be interested in her feelings.

Within the first few months of therapy, Kim became more aware of these internal mandates and saw how they were connected to her relationship with her mother. Kim had learned not to reveal her feelings and emotional needs, but rather to focus on taking care of her mother and siblings, and deal with any of her needs by herself. Initially it was a big step for Kim to identify

that she felt a need and to also feel her difficulty and discomfort in expressing it to me.

I suggested Kim experiment with looking at me and imagining allowing herself to let down and cry with me. She imagined me having a critical and rejecting response. As she worked with her reluctance over a period of weeks, and felt supported by me in doing only what she was comfortable with, her reluctance moved into the background and her organismic desire and need to experience and express her feelings became more figural. At that point she was able to let down into her feelings of loss and grief, thus beginning the process of getting the closure she needed around her mother's death.

Afterwards, Kim was surprised to discover that this felt OK. It was still difficult for her to ask me how I now felt toward her. Her strong pull was to be satisfied with not knowing how I felt, and what my reaction had been to her crying. I pointed out how not asking me about that left her with a blank space that might then be filled with her own fears. She decided to ask the question "How do you feel about me now?" I was touched by her courage in asking the question and told her so, along with my honest response to her openness. This was a pivotal moment in the therapy as Kim could take in and assimilate my genuine caring for her.

As we did this work and Kim opened up to deeper levels of feeling, another theme became apparent to both of us. Kim became fearful of relying on me, and afraid that I would leave her if she needed me. She had a first class radar system that detected the slightest sign of my lack of interest, lack of energy, or attention wandering. For example, if I looked at the clock she became silent, and withdrew. When I told her of planned vacations her response was to joke that she wondered if I'd want to come back. When we explored this, it became clear that my going away evoked fear that I would abandon her or lose interest in her.

We worked with this theme in a number of ways. As Kim focused on feelings and sensations, she was able to remember particular events with her father, such as his leaving the house in a flurry of loud words and emotion, and yelling things like "I never get any peace in this house!" One time Kim tried holding on to him to keep him from leaving and he pushed her away saying something like "Why can't you kids leave me alone?" The meaning Kim extracted from these experiences and his ultimate abandonment of the family was that it was her fault that her father had left and that she must have been unlovable and "too much" for him.

As we worked with these awarenesses, Kim could feel a little girl part of her that "had always been there" that she tried to ignore. I asked Kim to focus on this sense of herself and to talk to me as the little girl. What emerged from this was that she felt shameful, and desperately wanted to hide or disappear. She went back to her adult perspective and told me she wished that little girl would disappear or at least "grow up." I suggested a dialogue between the adult Kim and the little girl. As the dialogue developed, the adult Kim began to feel sad and realized that rather than wanting the little girl to disappear, she wanted to hold and comfort her. She didn't see her as "unlovable" or "too much," but instead felt compassion for her loss and pain, and was able to tell her so. This newfound ability to experience compassion toward herself was a key in helping Kim integrate her softer "little girl" feelings with her "adult." This occurred over a number of months as she continued to work with these aspects of herself.

When we worked directly with Kim's father she was able to, in fantasy, tell him she was hurt and angry that he hadn't loved her enough to stay in her life even if he had to leave her mother. She finished her tearful dialogue with him by saying "It wasn't my fault you left. You failed me, not the other way around." She also became aware that she had never been able to grieve the loss of her father, that her mother would not tolerate her tears and told her she had to be strong and that crying "wouldn't do any good." At that point she was able to grieve the loss of her dad with me and have more of a sense of closure.

In our sessions Kim came to see how the belief "I'm too much" affected major aspects of her emotional and interpersonal existence. This was especially evident in how she experienced her relationships with men and the type of contact she could have with them. She saw that with her husband, she made no demands, rarely got angry, and focused her attention on his needs to the exclusion of hers. Our work included Kim experimenting with new ways of interacting with her husband such as being more assertive with her needs. Initially this made her anxious. As we worked with the anxiety and she realized the responses she feared were not likely ways that Bill would respond to her, she became less anxious and more excited and playful with the possibilities of being bolder about asking for things she wanted. This affected all aspects of their relationship including their sexual relationship.

A little over a year into the treatment, Kim reported that she "couldn't remember the last time" she had felt depressed. She said she felt better about herself, her re-

relationships, and the possibilities for her life than she ever had. She began to spend less time working and signed up for a beginning ballet class, which was something she had “always wanted to do.” She developed closer relationships with a few women friends, revealing more personal things and accepting support from them.

I asked Kim to reflect on where she was now and where she had been when she entered treatment. Kim reported that she felt more at peace with her parents, even though she still felt sad about her childhood. She said that it had been “life changing” to risk opening up to another person and allowing herself to need and depend on me. Kim saw the connection between her process of shutting down on her feelings—her self-criticalness, rejecting the little girl part of herself, avoiding feeling her anger and grief, and not allowing herself to need anything from others—and the depression she had experienced for so long.

Kim and I agreed that she was ready to terminate therapy and we allowed a month for this process. Given Kim's issues of abandonment and loss, it was important to set an ending date and not dilute the fact that we were ending by meeting less frequently. In this way Kim had sufficient support and a structure for dealing directly with the loss of her relationship with me. We celebrated her gains together, and cried together. At our last session we said goodbye in a complete way that Kim said she had never had the opportunity to do with anyone else.

A. Outcome

Growing up, Kim experienced a lack of awareness of and responsiveness to her emotional needs from both of her parents. Her father abandoned Kim completely, and her mother was unavailable for Kim's needs, requiring Kim to attend to her needs instead. Kim's creative adjustments involved both the awareness stages and the action/expression stages of the figure formation/destruction process. She learned to cut off the experience of certain feelings and to avoid showing and expressing them. The meaning she made of her father's leaving (“I'm unlovable” and “I'm too much”,) and introjects like “Be strong” created her retroflective process of cutting off and alienating aspects of herself, focusing on the needs of others, and not showing or expressing her own feelings and needs. This process resulted in unfinished emotional situations in which she had not been able to get closure. It resulted in the sense of emptiness, lack of meaning and numbness that she

described at the beginning of treatment, as well as in unsatisfying interpersonal relationships that lacked depth. It also contributed to her career success, which was in part based on her skill in attending to the needs of others and her willingness to work hard so that she would not be rejected or abandoned.

All of these issues emerged and were worked in the context of the therapy relationship. As Kim's awareness increased, she was able to work through her fears and reluctance, and to feel the need to express and show her authentic feelings. She came to feel compassion for a part of herself she had previously cut off and wanted to be rid of, and through this experience of compassion she was able to re-identify with and integrate this part of her that included needs and softer feelings. She was able to redirect her self-criticism and see that it was not her being “too much” that caused her father to abandon her and her mother to be unable to attend to her needs. She came to feel that her “little girl” had deserved to be better taken care of.

In Kim's relationship with me she could experience my genuine caring and also see that when I was not there for her, for example when I went on vacation, it was not because she was “unlovable” or “too much.” She learned to express disappointment with my limitations, or anger at me for leaving, in a way that she had never had the opportunity to do with her parents.

The therapy carried over to and influenced every aspect of Kim's life and interactions. Her relationship with her husband deepened, and she began to consider what she wanted to do in her life besides working. However, it was Kim's relationship with herself that changed most dramatically. Kim no longer criticized herself or felt she was weak if she had feelings and needs. She no longer cut off and numbed a major part of who she was. She had greater range of emotional experience and expression. Kim understood that her lifelong depression was the result of ignoring, denying, and cutting off her feelings, which led to an inability to identify and act on her needs. This resulted in a lack of closure on difficult emotional situations as well as unresolved issues of grief and loss.

VI. SUMMARY

The practice of Gestalt therapy is based on the philosophical foundations of field theory, phenomenology, and dialogue. Gestalt therapy is a process-oriented approach that focuses on the person/environment field. The goal in Gestalt therapy is increased awareness, and

change occurs through focused attention on “what is” not by attempting to achieve a particular goal or agenda. As the therapist brings himself or herself to the meeting with the patient, a type of contact that is in itself healing becomes possible. Gestalt therapy is based on a theory of health, and the focus is on how the patient interrupts his natural self-regulation process. The method is experiential and experimental, relying on meaning emerging from experience rather than interpretation. Gestalt therapy has wide applicability with a variety of patient populations, problems, and treatment modalities. Research, while limited, indicates its usefulness for a variety of populations and issues.

GLOSSARY

assumptive reality The newly acquired ability of early adolescents to detect flaws and errors in adults' thinking.

cognitive conceit Once early adolescents detect a singular flaw in an adult's thinking, they automatically assume that adults are wrong in most other areas of logic.

cognitive disequilibrium During a transition from one cognitive level of another, chaos reigns as the old system is discarded before the new system is fully implemented.

concrete operational thinking Children, ages 6 to 12, view everything from what they see, hear, or experience. They are unable to go beyond the facts or immediacy of their experience.

entitlement An exaggerated feeling, from infancy, that the individual desires special treatment. This covers up the infant's, or is a projection of the parent's own, poor self-esteem.

formal operational thinking The defining quality of early adolescence. Early adolescents gain the ability to build ideas, abstract theories, or concepts without regard to whether they have been previously experienced. Early adolescents now think about the future, what "could be," rather than just the past or present.

imaginary audience The belief early adolescents have that everyone is as preoccupied with their thoughts, behaviors,

and feelings as they are. This dynamic causes them to feel judged as defective and, hence, shamed in front of others.

narcissist, hypervigilant Hypervigilant to the slightest rejection, yearn to connect, extremely shy and inhibited, shun attention, yet a hidden omnipotence, underlying sense of defectiveness and shame, responds to an empathic approach in therapy.

narcissist, oblivious The classical narcissist, oblivious to the reactions of others, arrogant and aggressive, self-absorbed and seeks attention, impervious to hurt feelings of others, a more confrontational approach works better in therapy.

personal fable Exaggerated sense of self that allows early adolescents to believe that their parents could never have experienced feelings or thoughts the same way they do.

psychic structure An unconscious mental function that allows an individual to interact with the world. When the system does not function well, the person is not able to smoothly modulate feelings and interactions with the world.

right brain The earliest, non-verbal part of the brain, the amygdala, in particular. Includes the old limbic system. It is active at birth. Functions include: facial recognition, response to vocalization, and the startle response, that is, the autonomic nervous system.

I. INTRODUCTION

Early adolescence, ages 12 to 14, is one of the most creative and yet, most challenging times of one's life. A cognitive shift into abstract thinking, starting around 11 or 12, stimulates a disequilibrium that creates an

internal chaos characterized by an extreme egocentrism, as well as intense affect states. This internal chaos often causes early adolescents, especially males, to emotionally disconnect from their feelings by disavowal, dissociation, denial, or acting out.

This article focuses on a select group of early adolescents, the exceptionally gifted, who typically have I.Q.'s of 140 or higher. In later years, they often score 700, or more, in each of the SAT subsets.

I first summarize several cases that illustrate the issues that I frequently encounter with this age group. I then present an overview of my psychoanalytic approach to working with this most fascinating group of young teenagers. Following a section on Empirical Data, I conclude with a summary of my work, with this group of highly gifted youths. Understanding the characteristics, dynamics, and psychotherapeutic approach of this highly gifted group has helped my work with the overall population of early adolescents.

II. DESCRIPTION OF TREATMENT

Early adolescence is perhaps the most creative, yet volatile time of one's life. With the intense disequilibrium stimulated by not only the cognitive changes, but physical, hormonal, sexual, and social changes, early adolescents feel out of control; feeling out of control precipitates struggles with affect and self-esteem regulation. This, in turn, stimulates early adolescents disconnecting, emotionally, to avoid feelings of defectiveness, shame, as well as a rage from being chronically misunderstood. An additional component of this internal chaos is the struggle early adolescents have, especially gifted ones, with fitting into their family system. Extremely sensitive to the internal life of their parents, gifted early adolescents struggle with the inability of their parents to come to terms with struggles in their own lives. Because of these conflicts, gifted early adolescents live in a state of suppressed, or often not so suppressed, rage, as they struggle to find a niche within their family and society.

Although I occasionally have a gifted teenager who openly talks to me and shares emotional struggles, most, especially males, refuse to share intimate details of their lives. Feeling totally vulnerable and wondering whether I, too, will force them to continue to accept the fallacies they see in their lives, walking into my office is a "life and death struggle." With this state of mind, my therapeutic goal with early adolescents is quite simple—to help them and their families get through early adolescence with the minimal amount of emotional and physical damage.

I often work with early adolescents identified as, "lazy." Often, these individuals are actually exceptionally gifted adolescents who are totally overwhelmed. They struggle with intense perfectionism, a terror of failure, a rage over chronic misattunements, as well as feeling responsible for everything. These youths are hypervigilant narcissists, who yearn to connect with their parents. As they are not overwhelmed by intense rage, or shame as oblivious narcissists are, and have not given up their connection to adults, they are more responsive to "talk" therapy, than oblivious narcissists. Such was the case with my first female adolescent, a 13 year old, who presented with behavioral problems at home and academic problems at school. She was barely achieving "C's," at her prestigious high school. Early in therapy, she said,

If I try harder and get an "A" on a test, then someone who used to get an "A" will get a "B," then someone who used to get a "B" will get a "C," then someone who used to get a "C" will get a "D," then someone who used to get a "D" will get a "F" and then someone who used to get a "F" will get kicked out of school, and it will all be my fault!

Working through her perfectionism, fear of failing, as well as her feeling responsible for everything that happened around her, she began to work harder. Unfortunately, a teacher did not acknowledge her increased effort, which devastated her. Later, she connected with an English teacher who recognized her increased efforts. Although she became a honor student, she continued to struggle with a series of disappointments due to her perfectionism.

Many early adolescents begin psychotherapy already battling their parents over communication. Not wanting to recreate these power struggles, I have successfully treated numerous teenagers nonverbally. One example is a 14-year-old male, I treated by playing double solitaire. The "golden boy" in elementary school and a straight "A" student in junior high school, his arrogance, in 9th grade, alienated his classmates. One day a row of gym lockers "mysteriously" fell over on top of him. He stopped attending high school, his grades dropped, and he became combative at home. During our first meeting, with his parents present, he refused to talk, answering everyone of my questions with, "Everything is fine!" Refusing to talk, double solitaire became a non-threatening form of interaction. Initially playing hesitantly and noncompetitively, I matched his playing skill, allowing him to win. These wins gave him a renewed sense of being in control. Playing cards also

helped him to become more assertive, while slowly delinking his assertiveness from his aggressiveness, which he experienced as destructive.

As most early adolescents respond better to actions than to words, I fed him, gave him presents for his birthday, took him for walks, and joked around with him. Over time, as he became less perfectionistic, he became increasingly competitive. The more he relished beating me, the more comfortable he became with his intense feelings, including his rage. As he gained greater confidence, he slowly returned to doing well academically. In addition, his relationships with his peers and family improved. As family sessions, early in therapy, were too volatile, his parents were seen separately. I helped his parents to acknowledge and to support his unique talents and future dreams. After 18 months of twice a week psychotherapy, one day he announced that, "Everything was fine," and quit. Unexpectedly, two years later, he returned to therapy. During his last semester of high school, he talked, nonstop, openly dealing with sensitive issues that he had desperately fought to avoid talking about during our earlier work.

Early adolescents, whom I view as oblivious narcissists, are even less able to self-regulate their feelings, due to their intense rage toward and disconnection from their parents. This was evident in one of my highly gifted 13-year-old males, who, by junior high school, was already involved with drugs, including cocaine. He arrived, with his devoted parents, for his first session, wearing Birkenstocks, a t-shirt with very provocative lettering, shorts, and a mohawk haircut. He was noncommunicative, other than to express, "There's nothing wrong with me!" "I'm fine!"

Working out of my house, he noticed my dog, a very friendly, 65-pound Samoyed. Surprisingly, he asked me, very politely, if my dog, Bushski, could come into our sessions. Although totally disconnected, emotionally, from adults, he could not resist Bushski giving him his total, undivided attention. Slowly, with the help of Bushski, Prozac, and our work together, he slowly emerged from his depression. However, unable to view his chronic drug usage as destructive, this issue remained "off limits." Immediately on graduating from high school, he terminated, as he knew that his father would not force him to continue. Although doing well in college, his poor self-esteem, unresolved rage, and use of drugs left him emotionally vulnerable to setbacks.

A frequent problem I encounter, especially with brilliant early adolescents, is "school phobia." Many of these early adolescents are also hypervigilant narcissists. They are more worried about leaving their mothers, than a fear of being at school. Most have, from a

very early age, assumed responsibility for their mother's emotional well-being. In addition, they have difficulties regulating their affects, which makes being away from their mothers difficult. For example, one 13-year-old female had to be forcefully removed from her mother's care for 6 months. Immediately after leaving her daughter, the mother would call me for support of "what she had just done to her daughter." Her daughter also slept in her parents' bedroom at night, as she needed her mother's physical presence to emotionally soothe herself. A combination of talking with this gifted early adolescent, Prozac, and playing double solitaire, competitively, helped this teenager to feel more comfortable with her feelings. Slowly, she gave up feeling responsible for her mother's emotional needs and learned that her anger, at her mother, would not cause her mother harm. Weekly family sessions helped both parents to allow their daughter to express more intense feelings and to facilitate her individuation.

III. THEORETICAL BASIS

A. Cognitive Changes in Early Adolescence

There is a dramatic shift in cognitive functioning from the "here and now" concrete operational thinking of latency to the "future oriented" formal operational thinking of early adolescence. As a result, early adolescents, even more so brilliant ones, are confronted with a developmental milestone in cognitive functioning that is very similar to the toddler. They must grapple with the excitement of being exposed to a rapidly expanding world of information and ideas, while also struggling with the terror of becoming insignificant and lost in the sudden and massive expansion of their universe.

This cognitive shift stimulates a tremendous creative spurt, as well as a massive disequilibrium. This disequilibrium is further intensified by the physical, hormonal, sexual, and social changes that bombard them. Under such an assault, early adolescents are suddenly unable to easily assimilate the massive influx of information that is pouring in around them. This creates a "softening" of their psychic structure, that is, issues having an emotional component, even if a minor one, create massive changes in how they react or accommodate to a situation. As a result, this "softening" of the psychic structure of early adolescents, particularly gifted ones, often disrupts their maintaining a solid sense of self. This "softening" intensifies their reliance on external sources to maintain a sense of well-being. Unfortunately, with early

adolescents struggling for increased freedom from their parents, early adolescents often reach outside the family, toward peers, for their primary emotional support.

In addition, the resulting volatility of early adolescents manifests itself in a dialectic of creative expansiveness, moodiness, impulsiveness, self-centeredness, and a terror or intolerance for things that are different. This volatility causes self-esteem problems, which again draws early adolescents even closer to their peers who are also drowning in their own shame. Often, they hide their struggles, rage, and depression through the use of drugs, as well as antiauthority and sexual activities.

B. Characteristics of Early Adolescents

Characteristics that are stimulated by the cognitive shift, in early adolescence, include the “imaginary audience,” where they feel that others are always watching and judging them; the “personal fable,” in which they feel that no adult has ever emotionally experienced anything like they’ve experienced before; “assumptive reality,” where they realize that they now know more than their parents; and “cognitive conceit,” where they now believe that because they know more than adults in one area, adults are dumb. This combination, along with brilliant early adolescents’ struggling with either pleasing their parents or openly challenging the pathological “family illusions,” leaves early adolescents feeling emotionally vulnerable and isolated from their parents. In turn, this vulnerability stimulates much of the early adolescent’s egocentrism, narcissism, and volatile moods and behaviors. As a consequence, many early adolescents, especially gifted early adolescents, use a heightened sense of entitlement, as well as omnipotence to protect themselves from feeling so vulnerable, especially from counterattacks by their overwhelmed parents.

C. The Infant Morality System

While early adolescence can be an exceptionally fascinating and creative time, it is also a very difficult time. This is particularly true for gifted teenagers. The more brilliant they are as toddlers, the earlier they begin to judge their world. Hence, the more primitive their judgments are. This intense primitiveness creates an inner world that is very “black and white,” “all or nothing,” perfectionistic, rigid, cruel, unrelenting, and unforgiving. Trying to make sense of the bewildering world around them, infants also take responsibility for every-

thing that happens around them. This system, which I refer to as the infant morality system (IMS), occurs by 3 years of age. Soon thereafter, these now brilliant children must also struggle with the illusions within their family system. Hypervigilant narcissists, who are hypersensitive to the slightest emotional withdrawal by their parents, must often give up many of their own feelings and perceptions to remain connected. Those who become oblivious narcissists are devastated by intense chronic misattunements. Their protective rage against their parents often prevents them from experiencing intimate connections later in life.

Years later, when the dynamics of “the infant morality system” are added to the early adolescent’s cognitive disequilibrium, life becomes overwhelming. Internally, gifted early adolescents are further overwhelmed by an even greater intensity of perfectionism, criticalness, and rigidity, as well as intense struggles with defectiveness and shame. Externally, they struggle with whether to accept what they see as the hypocrisy of the parental system, or to fight it. These conflicts often devastate parents, as they experience their early adolescents explosively projecting all of their struggles onto the rest of the world.

D. Protective Mechanisms

Terrified of their own emotional regression, feeling defective, overwhelmed by shame, and struggling with a blind rage, early adolescents often protect themselves by emotionally regressing to earlier protective mechanisms including: disavowal, dissociation, and denial. This disconnection helps foster the volatility and rigid nature of the regulatory systems of this age group.

E. Affect and Self-Esteem Regulation

As the cognitive disequilibrium intensifies, affect regulation becomes tenuous. The “softening” of their psychic structure makes it difficult for early adolescents to modulate intense feelings, whether positive or negative. Constantly feeling overstimulated, early adolescents struggle to “hold on to” whatever unconscious sense they have, from infancy, that “Everything will be okay.” This intense unsettledness leaves early adolescents at the mercy of external sources to help them modulate their feelings. Once again, fighting for independence, early adolescents frequently shut out their parents. The result is that an important external source for the maintenance, repair, and integration of the self is unavailable, at a time of greatest need. This leaves

early adolescents depending almost exclusively on their peers to help them to modulate their feelings. Unfortunately, their peers are just as destabilized, as they endure the same stress and struggles.

The same cognitive disequilibrium also creates a tenuousness in their self-esteem regulatory system. Continually struggling with perfectionism, feeling defective, drowning in shame, as well as flooded with rage, brilliant young teenagers tend to hear and react mostly to negative comments. Fearful of being attacked, creative ideas, exciting events, or anything that feels vulnerable to criticism is hidden from their parents. Once again, the ensuing vulnerability creates an intense need for external supports. As with affect self-regulation, young teenagers, in particular brilliant ones, gravitate toward their peers. These peers are often breaking away from parental authority, through drug usage, delinquency, and sexual acting out.

F. Consolidation of Formal Operational Thinking

A major milestone signifying that early adolescence has ended is the lessening of their internal chaos. This lessening of the internal chaos is due to the consolidation of formal operational thinking, as well as to the diminishing of their physical growth spurts, surging hormones, changes from sexual maturation, and social changes at school.

As a result, the psychic structure of midadolescents once more becomes "solid." With this consolidation, midadolescents have a growing ability to self-reflect; they can think before they act. This calmness, facilitated by a diminishing of their rage, allows for more stable affect and self-esteem regulatory systems. Consequently, mature adolescents can deal with more emotionally complex issues, with far less internal chaos and disruption of their psychic structure. Teenagers who are still experiencing difficulties at home, with peers, or in school, by 11th grade, are still lost in the ongoing struggles of early adolescence. Without a "solid" psychic structure, they are at risk for failure in their impending entrance into the "adult world."

IV. EMPIRICAL DATA

The few studies that deal with the value of psychoanalytic psychotherapy often show that different theoretical orientations have similar results. Thus, it is the interactions between the patient and therapist and not

one's orientation that facilitates meaningful psychic change. My focus, for years, has been an intersubjective model, which focuses on the importance of the dyadic interaction. This interest in dyadic interactions has also led me to study the right brain (the old limbic system), where affects, vocal timing, and facial recognition are part of an early, unconscious, action-oriented process. The closer we can recreate these nonverbal right brain interactions between mother and infant in our work, the deeper and more meaningful the psychic changes will be in our patients. This has particular relevance when working with gifted early adolescents. As most early adolescents, in treatment, are depressed, of equal importance is the use of SSRIs. Studies show the value of combining psychotherapy, with medication, to prevent a relapse of their depression.

V. SUMMARY

In summary, early adolescence, is a time of great excitement, enormous creativity, as well as tremendous volatility. The leap into formal operational thinking creates a disequilibrium that overwhelms early adolescents, especially gifted ones. The ensuing chaos stimulates not only a creativity, often unsurpassed in one's life, but also an emotional volatility and regression. This volatility creates a "softening" of their psychic structure, which leaves the well-being of early adolescents susceptible to external sources, including parents and peers. However, this "softening" also presents an important opportunity for "correcting" past negative unconscious expectations. Healthier interactions, whether by peers, parents, therapists, teachers, or others, allow for the layering of new unconscious patterns about relationships and the world. This potential for layering new expectations is even more crucial for gifted youths, as they tend to be so negativistic about their world. This negativity is not only due to their perfectionism and criticalness, but also to their struggle of whether they adapt to, or reject, the family illusions.

Psychotherapy with this age group is often extremely difficult, especially with gifted early adolescents. They experience overwhelming stress over perfectionism and a fear of failure. In addition, their sense of defectiveness, overwhelming shame, and intense rage causes even the most brilliant youths to use their incredible intellectual talents to avoid their inner chaos and feelings, through disavowal, dissociation, denial, or through acting out.

Working with families is crucial, as the therapist of adolescents must recognize the impact of their validating their patient's perceptions and feelings

about their family, friends, and even themselves. Although needing to support their patients, premature unleashing of their hurt and rage, from chronic misattunements by their parents, can leave long-lasting emotional scars.

The consolidation of formal operational thinking coincides with the lessening of the physical, hormonal, sexual, and social changes. With the lessening of their rage contributing to a calmer internal world, midadolescents now have a more solid psychic structure, which facilitates their exciting adventure into the world outside their family.

procedure rather than extraneous factors by comparing performance under different conditions applied to the same individual or group of individuals over time.

GLOSSARY

ABAB design A type of single-case design that evaluates the effects of intervention through the repeated alternation of baseline (A) and intervention (B) phases.

differential reinforcement of low rates of behavior A schedule of reinforcement in which individuals receive reinforcement if their behavior or responses during a particular time period are kept below or equal to some specified criterion level.

group-oriented contingency A contingency in which some behavior is required of a group of individuals and the presentation, or loss, of a reinforcer is based (i.e., contingent) on the performance of a subset of or the entire group.

interdependent group-oriented contingency A group-oriented contingency, such as the Good Behavior Game, that requires some collective level of group behavior or performance in order for the group to receive reinforcement.

internal validity The extent to which the results of an experiment can be attributed to the independent variable or treatment only.

multiple baseline design A type of single-case design in which intervention is introduced sequentially across different individuals or groups, behaviors, or settings at different points in time.

single-case experimental design A methodology used to make inferences that an observed change in behavior is causally related to the implementation of an intervention

The Good Behavior Game (GBG) is a type of interdependent group-oriented contingency management procedure used primarily for behavior management in classrooms and school-related settings. This article describes the game's components, theoretical underpinnings, as well as the variety of adaptations and applications that have been used since its inception.

I. DESCRIPTION OF TREATMENT

As initially reported in 1969 by Harriet H. Barrish, Muriel Saunders, and Montrose M. Wolf in their seminal article in the *Journal of Applied Behavior Analysis*, the GBG is a group-oriented contingency management procedure that has been used primarily to control the disruptive behavior of students in classrooms and other academic settings. In its original and most basic form the GBG includes only a few integral components that have been used with various modifications in numerous empirical investigations since its initial introduction.

In the game, the class is divided into two or more teams, and team names are posted on the blackboard. Target behaviors (rules) are established and defined that must be followed (or existing classroom rules may be

used). The teacher places marks on the blackboard under a team name whenever a child on that team violates one of the rules. At the end of a period of time (e.g., end of class period, morning, afternoon, end of day) the team with the fewest marks wins the game and receives an agreed on reward(s) (e.g., extra free time, special privileges, victory tags, etc.). Further, any and all teams can “win” if they keep below a preestablished criterion number of marks.

In Barrish, Saunders, and Wolf’s original study, a fourth-grade class was divided into two teams. The class was informed that they would play a game in which team members would earn marks (placed on the blackboard) against their team for talking out or being out-of-seat. The team with the fewest marks, or both teams if neither team received more than five marks, would win the game and receive special privileges (e.g., wearing victory tags, stars on a winner’s chart, lining up first for lunch, 30 min. of free time at end of the day). The game reduced talking and out-of-seat behavior and was popular with students and school officials. Systematic analysis of the game’s major components by others have found that the effective components include dividing the class into teams, setting criteria for winning, and reinforcement for the winning team.

Although most applications of the GBG have been for the management of disruptive classroom behavior and typically teams must avoid the accumulation of points, another variation has also been used effectively in which teams earn points for appropriate, prosocial behaviors. The game has also been used successfully for academic behaviors such as assignment and work completion, active participation, attention to task, and even written expression. In addition to daily rewards, weekly rewards are also frequently used. The game can be designed to be as simple (i.e., following the above-minimum components only), or as complex as desired. The simpler and more basic the game is kept, the better. Otherwise, teacher monitoring and implementation become overly cumbersome and unwieldy, thus defeating the purposes and attendant advantages of the game. At least two teams are needed to capitalize on team competition, although more than three teams can result in monitoring difficulties.

II. THEORETICAL BASES

A. Differential Reinforcement of Low Rates

The GBG is based on a particular schedule of reinforcement referred to as differential reinforcement of low rates (DRL). In such an arrangement the group or

team receives reinforcement if their behavior or responses during a particular time period are kept below or equal to some specified criterion level. Because the GBG is a type of interdependent group-oriented contingency, it also utilizes features of group competition and conformity (discussed further later).

B. Group-Oriented Contingencies

Group-oriented contingencies have been classified into three types: (1) independent, (2) dependent, and (3) interdependent. Independent group-oriented contingencies require the same response requirements from all members of the group, but access to reinforcement for each individual is based solely on that member’s own behavior (e.g., “whoever turns in a rough draft of their project by Friday morning can have extra free time Friday afternoon”). Dependent group-oriented contingencies make the group’s access to reinforcement dependent on the performance of a selected individual or individuals (“On Friday morning’s spelling quiz, if Erin and Andrew can improve their spelling grade by 10% above their scores from last week, we’ll all have extra recess time Friday afternoon”). Interdependent group-oriented contingencies, such as the GBG, require some collective level of group behavior or performance in order for the group to receive reinforcement (“If the class average is 80% or higher on our spelling quiz, we’ll all have extra recess time Friday afternoon”). In this latter arrangement, although some individual students may not meet the criterion, all students are reinforced as long as the group meets the criterion.

Contingencies that are applied individually in classrooms to manage disruptive and/or appropriate behavior can be impractical for teachers and generally difficult to manage. Group-oriented contingencies on the other hand, particularly the interdependent variety like the GBG, have several advantages in that they tend to be easier to manage, more efficient, and require less teacher time because individual contingencies do not need to be monitored; less time is required when the same reinforcer is used with all students. In addition, group-oriented contingencies avoid common concerns of teachers that a particular student will be singled out and treated differently. They may also increase prosocial and cooperative behaviors among students. Group-oriented contingencies have been found to be at least as effective as individual contingencies, if not more so.

The GBG also capitalizes on team competition and issues related to group conformity and peer influence. The peer group is essentially used to assist in managing behavior. Quite typically, attention from one’s peers often works against the classroom teacher by reinforcing and

maintaining disruptive behavior. However, in interdependent group-oriented contingencies like the GBG, students either withhold their social attention (e.g., laughs, snickers, smiles) for disruptive behavior by peers, or substitute disapproval for this social attention.

Although the peer influence that operates in the GBG can be an advantage, researchers have also noted potential disadvantages of this influence. Some, for example, have cautioned that this peer influence can become undue peer pressure verging on harassment toward the individual(s) who may not be capable of performing the necessary behavior. Students may complain about a lack of fairness of the system when others cause the loss of privileges or rewards and may direct their frustrations (which can escalate into aggression) at the offending student(s). Direct proactive measures taken in one study by the teacher to guard against potential excessive group pressure consisted of her warning that such pressure toward an offending student would not be tolerated and would result in a meeting with the teacher for corrective action.

Finally, some children may find it reinforcing to “sabotage” a program or refuse to conform to the classroom rules, thus continually causing the group or team to lose rewards as found in several studies. In such instances the offending student may be temporarily or permanently dropped from the game, their points not counted against a team, or a separate team may be formed with those offenders so as to not penalize other team members. Some investigators have used a combination of individual and group-oriented contingencies, which others have suggested may ultimately be optimal, to overcome this potential problem of sabotage. Others suggest the randomization of components (reinforcers, target behaviors and criteria, contingency, and students) in interdependent group-oriented contingencies like the GBG to overcome many of these problems associated with undue peer pressure and sabotage.

III. EMPIRICAL STUDIES

Empirical investigations of the GBG have found it effective in its original form and in a number of modifications and adaptations in a variety of settings for numerous target behaviors (both academic and social) and age groups.

A. Single-Case Experimental Designs

Researchers have typically employed some type of single-case experimental design methodology in evalu-

ating the effects of the GBG. Single-case designs derive their power to rule out alternative explanations of treatment effects (i.e., internal validity) by comparing performance under different conditions applied to the same individual or group of individuals (as in the GBG) over time. In most investigations of the GBG, performance or behavioral data from the group or class is aggregated and evaluated as would be done with data from a single individual.

The most commonly employed single-case experimental designs in studies of the GBG have been either one of the types of phase change designs (e.g., ABAB, etc.), the multiple baseline design, or combinations of the two. In an ABAB design, the first A phase usually consists of baseline observations and measurements prior to implementation of the intervention (e.g., the GBG). The first B phase usually comprises the implementation of the game. After observing the effects of the game on the teams' or class' behavior (e.g., a reduction of disruptive behavior) for a period of time, it is withdrawn during the second A phase (i.e., second “baseline”). Finally, the game is reintroduced in the second B phase. When the teams' behavior changes reliably and in predictable directions during this sequence of phases, it can then be concluded that the game accounts for these effects. A multiple baseline design begins with baseline observations collected on two or more classes, settings (e.g., math versus reading instruction), or behaviors at the same time. The game is then introduced at different points in time across the groups, settings, or behaviors. If the game produces beneficial results on behavior when and only when it is introduced, it can be concluded that the game only is responsible for the change rather than other alternative factors. A few studies also gradually have made the criterion number of points allowable more stringent during treatment phase(s). All the studies that have manipulated the criterion number of points have found that teams adjusted their behavior to coincide with the changing number of allowable points.

B. Target Behaviors

Most applications of the GBG have targeted primarily disruptive forms of behavior such as talking, being out-of-seat, name calling, cursing, and verbal/physical aggression. In these studies teams usually must avoid the accumulation of points.

Some researchers have expressed concerns regarding the GBG's overemphasis on disruptive behavior and negatively stated rules. To address these concerns, for example, one study allowed merits to be earned for work completion and active class participation that would

negate some of the already earned negative marks against second-grade teams. In another study, other investigators stated rules positively and included student input into rule formation for fourth graders. Other modifications in which teams have earned points for appropriate, prosocial behaviors have likewise found the game effective. One investigation used The Principal Game in which teams in a disruptive fourth-grade class earned points and teacher praise for being on-task, and the winning team(s) was visited and praised by the principal. The game was somewhat more effective than individual contingencies in increasing on-task behavior. Another study implemented the Astronaut Game in which first graders were divided into astronaut teams and earned tokens for completed seatwork and good astronaut behavior. The game was successful in decreasing inattentiveness in a target student and increasing completed seatwork for the class. In the first application of the GBG with preschoolers, researchers increased compliance using only positive procedures (accumulation of smiley faces or dinosaurs, prizes, praise). Teams consisted of two-member pairs only; noncompliance was ignored. The game was successful in increasing compliance in both pairs of preschoolers. In a unique application of the GBG in a physical education class, the GBG was successful in reducing inappropriate social behaviors and increasing appropriate social behaviors but was not successful in appreciably affecting the quality of fourth-, fifth-, and sixth-graders' volleyball skills.

Probably one of the unique applications of the game targeting non-school-related behavior was the Good Toothbrushing Game in which the oral hygiene skills of first- and second graders were targeted. Two teams were formed in each class, and the object of the game was to be the team with the cleanest teeth. Four children from each team were randomly selected each day, and the team with the lowest score on an oral hygiene index won. The winning team had their names posted on a winners' poster and received a "scratch n' sniff" sticker. Children were also praised for low scores and received feedback regarding areas of their teeth not brushed well. The game was effective in improving students' hygiene scores.

A "no tattling" rule was added in one study to overcome problems of students raising their hands to tell the teacher of students breaking rules. In addition to talking, out-of-seat, and following directions, another group of researchers also targeted tattling as well as "bothering one's neighbor" with their second-grade participants.

Another series of studies found first graders who participated in the GBG were rated lower in aggression

and shyness by their teachers at the end of the year compared to their beginning-of-year ratings. These researchers later reported that the first-grade males who were initially rated high in aggression at the beginning of first grade, and who participated in the GBG throughout first and second grades, had lower teacher ratings of aggression in fourth and fifth grades, and into middle school. Thus, the GBG may serve a preventive function for aggressive young boys.

In addition to its applications with social behaviors, the game has also been used successfully with academic behaviors. One study that included a merit component in the GBG, in which teams could have negative marks erased for merits earned for assignment completion and for active class participation, produced increased rates of completed math assignments with 75% accuracy for the entire class, and even more so for two target children with histories of behavioral difficulties. First-grade students in another study showed an increase in work completion as a result of the game. Other researchers employed the Good Writing Game, a modification of the GBG in which fourth-, fifth-, and sixth graders attending a nonremedial summer school session earned points for usage of various parts of speech in written stories. The game resulted in an increase in compositional variables as well as ratings of creativity of written stories. Finally, although not a direct target of the GBG, another study found slight increases in math accuracy in fifth-grade participants.

C. Participants

Participants in a majority of the studies conducted with the GBG have consisted primarily of elementary-age students (first through sixth grades). Also, although not always specified, most studies have been conducted either with regular education students or students who have had some history of behavior management difficulties. Only a few investigations of the GBG have been conducted with students with disabilities. One study employed a modified version of the game to effectively reduce class levels of disruptive behavior with 6- to 10-year-old students with mild mental retardation. Another study that combined self-management and peer-monitoring procedures in a variation of the GBG successfully reduced uncontrolled verbalizations in third-grade students with Attention Deficit Hyperactivity Disorder. Researchers have also individualized the GBG across types and frequencies of a variety of inappropriate behaviors for three classes of 15- to 17-year-old students with emotional disturbance. The individualized GBG was success-

ful in decreasing inappropriate behaviors for these adolescents. Two studies successfully used the game with a wide age range of students with disabilities, from 9 to 20 years of age and from 12 to 23 years of age.

The youngest students with whom the GBG has been used thus far has been preschoolers. The researchers increased compliance in two pairs of preschoolers using only positive procedures. The GBG has also been used in a hospital setting with adults. In this study, the Good Productivity Game was used with four hospital residents who were trainees at a rehabilitation industry to increase their work output for a task for which they were paid a wage.

Last, the only cross-cultural application of the GBG used the game with Sudanese second graders. The game, patterned very closely after the original version, was successful in reducing talking and out-of-seat behavior, as well as aggression.

D. Reinforcers

One advantage of the GBG is that teachers can use those reinforcers that naturally exist in most elementary classrooms. For example, a common group of reinforcers used in many studies has been some form of free time, extra recess, or activity time. Other rather commonly available reinforcers also used have included various edible treats (e.g., candy, cookies, etc.). Still other privileges available that have been used consist of lining up first for lunch, public posting of results, going to library, helping the teacher, reading, playing games, working on special projects, viewing film strips, listening to records, serving as a tutor, and going outside to talk or read.

Unique and less commonly used rewards have consisted of leaving school 10 min. early at the end of the day, a special visit from the school principal, early work termination, a party and pencils, a weekly commendation letter or a positive note to a dorm counselor, or lunch with a staff member. Even many of these less commonly used reinforcers are often available or could be available in many or most classroom settings with a bit of planning and forethought.

E. Consumer Acceptance

In studies that have reported consumer (i.e., students, parents, teachers) attitudes and reactions to the GBG, most reports suggest that the GBG has been generally found to be popular and acceptable. The very first investigation of the procedure reported that the GBG was popular with teachers and school officials. Sudanese stu-

dents, teachers, parents, and the principal were pleased with the game in the one cross-cultural investigation of the game. Other studies have likewise reported that the game was acceptable or even highly acceptable to participating students and teachers. One study that used a variation of the GBG but without team formation or immediate feedback to students on rule violations reported that students and teachers preferred the individual contingency compared to the interdependent group-oriented contingency (modified GBG). In general, it appears that the GBG is usually popular and acceptable with students and teachers. For students it can be exciting (group solidarity and cooperation) and provides reinforcers for work and self-control that may not have been present previously; for teachers, in addition to its demonstrated effectiveness, the GBG can be an efficient, easy to manage, time-saving procedure. Finally, an additional feature of the GBG that may contribute to its utility and popularity is that at least one study has reported that the game did not require rigorous compliance to be effective. These researchers concluded that the system may be robust enough such that complete adherence is not necessary to achieve meaningful behavior change.

IV. SUMMARY

The GBG is a form of interdependent group-oriented contingency management procedure that is used for the management of behavior primarily in classrooms and other academic settings. The game is designed to be time efficient and easy to manage for teachers and is usually used with an entire classroom in which two or more teams are formed, criteria are set for winning the game, and reinforcement is provided to the winning team. It capitalizes on team competition and peer influence in that the peer group assists in managing behavior, although some care must be taken to ensure that this peer pressure does not become excessive. The GBG is usually popular with students and teachers and has wide applicability and versatility; its efficacy has been demonstrated with many social and academic behaviors in a variety of settings with a number of modifications and adaptations for many age groups.

 - III. Theoretical Bases
 - IV. Outcome Research
 - V. Summary
- Further Reading

Most people experience the loss of a loved one as a painful, confusing, and disruptive event. Several approaches to therapy with grieving persons have been widely applied. The two most well-known models of grief therapy are J. William Worden's "tasks of mourning" and Robert Neimeyer's "meaning reconstruction." Both of these approaches offer valuable specific therapeutic interventions. When applied well, they allow for the expression of feelings and provide bereaved persons with important opportunities to make sense of their grief experiences. Perhaps most significant, such grief therapies provide grieving persons with an important opportunity for self-perception and self-definition. Although grief therapy may be done in either individual or group contexts, group settings usually offer the advantages of support from others, of engaging in altruistic behaviors toward others, and of the recognition of some degree of universality in one's experiences.

I. FOUR TASKS OF MOURNING

There are four tasks in the mourning process, according to William Worden. The first task is to accept

the reality of the loss (death). On one level, this is straightforward: the facts of the loss need to be recognized. On another level, there are two other, more subtle, aspects of the loss—the meaning of the loss and its irreversibility. To accept the meaning of the loss means to recognize its significance. When a bereaved individual gets rid of all reminders of the deceased, or engages in forgetting the lost person, or denies the intimacy, impact, or importance of that person then it is likely that he or she has not engaged in the task of accepting the reality of the loss. Thus, the first principle of grief therapy is to help the survivor actualize the loss. This is accomplished primarily by facilitating the survivor's talking about his or her experience of the loss.

The second task of mourning is to acknowledge and work through the pain of grief. This is a particularly difficult task because no one wishes to feel such pain.

First, grieving persons may actively seek to avoid painful feelings and thoughts. They may, for example, use thought stopping, they may idealize the deceased to allow themselves only fond memories, they may use alcohol or other drugs, or they may even try a "geographic cure" (e.g., selling the house and moving away). Second, friends may prefer to avoid the pain of the grieving person's experiences. This leaves the griever isolated. Finally, therapists themselves may avoid the griever's pain in therapy. In conceptualizing a case, therapists may reduce the pain of grief to a concept with which they may be more comfortable within their theoretical framework. Above all, therapists may give in to an impulse to help. For some, this may mean

wanting to take away the pain. It is extremely important for therapists to recognize their inability to take away the other person's pain. The therapist's role is to both sit with the person's painful feelings and to help him or her express these.

A particular set of feelings should be noted at this point. Anger is commonly experienced but not always readily expressed by bereaved persons. They often harbor anger toward the deceased and toward God, fate, or life in general. It is usually a fruitful therapeutic exercise to ask "In what ways have you been angry with ... (God, etc.)?" Permission to express such anger usually results in a sense of relief at a burden lifted and at not being alone in having such feelings.

The third task of mourning is to adapt to an environment in which the deceased is missing. A deceased person has often played many roles in the survivor's life. Sometimes these roles do not become apparent until some time after the death when the survivor is coping with the everyday tasks he or she must now take over. At this time, it is usually therapeutic to problem solve in concrete ways.

In some cases, the survivor's self-definition has depended heavily on his or her relationship with the deceased person. In such cases it is often helpful to engage the survivor in an active process of self-perception. Group therapy is an especially powerful venue toward this end.

Self-perception theory, as first articulated by Daryl Bem in 1972, asserts that we come to know ourselves in the same way that we come to know others: by observing our own behaviors in various situations. In a bereavement group, members can have many opportunities to engage in altruistic, supportive, and empathetic behaviors toward other members. The group leader points out and labels these kinds of behaviors as they occur and encourages the group member to notice what sort of person would do these things. Under such conditions members can begin to see themselves not as confused and grieving but as active and engaged with others.

According to Worden, the fourth task of mourning is "to emotionally relocate the deceased and to move on with life." It is unclear from his writings if this is intended to be a resolution of the grieving process. In therapy, it is often more useful to facilitate the grieving person's recognition that the lost person is never really forgotten and in that sense that the grieving process never ends. Nevertheless, it is possible to go on with other loving relationships. Such recognitions on the part of the client represent a valid therapeutic goal.

This model has several strengths. It places a strong explicit emphasis on the feeling experiences of grieving

persons. It is relatively easily understood and applied without necessarily relying on its psychodynamic underpinnings. Perhaps most significant, by presenting "tasks" it provides a structure for the grieving person as well as for the therapist. In the face of the intrinsically confusing experiences of grief, a set of tasks can provide grieving persons with a sense of order, self-control, and self-determination in their lives.

The main criticism of this approach is its implicit stagelike quality. It is very tempting to fit all grieving individuals into a mold of "working through the stages" (tasks) of grieving. Nothing could be less therapeutic.

II. MEANING RECONSTRUCTION WITH GRIEVING PERSONS

Another widely accepted approach to grief therapy is a reconstruction of meaning model. Robert Neimeyer, the editor of the journal *Death Studies*, has most effectively articulated this highly idiographic model. This approach emphasizes the uniqueness of individuals' experiences of grieving. The basic premise is that the revision of one's life story in response to a loss is the central process in grieving. Grief therapy is, therefore, primarily an opportunity for grieving persons to tell their stories in ways that will help them to make sense of loss and of life.

This approach views life itself as a story-telling process. People "write" and rewrite their stories and thus develop a sense of meaning, purpose, and identity. Losses, particularly through death, disrupt our stories. They may invalidate or threaten beliefs and assumptions that have lent meaning and order to our lives. Significant losses often trigger a search for meaning. Consequently, grief therapy is focused on a retelling or reconstruction of the grieving person's narrative. This work is done in a way that will allow the survivor to once again find meaning in life in the context of a new reality.

Such grief therapy often consists of a variety of activities, all intended to facilitate self-reflection, a search for meaning, and ultimately a new story about oneself. Writing letters to the deceased may help the grieving person not only to express feelings but also to place the deceased into the context of a new reality (without the deceased person). Keeping a journal can help grievers to label their own experiences during a loss and afterward. Putting together a book of memories can help to affirm the importance of the lost person for the griever. It can also underscore both those aspects of the griever's self that he or she chooses to hold on to after the loss and those aspects that he or she chooses to change. For

some, writing poetry can serve all of these functions but in metaphorical, indirect, and subtle ways.

For others, less verbal techniques can be more productive. Such activities include drawing stories of events in one's life, including a drawing about the loss. Compiling a book of photographs (perhaps mixed in with drawings) can be effective for some. These less verbal activities can become small rituals. Indeed, many personal rituals can symbolically express grievers' feelings and help them to put their experiences into the context of their life narratives.

Authoring an autobiography has been considered a good opportunity to redefine oneself. However, writing an autobiography can be a daunting exercise, even for the best writers among us and even without the pain of grieving. One specific format, sometimes employed in addictions counseling, that lends itself to telling one's story is an exercise known as "lifeline."

Constructing a lifeline consists of drawing a line graph of the experiences of one's life along a horizontal axis that can be divided into 10-year increments. The line goes up or down as it traces events through the years, to reflect one's feelings during those events. The vertical axis can be described as a feeling meter. Thus, the drawn line goes upward when feelings were happy and downward when one's feelings were sad.

A lifeline completed in a group therapy context can be very powerful. Each group member narrates his or her own life using the lifeline as an anchor. (It may be used as a visual aid while telling one's story, but this isn't necessary.) Saying one's story to others is important because it allows others to accept and validate one's experiences.

Saying one's story aloud allows narrators to hear themselves. Hearing one's own story is an instance of self-perception. One learns about oneself by observing one's own behavior and constructions. Thus, the therapist's role is to draw the narrator into an active process of recognizing who he or she is. In this way, grief therapy can be a process of self-perception and self-definition.

There are several strengths of the meaning reconstruction approach. First, this is ultimately an existentially oriented approach to a peculiarly existential dilemma of human life. It begins with people's search for meaning in the face of loss. Second, it encompasses a variety of techniques with the goal of helping grieving persons to make sense of their lives again. Third, serious research efforts have been made within this school of thought to validate the approach and to examine such issues as the applicability of treatments to different types of losses and grievers.

On the other hand, this approach might be criticized as placing too much emphasis on the cognitive and voli-

tional aspects of the person. Such emphasis might be done at the expense of affective, feeling aspects.

III. THEORETICAL BASES

Grief therapy, whether utilizing the tasks of mourning or focusing on the reconstruction of one's meanings, can be understood as an opportunity for heightened self-perception. Recent studies have indicated that at least 70% to 85% of bereaved persons typically engage in a search for meaning in their lives following a death. This means that for most people bereavement holds the potential to be a time when they are looking at such existential questions as "What is the purpose of my life?" and the corollary "Who am I, after all?"

While completing the many therapeutic experiences described earlier, grieving persons observe their own responses to the urgent experience of death and loss. With the therapist's aid, they can examine their own answers to existential questions and learn who they are. If therapists explicitly foster such self-perception, grieving persons have unique opportunities to redefine themselves.

Both a grief therapy centered on the tasks of mourning and one focused on a reconstruction of one's personal meaning allow the person to redefine oneself through observing one's responses to the existential questions posed by the urgent experience of death and loss. However, the two approaches have very different theoretical roots. William Worden's scheme of the four tasks of mourning is firmly grounded in psychodynamic theory. This is most evident in his emphasis on the importance of "working through" the tasks. It seems clear that working through is meant in the psychoanalytic tradition of repetition, elaboration, and amplification.

The meaning reconstruction approach, on the other hand, is rooted in George Kelly's constructive alternativism. Kelly emphasized that everyone construes events in his or her own way. Indeed, we construe ourselves. Constructive alternativism is an existential theory in the sense it assumes no special motivational force in people and no essential human nature. Rather, we are what we do. Humans are self-determining; we are nothing more than what we make of ourselves. Our responses to loss are special instances of such reconstruction of ourselves and of the meaning of our lives.

A search for meaning typically addresses two questions. An early question in this process seems to be "Why? What is the meaning of this death (loss)?" A somewhat later question is "What can I learn from this experience?" or "What is the meaning of this experience in my life?" In 1998, Davis, Nolen-Hoeksema, and

Larson studied over 200 people who had lost loved ones to a slow, progressive death (mainly by cancer). Their work indicates that a search for meaning is really two separate processes: an earlier making sense of the loss and a later finding benefits from the loss. Thus, a search for meaning may be developmental. A shift from making sense of the loss to finding some benefit from it should be a goal in a course of grief therapy.

Neimeyer has defined the reconstruction of one's meanings following a loss to include six elements. First, it is an attempt by the grieving person to find new meanings both in one's own life and in the death of the loved one. Second, these new meanings are integrated into the grieving person's overall scheme of things. Third, any construction of meaning is an interpersonal (and personal) process. Therefore, group therapy with grieving persons can be very fruitful. Fourth, meaning is always found within a cultural context. Finding meaning after a loss must include cultural traditions and rituals of bereavement and grieving. Next, personal meanings are tacit and preverbal as well as explicit and articulated. Simplistic assumptions of therapy as a rational and verbal process may not be particularly applicable to grief therapy. Finally, meaning is not a cognitive "product," it is a process.

The process of grieving had, in the past, been conceptualized as having an ending. Several theorists proposed that following a set of "stages," grieving persons could be expected to reach some sort of resolution. John Bowlby called such a resolution "reorganization." Colin Murray Parkes referred to it as recovery. It was thought by some (notably George Engel) that after having gone through the cycle of a full year following a death the "normal" grief process would end. Contemporary views of grieving do not emphasize such time-delineated resolutions. Catherine Sanders has strongly argued that the bereavement process does not have clear-cut starting and stopping points but is a free-flowing process. She has proposed that the process is best described as consisting of permeable phases rather than fixed stages. Neimeyer has likewise proposed that there are three phases in a typical grieving process: avoidance, assimilation, and accommodation. Such a grief cycle lasts a lifetime.

IV. OUTCOME RESEARCH

Since 1975, when the first controlled research of such therapy appeared, there have been at least 23 empirically based outcome studies of grief therapy. A significant caveat must be underscored before a

discussion of this body of literature can be described. Many of the controlled investigations of grief therapy have not described the theoretical models of the therapy being reported. This stands in stark contrast to the vast body of psychotherapy outcome studies in general. Psychotherapy outcome research usually describes the effectiveness of, for example, a behavioral, a client-centered, or other specific approach to a given problem. The lack of such specificity limits the evaluation of grief therapy.

Barry Former and Robert Neimeyer completed a meta-analytic review in 1999 of 23 controlled outcome studies. Their findings showed that grief therapy outcomes have been better when clients are younger (rather than older) and when clients' grieving has gone on for a longer period of time and is complicated (as opposed to therapy soon after the death). Perhaps the most robust finding is that grief therapy for traumatic death is highly effective. That is, a person who has lost someone to a violent, accidental, or otherwise unexpected death may be the most likely candidate for a positive outcome of a course of grief therapy.

Therapy outcome research in the future may be improved by focusing on several specific issues. First, outcome measurement may be more accurate if it is done after some time has passed as well as immediately after therapy. Very often clients report an increase in their discomfort at the end of a series of grief therapy group sessions. Perhaps a consolidation of learning about oneself needs to occur. Likewise, a course of therapy may serve as the beginning of a search for meaning whose outcome does not occur until some time has passed.

In addition, outcome measures may need to be more specific than they generally have been. The majority of studies to date have used global indicators of improvement such as depression, anxiety, and physical symptoms. It may be more valid to measure specific indicators of grief that are grounded in contemporary theoretical models and empirical research.

V. SUMMARY

The experience of loss, particularly through death, is usually a confusing experience that triggers a search for meaning in the majority of bereaved persons. Grief therapy, especially in a group context, can provide grievers with a scheme of mourning and recovery such as the one provided by working through the four tasks of mourning. These are accepting the reality of the loss, acknowledging

the pain of the loss, adapting to an environment in which the deceased is missing, and emotionally relocating the deceased and moving on with life. Grief therapy can also aid the griever in reconstructing the meaning of one's life. This can be done with several techniques. One such technique is to review one's life with a special emphasis on placing the meaning of the loss into one's lifeline and defining oneself following the loss.

GLOSSARY

general systems theory The basic theory of understanding groups; groups are seen as “organized complexities,” or “systems” that are the product of the dynamic interaction among their parts rather than the sum of their absolute characteristics. Neither the resultant whole nor its new characteristics can be fully explained by the nature of the parts themselves.

group dynamics This refers to the interactional patterns within groups. This includes group-level experiences such as group cohesion based on seeing the group as attractive and helpful and that provides an important supportive function. Group norms evolve from the group interaction with guidance from the leader that give stability and safety within the group. Members will also adopt group roles based on their own outside behaviors that will provide important learning experiences in the group interaction.

1. Group dynamics also embraces the concept of therapeutic factors. These provide supportive and motivating experiences that create a powerful change environment.
2. Supportive factors:
 - a. Universality by understanding that others have had similar experiences
 - b. Feeling acceptance by the group
 - c. Experiencing altruism by helping each other

psychodynamics This is a broad concept referring to the psychological operations that govern thoughts and behaviors and of which the individual may not be consciously aware. In particular, from a therapeutic perspective, the psychodynamic tradition described the presence of wishes in the context of relationships (for example to be more assertive) that may lead to fears of the response of others (for example being rejected) or of response of self (for example, remaining passively silent). These patterns are seen as arising from early experiences.

All these features of the group dynamics develop from within the membership as they relate to each other. The therapist's principle function is to create a positive and safe group culture in which these therapeutic experiences can take place. Therapy then truly takes place, not from the wisdom of the therapist, but from the interpersonal learning among the members. These processes will be

found in all groups to a greater or lesser extent. They will be used in various ways depending on the group model that is being used. In psychoeducational treatment models there is a class room-like atmosphere to learn a skill such as assertiveness, or to become informed about a diagnostic syndrome such as the symptoms and problems associated with bulimia nervosa. The group dynamics will be operating more or less in the background. Cognitive-behavioral models make more use of the group process through active discussion and challenge around the efforts to address negative thoughts about self or address behaviors such as obsessive-compulsive patterns. Interpersonal and psychodynamic group models make extensive use of group-based learning among the members. This spectrum of group models, each with its own set of unique techniques may give the group literature a scattered feeling. However, the important common base is the power of group interaction to support and promote change for a wide range of conditions.

I. DESCRIPTION OF TREATMENT

Group psychotherapy is a widely used treatment modality. However, there are many types of groups for different conditions and often several models of groups for a particular condition. This makes a description of the field somewhat complex, and even the term “group therapy” relatively lacking in meaning except that several people are meeting together. Group psychotherapy is widely used as an intensive treatment modality to address psychological issues especially those involving unsatisfactory interpersonal patterns. Group therapy is also used in a more structured manner to address negative cognitions, to learn skills such as assertiveness, and for psychoeducational purposes. This wide range of group applications involves the use of groups that are conducted in quite different ways.

This article begins with an overview of the effectiveness of group therapy and the sorts of problems that can be treated in groups. This includes the question of how many group sessions are needed to be helpful. Then an overview of basic group theory is provided emphasizing the importance of considering the whole group as the vehicle for treatment. This is followed by a discussion of the generic processes that occur as a group develops. Different types of group models are then reviewed and what problems each is designed to address. Finally, there is a description of how group programs can be developed for use in larger systems of health care.

Group therapy has been studied extensively and in particular there have been a number of large and com-

prehensive studies over the last decade. A recent survey of 23 high-quality randomized outcome studies found effect sizes (a statistical measure of change) in a range of 0.76 to 0.90. This means that treated patients were doing significantly better than 78 to 82% of control patients who did not receive active treatment. The clinical literature derived from regular treatment settings suggests similar outcome changes. A number of studies have directly compared the results of group therapy and individual therapy for a similar patient population and using the same theoretical treatment model. With very few exceptions, both modalities have about the same clinical outcome across a wide range of clinical applications.

The list of conditions treated in groups is extensive. Virtually all models of individual therapies have been used in group therapy. The highest use of intensive group models is with the more common conditions of depression, anxiety states, eating disorders, and personality disorders. Groups of a more supportive nature are widely used as an adjunctive treatment for more severe and chronic conditions such as bipolar disorder and schizophrenia.

II. THEORETICAL BASES

There is a clearly articulated theoretical basis for group therapy based on general systems theory. The major difference between individual therapy and group therapy from a process viewpoint is the presence in groups of a range of relationships rather than the single relationship of individual therapy. This makes groups a more complex treatment system and has led to the idea of therapy through the group process as opposed to therapy of the individual in the group or therapy provided solely by the leader. The role of leader in a group is quite a different task than the role of the individual therapist. The leader must be monitoring each member as well as the general climate of the group.

A group becomes an entity when there are identifiable patterns of connections among the members. Before that occurs the group is simply a number of people more or less together. Systems theory provides a model for describing the properties of a group. Organized complexities, or “systems,” are the product of the dynamic interaction among their parts rather than the sum of their absolute characteristics. The whole group and its characteristics cannot be explained by the nature of the parts (the leader and the members) but by how they interact. This dynamic interaction can be understood as the flow of factual and emotional information across a series of boundaries.

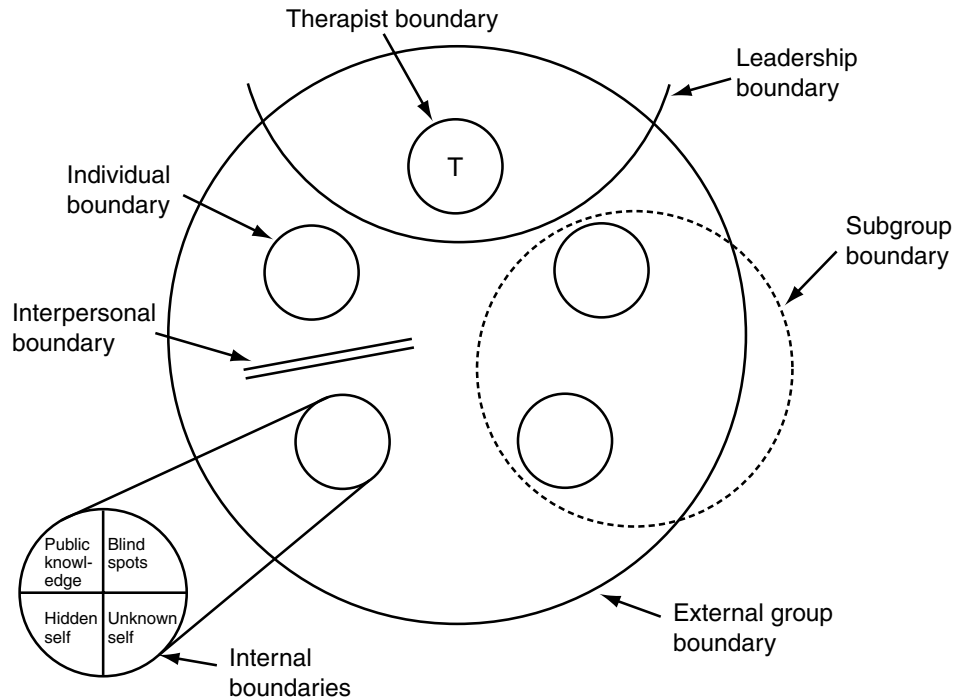

FIGURE 1 The group system. A schema of important boundary structures in groups. From MacKenzie, K. R. (1997). *Time-managed group psychotherapy: Effective clinical applications*. Washington, D.C.: American Psychiatric Press, Inc. Reproduced by permission.

The term “boundary” is being used in a double sense. Boundaries can be conceptualized in physical terms: Closing the door of the group for the first session is a powerful message that a group has been created; the number of members in a group will have an influence on its process. However, of greater interest to an understanding of the group process is the idea of the boundary being created by an awareness of transactions across the boundary and particularly of differences on either side of the boundary. For example, an early phenomenon in therapy groups is the awareness of universality, as the members understand that they share many common symptoms, experiences, or emotions. Technically this could be seen as the development of an external boundary to the group: “We in this room are a special category of people who can understand each other,” as opposed perhaps, to the perceived lack of understanding of spouses or friends outside the group. The nature of boundary regulation is expected to vary over time as the group proceeds. The format of a time-limited closed group provides an ideal model for application of group systems concepts.

The concept of group psychotherapy as treatment through the group process does not mean that a psychodynamic model must necessarily be used. If several members are participating together, the nature of their

interaction cannot be ignored in trying to understand the effectiveness of the treatment. It is useful to distinguish the difference between the psychodynamics of the internal processes going on inside the individual and the group dynamics that are going on among the members and leader.

The boundary structures form a hierarchy of levels: A minimum list includes the whole group as a unit in its external context, interactional phenomena occurring between members including the leader(s), and the internal psychological processes within each member. Many group therapy research reports confuse or ignore these levels in their analyses. They may provide a full discussion of the technical strategies and outcome but no information regarding the group process through which it occurred. Figure 1 gives a visual portrayal of the most important boundaries.

1. *The whole group external boundary*: This defines the properties of the whole group that must be dealt with as collective in nature. This perspective of the whole group has direct application to pregroup decisions. For example, a group composed of all members experiencing the same disorder is likely to have an experience of early cohesion. The whole group focus also

includes stability of membership and attendance patterns including closed or open group models. Behaviors such as extragroup socializing and breeches of confidentiality transgress the external boundary and may have an important influence on outcome. The external boundary also includes a consideration of the properties of the whole group such as cohesion, group climate/atmosphere, or group development that are derived from the overall membership.

The idea of group roles is also a group-level conceptualization because the role designation is based on a process of negotiation between the individual and the collectivity. The same person might behave quite differently in a different group. There are four basic roles.

a. *Sociable role*: Someone who assumes this role tends to be friendly and supportive, seeking to keep relationships on a positive tone. They are eager to help others sometimes to their own disadvantage. They play an important function in promoting cohesion and engagement and are comfortable with emotions, especially positive emotions. Their role is particularly important as the group forms.

b. *Structural role*: These are members who are active in organizing the group. They tend to emphasize cognitive ideas and the need for the group to stay on-task and may be seen as controlling. They are of value to the group in keeping a focus on therapeutic work.

c. *Divergent role*: These members are challenging and questioning and often take an oppositional stance. They play an important function of making the group address important issues. They are comfortable with negative emotion that promotes interaction but are in danger of being isolated by the group. Their involvement is particularly important in the differentiation stage of the group described later.

d. *Cautionary role*: These group members are reluctant to participate and are anxious about revealing much of themselves. They are in danger of being ignored by the group or being subtly criticized for not participating. They may highlight for the group the dangers of becoming overinvolved.

2. *The subgroup boundary*: It may be useful to understand the role of subgroups. These may consist of clusters of members who create helpful or hindering effects on a group. Subgroups within the same group may respond quite differently to specific therapeutic models according to characterologic features. These considerations may have an important bearing on composition decisions. For example, a group with quite diverse levels of symptomatic dysfunction among the members may have trouble developing cohesion because of the disparity in the sorts of issues they bring to the group.

3. *The leadership boundary*: Leadership involves both the choice of a particular theoretical model to be used and the technical style used to deliver that model. The role of leader plays an important function in groups but with different implications than in individual therapy. The leader may be seen as a director or authority and more remote because the leader's activity must be shared with all members. The more complex situation of co-leadership offers the opportunity for collaboration or competition around theoretical beliefs or technical strategies. Different theoretical models will bring with them implications for group leadership. For example, group behavioral therapy may have quite high levels of process control through the use of structured procedures and review of homework, whereas group psychodynamic therapy is likely to have quite low levels. The theoretical model may be given credit for effectiveness that is actually due primarily to the nature of the process component.

4. *Therapist boundary*: The therapist is also present as a person with personal characteristics that may have an important impact on the group or some of its members just as in individual therapy. In the case of co-therapists, the leakage of subtle messages between them will be closely watched by the members, especially if there is a female-male pair. Self-disclosure by the therapist(s) may go beyond that prescribed by the technical model being implemented but driven by the interactional pressures of the group.

5. *The interpersonal boundary*: Most of the action in groups occurs between the members. Later in this chapter there is a discussion of the impact of group composition and size on interpersonal patterns in a group. An interpersonal learning cycle that is based on disclosure and feedback among the members is also described. All groups develop norms, general ideas about how the group should function. Often the leader is active in specifically discussing how the group can most effectively operate, an issue discussed later under the heading of Group Development. However, groups also develop their own set of norms; one clear example is how a group for adolescents will carry on the group with their own agendas in parallel with those of the therapist. Addressing these differences may provide most of the therapeutic learning. Once established, norms tend to persist even if there is a major turnover of membership.

The role adapted by the leader has a major impact on the nature of group interaction. Skill-based groups, such as some forms of cognitive training for challenging negative cognitions, may be conducted with a classroom atmosphere and little discussion. At the other end of the

spectrum, process-oriented groups may pay less attention to outcome application and focus primarily on the meaning of group process. The research literature suggests that neither extreme is optimum. The group process can provide non-specific support and motivation that enhances group goals. Application to real-life situations forces the need to address resistance to change. The group therapist must be aware that group process is always going on whether overtly or covertly and will have a positive or inhibiting effect on outcome.

6. *Internal member boundaries*: Therapists vary considerably regarding the level of attention to enacted interpersonal behaviors versus internal processes depending on the theoretical model being used. But of course there is much going on inside each group member that may or may not be revealed. Tapping such internal phenomena may provide useful information for understanding both the individual and the impact of group events on each member. The importance of such findings is not restricted to psychodynamic models.

III. APPLICATION

A. Group Development

There is substantial evidence from the group process literature for the phenomena of group development. Indeed, research findings indicate that those groups that follow a developmental sequence produce better outcome for the members. The most basic description of group development consists of a four-stage model of engagement, conflict, interpersonal work and termination. Additional stages have been described that would fit either as subunits under the broad heading of interpersonal work or as identifying issues regarding greater independence from the leader. The group development perspective is a powerful metaposition from which to understand group-level events. In the following description of group development, strategically helpful interventions that augment the characteristics of each stage are described. Although the specific applications must be adapted for any particular group, the basic positioning of therapeutic intent will help to maximize the outcome.

Group development is most evident in closed time-limited groups of 3 to 6 months duration. This format is widely used, making an understanding of group development a particularly helpful theoretical perspective for the clinician. The stage descriptions that follow are based on this type of group format, and important therapist tasks for each stage are described.

Open-ended groups will go through minidevelopmental stages when membership is altered. This is most evident in regard to the new member(s) but the entire group also participates because group roles may be lost or challenged by the changes. Some groups, such as acute crisis groups, may change membership with each session but compensate for this with a higher level of group structure.

Assessment and preparation tasks are discussed first for, although they are not formally part of the group development sequence, they are part of the early tasks that the leader must address.

1. Assessment

The first set of tasks in assessment is to identify the predominant diagnostic difficulties. The purpose of this is to establish what treatment approach will be most likely to be effective in this specific clinical setting. A closely related task is to match to the extent possible what type of group (or other treatment) is likely to be most effective. The goal is to maximize the accuracy of prediction of who will benefit from what type of treatment.

The second set of assessment objectives is to develop a focus for treatment. This will begin with a review of the most troublesome symptoms. Going through these in some detail is helpful because the discussion serves as an acknowledgement of the reality of symptoms. Often patients will feel that previous caregivers or family members have not understood what they are experiencing. It is particularly helpful to go through a careful chronology in relation to life events or other stress-precipitating triggers.

Most patients present for treatment in the context of some type of stress. This is most frequently in relationship to interpersonal events. A review of an interpersonal inventory of important people may reveal associations that even the patient is only vaguely aware of. The principle focus will be on current spouse/partner, current extended family, and current friendship circle. Past significant intimate relationships, nuclear family of origin, and extended family of origin will help to understand the quality and patterning of interactions over time. Major themes can be elicited by inquiring about three relationship dimensions: the overall tone of a relationship in terms of affection versus negativity/anger, the status of control versus submission of both participants, and whether relationships tend to be overinvolved versus underinvolved in nature. An understanding of the management of the spectrum of emotions will be important. Finally, an effort to identify chronic stresses, the nature of living arrangements, finances, friendship circle,

and involvement in community activities provides an assessment of the social context.

Because groups by their very nature involve interpersonal functioning, it is useful to go beyond syndrome diagnosis by applying the interpersonal inventory to identify basic interactional patterns and triggering events. The use of brief questionnaires may provide useful information, especially in regard to interpersonal patterns. From this database it is possible to develop target goals to provide a focus for clinical work. This task should be addressed from a position of neutrality and cognitive clarity about issues that have emerged during the assessment. It is helpful to elicit real-life examples and the role the patient plays in these. A direct approach to this sensitive task ensures the patient that he or she is being understood but also that the important issues will not be avoided. It is helpful to specifically connect symptoms to triggering circumstances. The overall goal is to establish a serious working engagement at an early point with initiative coming from the patient, not just the clinician.

Following one or two individual assessment interviews, a final decision is required regarding the suitability of the patient for the type of group being planned. It would be better to delay treatment for a more suitable type of group than begin the patient in a group where integration might be difficult. From the other perspective, the clinician needs to consider the impact of the member on the group. Groups are generally able to absorb quite a range of problems. However, particular care should be taken to identify potential outriders, especially patients with a strong negative and autonomous controlling style. They are able to shut down group process, and the therapist has a double responsibility, to the individual and to the group. Some studies suggest that such patients do better in individual therapy.

2. Preparation

The empirical literature is clear that careful preparation leads to early group cohesion and therefore to fewer early dropouts and better eventual outcome. A systematic introduction to the nature of group therapy is indicated. This can be done verbally or preferably with the assistance of a brief handout. This might include mention of the research basis for group therapy and a brief description of how to get the most out of the experience. Some of the myths about groups may be discussed. For example the notion that it is a second-rate treatment, that people will be put on the hot seat, that talking with people who have similar problems will make everyone worse, and that the group will get out of control as sometimes portrayed in the media.

Frankly discussing these issues along with any questions the patient might have will be reassuring.

There are multiple tasks for the therapist before the group commences. These include a careful description of the proposed treatment and clearly setting a time frame, including the date of the final session. This has the added advantage of uncovering problems in attendance that might preclude a patient joining this particular group. It is useful to emphasize the patient's role in defining patterns concerning issues to be addressed and in participating in the group interaction. If the group is to be process oriented the importance of working with other group members should be emphasized and the less active role of the leader in facilitating group interaction. If the group is of a structured nature, the pattern of sessions should be described as well as the role of specific homework tasks.

3. Developing a Focus for Treatment

The choice of issues to focus on is a central task in the pregroup interviews. The therapist can function as a helpful technical resource always trying to cite the patient's own words in describing issues. The use of descriptive language rather than interpretive comments makes it more palatable to discuss dysfunctional patterns. Being direct about this task brings relief at being understood and often clarifies the patient's own partial awareness of difficulties. If questionnaires are used it is helpful to give the patient copies of the results. Various treatment models will emphasize specific types of goals as described later.

Effective goals should be seen as important and relevant to the patient. They should be realistically achievable for the treatment model offered and the time frame of treatment. They should emphasize changes the patient can make, not that others have to make. It is important to elicit collaborative discussion and to state clearly that the goal of treatment is to address these issues. The past may be used as a template, but application must be addressed in the present both in the group and outside.

Group rules or expectations should be addressed specifically. These include the importance of regular and punctual attendance and tardiness. A full and clear discussion about the absolute necessity of confidentiality is essential, as any member joining a group will be concerned about this. There needs to be a clear guideline in regard to extragroup socializing. This will be stringent for most groups but on the other hand may be encouraged in groups that are largely supportive in nature. The important task is to be very clear about the

expectations in this regard. Some mention that the members must not come under the influence of alcohol or non-prescription drugs is useful for the rare occasion when such events happen. It is also wise to clarify whether or not active concurrent individual psychotherapy is to be allowed.

Careful pretherapy preparation promotes early cohesion and reduces chances of early dropouts. It establishes a bond with the therapist that provides motivation in early sessions and a sense of security that the leader is in control though not controlling.

4. Engagement Stage

The initial task when starting a new group is to create a sense of membership in the group. The members of successful groups report an increasing feeling of belongingness over the first few sessions. The leader should take a modestly active stance particularly directed at stimulating intermember communication patterns. This can be done in an unobtrusive manner by brief interventions such as "Have others had this sort of experience," "John, you look as if you understand what Mary is talking about," and so on.

This simple strategy will facilitate interaction between members and away from the leader. This promotes the emergence in the group of important supportive therapeutic factors. The first of these is the experience of universality, that others have similar problems, ideas, and experiences. This process is enhanced when the group has been composed according to some common theme, such as a specific diagnosis, or an experience such as having trouble dealing with a death. The second therapeutic factor is that of experiencing acceptance. Many people seeking psychological help feel blocked in some way with interpersonal difficulties and real or feared concerns about not being adequate or being rejected. In a beginning group there is a strong need to be understood which is why similarities need to be stressed. The experience of feeling understood and becoming part of the group forms a foundation for self-acceptance and enhanced self-esteem. This process inevitably involves acts of altruism, of people helping each other. This allows the individual to feel appreciated and valued. These three mechanisms converge to produce the generation of hope that change is possible.

The initial group environment will be to some extent a reflection of the care taken in the assessment and preparation procedures described earlier. One method of enhancing these connections is for the leader to suggest at the beginning of the first session that people introduce themselves in terms of what they want to focus

on in the group. This automatically links a working focus with the engagement task.

Initial factual self-disclosures are important, not so much for their content, as for the process of participating and for the recognition of common issues and problems. This creates a sense of safety and acceptance that will be reflected in increasing group cohesion. The sense of groupness consolidates the group external boundary and can be reinforced by comparisons between events within the group and with those outside. A common theme is the uniqueness of sharing personal issues and the difficulty of doing this outside. At an internal level, participation in the developing group system is accompanied by an early sense of well-being at finding that one is accepted and understood which has the effect of encouraging greater self-disclosure as well as improving a sense of self-esteem.

The tasks of the engagement stage have been met when all members have demonstrated a firm sense of commitment and have participated to some extent with important self-disclosure. This is usually accomplished in the first three or four sessions. Within the process development, there will also be a content focus on revealing problems. The leader can encourage this but primarily in terms of increasing information, not solutions. The group needs to have a sense of consolidation before addressing issues more deeply. Attention to these initial engagement functions is important in all groups. They provide a powerful set of common factors that have been demonstrated to predict better outcome in highly structured groups as well as in process-focused groups.

Most group dropouts occur in the first four sessions. This is primarily linked to whether or not the patient feels engaged in the group. Measures of the therapeutic alliance to the group, of the alliance with the leader, and of group cohesion are important predictors of dropouts. The sequence of careful assessment, preparation of the member for the group, and the management of the first few sessions are key to reducing dropout rates. This is particularly important because a group that begins to lose members also becomes demoralized, and this may initiate a process of continuing attrition.

5. Conflict Stage

The positive collaboration of the engagement stage then shifts to an atmosphere of interpersonal tension that is characterized by a more confronting and challenging quality that may have an angry or resentful component. The essential task is to develop patterns for conflict resolution and tolerance of a more negative atmosphere. This stage is a necessary component for the

developing group. The term “differentiation” has been used to emphasize the importance of self-assertion and self-definition that underlie the process. The interactional themes tend to shift from ones of commonalities to those of differences. This addresses the potential liability that the engagement stage group may have of avoiding difficult but important issues. The challenge within the group is accompanied by a parallel internal challenge regarding negative or shameful feelings about self. Generally, the confrontive style is also demonstrated toward the therapist as the collective group seeks to differentiate itself from the leader. This includes a reworking of group norms that now become the “property” of the group, not just the leader. This stage often has a somewhat adolescent quality of challenge for challenge’s sake.

The leader can assist this stage by showing interest in the issues arising and endorsing the importance of addressing them. Explicit acknowledgement may be made that tensions in the group are a positive sign that important topics are being addressed. Almost inevitably some of the negative atmosphere will be directed at the leader. This often takes the form of not getting enough guidance (in process-oriented groups), or of too much focus on tasks and not enough on process (in highly structured groups). The principle task of the leader is to acknowledge the issues being presented and encourage open discussion about them. A defensive response will tend to shut down the group and result in a demoralized atmosphere.

The therapist needs to appreciate that this is a normal group phenomenon, not an individual member issue. The energy within this stage of the group can be channeled into expanding an understanding of the details concerning the difficulties that members are addressing. The therapist may use this stage to increase the expectation of applied work in the group. This may be of an introspective or interpersonal nature or of expectations in terms of applying behavioral or cognitive strategies. The member is thus encouraged to challenge self as well as other group members. This lays the basis for greater self-introspection later. A group that is not demonstrating the features of the conflict stage by the sixth session is falling behind the expected curve and is in need of examination.

The first two stages of engagement and conflict provide the experiences required to develop a deepened sense of group membership and participation. The group is able to provide support and acceptance, while also able to confront issues. In terms of group development, these are early phenomena, but they also begin

to address core difficulties regarding trust and acceptance and with difficulties surrounding assertive behaviors that are commonly found in people experiencing psychological distress. Self-esteem is often improved, and symptoms begin to ease. Early response is a strong predictor of later outcome. Group members who are not beginning to respond during the first 6 weeks in a closed weekly format need special attention. Helpful strategies would be to maintain a consistent focus on their comfort in the group, further exploration of the nature of the issues they are addressing and efforts to keep them actively involved in group discourse. Often approaches by other group members may be as useful as those directly from the therapist. The leader may use techniques such as “What do others make of the issues Henry is raising,” or “Can anyone help Marilyn sort out the tensions she is describing in her marriage.” It is not helpful to assume that the situation will improve in the later part of the group.

6. Interpersonal Work

The group is now equipped to address individual problematic matters in a more vigorous manner. The focus tends to shift to greater introspection and personal challenge. This promotes increased closeness among the members as they align in the exploration of more difficult common issues. This stage of the group is likely to stimulate themes central to interpersonal functioning such as tolerance of intimacy, management of control–dependency in relationships and fears of becoming overinvolved in relationships and losing a sense of self.

The importance of the therapeutic alliance and cohesion has been discussed earlier with the supportive working factors that are operative. A supportive group environment promotes a sense of safety that allows more challenging interactions. As the group moves into the interpersonal work stage these factors begin to give way in importance to the working alliance factors that place greater demands on the members to deepen the level of participation in the group.

A practical way of conceptualizing the interpersonal work stage of the group is based on recent detailed process research. As the sense of security in the group grows there is an increase in personal self-disclosure and catharsis. This elicits feedback from other members regarding this new information. Tolerating discrepant feedback is correlated with change in maladaptive patterns and promotes a process of interpersonal learning. This occurs on two levels. The actual interchanges in the group help to clarify interpersonal patterns and thus lead

to modification of those aspects that produce difficulty. This process leads to enactment within the group of a change of style. At the same time, an internal process of self-examination is triggered that results in changes in real life outside relationships. Success in these relationships provides a reinforcing cycle of positive experiences that serves to diminish symptom distress.

7. Termination

This stage may occur at varying points in the development of a group depending on the circumstances promoting or impeding development. It will have greater salience in groups that have developed a strong interactive milieu, that have met at least for several months or in an intensive format, and that end together. Endings are often a problematic area for people seeking psychotherapy. It is common for complicated grief issues to emerge; some members may experience acute anxiety around themes of abandonment or rejection, or of not getting enough. Termination confronts the members with the issue of assuming responsibility for managing one's self. These termination themes incorporate basic maturational tasks that are central to the human condition.

Paradoxically, the imposition of a time limit creates an arena in which such lifelong issues can be directly experienced and addressed. Termination issues are often avoided in psychotherapy. A systematic approach to managing termination will ensure that all members participate in the process. The ending of a closed time-limited group offers an opportunity to systematically maximize an exploration of the important issues related to loss.

The leader should make it clear as a patient enters a group exactly what the time line is expected to be. If it is a closed time-limited group the ending date should be clearly identified at the beginning. About 4 weeks from the end the topic of termination needs to be introduced and discussed. The theme of termination will be lurking throughout all subsequent sessions, and the therapist can be active in identifying it and encouraging further discussion. The final session is best focused primarily on termination reactions. This may be woven in with other termination matters such as relapse prevention material. An ending set of go-arounds with each member saying something by way of good-bye to all other members evokes many supportive and validating comments. A follow-up visit in a few months time is useful and provides an incentive to continue with personal therapeutic work. It should be on an individual basis, not a group meeting.

The description of the change process in psychotherapy groups described earlier applies to all types of groups,

not just those using an interpersonal model. In individual therapy, the interactional process is not as complex and under greater control by the therapist. The distinction between a cognitive and a psychodynamic individual session is obvious. In group therapy, there is a large informal interactional process that has been shown to have a significant impact on output. Therapy through the group process is not just a theoretical concept; it is enacted inevitably in any group treatment. A recent survey of process research in behavioral and cognitive groups has provided provocative findings. Some studies specifically found no correlation between a change in negative cognitions and outcome. Others found that characteristics of the group process, mainly cohesion/alliance measures, or patient characteristics accounted for as much or more predictive power regarding outcome than technical strategies. These findings suggest that clinicians employing a more highly structured treatment model need to be alert to the implications of selection and process impacts on outcome. Group process dynamics provide a supportive and motivational component quite apart from the impact of technical strategies.

8. External Structural Factors

Clinical experience suggests that numerous external factors will have a significant impact on the process of group development. The number of sessions available will in part determine how far the group can progress. For example, a group restricted to six or eight sessions is unlikely to move beyond engagement tasks because it will shift directly from engagement to preparing for termination. Inpatient groups or crisis intervention groups that have changing membership almost every session will not be able to progress beyond the engagement stage. Highly structured groups that are designed for psychoeducational purposes, or for specific skill training such as assertiveness, may be limited in the amount of interaction that occurs and will therefore show weak developmental progress.

The therapist for such brief groups may need to be relatively active to keep the group at the appropriate level. The leader needs to calibrate interventions therefore toward encouraging early-stage tasks that make full use of the supportive cluster of therapeutic factors that encourage group interaction and promote cohesion around addressing problems or topics that are external to the group itself. Trying to push such groups forward into more conflictual or introspective work will inhibit achievement of the goals of the group and may lead to dropouts.

The interactional capacity of the members chosen for the group will also have an impact on the speed at which it can develop. For example, groups for schizophrenic patients generally show a developmental process measured in months or years. Groups operating in a corrections environment where there are high levels of control and distrust will have difficulties developing an initial cohesive group. Groups for more difficult populations such as personality disorders are often treated in a brief group format but usually with a behavioral or cognitive model in which group interaction is contained in the service of information or skill focus.

A traditional format for group psychotherapy has been the longer-term slow/open group format in which members are added only when an opening becomes available. In such groups, the working atmosphere of the group is maintained with fluctuations related to tension and resistance as important issues are addressed. Any change of group membership will force the group to address engagement issues, but in such an ongoing working group with a small membership change there is not usually a major shift in atmosphere. This process might be more realistically understood as one in which the new member goes through the stage processes to rise to the level of interactional work of the ongoing group.

9. Role of the Group Therapist

The therapist is in a position to manage group development by selecting a particular theoretical model or group format, and by virtue of intervention techniques strategically selected to promote group development. The therapist should consider, before the group begins, the extent to which the more challenging atmosphere of the differentiation stage is best managed. For time-limited groups this is the most critical period.

Groups that follow a highly structured psychoeducational or behavioral format generally choose to stay in a classroom or seminar atmosphere throughout their course and make less use of interaction among the members. Group interaction would be noted and managed to maintain a working atmosphere but not explored. The focus needs to stay on the material being presented with encouragement of active group discussion around the material and elicitation of examples but not intimate personal self-disclosure. Leaders need to beware of slipping into a more intimate therapeutic mode.

Cognitive-behavioral models more commonly use engagement stage interaction actively to reinforce learning through the interpersonal process while managing differentiation issues without exploring them in

detail. The goals of such groups will be addressed primarily through application to outside circumstances, and the group may be used to rehearse new behaviors. The therapist may, for example, manage leader challenge by acknowledging the issues, appreciating that different viewpoints are helpful, but using the process to highlight the value of recognizing negative thought styles. This requires a clear distinction between group dynamics and psychodynamics. Paradoxically, the early structure of these groups promotes a rapid sense of security leading to cohesion that moves the group toward the differentiation stage quite rapidly.

Interpersonal groups will encourage member-to-member interactions from an early point and thus promote a strong sense of groupness. Groups employing an interpersonal or psychodynamic model are designed to use the group process as a major therapeutic vehicle. The leader will want to promote the differentiation stage and use it as an opportunity for interactional learning. The goal is to have the group move through the engagement and differentiation stages vigorously but without delays so that maximum time will be available for the interpersonal work stage before termination issues need to be addressed. Thus the developmental format forms a semistructured background that will guide therapist interventions.

Providing some structure within the first few sessions has been shown to increase levels of self-disclosure though care needs to be taken that the structure does not dampen individual initiative. In all types of time-limited groups there are advantages to creating a cohesive atmosphere quickly suggesting that consideration be given to introducing a modest degree of structure in early sessions. For example, the first two or three sessions of an interpersonal group for depression might be structured around discussion of the experiences of the members with depression. This might be followed by psychoeducational input regarding the signs and symptoms of depression, and a go-around discussion regarding what factors seem to be involved in triggering or maintaining the depression. Such structure has two goals: to elaborate on issues pertinent to the presenting diagnosis, and to provide a vehicle for rapid involvement in group interaction.

Several studies have found that the intentions of the therapist are a good predictor of outcome. This suggests that the actual overt behavior of the therapist is modulated by a range of implicit messages that surround and enhance the specific interventions. It would be wise for the therapist to specifically consider what therapeutic techniques would have the most impact at

regular intervals. These same studies however, also indicate that the impact of the therapist's intentions will be modified by the group climate, implying the need to monitor the atmosphere of the whole group regularly. As an example, in one study, therapist intentions to develop an interpersonal focus and provide group structure generally were associated with later group outcome. However, the same intentions in the presence of a group climate with significant conflict did not have an effect on outcome.

The therapist is also in a position to model interventions congruent with stage tasks. For example, early in a group the therapist will model empathic and supportive techniques to build an interactional atmosphere of trust. As the group moves into the differentiation stage, the therapist may model a somewhat more confrontational style. In the interactional work stage, the therapist may, if anything, increase levels of interventions with a greater depth of focus on individual member issues. During termination, the therapist may provide a model of openness to termination themes and a comfort in addressing them directly by focusing on important issues concerning self-sufficiency and loss.

10. Models of Group Therapy

It is estimated that there are several hundred types of groups. It would be unrealistic to describe even a small portion of them in detail. Table 1 provides an outline for placing a group model within a spectrum of possible groups.

In terms of the rows of "Time frame" and "Group entry" in the table, the models go from relatively unstructured through to time-limited and closed groups, to variable intensive group formats. GCBT and IPT-G represent more recent models developed for use in empirical research studies that are now widely used in general clinical use. They have the benefits of clinically oriented manuals and strong empirical validation that still allow the therapist reasonable room for individuality. Several studies have found that clinicians who use a defined model and adhere to the manual achieve better outcome results. The Yalom model differs from IPT-G through greater emphasis on the importance of "here-and-now" process interpretations. The literature makes frequent reference to this model though in practice it takes a variety of forms. The description of therapeutic factors is particularly useful in orienting the new clinician to general principles of group leadership. The empirical base is less robust because of the absence of a formal manual. Psychodynamic group psychotherapy differs from the Yalom model primarily through the ad-

ditional use of individual transference-oriented interpretations.

In terms of group composition, GCBT and IPT-G both focus on specific diagnostic clusters. Within the large encompassing criteria defined in the columns of the table, there is a multitude of formal adaptations for different target populations. The Yalom and Psychodynamic models tend to focus on goals related to interpersonal issues and to select members for a particular group on the basis of their level of interpersonal functioning.

Recent strong evidence indicates that patients with higher levels in the quality of their intimate relationships do better with an interpretive approach, whereas those with more imbalanced or chaotic levels of interpersonal relationships do better with a supportive approach. The interpretive group model focuses on unconscious processes and early relationships that is designed to increase anxiety and regression, and the supportive group model emphasizes basic group common factors such as universality, altruism, and cohesion and focuses on adaptation to the patient's current life. More interesting, these same studies found that the level of psychological mindedness predicted better outcome in both supportive and interpretive models.

In the remaining rows in the table, it is clear that support groups have their own unique features. For the other four columns there is a general trend from left to right for lower therapist activity, structure, and homework, and higher process focus and affect evocation. Mediating strategies move from external to internal focus.

To take depression as an example, GCBT groups emphasize a detailed examination of symptoms. The goal is to identify and change negative thought patterns that are a major feature of the illness. For panic disorder, there is a focus on learning control of the physiological symptoms and challenging the tendency to avoid anxiety-producing situations. Specialized protocols are used for other anxiety subcategories such as phobias and obsessive-compulsive disorder. IPT-G groups place the major focus on the quality of relationships and general socialization patterns with some attention to the origins of these difficulties. Yalom and Psychodynamic groups will focus in detail on relationship patterns and to varying extent on internal conflictual tension. Intensive personal therapeutic work with applied application to outside circumstances is anticipated in all these types of groups. GCBT generally uses specific homework assignments whereas the other models expect current application of change to be reported back into the group. This expectation of personal responsibility

TABLE 1
Comparison of Time-Limited Group Models

<i>Model features</i>	<i>Support groups</i>	<i>Group cognitive-behavioral therapy (GCBT)</i>	<i>Interpersonal therapy for group (IPT-G)</i>	<i>Yalom model interpersonal psychotherapy</i>	<i>Psychodynamic group psychotherapy</i>
Time frame	Open ended	Time limited	Time limited	Time limited	Time limited
Group entry	Open	Closed	Closed	Longer term	Longer term
Composition criteria	Variable, often by condition or circumstance	Common diagnosis or situation (i.e., binge eating, depression)	Common diagnosis or situation (i.e., binge eating, depression)	Open/closed	Open/closed
Formal pregroup preparation	Low	Moderate/high (Incorporated into early sessions)	High (Incorporated into early sessions)	Common interactional capacity	Common interactional capacity
Therapist style	High activity	High activity	Moderate activity	Low/moderate	Low/moderate
Group structure	Moderate/high	High (Programmed sessions)	Moderate (Problem areas/goals established and actively kept in focus)	Low/moderate	Low/moderate activity
Extragroup socializing	Encouraged	Permitted, perhaps encouraged	No	No	No
Process focus	Variable	Low group process focus; (managed to preserve a teaching environment)	Moderate group process focus (managed to preserve group integrity, not interpreted)	High "here-and-now" group process focus (interpreted re interpersonal conflict)	High "here-and-now" group process focus (interpreted re interpersonal and intrapsychic conflict)
Homework	Informal	Written homework and behavior change expected	Changing interpersonal/social patterns expected	Not formally prescribed	Not formally prescribed
Mediating strategies	Variable: Adapted to the common composition criteria	Identify and block negative cognitions	Identify and alter current interpersonal/social coping	"Here-and-now" interpersonal learning existential awareness	Identify and understand interpersonal and intrapsychic conflicts
Focus on affect	Variable	Low/moderate	Moderate (identification of excessive or blocked affect re current interpersonal tensions)	Moderate/high	Moderate/high

in the therapeutic process contrasts with the use of medication.

It is common to find a combined approach of medication and psychotherapy. Again using depression as an example, some symptomatic relief is expected in the first couple of weeks whereas the impact of psychotherapy becomes more evident by the beginning of the 2nd month.

IV. DESIGNING PROGRAMS

There is an increasing interest in the development of group programs in larger service systems. A larger flow of patients provides the opportunity to develop group programs for the most frequent diagnostic populations. Efforts to implement group programming often have had difficulties largely due to a failure to develop a comprehensive program. Nonetheless, the current focus on the development of organized service systems for a defined population base provides an opportunity for a resurgence in the use of group psychotherapy models. To maximize this opportunity it will be necessary to address potential resistance in both the attitudes of clinicians and the organization of service systems. The present health care context contains many of the same accessibility pressures that occurred during wartime and with the development of community mental health clinics. These periods were times of great enthusiasm for groups. For similar service demands and economic reasons, there are again strong pressures to treat a given clinical population in the most cost-effective manner.

There is a well-established literature concerning the way in which patients use psychotherapy services. Much of this information dates back before the major changes in health care delivery of the 1990s decade in the United States. In practice most patients attend relatively few sessions. By the end of 2 months, almost all service systems indicate that only about 20% of those entering will still remain in active treatment. Once this remaining cohort has reached the 6-month point, it is likely that attendance will continue for a longer period. It is worth noting that this curve is based on data collected prior to the major impact of managed care systems.

Empirical outcome studies have been quite consistent in their findings. Most patients respond quite quickly to formal therapy with over 50% improvement within the first 2 months. The rate of response continues to rise, though at a somewhat slower rate over the next 4 months so that by the 6-month point there is a 75% response rate. By the end of 2 years the improvement curve has risen slowly to 85%. This curve re-

flects an impressive response to psychotherapy, better than many medical treatments. This perspective on the predictable rates of change of a larger clinical population is a valuable guide in the development of clinical service programs.

The first step in designing a group program is to address the large percentage of patients who present with acute stress-precipitated depression and anxiety, generally more than one half of new assessments. This population can be effectively managed with therapy of up to about eight sessions. The brief time and the high turnover rate make this category less than ideal for the use of groups. However, several specific models have been developed for this purpose using crisis intervention theory. For example, a rapid access group may meet weekly, or more often, with an expected change in membership every session. The sessions are highly structured with a series of go-arounds so individual members are mainly the focus, with the group offering feedback, ideas, and encouragement. Practical goals will be set for each member to work on between sessions. A limit is set for maximum attendance, probably not more than eight sessions, but these may be spread over 3 or 4 months. Such groups are designed for supportive work to address a current issue, not for exploratory psychotherapy. The leaders need to keep this in mind even though the group may become surprisingly evocative at times. This type of group has much in common with inpatient ward groups. Referral criteria would need to specify that the group is not able to contain serious acute potential for self or other physical harm. Experienced co-therapists are indicated, at least one of whom should be quite knowledgeable about community mental health resources. This is not a group for neophyte leaders.

The next segment of a group program would deal with more intensive but time-limited groups in the 12- to 20-session range. This is the range that has been applied in most of the formal individual and group time-limited literature. More ambitious intensive therapy goals can be addressed. All time-limited models emphasize the importance of establishing specific goals. An active therapist stance is required to keep to the focus and still maintain a strong working alliance. This requires a careful assessment process to develop a collaborative agreement about focus as well as to prepare and motivate the patient for therapeutic work.

Time-limited groups should be developed for the most common diagnostic categories. Most of these models are relatively complex, and specific training in both the model and its application in a group format is required

for their successful application. Groups may also be formed, not so much by diagnosis, as by situation. Examples of these would be grief groups, divorce/separation groups, and preretirement groups. These groups vary in their balance between group process and leader-centered informational content. The therapist needs to be clear about what model is being used.

General interpersonal groups share many of the techniques of the just-mentioned groups but place more emphasis on learning from the group interaction. This approach is particularly helpful for issues of self-esteem and entrenched dysfunctional interpersonal patterns. Assessment procedures would focus on the more complex issues involved. Although these assessment procedures are based on an understanding of earlier childhood experiences, the application of them is maintained primarily on current situations. These groups offer more possibilities of process complications and require leaders who are experienced in such techniques.

Finally, a range of groups dealing with specific topic areas in an educational/skill development format may be considered. Although the range of possibilities is large, some examples would include eating disorder psychoeducational groups, stress management groups, assertiveness training groups, family communication groups, and childhood development groups. These formats make less use of the group process and tend to be leader centered. Nonetheless, the group format provides general properties of the supportive therapeutic factors that reinforce motivation and amplify learning. Leaders require less intensive training in group therapy but must be alert to group management problems. Ready access to clinical supervision is advised.

This leaves a much smaller number of patients with more severe levels of dysfunction often involving longstanding characterologic features or treatment resistant conditions. Group methods are particularly appropriate for this population as the group format provides a strong containing quality that serves to dampen reactivity. Longer time frames would be appropriate, often in the 6- to 8-month range. There is a double goal in these programs. First is active treatment, and second is to decrease use of intensive treatment services such as acute admissions and emergency room presentations. Some programs have had success with long-term maintenance programs for this population.

Most communities have support groups for many conditions. These are generally adapted over time to address the specific features of a condition. The most familiar and largest example of this is Alcoholics Anonymous with the emphasis on abstinence and the need to address

the alcoholic's sense of personal power by insistence on the acceptance of being subject to a higher power. It is recommended that the professional clinician be familiar with support group resources in the community and maintain a collaborative referral relationship and be available to self-help organizations when their members present with problems beyond the group's capacity to manage. It is also recommended that the self-help strategies be respected and that there not be efforts to turn them into amateur clinicians, a move that would undercut their value as self-help leaders.

This emphasis on specific models has a sound rationale. The use of a group format and the imposition of a time limit combine to pose limitations on what can be accomplished. Specific models provide clear guidelines to follow that are generally outlined in clinical manuals. These serve to keep the therapist on track, and outcome research indicates that following such guidelines results in more predictable positive outcomes. Most manuals primarily deal with positioning strategies for the therapist, leaving reasonable room for clinical flexibility. Some of these use a classroom atmosphere that provides greater emphasis on the learning of designated material. It is likely that clinicians will be increasingly expected to justify their choice of model in the light of empirical knowledge, as well as their competence to provide it.

V. SUMMARY

A. Group Programming

It is likely that the development of expanded group programs will become widespread in larger treatment systems. In this process, it is important that care be taken in matching patient characteristics to the programs available, or perhaps more important, that programs be developed for the sorts of problems presented by the patients. There are clear indications that many administrators favor tightly controlled models with scripted sessions. These can be conducted by therapists with less training and are easier to document. As a counterbalance to this, patients are becoming increasingly knowledgeable and outspoken about the sorts of treatments that are available and the indications for their use. In the long run, this is likely to serve as an important influence on program development.

There is reasonable evidence that longer-term treatment or maintenance programs can significantly reduce utilization of intensive resources. However, at the same

time, clinicians need to recognize that the majority of patients do well with much shorter treatment. This reflects in part a truly unfortunate but major split in the group psychotherapy community between a dedication to longer-term process-oriented approaches for senior clinicians in the field, and training in only quite structured models for many clinicians entering the field.

B. Group Research

There has been a remarkable increase in the quality of group research over the last decade. The importance of early group cohesion and a positive therapeutic alliance (to both the group and the leader) are now well established and need further investigation only in relationship to other variables. Similarly the concept of group development has substantive support in the time-limited closed group clinical literature with modest support regarding prediction of outcome. It is no longer possible to claim that process-oriented groups have little or no empirical validation as often stated in the service literature. An intensive psychodynamically oriented milieu program has demonstrated significant response for patients diagnosed with borderline personality disorder and other personality disorders. The clinical belief that patients with more severe functional status do better with a supportive approach has been validated, but also that those patients functioning at a higher level of interpersonal relationships do better with a dynamically informed interpretive approach of a time-limited nature. The value of structure in the early group has been reconfirmed as well as the importance of identifying at an early point, preferably during assessment, important issues to serve as a focus for treatment.

This research foundation can be developed further with attention to several research strategies. The nature of the group process is an important variable in all types of groups and needs to be regularly reported. Several studies indicate that aspects of the group process predict outcome as well or better than the hypothesized technical strategies in structured groups. Given the general positive outcome in almost all groups studied, a focus on linking patient, therapist, and process variables should now be of high priority. Assessments of characterologic traits predict outcome in relationship to therapeutic strategies, but there is much more to be learned about these phenomena. Single-point assessment of group process is not of value, sequential measures are necessary to be meaningful. External ratings from video/transcript sources are

needed to balance the current preponderance of member and therapist ratings. Leadership/therapist studies are weak and few between.

C. Group Training

Given the earlier program and research scenarios, to equip clinicians entering the field there are several guidelines concerning the nature of group training programs. It seems absolutely crucial that clinicians be prepared to apply a range of group models. There is overwhelming evidence that both structured and process-oriented formats are effective. On the structured side, expertise in applying cognitive and behavioral strategies is required. These have demonstrated effectiveness for depression, anxiety, and eating disorder syndromes, the most common presenting complaints. However, it is also evident that applying these techniques in a group setting benefits from an applied knowledge of group dynamics. This is particularly relevant to the early group where the development of a cohesive working atmosphere enhances outcome.

In terms of dynamically informed process-oriented group therapy the effectiveness literature is equally strong. Clinicians should be particularly trained in the indications for use of supportive versus interpretive models. Personality disorders also respond to the process-oriented approach. Many day/evening/inpatient milieu programs use a combination of structured modules and process-oriented groups. These programs generally use the same therapists for both components. This has a strong added advantage that the therapists will be acutely aware of the different strategies being employed and can implement them in a knowledgeable manner.

Group training needs to be grounded in basic group theory that applies to all types of groups. This is most effective when it is actively related to clinical technique and therapeutic strategies. Training should also involve an experiential component as a member of a group. This does not imply the need for treatment, but rather the importance of appreciating the power of group process on the individual. It is of great value in understanding the response of members to group events and to be aware in advance of possible situations in which interventions may be required. An experienced individual therapist may not necessarily make the transition to group therapy easily. Group therapy makes use of the group as a therapeutic agent, and the individual therapist may experience a sense of loss at the greater therapeutic distance from the individual members.

Therapists may also feel a loss of control of the therapeutic process. The same issues arise if a program therapist is supervised by a senior clinician who is not familiar with group theory and practice.

GLOSSARY

defensive behaviors Behaviors that people use to cope with an activity about which they do not feel confident and that limit the proficiency and/or flexibility of performance.

self-efficacy Peoples' beliefs in what they can do and how strongly they believe it.

Guided mastery therapy is focused on changing clients' self-efficacy. This article will present the treatment process, the theoretical bases of guided mastery, and its empirical bases.

I. DESCRIPTION OF TREATMENT

A. General Strategy

Guided mastery therapy focuses on changing clients' self-efficacy, that is, the clients' beliefs in what they can do and how strongly they believe it. It is assumed that actual performance or nonperformance of challenging

tasks is the most potent determinant of the self-efficacy related to these tasks. With this emphasis on performance, it is not surprising that guided mastery first and foremost has been used in the treatment of the anxiety disorders, which are characterized by avoidance and other performance deficits. This presentation of guided mastery will therefore concentrate on the use of guided mastery for anxiety-related problems and largely be based on Stuart Lloyd Williams' formulation published in 1990.

In guided mastery, agoraphobic clients are assisted and guided as they enter grocery stores, enter freeways by car, or ride the bus; height phobic clients are helped as they enter a balcony of a tall building; and social phobics are guided to order and eat in a café. The therapist acts as a field expert, not only encouraging clients to perform tasks, but also guiding performance according to the principles of the self-efficacy model. The overall principle is to promote a positive feedback circle between performance and self-efficacy. Tasks are selected and structured so that they may lead to a maximal increase and generalization of self-efficacy, leading to further improvements in performance. Therapists remain alert to the actual performance of each client as well as to the way clients process the experience. For enhancement of self-efficacy, it is important that clients attribute performance successes to their own capabilities and not to external circumstances or aids. Therapists guide clients to perform progressively more difficult tasks as rapidly as possible according to

the principles: first to increase their level of performance, then to increase their proficiency and flexibility of performance, and, finally, to stimulate independent performance.

B. Case Example

The typical course of treatment is illustrated in the following example: Per suffers from severe bridge phobia. He is not able to walk or drive a car across bridges. When he is reminded of bridges or sees a bridge, he engages in vivid imagery of himself falling from the bridge. As a first task, Per agrees to walk accompanied by the therapist to the start of a 100 meter long bridge that crosses a river. The bridge is equipped with a lane for pedestrians and has 1 meter high railings on both sides. Next, Per agrees to walk 10 meters onto the bridge with the therapist walking beside him holding his arm. After successful completion of this task the therapist models the behavior unaccompanied and asks Per to do the same. After several intermediate steps, Per is able to walk alone to the middle of the bridge, which is his most feared place. His performance is awkward and restricted; still he tenses his muscles, stares at a distant point, and avoids moving close to the railing next to the river. The therapist models more appropriate behaviors and instructs Per concerning their performance: "Relax your legs, feel the ground under your feet." Before and after each task, self-efficacy is probed on a 0 to 100 percent certainty scale. Also, 0 to 10 scaled anxiety ratings are collected, especially when working with the awkward and restricted behaviors. Finally, Per is able to perform the criterion task: to lean over the railing and look into the water, holding his hands behind his back.

C. Increase Performance Level

The example illustrates several of the techniques used as part of the strategy to increase performance level rapidly. The main purpose of joint performance is to promote self-efficacy by reassuring clients that assistance is available if they should lose control. Thus, clients usually do more when accompanied than they would have been able if initially asked to engage in these behaviors by themselves.

Therapeutic tasks can be modeled overtly and through verbal coaching. The therapist in the example both demonstrates how to perform the difficult task and verbally coaches the client concerning awkward and restrictive behaviors. When people have difficulty initiating treatment behavior, treatment tasks are

divided into more easily achievable subtasks. Performance of each subtask is set as a proximal goal. The *setting of proximal goals* enhances self-efficacy by making clear what has to be done, by making performance successes possible, and by providing immediate feedback of success upon subgoal attainment. Therapy may also involve graduated exposure to treatment settings. In the case of Per, for example, after successfully confronting the 100 meter bridge, he would be encouraged to use a larger bridge. Additionally, the technique of giving physical and mechanical support is illustrated by the therapist holding Per's arm the first time he walks onto the bridge.

D. Increase Proficiency and Flexibility of Performance

Anxious people typically engage in defensive behaviors to help themselves cope with an activity about which they do not feel confident. Such behaviors may include clinging to the shopping cart when in a supermarket, holding one's breath at tense moments, or—as Per did—tense his muscles and stare at a distant point when walking on a bridge. In this way, people limit their proficiency and flexibility of performance. Proficiency of performance refers to the ability to perform without defensive rituals. Flexibility refers to the ability to do tasks in varied ways, without self-restrictions on the range of performance. It is assumed that these defensive behaviors maintain a state of low self-efficacy because they prevent the person from receiving positive feedback, as well as the belief that performance successes are due to the defensive behaviors and not to their own effectiveness. This conceptualization is explained to patients as a rationale for dropping these behaviors. Defensive behaviors are identified by observing clients' performance and by asking what they do to help themselves cope with the threatening activities. It is amazing how quickly anxiety arousal often declines on dropping defensive behaviors. Anxiety ratings provide a sensitive moment-to-moment indication of progress, and are particularly useful when working with defensive behaviors.

E. Stimulate Independent Performance

Initially, guided mastery involves accompanying patients into feared situations and providing assistance and guidance. This ensures that clients actually initiate therapeutic activities, that they progress rapidly, that the

therapists can observe the use of defensive behaviors, and that the therapist can immediately assess the clients' cognitive processing of performance information. However, the goal of therapy is for clients to become confident that they can function without assistance. To promote independent performance three principles are followed. First, the lowest level of assistance necessary for success is provided. Clients are accompanied and assisted only on tasks they would find difficult to do on their own. Second, assistance is faded out as soon as possible. Finally, patients are trained to be their own therapists. The principles of guided mastery are explained to the patients during therapy in order to enable them to apply the guided mastery approach on their own. The principles may also be discussed in group sessions with patients receiving guided mastery.

F. General Aspects

Performance levels are raised because proficiency and flexibility in coping behavior tend to increase as a by-product of each success. Therapists collect self-efficacy ratings (0–100 certainty) both before, during, and after performance in order to select appropriate tasks and to examine how mastery experiences have been interpreted by clients. As regards the therapeutic relationship, the guided mastery therapist adheres to the humanistic principles that are typical of various forms of psychotherapy: to show an optimal amount of empathy, warmth, and respect. The style of therapy is collaborative rather than directive and confrontational.

II. THEORETICAL BASES

Guided mastery therapy is based on self-efficacy theory. This theory holds that cognitive processes play a dominant role in the acquisition and retention of new behavior patterns. New behaviors may be learned by observing others. The effect of the model's behavior also influences learning. Efficacy expectations are distinguished from outcome expectations. An efficacy expectation can be defined as a person's conviction that he or she can successfully execute the behavior required to produce certain outcomes, whereas an outcome expectation is the estimate that a given behavior will lead to a specific outcome.

A main assumption of the self-efficacy model is that psychological procedures, whatever their form, serve as a means of creating or strengthening expectations of personal efficacy. Self-efficacy may be affected by verbal persuasion, vicarious experience (seeing another person

cope with the task), imaginal enactment (imagining oneself doing it), or emotional arousal, but direct performance accomplishments are believed to provide the most convincing evidence that one possesses the needed abilities. Thus, although the self-efficacy model is based on cognitive processes, it postulates that change is achieved mainly through behavioral performance.

Performance inhibitions and deficits are obvious features of anxiety, and, as mentioned above, the self-efficacy model has been applied to the analysis and treatment of anxiety disorders. People perceive threat and become anxious when they believe that they are powerless in the face of a threatening stimulus. This belief may either be based on efficacy or on outcome expectations: People can experience threat because they lack a sense of efficacy in achieving the behavior required to avert the dangerous events, or because they believe that the events are uncontrollable. Theorists from various orientations generally agree on these statements. However, self-efficacy theory also claims that anxiety and anxiety disorders are primarily maintained by low self-efficacy that one is able to exercise personal control, and not by beliefs that the threatening events themselves are uncontrollable. Recently, the concept of self-efficacy has been extended to covert activity. It is supposed that an individual's perceived ability to control and dismiss scary thoughts may be an important determinant of anxiety.

This general view of anxiety is reflected in self-efficacy models of specific clinical disorders. For instance, the self-efficacy model holds that agoraphobia is maintained by beliefs that one lacks the capabilities required to perform the feared activities. Low self-efficacy is maintained by avoidance behavior and by performing feared activities in an awkward and restricted way. By contrast, cognitive therapy models hold that agoraphobia results from catastrophic misinterpretations of bodily sensations. Agoraphobic avoidance is construed as safety behavior, designed to avert the occurrence of uncontrollable events such as having a heart attack or going crazy. Both of these models contrast with behavioral accounts, where agoraphobic avoidance is seen as a way of reducing anxiety and panic. With regard to panic disorder, self-efficacy for exercising control over scary thoughts is suggested as an important target of treatment.

There is an interesting mismatch between the general self-efficacy model of anxiety and the principles of anxiety treatment. In the general model, it is assumed that self-efficacy is enhanced by demonstrations that one is able to behaviorally prevent the occurrence of a threatening, aversive event. In guided mastery practice one relies heavily on demonstrations that one is able to

overcome the tendencies to avoid feared activities or to use defensive behaviors during performance. Direct evidence that one is able to exert personal control over the occurrence of a threatening event is seldom involved. Thus, self-efficacy with respect to overcoming avoidant and defensive tendencies and self-efficacy with respect to behavioral control over threatening events should be conceptually separated. This distinction may lead to more differentiated treatment interventions.

III. EMPIRICAL STUDIES

A core assumption of guided mastery therapy is that performance guided by the principles of the self-efficacy model is more effective than pure exposure treatment, that is, performance without such assistance. For height phobia, driving phobia, and snake phobia, guided mastery has been found to be more effective than mere exposure. With respect to agoraphobia, the results are mixed and less promising. In agoraphobic individuals who could perform the exposure tasks, but only under intense anxiety, performance-related anxiety declined more among those who received guided mastery than among those who received exposure. However, the two groups were not different on a measure of self-efficacy. Another study of agoraphobic individuals with little avoidance but intense performance-related anxiety did not find any differences between a guided mastery condition and an exposure condition. One study has compared cognitive therapy and guided mastery for severely agoraphobic subjects, and found cognitive therapy to be associated with better outcome on several measures 1 year after the end of treatment.

Concerning mediating mechanisms, the self-efficacy model states that phobia-related fear and avoidance behavior are maintained by low self-efficacy. Anticipated anxiety/panic and danger are assumed to be effects of low self-efficacy. Furthermore, the self-efficacy model predicts that changes in self-efficacy will lead to changes in these variables. Several of these predictions have been found for height-phobic patients. With regard to agoraphobia, the findings related to these predictions appear to depend on the research methods used. When ratings of the cognitive variables are anchored in specific behavioral tasks, self-efficacy predicts approach behavior, even when other factors such as previous behavior, anticipated anxiety, anticipated panic, catastrophic beliefs, and subjective anxiety are held constant. Catastrophic beliefs do not predict treatment effects when these other variables are controlled. However, when self-report cognitive measures not an-

chored in specific situations are used, and the analyses are based on the temporal sequence between predictors and outcome, the results are consistent with a cognitive therapy model and inconsistent with a self-efficacy model. Overall, a self-efficacy analysis of agoraphobia has not been clearly supported.

IV. SUMMARY

Guided mastery therapy focuses on changing clients' self-efficacy: clients' beliefs regarding what they can do. It is assumed that actual performance or nonperformance of challenging tasks is the most potent determinant of self-efficacy related to these tasks. Therapists act as field experts, guiding clients to perform problem-related tasks according to the principles of the self-efficacy model. Therapists are alert to the actual performance of clients as well as to the way clients process the experience. For enhancement of self-efficacy, it is important that clients attribute performance successes to their own capabilities and not to external circumstances or aids. Therapists guide clients to perform progressively more difficult tasks in order to increase levels of performance, to increase the proficiency and flexibility of performance, and to stimulate independent performance.

social support A component of habit reversal in which a significant other is enlisted to help the client control the habit behavior. The social support person prompts the client to use the competing response when the client engages in the habit behavior, and praises the client for engaging in the competing response and for refraining from engaging in the habit behavior.

GLOSSARY

awareness training A component of habit reversal in which the client learns to identify each occurrence of the habit behavior.

competing response training A component of habit reversal in which the client learns to engage in an incompatible behavior contingent on the occurrence of the habit behavior or on antecedents to the habit behavior.

differential reinforcement of alternative behavior (DRA) A procedure in which an acceptable behavior is reinforced so that it will increase and replace a problem behavior.

differential reinforcement of other behavior (DRO) A procedure in which reinforcers are delivered for the absence of a problem behavior during intervals of time.

habit disorder A repetitive behavior that does not typically serve any social function but occurs with sufficient frequency or intensity to cause distress to the client or significant others. Habit disorders include nervous habits (such as thumbsucking, nail biting, hair pulling), tics (such as head jerking, facial grimacing), and stuttering (word or syllable repetition, prolongation of word sounds, blocking).

I. DESCRIPTION OF TREATMENT

Habit reversal was developed by Nathan Azrin and Greg Nunn in 1973 as a treatment for nervous habits and tics. In 1974, these researchers also utilized habit reversal to treat stuttering. In the original study there were four major components to the habit-reversal procedure: awareness training, competing response practice, habit control motivation, and generalization training.

A. Awareness Training

Awareness training consists of a number of procedures designed to teach the client to become aware of every instance of the habit behavior as it occurs or when it is about to occur. The client needs to be aware of each instance of the habit in order to use the competing response contingent on the habit. In the response description procedure, the therapist instructs the client to describe the movements involved in the

habit. In the response detection procedure, the therapist teaches the client to identify each instance of the habit that occurs in session. In the early warning procedure, the client identifies and practices detecting the earliest signs or movements of the habit. In the competing response practice procedure, the client learns to engage in an incompatible behavior for a few minutes to heighten awareness of the muscles involved in the habit. In the situation awareness training procedure, the client identifies the antecedents or circumstances (situations, persons, places) in which the habit is most likely to occur.

B. Competing Response Practice

Through competing response training, the therapist instructs the client to identify a behavior that is physically incompatible with the movements involved in the habit and to engage in this behavior for one to three minutes each time the habit occurs or when the client is about to engage in the habit. The competing response involves isometric tensing of the muscles involved in the habit. The competing response is socially inconspicuous, so the client can engage in the behavior without disruption of ongoing activities. Examples of competing responses include the following. For nail biting, thumbsucking, hair pulling, or any habit involving the hands, the competing response involves holding the hands down at the side and making a fist or grasping objects. For a head jerking tic, the competing response involves isometric contraction of the neck muscles by pulling the chin in and down. For an oral habit such as mouth biting, the competing response involves lightly clenching the teeth. For stuttering, the competing response (called regulated breathing) involves slow, deep breathing with a slight exhale before speaking. The client practices the competing response in the therapy session and is instructed to engage in the competing response any time the habit occurs or is about to occur once the client leaves the session.

C. Habit Control Motivation

With these procedures (including habit inconvenience review, social support, and public display procedures), the therapist attempts to increase the client's motivation to get rid of the habit, thus making it more likely that the client will comply with the treatment procedures. With habit inconvenience review, the therapist reviews with the client all of the ways in which the habit is inconvenient or embarrassing. In the social

support procedure, the therapist calls the client on the phone at regular intervals and provides praise for the client's efforts and success in controlling the habit. The therapist also engages the assistance of a significant other (such as a parent, spouse, other family member, or friend) to help the client succeed in controlling the habit. The social support person praises the client when the habit is not occurring and praises the client for using the competing response. The social support person also reminds the client to use the competing response when an instance of the habit is observed. For young children, the social support person might need to manually guide the child through the competing response if the child does not initiate it independently. In the public display procedure, the client demonstrates his or her control over the habit in front of the therapist and significant others.

D. Generalization Training

The purpose of generalization training is to teach the client how to control the habit in everyday situations. The therapist first has the client practice the competing response until the client is using it correctly in session and then spends up to 30 minutes engaging the client in conversation while the client practices the competing response contingent on the occurrence of the habit. The therapist provides social support during this 30 minutes of practice by praising the client for the correct use of the competing response and reminding the client to use the competing response if the habit occurs and the client does not initiate the competing response independently. The therapist also uses symbolic rehearsal procedures in which the client imagines situations in which the habit typically occurs and imagines himself or herself successfully using the competing response in those situations.

The habit-reversal procedure is typically implemented in a small number of sessions (or one long session) with followup phone calls or booster sessions as needed. For example, in 1998 John Rapp and his colleagues used habit-reversal procedures to treat chronic hair pulling in three adolescents. Following two initial treatment sessions with clients and their parents, Rapp and colleagues then conducted booster sessions in the following months when clients were having difficulty successfully using the procedure. In each booster session, the therapist met with the clients and their parents, reviewing and practicing the procedures. In this study, the habit-reversal procedure was successful with one to three booster sessions.

II. THEORETICAL BASES

The success of habit reversal appears to be tied to the consistent use of the competing response contingent on the habit behavior or in anticipation of the habit behavior. Two mechanisms may be responsible for the success of the competing response in decreasing the occurrence of habit behaviors. One explanation is that use of the competing response contingent on the habit behavior works through a punishment process. One type of punishment involves the application of aversive activities contingent on the problem behavior. If the competing response is an aversive activity, then the behavior it follows (the habit behavior) will be punished and thus decrease in frequency. A second explanation is that the competing response is an alternative behavior that occurs and replaces the habit behavior. After the client learns to engage in the competing response in therapy sessions, use of the competing response is then reinforced by the therapist in the session and by the social support person outside of the sessions. The increase in this incompatible behavior then supplants the occurrence of the habit behavior. Unfortunately, it is not clear which conceptual explanation has the most validity. In all likelihood, the effectiveness of the competing response may be explained by a combination of these mechanisms.

The success of the social support procedure is due to the use of verbal prompts and two forms of differential reinforcement. Reminding the client to use the competing response amounts to a verbal prompt for the correct behavior. Providing praise to the client for the correct use of the competing response involves differential reinforcement of alternative behavior (DRA). The alternative behavior that is being reinforced in the DRA procedure is the competing response. Providing praise to the client for the absence of the problem behavior involves differential reinforcement of other behavior (DRO). In the DRO procedure, also called differential reinforcement of zero rate of behavior, a problem behavior (the habit behavior) is decreased when reinforcement is provided at periodic intervals for its absence.

III. APPLICATIONS AND EXCLUSIONS

Since the development of habit reversal in 1973, the procedure has been used to treat a wide variety of habit disorders in adults and children. Habit reversal has

been applied to motor and vocal tics associated with Tourette Syndrome and other tic disorders. It has been applied to habits involving the hands such as thumb-sucking, nail biting, hair pulling, scratching, and skin picking and to oral habits such as teeth grinding, mouth biting, lip chewing, and tongue protrusion. Habit reversal has also been applied to stuttering exhibited by adults and children as young as 6 years of age.

Because habit reversal requires the client to detect each occurrence of the habit behavior and use a competing response contingent on the habit, habit reversal can be used only by individuals who are capable of understanding the procedure, have the ability to carry out the procedure, and are motivated to use the procedure (they state that they want to stop the habit and are willing to use the procedures). The procedure may be ineffective with young children or with individuals with mental retardation because these individuals may not understand the procedure, may not be capable of carrying it out, or may not want to change their behavior.

Social support procedures may enhance the effectiveness of habit reversal with children when parents are diligent in prompting their child to use the competing response and praising the child for using the competing response and refraining from the habit behavior. However, when habit behaviors such as thumbsucking or hair pulling occur primarily when the child is alone, the parent may be unable to provide social support successfully. In such cases habit reversal may need to be supplemented with adjunct procedures, or other procedures may need to be used instead of habit-reversal procedures.

IV. EMPIRICAL STUDIES

Following the initial studies by Nathan Azrin and Greg Nunn in 1973 and 1974, much research has documented the effectiveness of habit-reversal procedures for the treatment of nervous habits, tics, and stuttering. In addition to showing that habit reversal is effective, researchers have also shown that simplified versions of habit reversal are effective. For example, in 1985 Ray Miltenberger, Wayne Fuqua, and Tim McKinley showed that awareness training and competing response training were effective in treating motor tics exhibited by adults. In 1985 Miltenberger and Fuqua further showed that awareness training and competing response training were effective in the treatment of nervous habits exhibited by adults. In 1996, Doug Woods and colleagues showed that awareness training

and the use of a competing response were also effective in the treatment of tics in children.

A number of researchers have shown that awareness training, competing response training, and use of social support are effective in the treatment of habit disorders in children. For example, in 1993, Joel Wagaman and his colleagues showed that these habit-reversal components successfully decreased stuttering in children, and in 1998, John Rapp and his colleagues showed that these procedures decreased chronic hair pulling in adolescents.

Other researchers have demonstrated the limitations of habit reversal with young children and individuals with mental retardation. In a study by Ethan Long and colleagues in 1999, habit reversal was not effective in the treatment of nail biting and other oral-digital habits exhibited by individuals with moderate to severe mental retardation. However, Long and colleagues found that the addition of differential reinforcement and response cost procedures following habit reversal decreased the habit behaviors for their participants. In these procedures, the participant was surreptitiously observed from another room, and, when the habit did not occur for an interval of time, the researcher entered the room and provided a reinforcer such as candy or money (differential reinforcement). When the habit was observed to occur, the researcher entered the room and removed some of the reinforcers (response cost). Other researchers have also shown that differential reinforcement and response cost are effective procedures when habit reversal fails to decrease habit behaviors in young children.

V. CASE ILLUSTRATION

The following case example illustrates the successful use of habit reversal with a 10-year-old girl, Jennifer, who engaged in chronic hair pulling to the point of having bald areas on her head. Jennifer's mother spent up to 30 minutes every morning fixing Jennifer's hair so that the areas of hair loss would not show, thus preventing Jennifer from being embarrassed at school by the hair loss. By their own report and the fact that they traveled a great distance for treatment, Jennifer and her parents were highly motivated to stop the hair pulling. They attended six therapy sessions over the course of nine days. The therapy sessions were conducted in such a short period of time because the client and her family had to travel a long distance to receive treatment. Outpatient treatment sessions would typically be conducted on a weekly basis.

The first session consisted of a behavioral assessment interview in which the therapist asked questions about the exact nature of the hair pulling, the antecedents of the hair pulling (where and when it happens, circumstances and people present, thoughts and feelings of the client preceding the hair pulling), and the consequences of hair pulling to identify or rule out any form of social reinforcement (e.g., attention) that might play a role in the maintenance of hair pulling. In this initial interview, the therapist also asked about the client's history, onset, course, and severity of the hair pulling, how the hair pulling was affecting the clients' lives, and the clients' motivation to eliminate the hair pulling. For Jennifer, hair pulling occurred in her classroom when she was taking a test or concentrating on other activities, and it occurred at home when she was studying or engaged in sedentary activities such as watching TV or lying in bed. There did not appear to be any form of social reinforcement for the hair pulling, for she often engaged in the behavior without others being aware of it. The initial assessment suggested that Jennifer was a good candidate for habit reversal and that adjunct procedures were probably not necessary. Had motivation been a problem or had there been some form of social reinforcement for the hair pulling, then these problems would have to be addressed with adjunct procedures. The first session ended with a description of the habit-reversal procedure to be implemented in subsequent sessions.

In the second session, awareness training and competing response training procedures were implemented with Jennifer and her parents. The therapist implemented the response description procedure by having Jennifer describe the hair pulling movements and then engage in these movements without actually pulling out any hair. Jennifer described and demonstrated all of the different ways in which she pulled her hair and the behaviors leading up to pulling out a hair strand. These precursor behaviors involved running her fingers through her hair, moving her hair back and forth between her first finger and her thumb, isolating one strand, and pulling the strand of hair with a plucking movement by holding on to the hair at its base. Jennifer demonstrated the behaviors from start to finish, ending with a simulated plucking movement.

After response description was complete, the therapist implemented response detection. Response detection is more difficult to implement with habit behaviors that typically do not occur around other people because clients will not naturally engage in the behavior in the session. Response detection is easier to conduct

with tics or stuttering because these behaviors will usually occur a number of times in the session, providing clients with opportunities to practice identifying their occurrence. With hair pulling (as with thumb sucking, nail biting, and other habits involving the hands) the therapist must have clients simulate the occurrence of the behavior during the response detection component of awareness training. The therapist instructed Jennifer to simulate her hair pulling movements in session about 10 times. During these simulations, Jennifer was told to imagine herself in various situations that she had identified as being antecedents for hair pulling. The therapist also had Jennifer simulate some of the activities associated with hair pulling while simulating the hair pulling movements. For example, she sat at a desk with paper in front of her and simulated taking a test while reaching up to pull her hair, or she sat on the floor against a wall simulating waiting her turn for an activity in gym class at school and simulated hair pulling in that position.

While she simulated the hair pulling movements, the therapist instructed Jennifer to stop at various points in the movement and notice how her arm felt or observe the position of her arm in space as it approached her head. Drawing her attention to the sight and feel of her arm at various points in the movement was intended to heighten her awareness of the hair pulling movement and make it more likely that she would detect the incipient hair pulling movements when they occurred in the natural environment.

The situation awareness training component of awareness training was begun in the first session when the therapist asked Jennifer and her parents to identify all of the circumstances in which hair pulling occurred. It was continued in this session as Jennifer simulated hair pulling in those situations or imagined hair pulling in those situations. Jennifer was also asked to identify thoughts and feelings that were antecedents to hair pulling. However, she could not identify any specific thoughts or feelings that preceded the behavior. It is not uncommon for children to be unable to identify thoughts and feelings as antecedents to a habit behavior; adults have been found to be better at providing such information. It is useful to obtain information on thoughts and feelings as antecedents to hair pulling or other habit behaviors because the occurrence of these thoughts or feelings may then cue the client to engage in the competing response to prevent subsequent occurrence of the habit behavior.

Before the second session was over, Jennifer and her parents were introduced to the concept of the compet-

ing response and the rationale for its use. The therapist told them that the competing response provides an alternative, inconspicuous activity to engage the hands so that the hair pulling cannot occur. The competing response, called the "exercise," was to be a behavior that was physically incompatible with hair pulling, that was easy to carry out, that was inconspicuous so that it did not draw attention to Jennifer, and that could be carried out for at least a few minutes each time hair pulling occurred or was about to occur. After introducing the concept and the rationale for its use, the therapist identified a number of different competing responses that Jennifer might consider using. The therapist then asked Jennifer and her parents to pick a few of the competing responses (or to identify other ones) that they were most comfortable using. Jennifer chose holding a pencil while at school, grasping a cushball while at home, and making a fist at her side to be used when she did not have an object to grasp. The therapist informed Jennifer and her parents that they would discuss the competing response and practice it in the third session.

The third session was devoted to practicing the competing response and social support procedures. Between sessions 2 and 3, Jennifer and her parents bought a cushball and other small items that she might grasp as part of her competing response and brought these items to the session. To practice the competing response, Jennifer simulated the hair pulling movements and then immediately engaged in the competing response for about one minute. After a couple of simulations of the complete hair pulling movements followed by the use of the competing response, Jennifer was instructed on subsequent trials to stop earlier in the hair pulling movement and engage in the competing response. For example, she was to initiate the competing response as soon as her hand touched her hair, as soon as her hand was raised above her shoulder, as soon as her hand was raised above her waist, and as soon as her hand was lifted off of her lap. By engaging in the competing response earlier and earlier in the movement toward hair pulling, Jennifer is more likely to catch herself before actually pulling a hair and engage in the competing response to prevent hair pulling outside of the therapy session.

Jennifer next practiced the competing response contingent on hair pulling movements as she simulated situations that were antecedents for hair pulling. By practicing the competing response while simulating natural situations, use of the competing response is more likely to generalize to natural situations outside

of the therapy session. Within this session, Jennifer practiced 12 to 15 times the competing response contingent on simulated hair pulling with instructions and praise from the therapist. During the course of this practice, the therapist introduced the concept and rationale for the use of social support.

The therapist told Jennifer and her parents that, although it was Jennifer's responsibility to detect each occurrence of hair pulling and use the competing response, she was more likely to be successful if her parents helped her. To help her, her parents must do three things. First, they should prompt her to "do your exercise" if they observed her engage in hair pulling but failed to use the competing response on her own. Second, they should provide praise when they observed Jennifer using her competing response. Finally, they should provide praise when they observed that Jennifer was not engaging in hair pulling, especially in situations that were usually antecedents for hair pulling. After describing the social support procedure, the therapist then instructed the parents to practice the procedures in session. The therapist asked Jennifer to simulate hair pulling without using the competing response a few times so that the parents had an opportunity to prompt her to do her exercise. The therapist then had Jennifer practice her competing response so that the parents had an opportunity to praise her for using it. The therapist also had Jennifer simulate an activity in which she usually pulled her hair and refrain from hair pulling to provide the parents an opportunity to praise her for the absence of hair pulling. The therapist observed the parents use the social support procedures and provided praise and any corrective feedback as necessary. At the end of the session, the therapist instructed Jennifer to use her competing response any time she engaged in hair pulling or was about to engage in hair pulling outside of the session. The therapist also asked the parents to provide social support outside of the session by prompting and praising Jennifer as they had learned in the session.

In the fourth, fifth, and sixth sessions, the therapist and clients discussed their use of the competing response and social support procedures outside of the sessions. The therapist provided praise for reports of accurate use of the procedures and answered any questions about use of the procedures. Additional session time was devoted to further practice of the competing response contingent on simulated hair pulling in a variety of simulated situations and the use of social support procedures by the parents. In the final sessions, the therapist also helped the clients plan use of the procedures in their home and school environments once

therapy sessions were terminated. The therapist and clients discussed Jennifer's typical daily routines at home and at school and planned use of the procedures at high-risk times in both settings. The therapist proposed scenarios that involved problems in implementing the procedures and worked with the clients to identify solutions to the possible problems. Finally, the therapist and clients worked out a plan to enlist the support of Jennifer's teacher as a social support person at school and defined the teacher's responsibilities in that role.

Once therapy sessions were terminated, the clients contacted the therapist at periodic intervals via e-mail and telephone to describe progress and to ask questions. Jennifer and her parents used the procedures consistently with few problems and reported that hair pulling had been almost completely eliminated for the 10 months since the therapy sessions were terminated. Jennifer's hair has grown in so there are no longer any bald areas, and she no longer requires her mother to fix her hair every morning to hide hair loss.

VI. SUMMARY

Habit reversal is a treatment for habit disorders and consists of a number of component procedures implemented on an outpatient basis in one or a small number of treatment sessions. Clients first learn to detect each instance of the habit behavior through awareness training procedures. They then learn to engage in a competing response contingent on the occurrence or anticipation of the habit. Motivation procedures such as social support help clients successfully utilize the competing response to control the habit. Generalization strategies help clients continue to be successful in controlling the habit outside of therapy sessions.

GLOSSARY

- chaining** Training an individual to complete a complex, multistep behavior by reinforcing each of the substeps for their occurrence in the proper order (chaining may also be done in reverse, starting with reinforcement of the final step).
- heterosocial** Relating to interpersonal interactions between opposite sex individuals.
- operant conditioning** Training behavior by manipulating an individual's environment. In a simple version of operant conditioning, desired behaviors are increased via reinforcement, while undesired behaviors are decreased via punishment.
- shaping** Training an individual to complete a complex behavior by reinforcing successive approximations of the target behavior.
- social learning theory** A theory of human behavior in which environmental influences on behavior are supplemented by cognitive processes including modeling, imitation, and self-reinforcement.

Heterosocial skills training (HSST) is one of many approaches to improving psychological functioning grounded in operant conditioning and social learning

models of human behavior. Within that context, heterosocial skills can be thought of as the social behavior repertoire necessary for successfully initiating, maintaining, and terminating social relationships with persons of the opposite sex in a socially sanctioned manner. Heterosocial skills training, then, is any effort to introduce, increase, or refine those behaviors in an individual.

I. DESCRIPTION OF TREATMENT

Heterosocial skills training is both easy and difficult to describe as treatment. It is easy to describe because nearly everyone agrees on what general components are required in the intervention. It is difficult to describe because there is no generally accepted definition of heterosocial skill and its behavioral substrates, nor is there a generally accepted notion of when such skills deficits indicate dysfunction. The latter point notwithstanding, however, HSST is a multimethod approach to assisting clients with minimal or maladaptive dating behaviors. A good beginning for heterosocial skill interventions involves identifying a client's specific heterosocial skill deficits and appropriate remedies. Unfortunately, as just noted, there is little general agreement on, and thus no definition of, the particular deficits associated with heterosocial anxiety. One thing that most researchers and clinicians agree on, however, is that heterosocial skill deficits appear to be a mix of behavioral, cognitive, and emotional concerns. As an example, in 1986 Adrian

Furnham indicated that the most reliable heterosocial problems gleaned from studies of self-report questionnaires were fear of negative evaluation (cognitive and emotional concerns) and a lack of an understanding about how to interact with a person of the opposite sex (behavioral concerns). Fortunately, behavioral interventions have been shown to be very effective in myriad disorders that contain cognitive and emotional components. In fact, theorists would predict that acquiring and using new behaviors, both in the therapy room and daily life, would lead to anxiety reduction and perhaps even reinforcement and pleasure. For example, increased enjoyment in heterosocial situations may result in increased positive cognitions about dating situations.

Assessment of potential heterosocial skill deficits usually includes self-report measures and role playing. Representative self-report measures include the Situation Questionnaire (SQ) developed in 1968 by Lynn Rehm and Albert Marston, the Survey of Heterosexual Interactions (SHI) developed in 1975 by Craig Twyman and Richard McFall, and the Survey of Heterosexual Interactions for Females (SHI-F) developed in 1978 by Carolyn Williams and Anthony Ciminero. Each of these measures lay out a variety of heterosocial situations, and clients rate how difficult it would be to handle the situation on a 7-point scale. The SQ and the SHI are both appropriate for men (based on content), and the SHI-F is for women. Other related constructs that might be assessed with self-report are fear of negative evaluation and self-consciousness. The advantages of self-report measures include ease of administration and, so long as clients are honest, a reflection of clients' genuine beliefs regarding their own skills, capacities, and coping abilities. Unfortunately, a number of researchers, both in and out of the social skills world, have indicated that broad, general self-report measures can be poor predictors of actual behavior.

Naturalistic observation and ratings of role-playing exercises may be truer tests of actual behaviors, but these too come with a number of associated difficulties. In 1990, Debra Hope and Richard Heimberg noted that the utility of role plays varies based on whether the role play is assessed via an overall global rating or via specific, easily measured or counted behaviors such as duration of eye contact. Global ratings of social skill made by objective observers, friends, and interaction partners are more likely to correlate with participants' self-reports of dating anxiety than are ratings of specific behaviors. Some investigators have found modest correlations between global measures of social skill and anxiety and certain discrete behaviors (e.g., talk time and eye contact). However, as Ariel Stravinsky indicated in 2000, it

is not entirely clear whether these global ratings have any relation to a person's actual behaviors in real situations. Also, as Hope and Heimberg point out, most studies do not find significant differences between groups of dating-anxious and non-anxious participants on more than a few, if any, specific behaviors. The specific behaviors that do differentiate between groups in one study often will not show differences in another study of similar design. Thus, finding the behavioral correlates of social skill has been difficult.

Several explanations have been advanced to account for the difficulty in assessing social skill. First, a dating-anxious person's social behavior is influenced by the behavior of the interaction partner. For example, in 1985 Stephen Faraone and Richard Hurtig found that anxious men's appropriate verbalizations were less likely to evoke a positive response from female conversation partners than those of non-anxious men. In other words, two men who had the same frequency of appropriate verbalizations had different impacts on their female conversation partners based on how anxious those men felt. Second, considering that most studies of specific behaviors simply count the frequencies of identified behaviors, there is little consideration as to quality of the behavior. It may not be the raw frequency of a behavior that determines its social utility; timing and other aspects of quality may matter more. Such subtle factors may be incorporated into more global ratings. Finally, it seems likely that there is more than one way to be socially skillful. Different individuals may employ dramatically different behaviors, all of which can be effective.

Regardless of these theoretical and practical problems with assessment of social skill, a number of specific behaviors are typically targeted in HSST. According to Jeffrey Kelly's 1982 book on social skills training, the behavioral repertoire should include eye contact, smiling, head nodding, synchronizing facial expressions, laughing, asking conversational questions and making self-disclosures, complimenting, following-up on and acknowledging statements, and requesting dates. Speech duration and voice qualities (pitch, loudness, and flow) were also regarded as important, and other researchers have indicated that behaviors indicating a genuine interest in the other person ("you" statements and questions) are important predictors of peer ratings of social competence. Although we will not go into detail, for assessment purposes each of these behaviors must be clearly defined (operationalized) so as to be accurately counted, and some consideration is due to whether more is better or whether the relationship is curvilinear (too little and too much are both problematic). A clinician attempting

to assess heterosocial skill via role play can increase the accuracy of the ratings by videotaping.

As a final note regarding assessment, it bears mentioning that physical attractiveness appears to play a significant role in peer and other ratings of social competence. Although some aspects of physical appearance are relatively fixed, behavioral interventions are possible at this level, too, and have often focused on clothing style, grooming and hygiene, complexion, weight, and other modifiable aspects of appearance.

Once assessment is complete, as Peter Trower indicated in 1986, a generic HSST protocol consists of instruction, modeling, rehearsal, coaching (including feedback and reinforcement), and homework. Instruction, according to Trower and others, is the process of describing the skills in question and the functions they serve. The skills are broken down into behavioral components to facilitate practice and learning. Modeling takes advantage of the average person's ability to learn from the example of others. Through modeling, clients are able to see the entire sequence of desired behaviors from start to finish with the expectation of adding the pieces they lack in their own repertoire. Modeling can be done by the clinician, through video tapes, recorded dialogue, and prose (more lifelike modeling is preferable). Following instruction and modeling, the client is given the opportunity to rehearse new skills in role plays. The goal is to practice a variety of scenarios until the intervention criteria have been met and continue to be met in novel situations. Throughout the rehearsal phase, the clinician is providing coaching in the form of guidance, feedback, and reinforcement, which can be enhanced with videotape review sessions. The key to rehearsal and coaching is short and frequently repeated role plays that maximize practice opportunities. With each role play, the clinician should positively reinforce what was done well (however much or little that may be) and prompt for new or alternative behaviors where needed. Finally, homework is essential to the transfer of training from the therapy room to the client's daily life. As such, homework assignments usually entail having the client try the new skills in real situations outside the therapy room.

Positive outcome for HSST is a combination of decreased heterosocial anxiety and increased heterosocial competence (both self-report and clinician rated), and improved dating activity in the natural environment. In addition, many learning theorists would suggest that clients should be able to detect when they are performing a particular heterosocial skill or set of skills well versus poorly. In that way, clients can become their own coaches and internalize reinforcement.

Although minimal dating among college students has been the major focus of HSST research, other potential uses have been investigated over the years. For example, a number of researchers have used HSST as an intervention with rapists and child molesters. The basic hypothesis, summed up by William Whitman and Vernon Quinsey in 1981, is that without necessarily ascribing an etiological role to heterosocial skill deficits in sexual deviation, it seems clear that poor social skill constitutes an important clinical problem for many sex offenders such that adopting acceptable heterosexual behavior patterns may help reduce maladaptive, illegal, and violent behavior. In addition, in 1998 Douglas Nangle and David Hansen recommended HSST for adolescents engaging in high-risk sexual behavior. In this application, HSST would be focused on bolstering the skills necessary for adolescents to be competent in enacting the sexual decisions they make for themselves. Application of HSST techniques, then, appears to be limited only by the scope of heterosocial situations.

Although the emphasis here has been heterosocial skills training, there is no reason to think that HSST principles would not apply to same-sex dating situations. Adjustments for any cultural and individual differences can be easily incorporated.

II. THEORETICAL BASES

Without attempting a comprehensive history, it is worth beginning this discussion with a brief history of social skills training (SST) in general. Both the phrase and the approach date back to the 1960s and 1970s when clinicians and researchers working with persons diagnosed with severe and persistent forms of mental illness began to focus on the role of adequate social functioning in recovery and rehabilitation. Reflecting on the development of SST, William Anthony and Robert Liberman noted in 1990 that improvement in the individual's ability to master the challenges and problems inherent in everyday life was an important part of successful long-term rehabilitation. Early SST investigators assumed that, for the most part, patients were trying to do their best; thus, problems in rehabilitation were not grounded in resistance or lack of motivation, but rather in a deficit of some sort (e.g., a skill deficit). In other words, the impetus for SST was the realization that persons battling with severe psychiatric vulnerabilities could be adequately medicated in a seemingly stable environment and still fail to maintain adequate functioning. What was missing, however, was not the motivation or desire for wellness, but rather the skills to act well in the world.

Application of behavioral psychology—particularly the methods surrounding experimental analysis of behavior—to clinical concerns was central to SST's development. Clinicians began to see that behaviors could be developed through shaping, chaining, and other forms of operant conditioning. In the psychiatric hospital, experiments manipulating environmental contingencies led to the development of token economies and other behavioral interventions. Those experiments provided evidence that comprehensive social learning programs (in combination with adequate but not excessive medication) could be more powerful than stand-alone medication regimens and milieu-based interventions. As Clive Hollin and Peter Trower wrote in 1986,

In the history of SST, two ... advances within psychology were crucial. The first of these was renewed interest in the process of human social learning, culminating in a full social learning theory. As well as environmental influences on behaviour, social learning theory also places emphasis on cognitive processes such as modeling, imitation, and self-reinforcement. ... (And), in keeping with the philosophy of learning new behaviours, the movement was also away from a traditional pathology, or "medical," model in which behaviours are to be eliminated, and towards a "constructional approach" in which new, socially acceptable and competent behaviours are trained.

The general concept of SST interventions, then, grew up around the idea that human behavior is flexible and responsive to subtle (and not-so-subtle) environmental contingencies. Abnormal behavior need not arise from a "broken brain," but rather can reflect the normal operations of a contingency-driven behavior regulation system. The earliest SST interventions for social anxiety were based on the presumption that the anxiety is related to deficient verbal and non-verbal social skills that lead to poor outcomes in social situations. Those poor outcomes serve to discourage further social interaction so as to avoid further pain. The proverbial vicious cycle is then created and maintained—avoiding anxiety-provoking situations prevents the acquisition of the skills needed to generate successful social outcomes. Thus, SST interventions were believed to increase these behavioral skills, thus removing the underlying cause of the anxiety and increasing the probability of successful social outcomes.

Heterosocial skills training reflects a multimethod approach, based on the principles elucidated earlier, to assist clients with heterosocial skills deficits. The intervention is intended to build the repertoire necessary for successful dating outcomes. Note that referring to heterosocial skills deficits as minimal dating is not

meant to undercut its importance. Establishing intimate social and sexual relationships is an important goal for most people, and some authors have argued that failure to do so in adolescence is a major precursor of serious psychological disorders in adulthood. In addition, minimal dating and dating anxiety are major sources of real-life concern for the population on which most of the research has been done, namely college students. For example, in 1978, Hal Arkowitz and his colleagues reported that 50% of their 3,800-student sample indicated interest in a dating skills program and 31% of the sample claimed to be "somewhat" to "very" anxious about dating. One could probably assume that similar (or perhaps greater) numbers apply to those who have gone through a divorce, been widowed, been involved in inpatient psychiatric care, and so on. Thus, although the research has focused on samples of convenience, the results are likely important for a much broader population.

Consistent with the earlier discussion, the heterosocial skills deficit model assumes that certain individuals lack important components of the behavioral repertoire needed to perform in social situations involving the opposite sex. (As a side note, there are some data indicating that heterosocial skill deficient men tend to be deficient in same-sex interactions as well. That pattern does not appear to be the case for women.) The general result is that anxiety develops and builds in heterosocial situations as a result of rejection or inadequate social performance. That, in turn, leads to avoidance of those situations. In other cases, such as when an individual does not have the skills to find desirable heterosocial situations or attempt to interact within them, social isolation may develop in the absence of anxiety. Several authors, including Randall Morrison and Alan Bellack, have also noted that heterosocial skill repertoires need not necessarily be faulty for a person to suffer in social settings—what appears to be a skill deficit might actually be inadequate social cue recognition. That is, failure in output (inappropriate behavior) may be the product of failure of input (misunderstanding the situation), rather than lacking behavioral capacity. If, as an extreme example, a person mistakes cues of attraction for cues of hostility and acts accordingly, the end result is not likely to be a dream date. Such cue recognition training can be included in HSST.

III. EMPIRICAL STUDIES

In 1998, Nangle and Hansen pointed out that the number of heterosocial skills articles published in major

American psychology journals has declined from a peak of about 15 from 1975–1979 to a low of about 3 from 1990–1994. Reviews of the literature, including the 1977 reviews by Curran and Hal Arkowitz and the 1990 review by Debra Hope and Richard Heimberg mentioned earlier, generally conclude that HSST is effective for improving scores on the various dependent measures used in the research. Unfortunately, the studies are also consistently criticized for a number of reasons. The first is that the dependent and independent variables are not consistent across studies, thus making it difficult to interpret the findings and draw useful generalizations. From an independent variable perspective, participant selection and categorization methods are often poor, consisting, for example, of asking college students about their dating frequency. As several authors have mentioned, this generates a “high-frequency dating” category that might include someone who has gone out on 10 fun and interesting dates with a number of different partners as well as someone who has gone out on 10 minimal dates with a partner whose basic appeal is that he or she is still around after the first few dates. In addition, the studies are criticized because they typically have not included adequate no-treatment control conditions, have assumed generalization of the relevant skills rather than testing for it, have shown small effect sizes, and have inadequate assessment and training of individual-specific skill deficits.

Despite the criticisms, there are a number of sound studies supporting the efficacy of HSST. In 1975 James Curran reported the results of a controlled study in which minimally dating college men and women were exposed to HSST, systematic desensitization (SD), or no treatment. Participants completed self-report instruments and semistructured interactions (with an experimental confederate) both before and after the interventions. The active interventions were in a group format with six sessions (75 min each) over a 3-week period. Specific behaviors (e.g., giving and receiving compliments, listening skills, and nonverbal communication) were targeted by HSST which consisted of instruction, modeling, rehearsal, coaching, and homework. SD participants received a comparable amount of therapist contact with a procedure designed to reduce heterosocial anxiety via graduated exposure exercises. In the control conditions, clients received no treatment at all, or relaxation training not specifically geared toward heterosocial anxiety. The results indicated reductions in self-reports of anxiety and increased social competence as rated in the semistructured interactions for both the HSST group and the SD group, but not for either of the control groups.

Elaborating on those results during the same year, Curran and Francis Gilbert reported a similar study in

which the therapy was an individual format and in which participants kept diary records to monitor “real-life” changes. The design also included a 6-month follow-up. The results were as expected. Self-reports and observer ratings of anxiety decreased from pre- to posttesting for the HSST and SD groups but not for controls. HSST participants were rated as more socially skillful than SD participants and at 6 months the HSST were rated as more socially competent than any other group. Perhaps most important, both HSST and SD participants reported increases in dating activity in their natural environments.

Overall, the results indicate that HSST increases perceptions of social competence and decreases anxiety. SD also demonstrated that ability, but was outpaced by individualized HSST at 6-month follow-up in at least one study. These well-designed studies, which include adequate controls, multifaceted assessment, and at least some follow-up provide a solid foundation for HSST efficacy claims. Although that speaks in favor of specific HSST effects, there is some evidence that simple practice improves heterosocial skills as well. In 1974, Andrew Christensen and Hal Arkowitz were able to generate improvement in both self-report measures and actual dating frequency by randomly pairing volunteer men and women for a number of practice dates; there was no actual training or intervention on the part of the researchers. Participants merely paired up, went out, and in the end reported feeling and acting better in dating situations. In a series of three studies, one each in 1982, 1983, and 1984, Frances Haemmerlie and Robert Montgomery demonstrated that largely unstructured but positively biased interactions with members of the opposite sex was a viable option for treating dating anxiety. Thus, one hypothesis that can be drawn from the literature—one that generalizes across the different active treatment modalities (i.e., SST, SD, practice dating)—is that skill rehearsal in and of itself, structured or unstructured (but in a relatively safe and positive context), plays an important role in overcoming dating anxiety. Of course, not all dating anxiety is alike. For some there will be more pronounced behavioral deficits while for others the skill set will be intact but the presence of dysfunctional cognitions will get in the way of dating success. The relative success of HSST will thus depend on how thoroughly each of these areas has been assessed and incorporated into the intervention.

Regarding the use of HSST as an intervention for sexual deviance, the results indicate that self-reports and observer ratings of social competence increase with treatment compared to control. However, non-HSST methods such as covert sensitization also affect social competence, a surprising finding that may speak to the non-specific effects of structured therapeutic

interactions. The results on actual physiological arousal in target scenarios are inconclusive, and there are no data on the ultimate impact on convicted offenders. Thus, HSST works in its direct application but has not been conclusively shown to affect the related and generally more important constructs of arousal and recidivism.

It is worth noting that other data exist that inform questions of the efficacy of HSST as a treatment for dating anxiety. For example, in 1993 Debra Hope and her colleagues reviewed a number of studies that used SST to treat social phobia. These data are particularly relevant because those studies assumed that social skills deficits underlie social phobia (a diagnostic category under which dating anxiety might properly be subsumed). According to Hope and her colleagues, all the studies reviewed showed skill improvement for social phobics from before treatment to after. Unfortunately, only one of the studies compared SST to a reasonable no-treatment control (specifically, wait-list control) and the results of that study showed no difference between groups.

IV. SUMMARY

This article began with the notion that heterosocial skills are difficult to define and that behavioral deficits

probably interact with other non-behavioral phenomena, especially emotion and cognition, to disrupt dating success in some people. HSST grew out of theoretical interests in social learning theory and approaches that emphasize remediating deficits, not just eliminating symptoms. The weight of the evidence suggests that minimally dating individuals can find assistance with heterosocial skills training. HSST is not the only treatment for minimal dating, given that systematic desensitization and practice dating show similar effects.

topographic model Sigmund Freud's first model of the mind.

The model described three systems. System Cs, the conscious, contained those ideas and feelings of which a person was overtly aware; system UCs, the unconscious, contained memories, ideas, and feelings which could not be brought into awareness; system PCs, the preconscious, was the reservoir for thoughts that were not in awareness at a given moment, but which could be called to awareness with effort.

GLOSSARY

moral therapy A system of treatment promoted in the early 19th century by Philippe Pinel in France and Samuel Tuke in England. Moral therapy stressed humane treatment of the insane, and use of rational persuasion, occupational activities, and recreational engagement. Moral therapy was most appropriately delivered in the philanthropic, tranquil setting of the asylum.

psychological disaggregation In the schema of Pierre Janet, a lowering of psychological energy and barriers, resulting from psychological trauma, that produced symptoms and other psychological phenomena including paralysis, somnambulism, and trance states.

structural model Sigmund Freud's second model of the human mind, including three mental apparatuses. Id was the domain of unmodified drive impulses and primitive modes of thinking; ego was the executive agent of the mind, using memory, perception, thought, emotion, and motor activity; superego was the repository of parental and societal ideals, morals, and restrictions.

From the dawn of civilization, human beings have been subject to disorders of thought, emotion, and behavior. The assumptions of modern society that such problems originate in the mind are fairly recent concepts. The development of current ideas about human psychological development, the sources of psychopathology, and the place and nature of psychotherapy begin in ancient times. Following their path leads one through the magical thinking of the Middle Ages, the rationalism of the Enlightenment, the drama of the psychoanalytic movement, and the splintering of psychoanalytic thought to modern postanalytic ideas of the nature of mental distress and its treatment.

I. EARLIEST APPROACHES

Although evidence left by preliterate societies seems to tell that shamans dealt with what we would today

identify as mental illness, and although Hindu physicians as early as 1400 BC described various forms of insanity and prescribed kindness and consideration, the beginnings of planned therapy for mental disorders probably lie in Greek culture. Hippocrates was among the first to view mental illness as a natural phenomenon and approach it without superstition.

Priest-physicians, who made Aesculapius their god, enlisted his aid through "divine sleep, divine feasts, the sacred performances." In their temples, called *aesculapia*, they used rest, diet, massage, baths, exercise, and a hygienic life to achieve their desired ends. In particular, they employed a type of mental suggestion called incubation: The patient would lie down on the floor on a pallet. Aesculapius would reveal himself in a dream, which either healed the disease or advised the treatment to be followed. Sometimes the attendants used ventriloquism to aid the patient's conversation with Aesculapius. The god's dictates were interpreted through the personal associations of the interpreter, not the patient. Hippocrates probably worked at one of these temples.

Plato suggested that mental disorders were the result of love, great trouble, and interventions by the Muses. He advised the curative effect of words, their "beautiful logic." Greco-Roman tradition advocated analogous therapies, and suggested innocuous deception to free patients from groundless fears. They did permit and recommend more punitive approaches in severe cases. Later Roman practices, however, focused on herbs and other somatic treatments. With the spread of the Roman empire, the Greek spiritual and psychological methods virtually disappeared.

II. THE CHRISTIAN ERA

The early Christian church, through its first millennium, emphasized the importance of forbearance to pain and the mutability of earthly pursuits. The Middle Ages saw an evolution of faith-healing through organized theology. Through this period, there was no unifying theory of physiology or disease; barber-surgeons and dentists practiced medieval medicine without control or regulation. Magic and alchemy were the science of the time. Mental illness was most often regarded as a defect of spirit divorced from therapeutic intervention.

The Christian era did, however, bring about the development of hospitals with a humanitarian motivation. Religious doctrines of patience, pity, and the possibility of absolution from guilt set in motion a

spirit that would later nurture the development of the precursors of psychotherapy. In the thirteenth century, Pope Innocent III initiated the medieval hospital movement, which brought humaneness and tranquility to the treatment of simpletons and madmen. The monastic tradition of treatment through loving care was directed to those suffering from mental afflictions.

In 1725 the Franciscan monk Bartholomew Anglicus (Bartholomew) wrote *De Proprietatibus Rerum* (Of the Nature of Things). The seventh book of this encyclopedic tome dealt entirely with mental illnesses. For the treatment of melancholics, Bartholomew recommended,

such patients must be refreshed and comforted and withdrawn from cause of any matter of busy thoughts and they must be gladdened with instruments of music and some deal be occupied.

Although Bartholomew spoke for his fellow Franciscans, his attitudes stood in opposition to the inquisitors of France and to the Dominican orders, who aided local courts in adjudicating cases of sorcery and witchcraft, often directed against the insane. The force of the Church's crusade against Satan fell disproportionately on the mentally ill throughout the Middle Ages.

III. RATIONALISM AND MORAL THERAPY

By the 1700s, intellectualism had taken root in Europe as a popular philosophy. Adam Smith, Johann Wolfgang vonGoethe, Jean-Jacques Rousseau, and other philosophical giants pled for the right of man to improve his lot through the application of civilization's accumulated knowledge. In England, the Deists viewed God as more benevolent than the punitive power of their medieval predecessors. Humanitarianism encompassed the aim of improving social relations at large, and hence conferred sanction on emotional and social problems as worthy of philosophical and scientific attention. A similar curiosity about the nature of the human soul became a thread in early neurology and psychology. Medical science, however, was still far too underdeveloped to make much progress even in the milieu of such open-minded attitudes.

By the mid-eighteenth century in England, William Cullen viewed many diseases as the result of neurosis, including insanity, somnambulism, painful dreams, and hysteria. The Quakers, a small but influential group, were instrumental in the treatment of the insane. William

Tuke, a tea merchant, convinced the Society of Friends in 1796 to establish a retreat at York, where the mentally ill could receive care on the basis of the humane spirit of Quakerism. Their afflictions were treated with a regimen of personal encouragement and routine work.

Across the English Channel, the philosophical and political forces that drove the French Revolution in the late eighteenth century also led to the emancipation of the insane from incarceration. Philippe Pinel was particularly influential. Appointed superintendent of the infamous Salpêtrière, a prison for paupers and lunatics, he released the inmates from their chains in 1793, and treated them instead with kindness and respect. Many won their release from the institution. Pinel forbade violence toward the inmates in favor of persuasion. For maniacal fury, for example, he prescribed, "bland arts of conciliation or the tone of irresistible authority pronouncing an irreversible mandate."

In Europe and North America, the nineteenth century was the era of asylums. Germany built institutions at Saxony, Schelswig, and Heidelberg; France featured Bicêtre, Salpêtrière, and Charenton; in the United States, treatment occurred at Bloomingdale, McLean, and the Friends' Asylums. The spread of moral therapy, based in the approaches of the French and English Enlightenment, convinced a number of physicians that insanity could be cured. In 1826, Dr. Eli Todd of the Hartford Retreat in Connecticut reported curing 21 of 23 cases he admitted. Others reported similarly remarkable outcomes. In the flush of enthusiasm that all mental illness could be curable, more asylums were built. Eventually, the statistics were found to be fraudulent and the pendulum swung against the asylum movement. But the door had been irreversibly opened to earlier recognition of mental illnesses and the allocation of resources for their treatment. Drs. Thomas Kirkbridge and Isaac Ray, at meetings of the Association of Medical Superintendents of American Institutions (predecessor of the American Psychiatric Association) between 1844 and 1875 enacted a series of resolutions embodying these evolving attitudes. Insanity, they resolved, is a disease to which everyone is liable, and which is as curable as other diseases. They discouraged the use of physical restraint and advocated activity, occupation, and amusement.

Rudolf Virchow's (1821–1902) cellular theory of disease established the nervous system as the seat of both somatic and mental activity, and brought neurology into the mainstream of nineteenth-century medicine. As a result, the nervous patient became one deserving of medical recognition and attention. Neurologists began to accept hysterics and neurasthenics as patients.

The restrictive social mores of the Victorian era gave rise to no shortage of such patients for care and study. These shifts in patient profile and clinical practice also served to move the insane into the doctor's office and away from exclusive assignment to the asylum.

Among those adventurous enough to undertake the treatment of hysterical patients were two Parisians, Jean Martin Charcot (1825–1893) and Pierre Janet (1859–1947). Charcot, a pathologist, was instrumental in initiating the scientific study of hypnotism. Janet, his pupil at the Salpêtrière, directed his studies toward neurology, and specifically to hysteria. Under hypnosis, hysterical patients recalled long-forgotten memories, suggesting the existence of a separate type of consciousness from that which is active in everyday awareness. Janet believed that trauma led to a "psychological disaggregation," a lowering of psychological energy and barriers, that produced symptoms and other psychological phenomena including paralysis, somnambulism, and trance states. The split-off ideas became "emancipated" from their original stimulus and gained a life of their own as neurotic symptoms. He used hypnosis as a means to enter this other world of consciousness and direct the patient's perception and behavior.

IV. THE PSYCHOANALYTIC MOVEMENT

Charcot and Janet attracted many students from across Europe. Among these was the young Sigmund Freud (1856–1939). After graduating from the University of Vienna, Freud studied the biology of the nervous system under mentors including Ernst Brücke. Unable to support himself as a scientist, he opened a practice in neurology and found himself fascinated by his patients with hysteria. In 1885, he traveled to Paris to study with Charcot and Janet. He learned how to use hypnosis to treat the symptoms of hysteria, but was more interested than his teachers in the stories his patients related while in their trances. Back in Vienna, he found a kindred spirit in Josef Breuer, who believed that the secret to unraveling hysteria lay in allowing them to speak freely about their recollections, a technique that would give rise to free association.

In listening to these tales, Freud went a step further than Janet's psychology of dissociation, and postulated a dynamic quality of the mental apparatus through which unacceptable ideas were split off by some yet-undefined mechanism to reappear as psychological and behavioral symptoms. The recall of these memories

under light hypnosis allowed the repressed emotions to be expressed, resulting in at least transient relief of symptoms. He and Breuer took their first steps to describe the mechanisms of these processes in the cases published as the *Studies in Hysteria* in 1894.

Freud postulated that painful ideas were turned away from conscious awareness to avoid mental distress (unlust, or “un-pleasure”). The ideas were converted into symptoms through pathology that was exclusively psychological, not physiological. He identified repression as a mental activity that had to be overcome. Freud and Breuer eventually parted company over differences of opinion about Freud’s emphasis on sexuality as a driving force behind emotion and behavior.

By 1910, Freud had developed the major ideas that would form the core of psychoanalytic thinking. He identified the unconscious as the seat of most mental activity. He postulated the pleasure principle, which drove the human organism to maximize pleasure while minimizing displeasure. He identified the mental mechanisms that yielded the tales and images of dreams. From these, he extrapolated the mechanisms of psychological defenses. He began to study not only dreams but also parapraxes, wit, obsessions, and phobias for the meaning of their content.

In his first model of the human mind, the topographic model, Freud divided mental activity into three domains: The conscious, which he called the system Cs, contained those ideas and feelings of which a person was overtly aware. More revolutionary was the larger system UCs, the unconscious mind, which contained memories, ideas, and feelings that could not be brought into awareness. The preconscious, the system PCs, was the reservoir for thoughts that were not in awareness at a given moment, but which could be called to awareness with effort. The energy source for this apparatus was the drive. Originally, the drive was considered to be an internal somatic entity, aimed at self-preservation and sexual expression. At this early stage, the only drive was the libidinal drive.

The human organism, Freud postulated, sought to maintain a constancy of pleasure and a minimum of suffering. Drive would seek its own expression, but reality would often impede its attainment of its desires. Under these circumstances, the mind would use memory and dreams to fulfill drive wishes. This model accounted for much, but left many behaviors and emotions unexplained. Two subsequent developments expanded the theoretical and clinical power of psychoanalysis. First, Freud defined a second drive, the aggressive drive, which sought destruction and separation. Second, he augmented the topographic model with the structural model. Now the mental apparatus included the id, ego,

and superego. Id was the domain of unmodified drive impulses and primitive modes of thinking. Ego was the executive agent of the mind and the vehicle for the implementation of drives, using memory, perception, thought, emotion, and motor activity among its tools. Superego was the repository of parental and societal ideals, morals, and restrictions on activity and thought.

This schema allowed for a broad-ranging explanatory model. Drive impulses initiated in the id, demanding satisfaction. Ego would try to gratify id, but might run into limitations of reality or restrictions of society. In such cases, ego would need to turn back and tame the id. This conflict between ego and id could generate a panoply of unpleasant emotions and maladaptive behavior. In the opposite direction, ego’s confrontations with reality on the behalf of id strivings would generate conflicts as well. Superego represented an internalization of those elements of power and judgment from the environment. It provided the mind with guideposts for ideals and restraint. However, superego could thus stand in opposition to ego, generating a different kind of internal conflict.

A. Freud’s Followers

These powerful and revolutionary ideas, articulated by the eloquent and charismatic Sigmund Freud, attracted much attention worldwide, and a dedicated circle of followers in Vienna. Karl Abraham extended Freud’s sketchy ideas about human development into major contributions in the realm of character formation. Such contemporary designations as the easygoing “oral” personality and its controlling, possessive “anal” counterpart, are products of Abraham’s work. Sandor Ferenczi, a passionate follower of Freud, was less interested in pure theory and urged experimentation with treatment. He advocated “active therapy,” in which the analyst would deliberately promote or discourage the patient’s specific activities. He promoted deliberate mobilization of anxiety in the treatment to make it more available for analysis.

B. The Dissenters

Others of the Vienna group found Freud’s ideas inadequate or limiting, and advocated dissenting viewpoints. While Freud dreamed that mental activity would one day be explainable on the basis of neurologic principles, his work remained exclusively psychological. Alfred Adler sought actively for a unifying theory of biologic and psychological phenomena. He postulated the aggressive drive as the source of energy used by an

individual to overcome organic inferiorities through compensation (and hence gave birth to the phrase inferiority complex). Where Freud took sexuality and the Oedipal situation as literal motivations for development and behavior, Adler regarded them more in the symbolic sense. On the technical level, he engaged patients face to face in free discussion, rather than free association on the couch to an unseen analyst.

Otto Rank stressed emotional experiences over the intellectual constructs of psychoanalysis. He postulated that birth trauma was a universal human experience, and that the individual was forever seeking to return to intrauterine bliss. Healthy development could occur when, through later successful experiences of separation, the child is able to discharge this primal anxiety. Pathological states resulted from a fear of the womb and conflict with the wish to return. Rejecting the id and superego, he postulated the existence of will and counter-will as positive and negative guiding influences toward separateness. He ultimately turned his focus away from individual psychology and psychopathology to the realm of art and the soul.

Most prominent among the dissenters was Carl Jung, who originally clung to the Freudian vision in the extreme. Freud became strongly invested in Jung as his protégé and eventual heir to his position in the psychoanalytic movement. Jung began to extend Freudian principles to ideas that had excited him earlier including myth and legend. Freud had certainly done the same, invoking the tales of Oedipus and Electra, and analyzing the art of Michelangelo. But where he saw parallels or analogies, Jung saw a direct continuity of archaic material gathered into the collective unconscious. This storehouse of human experience, he posited, contains primordial images and archetypes that represent modes of thinking that have evolved over centuries. Jung saw Freud's view as too limited. Symbols, which were vehicles for the expression of wish and conflict for Freud, represented for Jung unconscious thoughts and feelings that are able to transform libido into positive values. The techniques derived from these values include active imagination, where the patient is encouraged to draw fantasied images and to associate more deeply by trying to depict the fantasy precisely.

Working at the forefront of the elucidation of the unconscious and the drives, Freud and his immediate successors devoted their efforts to understanding and analysis of the id. The success of their psychoanalytic techniques in addressing previously untreatable problems, brought broad appeal to psychoanalysis, and brought to the analysts patients with conditions more complex than hysteria. Questions of how the id is

tamed and what happens to its drive energy propelled the next generation of theoreticians and clinicians to focus more directly on the ego.

V. EGO PSYCHOLOGY

In retrospect, it is Sigmund Freud's daughter Anna Freud (1895–1982) who is often identified as the first voice of ego psychology. Encouraged by her father to extend the study and practice of psychoanalysis to children, she is best known for elucidating the defense mechanisms by which the ego masters the environment, the id and the superego, and which are the shaping forces of each individual's psychopathology. The names and definitions she assigned are still the benchmark terminology of psychoanalytic psychology: repression, suppression, denial, reaction formation, undoing, rationalization, intellectualization, sublimation, symbolization, and displacement. Still, however, she maintained that analysis of the ego paled by comparison with analysis of the id.

The promulgation of ego psychological theory fell to a generation of analysts who were mostly refugees from Hitler's advance through Europe, and who had to postpone their major work until they could resettle in the 1930s: Ernst Kris, Rudolph Lowenstein, Rene Spitz, and chief among his peers, Heinz Hartmann (1894–1970). A trainee of Freud's, Hartmann undertook the expansion of his mentor's model to explain some of its lingering questions: What was the origin of ego? How did ego tame id, which was powered by the potent energy of the drives? What was the purpose of the aggressive drive? What role did these structures and forces play in normal development?

For Hartmann, the unifying process of human psychological development was adaptation, a reciprocal relationship between the individual and his or her environment. The outcome of successful adaptation is a "fitting together" of the individual with the environment. Conflict is thus neither the cause nor the outcome of psychopathology, but a normal and necessary part of the human condition. In Hartmann's model, the ingredients of ego and id are present at birth in an undifferentiated matrix. Normative conflicts with the environment separate out ego from id. Defense mechanisms are tools for adaptation to the environment by either alloplastic means (changing the environment) or autoplasmic ones (changing the self).

Because psychic structures enable the individual to be less dependent on the environment, structure formation serves adaptation. Superego is one outcome of

adaptation to the social environment, a product of continuing ego development. Id, ego, and superego continue to separate by the process of differentiation. Within the ego, primitive regulatory factors are increasingly replaced or supplemented by more effective ones.

There is also a conflict-free sphere of ego development. Certain capacities have an inherent capacity for expression and growth, promoting adaptation to the environment without need to invoke conflict. In the motor sphere, these capacities include grasping, crawling, and walking. In the mental realm, they encompass perception, object comprehension, thinking, language, and memory.

Ego psychology used the language of Freud's original drive-structure model, and maintained most of its core assumptions. It stretched the explanatory capacities of the model and allowed for the treatment of cases previously impervious to psychoanalysis. Because these patients exhibited more interpersonal problems than strictly intrapsychic ones, and because the model of ego development was contingent on interactions with the personal and social environment, the door was opened to schools of thought that described something broader than a one-person psychology. Even while ego psychology was developing further in the 1930s, the school of object relations was branching off.

VI. THE OBJECT RELATIONS SCHOOL

A. Melanie Klein

Melanie Klein (1882–1960) studied under Sigmund Freud. With Freud's encouragement, she undertook the psychoanalysis of children. Finding the free association technique useless in such young patients, she originated the use of the content and style of children's play to understand their mental processes. Like many early psychoanalysts, she used her observations from the clinical sphere to generate theories of human development and psychopathology.

Klein's earliest papers shared and expanded Freud's emphasis on libidinal issues. The child, she noted, spins elaborate fantasies about food, feces, babies, and other aspects of the mother's body. Attempting to explore these curiosities, the child is inevitably frustrated, resulting in rage and fears of castration. Unlike her mentor, Klein found the seeds of the oedipal constellation in the first year of life as the disruption of weaning precipitates a turn to the father. In her view these urges take on a gen-

ital coloration. The harsh self-criticism that accompanies these fantasies is a precursor of the superego. She eagerly adopted Freud's emphasis on aggression in the 1920s. By the early 1930s, aggression had come to overwhelm all other motives in her schema. Even the seeking of pleasure and knowledge was defined as a desire for control and possession: "The dominant aim is to possess himself of the contents of the mother's body and to destroy her by means of every weapon which sadism can command." The oedipal conflict was recast as a struggle for destruction and power, and a fear of retaliation, rather than a search for forbidden love.

Freud had posited that fantasy was a defensive substitute for real gratification. Klein's elaborate mental processes resided in a world of unconscious *phantasy*, one which is inborn and constitutes the basic substrate of all mental processes. In this world of phantasy, the child houses vivid and detailed images of the insides of the mother's body and his or her own, filled with good and bad substances. He or she becomes focused on attempts to obtain good objects like milk, children, a penis, and to eliminate or neutralize bad objects such as feces.

Over the decade from the mid-1930s to the mid-1940s, Klein elaborated a model of development. The infant's earliest organization, which she called the paranoid position, involves the separation of good objects and feelings from bad ones. Mother is perceived only in terms of her good (providing) and bad (withholding) parts. By the middle of the first year, the infant is able to perceive the whole mother and experiences depressive anxiety as a result of his or her aggressive feelings toward the mother's bad parts. The child attempts to compensate by way of phantasy and reparative behavior. The Oedipus complex is a vehicle for such attempts at reparation.

Klein's ideas represented more than just a furtherance or modification of the Freudian model. They were entirely revolutionary. Klein left Germany in 1925 for England, where she stayed until her death in 1960. Her provocative ideas split the British Psychoanalytic Society, and eventually the entire international psychoanalytic community, as they blossomed into the various theories of object relations.

B. Margaret Mahler

Margaret Mahler (1897–1985) began her career as a pediatrician in Vienna. Like many of her peers, she was fascinated by the theories of the psychoanalytic movement and applied them to her work with children. She soon found, however, that the classical model was unable to explain much of what she observed. The linearity

of the drive structure model failed to encompass the richness and variety of emotional experience of the developing child. Her model instead emphasized the specific relationship between child and mother, and hypothesized that drives are not the root of interpersonal relations, but the result of them.

Just as Hartmann was proposing that id and ego begin in one undifferentiated state, Mahler posited that the child is born with an initial state of undifferentiated energy. It is by virtue of attachment to good and bad self objects that this energy differentiates into libido and aggression. The central theme of the developmental process is the need for the child to differentiate himself or herself from others to achieve autonomy and individuation. Such differentiation requires separation from the object(s), entailing a struggle between the wish for independence and the urge to return to the comfortable state of fusion. Mahler outlined a detailed agenda for psychological development:

1. The normal autistic phase occupies the first few weeks of life. The newborn is oblivious to stimulation, and lacks any capacity for awareness of other objects. He or she sleeps most of the time and is concerned only with tension reduction and need satisfaction.

2. The normal symbiotic phase lasts until about age 4 to 5 months, and is marked by an increased sensitivity to external stimuli. The infant is dimly aware of mother as an external object able to reduce tension. She is not yet a separate object, but rather part of a dual unity. Experiences are either all bad or all good. Nodes of good and bad memory traces form in the undifferentiated matrix of ego and id.

3. The differentiation subphase lasts until about 10 months of age, and begins with what Mahler called "hatching." The child is alert, and begins to search and explore the world beyond the mother-child orbit. He or she acquires the ability to differentiate internal and external sensations. With the developing ability to discriminate between self and object comes the ability to distinguish objects from each other. Stranger anxiety at about age 6 months is a marker of this capacity.

4. The practicing subphase begins with the capacity to crawl. The child's interests extend to inanimate objects. For Mahler, "psychological birth" coincides with the capacity for upright locomotion. The child takes pleasure not only in his or her own body, but also in the acceptance and encouragement of adults. In practicing walking, the child uses mother as home base, going out and returning. For successful completion of this subphase, mother must strike a balance between supportive

acceptance and a willingness to relinquish possession of the child.

5. The rapprochement subphase (15 to 24 months) is marked by the child's realization that he or she is a small person in big world, and that mother is a separate person. Language is a key skill in negotiating these currents, as the child alternates between "wooing" mother with needy clinging and rejecting her with hostile negativity. Mother's reaction is again critical to the outcome of the struggle. Successful resolution of this subphase was as important to Mahler as Oedipal resolution was to Freud.

6. The phase of libidinal object constancy, the ideal outcome of all earlier development, should be reached by age 2 or 3 years. Now the child forms a stable concept of himself or herself and others. These concepts require the unification of the heretofore divided perceptions of good and bad objects. The libidinal and aggressive drives that have become cathected to these dichotomous representations must now be merged. In a context of parental response that reinforces the perception of constant objects, the child is now in possession of stable and adaptable psychic structures for the rest of his or her life.

C. W. R. D. Fairbairn

Both Klein and Mahler elaborated schemes of development and psychopathology that relied on the classical unit of energy, the drive impulse, for their motivation. By the early 1940s, W. R. D. Fairbairn rethought the whole problem of motivation. Like Klein, he saw libido as inherently object-seeking, and conceived of ego structures as powered by object-directed energy. Just as Hartmann had formulated the ego in terms of natural adaptation, Fairbairn saw the roots of relation-seeking in biological survival. All human behavior, he concluded, derived from the search for others. Psychopathology, in this scheme, was not the outcome of misdirected drives, but of disturbed relations with others.

Unsatisfactory relations with real objects (e.g., parents) would lead to the creation by the ego of compensatory internal objects. If the environment is filled with unsatisfying or frustrating objects, the ego becomes filled with so many fabricated objects that it becomes fragmented. Ego then splits this population into good or ideal objects and bad (exciting or rejecting) objects. Splitting of the ego results from the child's attempts to maintain the best possible relations with a suboptimal mother, and continue through adult life if not somehow corrected. The psychoanalytic setting and process provide the opportunity for restoring to the ego a capacity

to make full and direct contact with others, thereby restoring psychological health.

D. D. W. Winnicott

D. W. Winnicott, who produced most of his work between about 1945 and 1970, took the object relations movement yet a step further from the one-person psychology of the classical model. Some of the catch phrases of his terminology have found their way into the everyday language even of those who have heard of their author.

In Winnicott's formulation, the infant begins life unable to integrate the disparate pieces of his or her experience with his or her environment. Mother ideally provides a holding environment for these early experiences. Mother, impelled by biologic dictates of adaptation, is absorbed with her baby for the first few months of its life. When the infant is stimulated (by hunger or cold, for example), he or she conjures up an image of an object to meet those needs. The sensitive and devoted mother provides exactly that object; the infant believes he or she has created it, and finds comfort in this power. This confidence is necessary for the emergence of the individual.

Mother also sees the baby and reflects its emotions and behavior, functioning as mirror of baby's experience. If the baby is seen, then he or she exists. Finally, mother must be sensitive to the developing child's need to be alone in a quiet, unintegrated state at times, in order to integrate experience and to develop a tolerance for aloneness.

By the end of the first few months, the child begins to learn about reality of the external world, and the limits of his or her own power. Reality itself does much of this work, but mother contributes through her gradual withholding of actions shaping the world to her infant's needs. Underlying these interactions is the child's natural push toward separateness. In order to adapt, the child learns to express his or her needs through gestures and utterances.

Mother can fail here in two ways: She may fail to provide hallucinated objects, or she may fail to tolerate the child's formless quiet states. The former failing leaves the child insecure and anxious. The latter fault fragments the child's experience. As his or her personal time is subjugated to parental intrusion, he or she becomes overly attuned to the claims of others, and his or her person fragments into a true self and a false self. The latter force aims toward compliance. The false self protects the true by hiding it, but deprives the child of a necessary sense of authenticity.

A critical tool on this path of development is the transitional object. Such an object, usually illustrated with a teddy bear or blanket, is one that the child believes he or she has created out of imagination to fill a need. The adult ideally does not question its origin, and simultaneously acknowledges its existence in the real world. This deliberate or intuitive ambiguity helps the child negotiate a transition from a world where he or she is at the center to one where he or she coexists with others. Even as the child's views of reality solidify, this configuration is never discarded. It remains a state of mind valuable for creativity and fantasy in healthy adult life.

Interactions in Winnicott's world are based not on drive needs, but on the perceptiveness of the parents and the developmental needs of their child. The gratification of drive derivatives, to which he gives only lip service, are less important than the attitude of the provider. Just fulfilling needs does not allow for the development of a healthy, true self. He redefines aggression not as a destructive drive impulse, but as a general state of vitality and motility. The origin of psychopathology is in conflict, not conflict between aggression and libido, or among drives, psychic structures, and reality, but conflict between the true and false selves. The object of psychotherapy is to free the true self from its bondage and allow the emergence of the genuine person.

VII. SELF PSYCHOLOGY

The theories of object relations were successful in addressing the limited ability of ego psychology and defense analysis to address the problems of those patients whose problems lay deeper than those of the classical neuroses. A different approach to the same challenge gave rise to self psychology. In the 1960s, Heinz Kohut was a prominent figure in the mainstream of psychoanalysis. Erudite, articulate, and charismatic, he was widely assumed to be the heir to Heinz Hartmann's mantle as the leading spokesman for ego psychology. But his disappointment in the limitations of classical and ego psychologies led him to follow his curiosity in a new direction.

Kohut began by redefining the observational position of the analyst. Exploration of the external world, Kohut reasoned, requires an outwardly directed observational stance. Exploration of the internal world, the realm of psychotherapy, requires an empathic, introspective stance. He rejected the objective mechanical formulations of the ego and object relations psychologies, promoting instead a vantage point from within the patient's experience.

Psychopathologies, from this perspective as well as from most object relations perspectives, were seen not as the emergence of oedipal wishes, but as the reactivation of early needs the satisfaction of which in childhood should have served as the basis for healthy development. Self psychology went further to assert that unempathic interventions in psychoanalysis repeated early traumata. Symptoms and unpleasant affects represented fragmentation products of an injured self. Psychoanalysis, then, should properly focus not on the meaning of the products, but on the reconstruction of what precipitated their emergence in the transference, and on the genetic precursors of this constellation.

Whereas the object relations theorists continued at least to pay lip service to the classical drives, and maintained their allegiance to the structural model, Kohut ultimately rejected the need for the constructs of drive, id, ego, and superego. Instead, he formulated normal and pathological development and function around the single notion of the self. The nuclear self, which is present at birth, develops structures that allow it to take over functions previously needed from outside. This structure building happens by maturational transformation of what is internally given, and by the process of transmuting internalization, whereby functions of objects are metabolized into the self.

Self psychology, like object relations psychology, emphasizes the primacy of objects in healthy and pathological mental function. The objects in self psychology, however, are not separated from the self, but exist in the context of a self-selfobject matrix. The selfobject is an intrapsychic concept, describing how the self experiences the specific functions provided by others en route to the attainment of development goals. The need for selfobjects never disappears, but matures from infantile neediness to mature adult intimacy.

The self that emerges was described by Kohut as the bipolar self, bridging two poles. The pole of self-assertive ambitions contains the capacities for self-esteem regulation, the enjoyment of mental and physical activity, and the pursuit of goals and purposes. Its development requires a mirroring selfobject. This pole is paired with the pole of values and ideals, which is associated with self-soothing, the regulation of feelings, the capacity for enthusiasm and devotion to ideals larger than the self. The development of this pole is promoted by an idealizable selfobject. Between the poles there exists a tension arc that gives rise to innate skills and talents, including empathy, creativity, humor, wisdom, and the acceptance of one's own mortality.

Psychopathology results from imbalances between the poles of the self, and these imbalances are themselves the product of deficient selfobject experiences. Psychotherapy identifies these deficits by empathic reading of the transference. Therapeutic correction requires both interpretation of the selfobject needs and their successful reenactment in the therapeutic dyad.

VIII. POSTANALYTIC SCHOOLS

The evolution of classical psychoanalytic theory into ego psychology, object relations, and self psychology was propelled by expanding clinical experience, and by failures of older paradigms to explain a widening circle of psychopathologies encountered in therapy. In the closing decades of the twentieth century, forces outside the boundaries of the psychotherapy drove further changes. The culture of medicine demanded reproducible techniques and empirical validation. Third-party funding and the growing perception of the patient as a partner in the therapeutic enterprise promoted briefer and more active forms of therapy. The two most notable schools to arise in this context have been cognitive and interpersonal therapies.

A. Cognitive Therapy

Cognitive therapy was developed by Aaron Beck at the University of Pennsylvania in the early 1960s. Trained in traditional psychoanalysis, he became impatient with its results, and devised a structured, short-term present-oriented psychotherapy for depression. Other forms were developed by Albert Ellis (rational emotive therapy), Arnold Lazarus (multimodal therapy), and Marcia Linehan (dialectic behavioral therapy).

The cognitive model proposes that distorted or dysfunctional thinking influences a person's mood and behavior, and that such distortions are common to all psychological disturbances. Realistic evaluation and modification of thinking is used to produce rapid improvement in mood and behavior. Enduring improvement results from modification of the core beliefs underlying the dysfunctional thinking.

In practice, cognitive therapy emphasizes the collaboration and active participation of both patient and therapist. It is goal-oriented, problem-focused, and time-limited, but ultimately aims to make the patient his or her own therapist. Highly structured sessions teach the patient to identify, evaluate, and respond to dysfunctional thoughts. By elucidating patterns in

multiple circumstances, cognitive therapy offers the opportunity to change the underlying core beliefs and effect lasting change.

B. Interpersonal Psychotherapy

Interpersonal psychotherapy (IPT) was developed in the 1970s by Gerald Klerman as a time-limited treatment for depression, particularly for use in research. Its initial success in depression led to modifications for subtypes of mood disorders, and for nonmood disorders including substance abuse, eating disorders, social phobia, panic disorder, and borderline personality disorder.

IPT makes no etiologic assumptions about psychopathology, but uses connections between current depressive symptoms and interpersonal problems as a pragmatic treatment focus. The therapist links symptoms to the patient's situation in the context of one of four interpersonal problem areas: grief, interpersonal role disputes, role transition, or interpersonal deficits.

Grief may be the reaction to the loss of an individual, or to a more abstract loss. The therapeutic focus is to facilitate mourning and the establishment of new activities and relationships. Interpersonal role disputes consist of conflicts with significant others. IPT explores the nature of the dispute and the relationship, and helps the patient find options to resolve it. If these efforts fail, patient and therapist look for ways to circumvent the conflict or end the relationship. Role transition, a change in life status, is addressed by helping the patient recognize the benefits and challenges of the new role, the positives and negatives of the old role. Interpersonal deficits are traits and behaviors that prevent an individual from establishing or maintaining satisfying relationships. IPT trains such a patient in means to conduct more successful relationships.

IX. SUMMARY

Before the seventeenth century, insanity was attributed to supernatural influences. Although most responses consisted of religious interventions or extrusion of the sufferer from society, there were always some who sought to provide treatment instead. The rise of the scientific method during the Enlightenment, and the social and political forces of democracy that accompanied, began to foster an inclination to address mental disorders with caring, activity, and communication. In the nineteenth century, the results included moral therapy and asylums.

The closing decades of the 1800s brought the attention of neurologists to illnesses including hysteria and

schizophrenia. Hypnosis represented a first step toward the understanding of mind and brain. Sigmund Freud, the most notable figure in this thread, listened carefully and creatively to the hypnotic recollections of his hysterical patients, and drafted the first theories of unconscious mental processes. Over the course of decades, his thinking evolved into a complex and powerful schema of psychic structures and their functions.

Whereas Freud and his immediate associates focused on the analysis of id urges and drive derivatives, the first generation of successors to the psychoanalytic movement focused on the role of the ego. Anna Freud and Heinz Hartmann elucidated its defensive and developmental features. Psychoanalysis became a more powerful treatment as a result.

The success of psychoanalysis, both in its original drive model and in the form of ego psychology, led practitioners to apply its principles to an ever-expanding patient population, including individuals with pre-oedipal problems, and to children. The result was a rethinking of the role of the human environment in the development of the individual and in the genesis of psychopathology. The object relations school, represented most significantly by Melanie Klein, Margaret Mahler, W. R. D. Fairbairn, and D.W. Winnicott, elaborated theories of human interaction that furthered the explanatory reach of psychoanalysis.

In a later split from ego psychology, Heinz Kohut found classical theories of structure and drive inadequate to explain or treat too many of his patients. Breaking the classical mold completely, he rejected virtually all the underpinnings of classical, ego, and object relations psychologies, and defined self psychology. This system focuses on the development of the bipolar self through the use of selfobjects, and defines all psychopathology in terms of disturbed selfobject functions.

The successes of psychoanalysis bred psychoanalytically based psychotherapies from the 1940s on. By the closing decades of the twentieth century, clinical, scientific, and social forces propelled the emergence of a number of nonanalytic psychotherapies, including cognitive therapy and interpersonal psychotherapy, which focus on contemporary issues of perception and response, while mapping a route to permanent psychic change.

GLOSSARY

fading The process of gradually removing prompts as the behavior continues to occur in the presence of a controlling stimulus.

interval schedule A schedule in which a reinforcer is made contingent on the passage of a particular duration of time before the first response to occur after that period of time is reinforced, (a) fixed-interval—schedule in which duration is always the same (b) variable interval—schedule in which the time interval varies about a given average duration.

reinforcement A process in which a behavior is followed by the presentation of a stimulus and as a result, produces an increase in the future probability of that behavior.

response cost A procedure in which a specified reinforcer is lost contingent upon behavior and, as a result, decreases the future probability of that behavior.

target behavior The behavior of interest, or the behavior to be altered.

Home-based reinforcement is a procedure used to modify the school-based behavior of children and adolescents through the use of contingencies delivered in

the home. This article presents a description of the procedure along with the theoretical basis and empirical support for its use.

I. DESCRIPTION OF TREATMENT

Home-based reinforcement (HBR) procedures involve providing consequences for behavior that occurs in school settings. However, unlike traditional school-based contingency management procedures in which consequences are controlled and delivered by school personnel, consequences for school-based behavior in HBR are controlled and delivered by a parent, guardian, or other caretaker in the child's home environment. HBR is typically used with children and adolescents and is usually initiated by school personnel or clinicians who seek an improvement in school attendance or academic performance or seek a decrease in school-based disruptive behavior. Although HBR has been implemented in many different ways (described later in Section III), a general template for implementation is as follows.

First, the clinician, with the help of the child, the child's teacher, and the child's parent, identifies behaviors targeted for acceleration or reduction. Likewise, the teacher and parent (with input from the child) agree on daily goals for acceptable performance with respect to each targeted behavior. Each of the daily goals is operationally defined so the teacher and child are clear as to whether or not the child has achieved the

goal for that particular day. After target behaviors and daily behavioral goals are identified, the clinician establishes a simple observation system. In the observation system, the teacher monitors the occurrence of the targeted behavior(s) and determines if the daily behavioral goals are achieved.

After the targets, goals, and observation system are established, the remainder of the HBR program is explained to the parent and teacher. This is done by (1) having the teacher send a letter to the parents describing the procedure, or (2) having the clinician facilitate a face-to-face meeting with the teacher and parent. Using either method, the program is explained as follows.

Each of the daily goals, corresponding to the target behaviors, is listed on an observation sheet that is given to the teacher. At the end of each school day, the teacher indicates whether or not the child achieved each of the daily goals. The teacher shares this information with the student and places the information on a note that is sent home daily with the child. The parent receives the note, signs it, and returns it to the teacher via the child on the next school day.

On receiving the note, the parent(s) provides consequences for school behavior. If all daily goals are successfully reached, the parent praises the child and provides the child with a previously agreed-on consequence such as snacks, privileges, or other tangible items to which the child does not typically have access. If all daily goals are not successfully reached, the parent and child discuss what could be done differently to ensure success the next day, and the parent provides a previously agreed-on consequence such as a loss of privileges. If the child fails to bring a note home, this is treated as a day in which all daily goals were not met and should be consequenced accordingly.

Although the program is best implemented by having the child receive feedback via the home note on a daily basis, sustained good performance warrants the gradual elimination of the feedback system to promote treatment maintenance. Although a variety of fading procedures have been used, the clinician could recommend that the frequency of notes being sent home first decrease from daily to one note every second or third day, to once per week, and finally to once per month. In using this fading procedure, the clinician should explain to the teacher and parents that all behavior exhibited by the child since the last home report is considered when determining whether the child has met his or her daily goals. Again, a change in the frequency of notes being sent home should only be implemented if the child is consistently meeting his or

her target goals. Fading should not be implemented if the child is not consistently meeting his or her daily behavioral goals.

II. THEORETICAL BASIS

Home-based reinforcement is based on operant learning theory. Specifically, it is thought that the presentation or removal of certain stimuli have the ability to alter behavior when delivered in a response contingent format. Reinforcers are stimuli that produce increases in the future probability of behavior. Reinforcers can include stimuli that are added to the environment (e.g., providing praise contingent on a child's good behavior) or removed from the environment (e.g., a parent's candy-buying behavior is reinforced when his or her child stops screaming "Buy me candy!"). In contrast, punishers are stimuli that produce decreases in the future probability of behavior. However, like reinforcers, punishers can include stimuli that are added to the environment (e.g., painful stimulation is received when the child touches a hot stove) or removed from the environment (e.g., a child's toy is briefly taken away when he or she is destructive with the toy). In all cases, reinforcement and punishment are defined by their outcome on behavior. If the behavior increases in strength, the stimulus following the behavior is classified as a reinforcer, and if the behavior decreases in strength, the stimulus following the behavior is classified as a punisher.

Reinforcers and punishers exert more or less control on the behavior depending on various levels of deprivation, satiation, and other establishing operations experienced by the person. When paired with previously established reinforcers, neutral stimuli (i.e., noncontrolling stimuli) can come to function as reinforcers or punishers in their own right.

In HBR, the reinforcers and punishers are initially the consequences provided at home (i.e., earned or lost privileges, snacks, tangibles). However, delivery of the reinforcing consequences is often paired with praise or positive marks on the home note. This pairing process results in such stimuli also becoming reinforcers that may provide more proximal control over the school behavior. Although operant theory is quite clear that learning will be most efficient if consequences immediately follow behavior, HBR begins with a more temporally distal consequence because the children's parents have better access and control over a wider array of consequences for which the child

is likely to be under the control of a current establishing operation. Although the theoretical explanation just provided is based on operant principles developed from nonverbal organisms, it must be recognized that much of the learning involved in HBR is occurring within a verbal context and with verbal organisms. Thus, it is likely that behavioral processes unique to verbal organisms, such as stimulus equivalence, play perhaps an even greater role in explaining the effectiveness of HBR. Unfortunately, a description of such procedures is outside the scope of this article.

III. EMPIRICAL STUDIES

Home-based reinforcement was first evaluated by Jon Bailey and colleagues in 1970. Because this original study demonstrated the effectiveness of controlling school-based behavior with home-based consequences, a growing volume of research has evaluated various effective forms and uses of HBR. This body of research is briefly reviewed later and includes discussions of behaviors targeted with HBR, methods of implementation, effective consequences, child variables, maintenance programs, and treatment acceptability of HBR.

A. Behaviors Targeted with HBR

Home-based reinforcement has been successfully used to increase academic skills and decrease disruptive behaviors in the classroom. Specifically, HBR has been used to increase motivation, rule following, grades, homework completion, listening, asking and answering questions, staying on-task, and completing class work. It has also been used to successfully decrease aggression, name calling, making noise, talking without permission, physically disturbing other children, and out-of-seat behavior.

The effects of the HBR procedure may also generalize to other nontargeted behaviors, persons, or settings. In 1983 Joseph C. Witt and colleagues found that when HBR was implemented to increase academic behavior, decreases were also seen in disruptive behavior. In addition, it has been found that when a HBR procedure is used on selected target students, the positive effects of the procedure may be seen in nontargeted students. For example, if a teacher targets the classroom behaviors of only half a class, it has been found that the nontargeted half will also show decreases in disruptive behavior. Likewise, data suggest

that the positive effects of HBR can generalize from school to home settings.

B. Methods of Implementation

Also of interest is the specific method that should be used when implementing HBR. Issues such as how the plan should be communicated to parents, how often the home notes should be sent home, what information should be included on the home note, and who should be in charge of the home note at school, all must be considered.

In 1972 R. J. Karraker investigated how much effort was needed to instruct parents in the use of HBR. The researchers taught the procedure to three groups of parents during either two, 1-hour conferences, a 15-min. conference, or by mailing the instructions home. It was found that all three methods of implementation were equally effective in increasing academic behavior.

In 1997 Richard W. Saudargas investigated the rate that home notes should be sent home and found that sending notes home daily was more effective in increasing academic behavior than sending the notes home every Friday. In addition, research has shown that parents prefer daily school notes to both weekly and standard report cards.

There is considerable variation in the amount of information that is included on the home notes. Some home notes only have information on performance in a specific area, such as math completion or disruptive behavior whereas others give a global rating of the child's behavior for the whole day. Both methods have been shown to be effective in changing the student's behavior.

Student involvement in HBR has also been successfully varied. In some cases, the teacher has completed the home note without the student's knowledge, and in others, the teacher has instructed the student when to mark the home note and then signed it at the end of the class. To this date no studies have directly compared the effectiveness of the two methods.

C. Effective Consequences in HBR

One issue that is clear is that some type of reinforcing consequence is necessary for HBR to be effective. In 1972 R. J. Karraker investigated whether receiving the home note without reinforcement would be effective in changing the behavior of children and found that improvements in academic behavior were seen

only after the home note was paired with some rewarding consequence.

Although it is clear that a home-based consequence must be delivered, the most effective form of that consequence is less clear. A number of studies demonstrated the effectiveness of praise and tangible reinforcers for bringing home a note with good ratings, but not all researchers have been successful with only praise. In 1977, Jean B. Schumacher found mixed results in student behavior when using only praise but found consistent increases in school conduct, class work, and daily grades when praise and tangibles were contingent on a satisfactory home note. Some research also suggests that using contingencies that affect a group of individuals in the home, rather than just the target child, may also enhance the effectiveness of HBR.

Researchers have also had success by adding response cost to HBR. In 1995, Mary Lou Kelly and colleagues found that inappropriate behavior could be decreased using normal a HBR procedure, giving points exchangeable for rewards contingent on appropriate behavior, but found greater effects by having the children cross a "smiley" face off their home notes for inappropriate behavior. In the response-cost phase of the experiment the children needed to keep certain amount of smiley faces or points to earn reinforcers.

D. Child Variables

The effectiveness of HBR has been demonstrated with children from kindergarten to high school, in both special and regular education classes, and with children who have learning disabilities. HBR has also been shown to be effective in institutional or group home settings.

E. Maintenance Programs

As stated earlier, the goal of HBR is to have the child eventually function independent of the reinforcement program. To do this, fading or other procedures are often utilized. Some research has suggested effective ways to gradually reduce reliance on HBR procedures.

In 1973 Richard Coleman demonstrated that increases produced by HBR could be maintained while gradually altering the procedure to make the child's school environment more natural. Prior to the altering the procedure, points were rewarded contingent on appropriate behavior using a short, variable interval schedule. The teacher gradually made the child's environment more natural by (1) increasing the interval, (2) subtracting points for inappropriate behaviors instead of reinforcing

appropriate behaviors, (3) extending the period of time during which points were taken away, (4) and making the child's weekly allowance contingent on an acceptable report from the teacher.

Another successful method for removing HBR is to gradually fade the procedure by increasing the criterion level required to receive reinforcement. For example, going from daily reinforcement, reinforcement could be made contingent on two consecutive days of appropriate behavior, followed by three until the schedule has been thinned to the point where the program can be terminated.

G. Treatment Acceptability of HBR

Clinicians should not only consider treatment effectiveness when choosing a procedure but should also attend to the acceptability of the intervention. An effective, but unacceptable intervention will likely meet with resistance and may produce negative emotional reactions in those involved. Thus, the acceptability of HBR procedures are discussed next.

Research has been conducted to determine the characteristics of acceptable behavioral interventions. Thomas Reimers conducted a review of the acceptability literature of behavioral interventions and found that the most acceptable interventions were those that (1) did not require large amounts of time, (2) were positive, (3) were less costly, and (4) did not produce negative side effects. Given that these are all characteristics of HBR, one could predict that HBR is an acceptable procedure.

In fact, many HBR investigations have assessed parent and teacher acceptability of HBR. In all, results showed that parents and teachers found HBR to be an acceptable way to deal with a student's behavior or academic problems. In 1989 Brian Martens and Paul Meller asked teachers to rate the acceptability of a response-cost procedure and a HBR procedure. The researchers found that the HBR procedure was rated as more acceptable than the response-cost procedure.

IV. SUMMARY

In summary, home-based reinforcement is an efficient, effective, and acceptable behavior modification procedure that is used to improve school-based performance or behavior in children and adolescents. Although there are many minor variations of the HBR procedure, in general it involves the delivery of

home-based consequences by the child's parents, contingent on school-based behavior.

GLOSSARY

behavior therapy A systematic, direct, educational approach to therapy that uses principles and strategies that have been supported by research to change thoughts, feelings and behaviors to help clients.

cognitive therapy Very similar to behavior therapy but focuses much more exclusively on altering problematic thoughts and beliefs that are perceived as causing problems.

effect size A measure of how well therapy works.

meta-analysis A research methodology and set of statistical techniques that combine the results of several individual studies to get a more reliable answer to questions, such as "Does homework help therapy outcome?"

Homework assigned to be done outside of therapy sessions is believed to add to treatment effectiveness or even to be necessary for treatment effectiveness by therapists of most theoretical orientations. This article describes types of homework, the benefits of homework, the evidence that homework is useful, and some guidelines for increasing homework assignment compliance.

I. DESCRIPTION OF TREATMENT

Homework refers to therapeutic assignments given by a therapist to a client to complete between sessions. The use of such assignments has a number of purposes. First, homework is purported to enhance treatment generalization through *in vivo* practice. Consider the example of a client taught assertiveness skills in session. From a behavioral perspective, practice in a natural environment allows for nascent skills to come under the control of naturally occurring contingencies. Newly learned behaviors reinforced *in vivo* have a higher probability of further generalizing to other real-world settings than skills merely performed in the clinic with a therapist. Even unsuccessful attempts have their uses: they may be discussed with the therapist and used to shape new homework assignments addressing more specific problem areas. Second, homework assignments are meant to optimize treatment in a cost-effective way. Rather than investing in therapy for multiple sessions per week, clients are asked to practice skills on their own, leading to a more comprehensive and seamless therapeutic experience. In fact, many behavior therapy procedures, such as progressive muscle relaxation, depend on *in vivo* practice to attain meaningful treatment goals. Finally, consistent with Albert Bandura's theory of behavior change, experiences of success in homework assignments should increase clients' self-efficacy and thus improve general motivation for persisting with treatment.

A seminal work describing the importance of homework assignments in cognitive-behavior therapy is the

1979 depression treatment manual, *Cognitive Therapy for Depression* by Aaron T. Beck, A. John Rush Brian F. Shaw, and Gary Emery. These authors posit that homework plays a critical role in the therapeutic process. They conceptualize homework as a sort of trial in which clients strive to gain new insights about their thoughts, emotions, and behaviors that lead to the negative thinking that precipitates and maintains their depression. Assignments develop from collaboration between therapist and client, and their goal is not perfection, but practice. The function of homework assignments is to assist clients to effectively transfer skills learned in session to their home and work environments. With homework, progress made in session may be more likely to be applied throughout a client's life, across both time and situations.

Homework assignments first became incorporated into psychotherapy during the 1950s in G. A. Kelly's fixed role therapy, which encouraged clients to adopt different, more adaptive interpersonal behavior patterns or "roles" and to practice these patterns outside of the therapeutic environment. In recent years, cognitive-behavioral and rational-emotive therapies, as well as some psychodynamic therapies, have integrated systematic homework into their treatment paradigms. Homework assignments have been incorporated into manualized treatments for a wide variety of psychological problems, including depression, anxiety, substance abuse and dependence, personality disorders, posttraumatic stress disorder, sexual dysfunction, and schizophrenia as well as for parent training (child management).

Written assignments, self-monitoring procedures, and skills practice are three broad types of homework assignments. However, the structure, content, and quantity of homework assignments are a function of several factors, including the therapist's theoretical orientation and the client's particular problem and commitment to therapy. For example, in the 1979 Beck, Rush, Shaw, and Emery depression treatment manual, homework assignments are geared toward reducing the incidence of (or eliminating) the negative thinking that plays a role in depressive symptomatology. In this type of homework, a cognitive therapist might ask a client to monitor and write down pessimistic thoughts related to depressed mood, and then to practice replacing such thoughts with more positive thoughts. Similarly, a rational-emotive behavior therapist might direct a client to identify irrational thoughts, and then to produce evidence that both supports and counters their validity. With such evidence in hand, the client is instructed to weigh these pros and cons and then judge the truth

value of the cognition. A behavior therapist treating depression, on the other hand, might collaborate with the client to identify maladaptive behavior patterns, such as insufficient exercise or social withdrawal, and design homework assignments to alter these behaviors. It is not uncommon for a depressed client under the treatment of a behavioral therapist to leave a session with instructions to increase the frequency or duration of exercise, to visit at least one friend once per week, or to take time away from serving others to do something for themselves that they would ordinarily never do. Other typical homework assignments include exposure to feared thoughts, images, or situations, practice of social skills, biofeedback techniques, viewing videotapes, and practicing progressive muscle relaxation.

One clear example of the skills approach to homework used in behavior therapy is teaching a client applied muscle relaxation, which is often used for anxiety disorders. Applied muscle relaxation is a treatment in which an individual is taught a behavior that is incompatible with an existing response to specific situations. In the case of inappropriate or excessive anxiety, clients are taught to monitor their anxiety responses to environmental cues, such as increased heart rate and muscle tension, so that they can discriminate when they are becoming anxious. At the same time they are taught progressive muscle relaxation. For progressive muscle relaxation, therapists teach clients in a clinic session to focus sequentially on a number of different muscle groups while they first tense and then relax these muscles. This procedure is repeated until all muscle groups have been addressed, and the client reports lower levels of muscle tension and anxiety. After presenting the progressive muscle relaxation procedure in session, the client is typically provided with either verbal instructions and/or an audiotape of the therapist conducting the procedure along with homework instructions to practice the procedure at home. Initially, practice is done in a quiet, comfortable setting. Once mastery is achieved under those conditions, practice is done in progressively more distracting and less comfortable settings or situations. For example, a cancer patient who becomes anxious before and during chemotherapy sessions might first repeatedly practice relaxation at home, eventually add visualizing receiving cancer treatment while practicing, and then utilize relaxation just before and during the treatment itself.

Another type of homework assignment is *in vivo* exposure. Exposure involves persistently and repeatedly confronting feared objects or situations until feelings of anxiety subside. For example, in a 1993 study by Ruth

Edelman and Dianne Chambless, clients diagnosed with agoraphobia were assigned homework consisting of self-directed exposure between sessions. In comparison with clients who complied less, those who complied more with between-session exposure assignments reported significantly lower fear levels and fewer avoidance behaviors. By incorporating homework practice in treatment, it is believed that both the speed of learning a skill as well as the ease of acquiring that skill are enhanced.

II. THEORETICAL BASES

In general, homework assignments, as utilized in cognitive-behavioral therapies, are believed to improve client outcomes. Specifically, they are believed to increase the effectiveness and generalizability of treatment via between-session practice. This practice should both optimize the intervention and increase cost effectiveness for the consumer: homework, if adhered to, ensures multiple “sessions” per week for the price of one.

The major questions asked about homework deal with compliance with assignments. One question is whether the relationships found between homework compliance and treatment outcome are causal. That is, does increased homework completion lead directly to greater clinical improvement or is this simply a correlational relationship that is actually the result of some other factor or factors. The second question is how can therapists increase homework compliance and, relatedly, what factors are known to predict compliance difficulties. Awareness of the latter can assist therapists to be better prepared and have additional strategies in hand to aid compliance.

Several third-variable factors could account for the relationship between homework compliance and treatment outcome. Clients who are more motivated, either dispositionally or from early therapist interventions, might work harder in all aspects of therapy, including homework, and make more treatment gains. Parallel effects could arise from a more optimistic attitude or more openness to change. In either case, the effect of homework compliance on outcome would be incidental.

Also, the compliance–outcome relationship could work in the reverse direction: severely depressed clients might do little or no homework between sessions. This would imply that homework has no effect on outcome.

The evidence from two recent studies indicates that compliance does have a direct effect on treatment outcome. David Burns and Diane Spangler used structural equation modeling to answer this question in a 2000

paper and found support for a causal effect of homework compliance on outcome. Using a very different research strategy, repeated assessments of homework compliance and of improvement in depression, Michael Addis and Neil Jacobson found that early compliance predicted final outcome. Their results countered the reverse compliance–symptom severity alternative hypothesis and supports a causal relationship. Therefore, except for a very few studies that have found compliance unrelated to outcome, it appears that the more clients follow homework assignments, the more they improve.

Although homework is an integral part of many cognitive-behavioral therapies, it appears that client non-compliance may limit the benefits of assignments to treatment outcome. In a 1999 review paper, Jerusha Detweiler and Mark Whisman discuss failure to comply with homework assignments and possible methods for increasing compliance. Their review lists several factors that contribute to poor compliance: unrealistic goal setting (i.e., therapists making assignments too hard), lack of consideration of a given client’s ability to complete a particular assignment, poor client motivation, client expectations that their role in therapy is a passive one, and poorly designed assignments (e.g., those that do not come under the control of naturally occurring reinforcers). Other client-based reasons cited range from client perfectionism and fear of failure to comorbid personality disorders and high initial levels of symptomatology. These authors observe that, for homework to be beneficial, practice, commitment, and just plain hard work are required. This points out the importance of presenting to the client a sound, compelling treatment rationale to motivate this effort.

Detweiler and Whisman identify a number of task, therapist, and client characteristics relevant to increasing compliance. In terms of task characteristics, the more specific and concrete an assignment, the more likely a client will understand and complete it. For example, writing down assignments for the client may elicit more compliance than just verbally describing what they are to do. Providing concrete, specific details of what they are to do and when they are to do it can prevent misunderstandings and frustration for both the client and therapist. Shaping the client’s assignments, starting with brief and simple tasks and gradually increasing homework demands should also help by building self efficacy. Client characteristics that bear consideration include initial levels of symptomatology, motivation, or merely contextual barriers to completion. Consider a client who works on an assembly line and has been asked to write down instances of an intrusive

thought. Such an assignment is likely to end up a failure due to its poor feasibility. Using role plays with role-reversal, having the client act as the therapist and explain why homework and its completion are important, may enhance motivation. Therapist characteristics that may affect compliance are more difficult to define, as there are gaps in the empirical literature concerning this variable. Nonetheless, the authors posit that factors such as empathy and therapist behaviors related to recommending assignments may merit exploration.

In other studies done to examine factors associated with better homework outcomes, it has been found that the quality of the homework product is far more predictive of outcome than the quantity of homework produced and that more thorough reviews of one homework assignment will promote better compliance with subsequent homework assignments.

III. EMPIRICAL STUDIES

The primary question for homework is “Do homework assignments improve therapeutic outcome over and above in-session therapy effects alone?” In 2000, Nikolaos Kazantzis, Frank P. Deane, and Kevin R. Ronan conducted a meta-analysis of the literature on this empirical question. Combining 11 prior studies with a total of 375 participants, their analysis found strong effects of homework assignments on therapy outcome. Thus the answer seems to be a clear “yes.” These authors’ results also showed that the effect of homework was stronger for depression than for anxiety disorders. Homework assignments to practice social skills and watch videotapes had stronger effects on outcome than assignments to self-expose to feared objects or situations and relaxation practice. Finally, studies that used a range of homework assignments appeared to obtain better treatment effects than studies that used only single, specific homework assignments.

How large are the effects of homework on therapy outcome? The meta-analysis above found an effect size of $r = .36$. It is useful to see in more concrete terms how large a change a therapist can expect to see on a common measure of distress. The Burns and Spangler study described earlier separately examined two groups of depressed patients for the effects of homework on change in scores on the Beck Depression Inventory (BDI), a short, reliable questionnaire that is used by both researchers and private practitioners. For each of their groups, they found that homework accounted for a drop in BDI scores of 14 to 16 points. This improvement in BDI scores was comparable to a 1988 study done in a

private practice setting by Jacqueline Persons, David Burns and Jeffery Perloff. These authors found a 16.6 point BDI change with homework but noted that the vast majority of improvement occurred in their more depressed clients, those with initial BDI scores over 20. Homework had very little effect for their clients who had lower scores at the beginning of treatment. In general, the degree of BDI change produced by homework alone in these studies would move a client from being classified as “severely depressed” to “moderately depressed” or from “moderately depressed” to “mildly depressed.”

Psychodynamic and systemic or family therapies also often require or recommend homework. Although there is no literature to date investigating homework effectiveness within these therapies, there is no reason to think that the cognitive-behavioral research findings that support the use of homework would not generalize to these approaches.

IV. SUMMARY

Most theoretical orientations hold that what a client does in the natural environment outside of therapy sessions is a necessary condition for producing therapeutic change. Typically, clients are seen for about 1 hour each week. To extend what clients are taught in session to the time intervening between sessions and to implement what clients learn in session, therapists give homework assignments. Effective homework assignments can optimize the cost effectiveness of therapy for the consumer.

Homework assignments first became incorporated into psychotherapy during the 1950s, and since then, have become an integral part of both behavioral and cognitive-behavioral treatment paradigms. Other treatment modalities, such as systems therapy or psychodynamic interventions, also utilize homework. Homework is used in the treatment of a wide variety of disorders, which, along with factors such as therapist orientation and client commitment, may dictate the type of homework assigned. Common types of assignments include written assignments, self-monitoring procedures, and skills practice.

Research clearly shows that homework improves treatment outcome.

GLOSSARY

constructivist therapy Humanistic approaches that stress personal and social constructions of psychological growth processes.

existential therapy Humanistic approaches that emphasize freedom, experiential reflection, and responsibility.

humanistic theory Comprises two overarching concerns: What it means to be fully, experientially human, and how that perspective illuminates the vital or fulfilled life.

humanistic therapy Conditions or stances that assist people to grapple with and become more of who they aspire to become.

transpersonal therapy Humanistic approaches that accent spiritual and transcendent dimensions of psychological well-being.

Humanistic psychotherapy is the applied branch of humanistic psychology and philosophy. Humanistic psychology and philosophy are time-honored folk and academic traditions that stress deep personal inquiry

into the meaning and purpose of life. In particular, humanistic psychology and philosophy pose two basic questions: What does it mean to be fully, experientially human, and how does that understanding illuminate the vital or fulfilled life? Correspondingly, humanistic psychotherapy comprises the conditions or stances by which people can come to intimately know themselves and, to the extent possible, to fulfill their aspirations. Humanistic psychotherapy is characterized by three major practice philosophies—the existential, the constructivist, and the transpersonal.

I. HUMANISTIC APPROACHES: DESCRIPTION AND OVERVIEW

Humanistic psychotherapy is a broad classification that embraces a diverse ensemble of approaches.¹ Each of these approaches is like a spoke on a wheel, the hub of which is the humanistic theoretical stance. The humanistic theoretical stance derives essentially from ancient Greek, Renaissance, and even Asian sources,

¹ The terms “approach,” “stance,” and “condition” are used instead of “treatment” in humanistic nomenclature. The reason for this substitution is because “treatment” implies the medical-like application of a technique to a measurable and well-defined symptom; however humanistic psychotherapy emphasizes the significance of a relationship—a condition, atmosphere, or forum—within which not just symptoms but complex life issues can be explored and addressed.

which all uphold the maxim, “know thyself.” Although there have been many variations on this theme throughout the development of psychology, let alone humanistic psychology, it has come to acquire a core humanistic meaning. For humanists, to know thyself is far from a simple project with trivial implications; to the contrary, it is an intensive intra- and interpersonal undertaking with world-historical significance. In the parlance of modern humanistic psychology the maxim has come to be understood as a dialectic between profound self-inquiry, and inquiry into the world. Indeed, the self cannot be separated from the world, according to contemporary humanists, and must be understood as a “self-world” process or construct as James Bugental has put it. A corollary to the humanistic stress on inquiry is engagement of potential. It is not enough to ask questions about life’s meaning, according to humanists, one must also, at the appropriate time, translate those questions into a meaningful life. In short, humanistic psychology has both an inquiring and moral-ethical component that suffuses through every mode of its application. To learn more about the history and development of humanistic philosophy and psychology, see *The Handbook of Humanistic Psychology: Leading Edges in Theory, Research, and Practice* and *Humanistic and Transpersonal Psychology: A Historical and Biographical Sourcebook*.

Contemporary humanistic psychotherapy is composed of three basic practice traditions: the existential, constructivist, and transpersonal. We will now describe the structure of these traditions, highlight their conceptual underpinnings, and consider the empirical evidence on which they are based.

II. EXISTENTIAL THERAPY

Existential psychotherapy derives from the philosophical and literary writings of such thinkers as Søren Kierkegaard, Friedrich Nietzsche, Martin Heidegger, Jean Paul Sartre, and Maurice Merleau-Ponty; and from the methodological formulations of investigators such as Edmund Husserl, Wilhelm Dilthey, and William James. The basic thrust of existential psychotherapy, as Rollo May, one of the leading contemporary spokespeople for the movement put it, is “to set clients free.” Freedom is understood as the cultivation of the capacity for choice within the natural and self-imposed (e.g., cultural) limits of living. Choice is understood further as responsibility; the “ability to respond” to the myriad forces within and about one. Although many forces are

recognized as restrictive of the human capacity for choice, for example, influences that May terms “destiny”—genes, biology, culture, circumstance—they are nevertheless highly mutative, according to existentialists, in the light of—and through the tussle with—choice. For existentialists, choice is the key to an engaged and meaningful life.

The second major concern of existential psychotherapy is the cultivation not just of intellectual or calculative decision-making, but decision-making that is felt, sensed, or in short, experienced. The stress on the experiential is one of the primary areas of distinction between existential and other (e.g., cognitive-behavioral, psychoanalytic) modes of practice. The experiential mode is defined by four basic dimensions—immediacy, affectivity, kinesthesia, and profundity. By immediacy, we mean that experience is fresh, living, “here and now”, by affectivity, we mean experience is characterized by feeling or passion; by kinesthesia, we mean experience is embodied or intensively sensed; and by profundity, we mean experience has depth, impact, and transcendent significance. Another way to characterize the experiential is through recognition, as Arthur Bohart has put it. To the degree that a thought, feeling, or behavior is recognized, according to Bohart, it is experienced.

Existential therapists have a variety of means by which to facilitate freedom, experiential reflection, and responsibility. Some, such as Irvin Yalom, emphasize the support and challenges of the therapist–client relationship to facilitate liberation. Yalom stresses the building of rapport and repeated challenges to clients to take responsibility for their difficulties. Further, Yalom homes in on the immediate and affective elements of his therapeutic contacts, but he refers little to kinesthetic components. Following the philosopher Martin Buber, Maurice Friedman also homes in on the interpersonal relationship but stresses the dimension of authenticity or the “I-thou” encounter as the key therapeutic element. The I-thou encounter according to Friedman is the dialectical process of being both present to and confirming of oneself, while simultaneously being open to and confirming of another. The result of such an encounter is a “healing through meeting” as Friedman puts it in *The Psychology of Existence*—which is a healing of trust, deep self-searching, and responsibility. Through the therapist’s I-thou encounter, in other words, the client is inspired to trust, enhance self-awareness, and take charge of his or her own distinct plight. James Bugental, on the other hand, accents the “intra” personal dimensions of freedom, experiential reflection, and responsibility. For Bugental, choice and responsibility are facilitated, not

merely or mainly through therapist and client encounter, but through concerted invitations (and sometimes challenges) to clients to attend to their subtlest internal processes—flashes of feeling, twinges of sensation, and glimpses of imagination. Via these means, according to Bugental, clients discover their deepest yearnings, their strongest desires, but also, and equally important, their thorniest impediments to these impulses. By grappling with each side, however, Bugental maintains that clients learn to negotiate their conflicts, elucidate their meaning, and rechannel them into living fuller and more empowered lives.

Similarly, Rollo May stresses the cultivation of what he terms “intentionality” in the therapeutic relationship. By intentionality, May refers to the “whole bodied” direction, orientation, or purpose that can result from existential therapy. In his case examples, May shows how intellectualized or behaviorally programmed interventions persistently fall short with respect to the cultivation of intentionality, whereas profound struggle, both between the therapist and client and within the client, can, if appropriately supported, lead to such a quality. For May (as with most of the existential therapists), the struggle for identity is essential—enhancing clarity, agency, and ultimately commitment or intentionality in the engagement of one’s life.

The client’s internal frame, and his or her own subjective wrestling is also a hallmark of Carl Rogers’ client-centered approach. For Rogers, the therapist must create the conditions for client freedom, searching, and responsibility; he or she would not (except in rare instances) attempt to dictate or teach these capacities. The rationale for this stance is foundational—clients must learn for themselves what is meaningful or essential to their growth. In Rogers’ view, there are three facilitative conditions necessary for optimal therapy—the therapist’s warmth or caring, the degree to which he or she is congruent or genuine, and the degree to which the therapist communicates unconditional positive regard for the client. With the provision of these conditions, according to Rogers, clients are freed to verbalize and embody more of who they experience themselves to be, and by implication, to eradicate the incongruities and pretenses of who they have been. By discovering more of who they are, moreover, clients do not become licentious in Rogers’ view; they become responsive, both to themselves and to those around them.

With his Gestalt therapy, Frederick Perls also emphasizes the client’s side of the therapeutic encounter, but through a very different means. One might say that whereas Rogers “alerts” clients about their liberating po-

tentials, Perls “alarms” them; and whereas Rogers accents therapeutic receptivity, Perls stresses therapeutic confrontation. For example, whereas Rogers might use active listening or empathic reflection with a given client, Perls might encounter a client directly—“how is it that you continually meet men who are bad for you?” Or Perls might refer to a client’s body position or manner of speaking and concertedly encourage the client to amplify and attend to those modalities.

The upshot of this synopsis is that existential therapists use diverse means by which to foster a similar result—client empowerment and consciousness-raising. In recent years, and partly as a response to the ethos of managed care, existential therapists have endeavored to reassess and in some cases streamline their repertoires. Existential oriented investigators are increasingly raising two questions: Which of the various existential practices work best, and under what general conditions? Leslie Greenberg, Laura Rice, and Robert Elliott, for example, have developed what they term “therapeutic markers” to guide their work. Such markers are statements, gestures, or signs that clients are experiencing specific kinds of difficulty, for example, identity conflicts, unfinished business with significant others, loss of meaning. By identifying the markers, therapists are better able to both identify and specify the interventions (e.g., supportiveness, uncovering) that address those markers. Therapists such as those discussed earlier have also found that specific Gestalt techniques, such as “chair work” and “systematically building the scene” can be of particular value in the appropriate circumstances. Chair work entails a role-play between a client and an imagined other who “sits” on an empty chair. The client “works out” or simulates an actual encounter with the imagined other, and with the assistance of the therapist, processes the feelings, thoughts, and implications of that experience. Systematically building the scene entails the use of vivid and concrete language to help clients revive and work through suppressed or traumatizing material.

Eugene Gendlin’s “Focusing Therapy” and Alvin Mahrer’s “Experiential Therapy” also provide methodical and intensive guidelines to optimize existential practice. Gendlin, for example, homes in on that which he terms the “felt sense,” which is a preverbal, bodily experience of a given concern, to facilitate therapeutic change. Very methodically, Gendlin encourages clients to identify their felt sense, explore its nuances as it evolves, and clarify its meaning or implication for their lives. Mahrer has four basic aims in his experiential therapy: assist clients into moments of strong feeling, help them to align with or integrate those moments, encourage them

to enact or embody the inner experiences associated with those moments, and support them to live or translate their discoveries into the present. Mahrer's approach has two overarching goals: (1) to help clients access deeper experiencing potential so that they can become (to the degree possible) "qualitatively new persons," and (2) to help them free themselves from the limiting feelings that have plagued them in the past, and with which they grapple in the present.

Kirk Schneider, with the assistance and inspiration of Rollo May, has synthesized a range of existential approaches with his model "Existential-Integrative Therapy." Existential-integrative therapy draws on a diversity of therapeutic approaches within a unitary existential or experiential framework. The aim of the existential-integrative approach is to address clients at the level at which they chiefly struggle—be that physiological, environmental, cognitive, psychosexual, or interpersonal—but all within an ever-deepening, ever-beckoning experiential context. By "experiential" Schneider refers to four characteristic dimensions—the immediate, the affective, the kinesthetic, and the profound (or cosmic). The degree to which a client can be "met" within the experiential context is a function of his or her desire and capacity for change, but also, according to Schneider, an assortment of therapist offerings. Among these offerings are "presence," "invoking the actual," "vivifying and confronting resistance," and "meaning creation (or cultivation)." Presence, for Schneider, holds and illuminates that which is palpably (immediately, affectively, kinaesthetically, and profoundly) relevant, within the client and between client and therapist. Presence holds and illuminates that which is charged in the relationship and implies the question, "What's really going on here, within the client and between me and the client?" Presence is the "soup" or atmosphere within which deep disclosure can occur, and based on this disclosure, the client's core battles become clarified. Invoking the actual refers to the invitation to the client to engage that which is palpably relevant. By invoking the actual, the therapist calls attention to the part of the client that is attempting to emerge, break through, and overcome stultifying defenses. Invoking the actual is characterized by such invitations (and sometimes challenges) as, "What really matters to you right now?", or "I notice that your eye moistened as you made that statement", or "What feelings come up as you speak with me?" At times, invoking the actual calls attention to content/process discrepancies, such as "You say that you are angry but you smile." If invoking the actual calls attention to that which is emerging in the client's experience, vivifying and con-

fronting resistance call attention to that which blocks what is attempting to emerge. These blocks or resistances are seen as life-lines from the existential-integrative point of view, but they are also acknowledged as progressively defunct. Vivifying resistance "alerts" clients to their defensive blocks, while confronting resistance "alarms" or "jars" them about those blocks. Together, vivifying and confronting resistance serve to intensify and eventually mobilize clients' counterresistances (the "counter-will" as Otto Rank has put it); it is these counterresistances that liberate vitality, bolster choice, and incite change. In the final stage of existential-integrative encounter, therapists help clients to consolidate the meanings, values, and directions of their present lives. Although meaning creation evolves naturally and spontaneously following breakthroughs over one's resistance, sometimes it requires a gentle prod. For example, a therapist might challenge a client to translate her newfound boldness into her constricted work relationships.
