To sum, existential-integrative therapy, like existential therapy generally, assists clients to grapple with their experiences of life, not just their reports about life, and through this illumination, supports their intentional and embodied engagement with life.

III. CONSTRUCTIVIST THERAPY

"Constructivism"² refers to a group of theories holding the philosophical position that "reality" is, in some ways, created by (as opposed to thrust upon) persons. Constructivist therapists are faced with the challenge of understanding the lived reality of each client, not imposing some objective truths on all persons seeking their help. On this basis, constructivists believe that lives can be transformed and horrors transcended when we grasp the unique, personal, and richly powerful "realities" each of us has created. Therapy (and research, for that matter) is a cocreated experience between therapist and client, mutual experts on different aspects of the lived reality being created between them. This egalitarian relationship can be seen as more client empowering than approaches in which the more powerful therapist imposes diagnostic and treatment "realities" on the less powerful client. After briefly describing constructivism, we will discuss

² See also postmodernism/postmodern or poststructural philosophy/therapy.

some general aspects of constructivist therapy followed by a brief illustration of a few constructivist approaches.

Although all constructivists agree that reality cannot be known directly, different theoretical groups disagree on the exact nature of the relationship between the person and the world. Radical constructivists argue that it makes no sense to even speak of a reality outside of the meanings the person has created. Because reality cannot exist other than our construing it into existence, radical constructivists would argue that the meanings we create totally determine our experience of the world. Social constructivists would go to the other extreme. We are saturated with meanings created by cultures and imposed on us. Occupying a middle ground between these two extremes, critical constructivists argue that meanings are created in the dynamic interaction between the person and the world. In other words, although we cannot know it directly, the world is real, integral, and unfolding around us.

Constructivist therapies generally share certain attitudes about therapy. For example, most constructivists will listen to clients from the assumption that everything the client says is “true” in the sense of revealing important aspects of the client’s experiential meaning system. (This attitude is termed the credulous approach by some constructivists.) Similarly, there is a respect for contrast, oppositionality, or the dialectic as integral to meaning making. Most constructivists also are very attuned to making the therapy room a safe place for clients to experience life, explore, and grow. Without safety, creative encounter with the central meanings of one’s life is hampered; without creativity, reconstructing the bases of one’s existence is impossible. Finally, there is an emphasis on seeing the client as a process of meaning creation, rather than a static entity composed of specific meanings. This emphasis on seeing persons as processes implies that constructivists are always looking for the ways the client is changing from moment to moment or session to session. Art Bohart has taken this focus on client change and argued that therapy works because the self-healing client uses whatever the therapist does to grow and change.

As might be expected, different constructivist therapists employ these attitudes in different therapeutic approaches. Franz Epting, for example, is a leading proponent of George Kelly’s fixed role therapy. In fixed role therapy, the client first writes a character sketch that is open, revealing, yet sympathetic to the client’s experience. The therapist and client then cocreate an alternate sketch for the client to enact, typically for a 2-week period. Rather than being a behavioral prescrip-

tion, the procedure is designed to free the client to experiment with differing ways of experiencing life.

On the other hand, constructivist therapists such as Miller Mair, Robert Neimeyer, and Oscar Goncalves employ narrative approaches to therapy. These therapists believe that narratives give meaning and continuity to the lived experience of clients. Gaps, incompleteness, and incoherence in the client’s life story may indicate struggles in creating an integrated experience of self-in-the-world. Goncalves nicely illustrates constructivist narrative therapy with his “moviola” technique. This is a technique in which the therapist’s attention scans the settings of a client’s life, much like a camera in a movie. The therapist can zoom in on a detail or back off and get a more panoramic view. For example, a therapist might start by having the client describe the entire room in which a traumatic event occurred. Eventually, the therapist might help the client zoom in on the faces in the room, filled with fear and horror, while the abuse occurred. Because people intimately create meanings to understand their experiences, the experience of reviewing the abuse with an empathic therapist allows for new constructions to be created. These newer meanings, in turn, allow for newer experiences as clients’ lives move into the future.

Bruce Ecker and Laurel Hulley’s depth oriented brief therapy (DOBT) applies constructivist principles to understand and engage clients in radical change in a very short-term treatment. DOBT understands the symptom as painful because of the ways it invalidates important aspects of our experience. At the same time, there are other constructions, often at a lower level of consciousness, which makes the symptom absolutely necessary for the client. DOBT uses specific experiential techniques to help the client gain access to these deeper meanings. The client then can more consciously decide whether to keep or abandon these more unconscious meanings. For example, one client who described himself as a complete failure uncovered the ways in which his failure was rewarding. It served both as punishment for and proof to his parents that they had failed him in many ways.

Larry Leitner’s experiential personal construct psychotherapy (EPCP) is based on the relational, experiential, and existential foundations of constructivism. EPCP construes persons as simultaneously needing and being terrified of depths of emotional closeness. On the one hand, such intimate relationships can affirm the meanings that have formed the very foundation of our existence. On the other hand, we can experience devastating disconfirmation in intimate

relationships. Clients then struggle with needing to connect with others, risking terror to gain profound richness, versus retreating from intimacy, buying safety at the cost of the empty objectification of self and others. EPCP engages this struggle in the live relationship in the therapy room. Therapeutic growth can occur as the therapist offers optimal therapeutic distance, a blending of profound connection and separateness, when the therapist is close enough to feel the client's experience, yet distant enough to recognize those feelings as the client's and not the therapist's own.

Constructivist therapy also has been applied to special populations. For example, EPCP was an approach developed to understand and therapeutically engage the experiences of more severely disturbed clients, often those who have received *DSM* diagnoses such as "schizophrenia," "borderline," and "schizotypal." (Terms most constructivists would not countenance by the way.) Fay Fransella has applied constructivist therapy to stutterers. A central aspect of her therapy involves the creation of meaningful ways of encountering the world as a fluent speaker.

Tom Ravenette, using only blank sheets of paper and pencils, uses constructivist techniques to access the meaning-making system of children. For example, he will draw a bent line in the center of a page and have the child draw a picture incorporating the line. He then has the child draw a second picture, depicting an opposite to the one just drawn. As the child talks about the pictures, Ravenette enlarges the conversation to allow the child to say what she knows (but could not express) about her world. Linda Viney and Sally Robbins, working on the other end of the age spectrum, successfully utilize constructivist principles with elderly clients. Robbins, for example, has poignantly described using a constructivist version of reminiscence to help elderly clients come to terms with their lives and their deaths. Family system constructivists may use systemic bowties to help each client understand how their actions, based on their deepest fears, confirm the deepest fears of other family members. For example, in response to his fears that his wife does not love him, a client may respond vaguely to her when she is angry. She interprets the vagueness as his not respecting her, making her even angrier.

Finally, there is a growing literature empirically supporting the use of constructivist therapies. Linda Viney (in a 1998 issue of the journal *Psychotherapy: Theory, Research, Practice, Training*), for example, reviews 19 different studies exploring the effectiveness of personal construct therapy across different countries, ages, and

types of problems. Not only did she find substantial support for the effectiveness of constructivist therapy, she found effect sizes for client change to be at least as large as those reported in the cognitive-behavioral and psychoanalytic literature. In other words, good constructivist therapy respects the lived experiences of persons while being empirically supported using studies that meet the most rigorous of experimental criteria.

IV. TRANSPERSONAL THERAPY

The differences among the major humanistic approaches are certainly more of degree than of kind. There is a very wide overlap among transpersonal, existential, and constructivist modalities. However, whereas existential and constructivist therapies emphasize the interhuman, personal elements of client-therapist interaction, the transpersonal approaches accent the spiritual, religious, or cosmic implications of those dimensions. It is not that an existential- or constructivist-oriented therapist would exclude any such transpersonal theorizing—indeed, a number of them welcome such theorizing—however, on the whole, transpersonal therapists, above and beyond their existential and constructivist counterparts, bring to bear into their practices two basic knowledge domains: (1) religious faith traditions, and (2) mystical healing traditions. Religious faith traditions represent the seven major religious systems of the world—Buddhism, Hinduism, Islam, Judaism, Christianity, Taoism, and Confucianism—as well as the many indigenous lineages, such as Native American, Asiatic, and African traditions. Mystical healing traditions encompass a breathtaking span of indigenous, institutionalized, and individualized elements, but they all converge on one basic pattern—the experience of oneness with creation. While transpersonal therapists tend to be conversant with these transcendental viewpoints, it should be pointed out they do not draw on them to proselytize. Their essential task, by contrast—in accord with transpersonal pioneer C.G. Jung—is to facilitate client self-discovery.

In his essay from the germinal *Paths Beyond Ego*, edited by Roger Walsh and Frances Vaughan, Bryan Winitz sets forth several "postulates" of transpersonal psychotherapy. The first postulate proposes that transpersonal therapy embraces egoic, existential and transpersonal levels of human consciousness. This postulate derives from a "spectrum" model of human consciousness, developed formally by Ken Wilber, and used broadly by transpersonal scholars and practition-

ers. Roughly speaking, the spectrum model proposes a hierarchy of developmental psychospiritual stages, from the infantile “pre-egoic” stage to the culturally competent “egoic” stage to the personally inquiring “existential” stage to the unitive “transpersonal” stage. Although there are many nuances within this model, and diverse interpretations of its accuracy, it is nevertheless a core view for many transpersonalists.

The first postulate of transpersonal therapy then assumes a sweeping scope—all developmental stages of identity from the precultural (infantile) to the transcultural (sagely or saintly) are embraced. Moreover, for some in the transpersonal community, each developmental stage is a prerequisite to the next. One cannot, for example, simply “leap” from stage to stage, for example, from the conventional egoic stage to the transconventional “subtle” or “soul” level, without predictable difficulties and consequences. Among these are various kinds of regression, as manifested, for example, by the accomplished meditator who also semiconsciously indulges in alcohol, or the pious adept who concomitantly exploits others, and so on. Generally speaking, the more that clients can address and work through the stage of their developmental arrest, the greater their ability to advance to an expanded or “higher” developmental level. Put another way, the transpersonal therapist (like most depth therapists) must help clients “get through the night,” or manage their dysfunctionality, before he or she can assist them with profound or mystical realizations. Although other transpersonalists, such as Brant Cortright, believe that spiritual and mystical healing can, and often does, occur alongside of the dysfunctional, they do not discount the significance of addressing those dysfunctional states, and of supporting healing processes generally.

Wittine’s second postulate is that the therapist’s role in transpersonal therapy is critical. The therapist’s ability to hold and value psychospiritual healing refers directly back to his or her own psychospiritual work, awareness, and capacity to translate that work and awareness to the therapeutic setting. To the extent that therapists can “see” and acknowledge the unfolding spiritual implications in client’s quandaries, they embrace a deeper and broader therapeutic possibility for clients, a deeper and broader language within which to engage that possibility. Consider, for instance, the therapist who works strictly within a psychoanalytic frame and who views clients’ conflicts as derivative of circumscribed parental relationships; to what extent would such a therapist be open to implicit spiritual strivings in clients’ material—such as urges to wonder, yearnings to

transcend, or impulses to meld? The therapist’s presence to these spiritual possibilities is crucial—an entire therapeutic direction may hinge on what therapists ask about, how they inquire, and what they imply or suggest when they inquire. If a therapist is not attuned within himself or herself to the longing for or fear of an enlarged sense of spiritual meaning in a client’s rage or tearfulness, that client may never broach those motivations, and may feel shortchanged as a result. A conscious transpersonal therapist, on the other hand, can detect and call attention to emerging affects, images, symbolisms, and the like, that are bell-weather of profound spiritual or religious transformation; to the degree that one has not experienced and dealt with such intensities within oneself, however, it is doubtful that one could facilitate them in others. Great care, finally, needs to be taken in calling attention to emerging spiritual concerns—as with all humanistic therapies, it is the client, not the therapist, who must ultimately decide his or her fate, and the meaning or significance of that fate.

Wittine’s third postulate is that transpersonal therapy is “a process of awakening from a lesser to a greater identity.” By “awakening,” transpersonal therapists mean enlarging or expanding one’s identity. The enlargement of one’s identity invariably entails disruption, pain, and relinquishment. One cannot simply “leap over” one’s former way of living, particularly if it has been familiar and “safe,” and fail to experience disturbance. This disturbance becomes particularly acute if one lacks the means and resources to address it. For example, there is a major difference between an identity crisis that evolves gradually within familiar circumstances, and one that “shatters” or overtakes one abruptly. The experience that transpersonal therapists term “spiritual emergency” is an example of the latter variety of crisis. In spiritual emergency (which is to be distinguished from brief psychotic episodes or nonspiritual “breakdowns”), clients experience an acute transpersonal tear or rupture in their conventional experience of the world. This rupture may take the form of psychic openings, for example, visions, voices, telepathic states; or shamanic-like alterations of consciousness, such as channeling experiences, possession states, and UFO encounters.

According to Cortright, who draws on the foundational work of Stanislav and Christina Grof, there are three distinguishing features of those undergoing spiritual emergency: (1) They display changes in consciousness in which there is significant transpersonal consciousness; (2) they have an ability to view the condition as an inner psychological process, amenable to

inner psychological resources; and (3) they have the capacity to form a sufficient working alliance with a therapist. Although these features stand in marked contrast to relatively nontranspersonal, nonintrospective, and oppositional crisis clients, there are many gradations when it comes to spiritual emergency and there is as yet no firm consensus as to which clients fit which criteria. The general consensus for treating spiritual emergency clients, according to Cortright, is to help “ground” or support them, to offer deep and abiding presence to their struggle, and to draw on diet, exercise, massage, proper rest, meditation, and (when necessary) medication, to begin their healing path. Following these initial steps, a more depth-experiential approach can be implemented. The goal of such an approach, as with most transpersonal approaches, is to assist clients to integrate and transform split-off parts of themselves, and to facilitate expanded consciousness.

In general, transpersonal work proceeds through a series of steps that increase clients’ awareness. The more that clients can become aware of stifling or debilitating patterns, the more they are in a position to question and reshape those patterns. Although most therapists facilitate expanded awareness, transpersonal therapists create an atmosphere and make available methods that carry clients beyond conventional change parameters. Hence, whereas a cognitive therapist might help clients to deconstruct maladaptive beliefs, a transpersonal therapist would work with clients to deconstruct maladaptive attachments—beliefs, values—any core investitures that warp or curtail consciousness. Among the means that transpersonalists employ to facilitate such emancipations are meditative breathing, mindfulness and concentration exercises, guided visualization, stress reduction techniques, sustained self-observation, experiential reflection, disidentification exercises, demystifying dialogue, and somatic practices.

To sum, transpersonal therapists tend to be integrative therapists. They employ egoic stances (e.g., medical, psychoanalytic, cognitive) when questions of adjustment or personal identity are at stake, and transpersonal modes (e.g., spiritual-existential, contemplative) when issues of emancipation, enlightenment, or transpersonal identity arise. The question as to “who am I” is relentlessly pursued by transpersonal therapists. Although there are many gradations and variations among transpersonal practices, several principles stand out: Transpersonal therapy addresses the entire spectrum of (purported) consciousness; the therapist’s personal role is critical; and the enlarging or awakening of identity is the core of transpersonal practice.

V. EMPIRICAL STUDIES OF HUMANISTIC THERAPY

Humanistic therapy occupies a unique position among organized psychological practices. Whereas conventional therapies target overt and measurable symptom change as indicative of “effective” therapeutic outcome, humanistic approaches recognize many alternative criteria. Among these are shifts, not just in symptomatology, but in values, attitudes, and approaches toward life. To the extent that one becomes a “qualitatively new person,” as Alvin Mahrer puts it, or develops new talents, capacities, and appreciations for life, as Rollo May has put it, one fulfills humanistic standards. For humanists, it is one thing to “return to a previous level of functioning,” or to adjust to one’s spouse, or to become more productive at work, and quite another to supersede one’s previous level of functioning, to deepen one’s connection with one’s spouse, and to become passionate about one’s vocation. Whereas the latter tend to be overt and quantifiable, the former tend to be tacit, intimate, and qualitative. Given the confines of conventional research methodology (e.g., randomized controlled trials, objectified rating scales), humanistic therapies have become forgotten “stepchildren” in the competitive outcome battles. The empirical challenge of humanistic therapies is formidable: How does one assess the depth and breadth of intimate humanistic change? Or in short, how does one match the methodology with the mission?

Given these thickets of difficulty, humanistic researchers have turned to two basic investigative modalities to study therapeutic outcome—innovative quantitative methodology, and that which humanistic trailblazer Amedeo Giorgi terms “human science research methodology.” Although quantitative methodology has been found to be wanting by many in the humanistic community (e.g., because of its restrictive procedural requirements) for others, it has been considered both adaptable and informative. Since the 1950s, for example, Carl Rogers and his successors have undertaken a series of quantitative investigations of client-centered therapies. Among the prominent findings from these studies, and continuing today, are (1) robust support for therapist relationship factors—e.g., empathy, warmth, and genuineness—over therapist technical offerings (e.g., skilled interpretations), and (2) support for client agency, as opposed to therapist directiveness, as central to successful therapeutic outcome (as discussed in Bohart et al.’s 1997 review). Recent meta-analyses (large-scale analyses of aggre-

gated studies) confirm these findings. These have found, for example, that fully 30 to 35% of the variance in general therapeutic outcome is accounted for by therapist and relationship factors whereas only 15% of the variance is accounted for by techniques or therapeutic approaches (as discussed in Bohart and colleagues' 1997 review). Coupled with the research on affective expression and therapeutic outcome (see, for example, the studies in Greenberg et al.'s 1998 work), these quantitative findings provide broad support for humanistic practices.

In addition to these broad findings, there is specific quantitative evidence for the effectiveness of specific humanistic outcome. For example, there is specific evidence for the effectiveness of client-centered therapy for a variety of disorders; there is also evidence for the effectiveness of Gestalt therapy; and there is considerable evidence for the saliency of the underlying principles of meditative, experiential, and existential modalities. (See the Cain & Seaman volume for an elaboration).

There have also been important quantitative investigations of humanistic psychiatric practices. Drawing from the foundational work of R.D. Laing, Loren Mosher and his colleagues have studied numerous psychiatric "safe-houses." These facilities emphasize relational over medical and egalitarian over hierarchical therapeutic environments. Such programs, concluded Mosher after a 25-year review, are as effective or more effective than conventional hospital care, and on average, less expensive.

With regard to human science or qualitative inquiry into humanistic therapies, particularly therapeutic outcome, there have been far fewer rigorous studies. While the reasons for this situation are beyond the scope of this article, suffice it to say that there is a burgeoning new interest in such inquiry. Increasingly, sophisticated qualitative designs are being developed, such as Robert Elliott's Hermeneutic Single Case Efficacy Design, David Rennie's Grounded Theory Method, Arthur Bohart's Adjudication Model, and Kirk Schneider's Multiple Case Depth Research. These innovative formats hold the promise for important new inroads into outcome assessment. In the meantime, humanistic therapies enjoy wide qualitative support in a variety of case, observational, and testimonial modalities; the current emphasis is on formalizing those modalities.

VI. SUMMARY

Humanistic therapy is a multifaceted perspective that emphasizes existential, constructivist, and transpersonal practice philosophies. Varied as they are, these philosophies explore (1) what it means to be fully, experientially human, and (2) how that understanding illuminates the vital or fulfilled life. By assisting people to grapple with these perspectives, humanistic therapies empower people to become more of who they profoundly aspire to be; and in consequence more of who they are.

GLOSSARY

implosive therapy A technique that involves use of an *in vivo* or imagery presentation procedure designed to extinguish via repetition those aversive conditioned cues responsible for eliciting and maintaining symptom execution.

neurotic paradox Why neurotic behavior is at one and the same time self-defeating and self-perpetrating.

imagery exposure Imaginal exposure of the feared or anxiety-evoking stimulus, using flooding in implosive therapy.

Implosive (flooding) therapy is a learning-based exposure technique of psychotherapy designed to treat a wide variety of maladaptive behaviors in a relatively short time period. The underlying theoretical model for this behavioral cognitive treatment approach to therapy is based on an extension of two-factor avoidance learning theory.

I. DESCRIPTION OF TREATMENT

A. Introduction

Imagine the suffering of a woman who becomes so panic stricken by the obsession she has cancer that psychiatric hospitalization is required. No matter how much medical assurance she is given that she is in excellent physical health, the nagging doubt somehow persists that she is not. Or consider a man who is forced to relinquish his professional career because he is afraid to leave his home out of fear that dog feces may be in his yard. His day becomes dominated with disturbing thoughts that find relief only in repetitious washing of his hands, clothes, and body. Perhaps it is hard to comprehend how one could become so frightened of bath water that a life preserver must be worn, or that a sound of a locomotive whistle in the distance evokes such terror in an individual that he runs around in a circle screaming at the top of his voice. The range of human fears may be extended almost indefinitely. Some individuals break out in a cold sweat at the sight of a car, an airplane, or a tall building. Others become so afraid of their own sexual feelings that they avoid the opposite sex, having become convinced they will be sent to hell for such feelings. Still others fear failure, loss of control, taking responsibility, being angry, or giving love and expressing compassion.

Committed to the goal of seeking methods to ameliorate such psychological suffering, the mental health

worker is confronted with the difficult task of selecting from hundreds of different treatment techniques. The rather chaotic state of the field today suggests the need to isolate and maximize the central procedural variables that appear to be reliably correlated with behavior change. One factor common to most treatment techniques stems from the observation that behavior change appears to occur following the elicitation from the patient of a strong emotional response to material presented during the therapeutic interaction. Implosive therapy is a treatment technique that is designed to maximize in a systematic manner the last-noted common denominator of therapeutic interaction, that of emotional responding and its resulting effects. Disillusioned with the insight-oriented emphasis of the time period, Thomas G. Stampfl in the late 1950s developed the technique of implosive therapy which some authors today call flooding therapy or response prevention therapy. Each of these terms is frequently used interchangeably in the literature since the goal of therapists is to maximize emotional responding by getting patients to confront their fears directly. Stampfl was the first investigator to extend systematically his learning-based exposure treatment approach to the treatment of a wide variety of clinical nosologies. Borrowing a term from physics he labeled his newly developed cognitive-behavioral approach implosion, to reflect the inwardly bursting (dynamic) energy process inherent in the release of affectively loaded environmental and memorial stimuli encoded in the brain.

Stampfl was initially influenced by the extensive clinical experience he gained from conducting "nondirective" play therapy with emotionally disturbed children. He concluded from this experience that exposure to the emotional stimulus features of the play material could account for virtually all the positive effects of therapy. Consistent with his clinical observations was the insistence by Abraham Maslow and Bela Mittleman in their 1951 abnormal text that the neurotic's symptoms, defense mechanisms, and general maladaptive behavior resulted from a state of anticipation or expectation of an impending catastrophic event, which, in turn, provided the motivating force for symptom development. These authors concluded that, although the catastrophic even usually remained unspecifiable by the patient, it generally involved fears associated with anticipation of abandonment, injury, annihilation, condemnation and disapproval, humiliation, enslavement, loss of love, and utter deprivation. Stampfl reasoned that if therapy was to succeed, these anticipatory fears, as was the case for the children he treated, needed to be

confronted directly in order for the unlearning of the emotional response attached to these fears.

B. *In Vivo* Exposure Approach

Stampfl at first adopted an *in vivo* exposure approach in which he instructed patients to confront directly in real life their feared stimulus situation. For example, one of his patients, a college student, reported a compulsive behavior he had engaged in for years. Upon retiring at night, this patient reported an urge to check to see if he had left the radio on. Every night (without exception) he checked the radio up to 50 times. He reported that any time he failed to engage in radio checking he developed much apprehension and anxiety and the feeling that something "terrible" or "catastrophic" might happen. He would fear, for example, that perhaps a short circuit would occur and a fire would result. Stampfl then instructed the patient to confront his fears directly by forcing himself not to check the radio and imagine that his worst fears would happen. He was asked to let himself tolerate as much anxiety as possible. The patient was able to follow the therapist's instruction; he reported seeing the radio burst into flames and hearing his father's voice telling him to "turn off the radio." Following additional repetitions of the therapist's instructions, the patient recalled a number of traumatic memories involving his father. Once the affect associated with these memories was eliminated, his compulsive symptoms disappeared.

C. Imagery Exposure Approach

Thomas Stampfl recognized that although this patient followed his *in vivo* instructions to confront directly the anxiety he experienced, most patients avoid engaging in an *in vivo* task because of the strength of the fear response associated with the task. He also recognized that many of the fears motivating the patient's symptoms did not lend themselves readily to an *in vivo* approach. He then developed his implosive imagery procedure, which was capable of being presented within the context of a therapy session. In an attempt to illustrate the above point, consider the case of an airplane phobic. Although most phobic behavior is clearly amenable to an *in vivo* exposure approach, the use of this procedure with an airplane phobic would entail the therapist's accompanying the patient on repeated airplane trips. Stampfl recognized that his imagery exposure procedure had the advantage of presenting the feared cues in the therapist's office. Furthermore, and

most importantly, the imagery technique has the additional advantage of introducing the more salient and emotionally intense fear cues associated with the phobic reaction that do not lend themselves to direct *in vivo* presentation. Examples of such fear cues include the fear of the plane crashing, the fear of dying, and the fear of being punished for guilt-producing behavior in the after-life. Imagery scenes involving the incorporation of these non *in vivo* presented fears have been clinically shown to produce a powerful emotional reactivity and subsequently a lasting therapeutic effect.

In summary, the fundamental task of the implosive therapist is to repeatedly re-present, reinstate, or symbolically reproduce those stimulus situations to which the anxiety response has been learned or conditioned. By exposing the patient to the stimulus complex of fear cues that are being avoided, the patient will be confronted with the full emotional impact of these cues. As a function of repetition, this emotional exposure weakens and eventually eliminates the connection between the eliciting stimulus and the resulting emotional response. For example, imagine a patient who is terrified of viewing horror films and takes a job as a movie projectionist which requires him to show such a movie. Although terrified during the first showing, by the tenth time he is exposed to watching the film little emotional reactivity is left.

It may at first seem that the goal of specifying the aversive learned events in the patient's life history represents a difficult, if not impossible, task. Stampfl noted that it is feasible for a trained clinician to locate "key" stimuli associated with the patient's problem area following in-depth diagnostic clinical interviews. This information allows a trained clinician to formulate hypotheses as to the type of traumatic events that may have contributed to the client's problems. Of course, these initial hypotheses must be conceived as only first approximations in the quest to determine the aversive cues controlling the patient's maladaptive behavior. As therapy progresses, it is usually possible to obtain additional information as to the validity of these cues and to generate new hypotheses. The elicitation of these hypothesized cues in imagery frequently results in the reactivation of the patient's memory regarding the initial historical events associated with development of the patient's conflict and fears. However, it is not essential to present imagery scenes that are completely accurate since some effects of emotional unlearning or extinction effects will occur through the established learning principle of generalization of extinction. Naturally, the more accu-

rate the hypothesized cues are and the more realistically they are presented by the therapist, the greater will be the emotional arousal obtained and subsequently the greater the emotional unlearning to the cues presented. This process is continued until the patient's symptoms are reduced or eliminated.

D. Procedural Instructions

Following the completion of two to three interview sessions, a treatment plan is developed. Patients are provided the rationale and theory behind the technique. A commonly used approach is to ask patients the following question: if they were learning to ride a horse and fell off the horse, what would the instructor have them do? (The usual answer is to get back on the horse.) The therapist might then comment that failure to get back on the horse might result in an increase in fear and possibly the generalization of that fear to events surrounding riding horses. The point is to illustrate that fears can be overcome by directly confronting them. Patients are told that the procedure being used involves an imagery technique and they will be asked to imagine various scenes directed by the therapist. Patients are instructed to close their eyes and play the part of themselves. They are asked, much as an actor or actress would be, to portray certain feelings and emotions that represent important parts of the process. They are told that belief or acceptance, in a cognitive sense, of the themes introduced by the therapist is not requested, and little or no attempt is made to secure any admission from patients that the cues or hypotheses actually apply to them. Following the administration of neutral imagery practice sessions, the therapist is ready to start. Once the implosive procedure is started, every effort is made to encourage patients to "lose themselves" in the part that they are playing and "live" or reenact the scenes with genuine emotion and affect. Compliance with the technique is readily obtained and rarely do patients terminate therapy prematurely.

Thomas Stampfl's procedure encompasses an operational feedback approach that is self-correcting. If the hypothesized cues introduced into a given scene presentation elicit emotional affect, support for their continued use is obtained. The greater the emotional arousal elicited by these cues, the greater the support for their use. Cues that do not elicit emotional arousal are abandoned and replaced by new hypothesized cues. This process is continued until the desired emotional affect is obtained and unlearned. Therapy continues until symptom reduction occurs. Significant levels of

symptom reduction usually occur within 1 to 15 hours of treatment.

E. Stimulus Cue Categories

As a guide in using the therapy, Thomas Stampfl has outlined the use of four cue categories that can be conceptualized in terms of progression along a continuum that ranges from extremely concrete to hypothetical. These four cue categories, in order of their presentation, are as follows: (1) Symptom-contingent cues, those cues correlated with the onset of the patient's symptoms; (2) reportable internally elicited cues, those verbally reported thoughts, feelings, and physical sensations elicited by presentation of the symptom correlated cues; (3) unreported cues hypothesized by the therapist to be related to the second cue category; and (4) hypothesized dynamic cues, those fear cues suspected to be associated with an unresolved conflict situation being avoided by the patient.

As an illustration of the application of these cue categories, consider the case of a woman who had to wear a life preserver while taking a bath. The symptom-contingent cues would encompass the presentation in imagery of all those cues surrounding her taking a bath without wearing a life preserver. Upon presentation of these cues, she reported the feeling that the bathtub consisted of a "bottomless pit of water," the second category. This in turn led to the therapist's hypothesis that she was afraid of drowning (third category). Because the patient manifested considerable feelings of guilt, the therapist hypothesized that the patient's fear of drowning related to her fear of being punished in hell (the fourth cue category). The systematic presentation and repetition of all these fear cues led to the elimination of the patient's phobic response and to the recovery of a memory in which she almost drowned in a bath tub when she was a child. Since repetition of the feared stimuli is considered an essential requirement in producing symptom reduction and elimination, patients are expected to conduct homework that involves 20 minutes daily of repeatedly imagining the scenes assigned to them by the therapist.

II. THEORETICAL BASES

Implosive theory is unique in its ability to integrate areas of psychology, in its resolution of the neurotic paradox, and in its ability to define complex behavior

according to basic principles of experimental psychology. To explain theoretically the development, maintenance, and unlearning (extinction) of psychopathology, Stampfl adopted and extended O. Hobart Mowrer's 1947 version of two-factor avoidance learning. Mowrer was influenced by Sigmund Freud's conclusion in 1936 that human symptoms reflecting psychopathology resulted from patients' attempts to escape and avoid the anxiety elicited by stimuli ("danger signals") associated with past exposure to traumatic experiences. Mowrer then concluded that the development and maintenance of human and animal avoidance (symptom) behavior involved the learning of two response classes.

A. Emotional Learning

The first response learned is how one becomes afraid of a previously nonaversive stimulus situation. To explain how fear is learned, Mowrer relied on the well-established laws of classical conditioning. Fear and other emotional conditioning result from the simple contiguity of pairing this nonemotional stimulation, in space and time, with an inherent primary (unlearned) aversive event resulting in the production of pain, fear, frustration, or severe deprivation. This biologically reactive, pain-producing stimulus is referred to as the unconditioned stimulus (UCS). Following sufficient repetition of the neutral stimulus with the UCS, the neutral stimulus becomes capable of eliciting the emotional response with which it was paired. Once the process is learned, the neutral stimulus is referred to as a conditioned stimulus (CS) and its elicitation of the emotional response (e.g., fear) as the conditioned response (CR). Stampfl believes the conditioning events of humans to be multiple, involving a complex set of stimuli comprising both external and internal CS patterns. Such conditioning events are believed to be encoded in long-term memory and capable of being reactivated at a later point in time.

B. Avoidance (Symptom) Learning

Mowrer viewed the resulting conditioned emotional response as a secondary or learned source of drive, possessing motivational or energizing properties, as well as reinforcing properties. These motivational properties of the conditioned emotional response set the stage for the learning of the second class of responses, referred to as avoidance or escape behavior. Avoidance or symptom

behavior is believed to be governed by the established laws of instrumental learning. Avoidance behavior is learned because the response results in the termination or reduction of the emotional state elicited by the CS. It is this reduction in aversiveness that serves as the reinforcing mechanism for the learning of the avoidance behavior.

C. Emotional-Avoidance Unlearning

Finally, Mowrer's two-factor theory argues that both emotional responding and subsequent avoidance behavior can be readily unlearned via the well-established principle of Pavlovian extinction. This principle states that the repeated presentation of the classically conditioned CS will weaken and cease to elicit emotional responding via the principle of non-reinforced CS exposure. The extinction of the CS results in the extinction of its drive properties. Without any motivating state to elicit and reinforce the avoidance behavior, it also will undergo an extinction effect. This is the therapeutic premise on which implosive therapy is based.

D. The Neurotic Paradox and Symptom Maintenance

Implosive theory has been instrumental in resolving Freud's expressed concern and puzzlement as to why patient's symptomatology may persist over the course of a lifetime. Mowrer labeled this concern the "neurotic paradox." In Mowrer's words it is a question as to why neurotic behavior is at one and the same time self-defeating and self-perpetuating. In other words, why does the neurotic's neurosis persist to the point of seriously incapacitating the individual when the behavior has long outlived any real justification?

To resolve theoretically the issue of sustained symptom maintenance, Thomas Stampfl developed his serial CS hypothesis. He observed that, although some clinical symptoms do appear to last for lengthy periods, the CSs initially eliciting the symptom frequently undergo a change over time, with the cues originally triggering the symptom failing to serve as an eliciting stimulus to repeated CS exposure. However, as they weaken, these cues are replaced from memory by a new set of previously unexposed fear cues that upon exposure recondition secondarily the first set of cues. When the new set of released cues also undergo an extinction effect from nonreinforced CS exposure, the stage is set for yet another set of new cues to be released. This process con-

tinues until all the encoded fear complex of cues undergo an extinction effect. In other words, implosive theory maintains that there is a network of cues representing past conditioning events involving pain which are stored in memory and which, upon reactivation, are capable of motivating a symptom over time. Thomas Stampfl believes these conditioned cues are stored in memory in a serial arrangement along a dimension of stimulus intensity, with the more aversive cues being least accessible to memory reactivation. Repeated symptom execution prevents further CS exposure to these cues and to the elicitation of those cues stored in memory. As a result, the anxiety and fear level attached to these unexposed CSs are conserved or maintained until they are exposed by being released from memory. The presence of these unexposed cues stored in memory, along with the intense emotional reactions conditioned to them, can be observed by preventing symptom occurrence.

III. EMPIRICAL STUDIES

Over the last 50 years, O. Hobart Mowrer's two-factor avoidance theory and related fear theories have generated an abundance of experimental support at both the human and animal level of analysis. It still remains the dominant avoidance theory within the field. Stampfl's extension of the theory to the area of psychopathology has also received strong empirical support at the human, animal, and clinical levels of analysis. This includes his serial CS hypothesis and his extension of the conservation of anxiety hypothesis to explain symptom maintenance and the neurotic paradox. Stampfl's techniques of *in vivo* and imagery implosive therapy and related CS-exposure techniques of treatment have been experimentally supported by a host of controlled clinical outcome studies, including studies involving the treatment of phobias, anxiety reactions, obsessive compulsive behavior, trauma victims, depression, and psychotic behavior. The procedure has also been shown to be nonharmful. Today, CS exposure techniques of treatment are regularly recommended as the treatment of choice for a number of clinical nosologies.

IV. SUMMARY

Implosive (flooding therapy) therapy is a cognitive behavioral treatment approach to psychopathology. It was first developed by Thomas G. Stampfl and extended

to encompass the treatment of a wide variety of clinical nosologies. Treatment effects are regularly reported to occur within 1 to 15 treatment sessions. The technique involves the use of an *in vivo* or imagery presentation procedure designed to extinguish, via repetition, those aversive conditioned cues responsible for eliciting and maintaining symptom execution. The therapist's task is to help the patient confront these cues directly within and outside the therapist's office. The underlying theoretical framework behind this technique is based on two-factor avoidance theory which Stampfl has extended to account for symptom maintenance and symptom extinction. Both the theory and treatment technique has been supported by considerable experimental research over the last 40 years at the human, patient, and animal level of analysis.

GLOSSARY

behavior therapy A theory of psychotherapy in which problems are assumed to have been learned because the consequences of problematic behavior and feelings are rewarding. These treatments attempt to directly alter behavior and feelings by changing the pattern of consequences. The development of these models of treatment is most closely associated with Joseph Wolpe and B. Fred Skinner.

cognitive therapy/cognitive-behavior therapy Models of psychotherapy that attribute problematic feelings and behaviors to one's inappropriate or dysfunctional ways of thinking. The most recognized of these approaches was developed by Aaron T. Beck.

effectiveness studies Research designs that employ representative clinical populations of patients, as well as samples of therapists and psychotherapy. This type of research typically sacrifices some degree of experimental control for procedures that are closer approximations of actual clinical settings, procedures, and populations.

efficacy studies Research designs that employ randomized assignment, closely controlled and monitored treatments, and carefully selected and homogeneous samples of patients. This type of research typically sacrifices some degree of generalizability for experimental control.

experiential therapy Approaches to psychotherapy that emphasize the positive role of feelings and current experience. These approaches assume that efforts to stifle or avoid certain feeling states are at the basis of most human problems. They emphasize the role of the present, of feeling recognition, and of the innate human drive to grow (self-actualization) as processes that produce beneficial change.

exposure therapy Approaches to treatment that emphasize the importance of systematic exposure to situations and objects that evoke avoidance. This is a form of behavior therapy but has been incorporated into many models and approaches to cognitive and cognitive-behavior therapy as well.

integrative/eclectic psychotherapy Methods of intervention that draw from multiple theories. These approaches emphasize that the effectiveness of the procedure rather than its theoretical framework should be the guide to its application. These approaches range from those that blend different theoretical constructs to those that develop a case mix of specific techniques. Newer models are based on the development of cross-cutting principles of change rather than amalgamations of either specific techniques or general theories.

psychoanalysis The method of uncovering unconscious impulses and wishes that was developed by Sigmund Freud.

psychodynamic therapy: Approaches to psychotherapy that generally assume that behavior is caused by inner conflict and by disturbed psychic processes. These models of individual psychotherapy are generally short-term or less intensive variations of psychoanalytic therapies. Some of these variations include those built on object relations theory, ego psychology, and self-psychology.

Individual psychotherapy is the most typical form of psychotherapeutic treatment. It consists of one patient and one therapist. The psychotherapist, assuming the role of healer, authority, facilitator, or guide, employs a variety of theories and procedures to assist the patient or client to modify behaviors and feelings, gain understanding of self and others, change perceptions and beliefs, and reduce fears and anxieties. This entry will describe some of the more dominant methods of psychotherapy and the current status of research on its effects.

I. DEVELOPMENT OF INDIVIDUAL PSYCHOTHERAPY

The field of modern psychotherapy is over 100 years old. Freud is typically credited as the individual most responsible for introducing contemporary psychotherapy, in the form of psychoanalysis, to the Western world at the end of the nineteenth century. Almost from its inception, the developmental history of modern psychotherapy has been one of conflict, controversy, and change. Freud's early views were under attack nearly from the beginning, both from his students and from the established medical system. Conflict continues with the trend of growth and the emergent influence of various groups who present views that contrast with established schools of thought. In this environment, we have seen the emergence of literally hundreds of different theories and approaches to psychotherapy. Presently, psychotherapies differ in their theoretical constructs, their mode of delivery, their techniques, and the processes to which they attribute the patient's problems.

Those who are endowed by society with conducting and overseeing the field are also diverse, ranging from those with medical and psychological degrees to those with degrees in sociology, human development, social work, anthropology, group process, biology, and the like. Opinions about the nature of desirable credentials, advantageous types of experience and training, and the nature of psychotherapy itself are far from uniform. Yet, the prototype of "Individual Psychotherapy," a process that occurs between an individual person who has a problem and an individual practitioner who offers assistance, as originally set by Freud, continues to be the dominant model. Although there has been a good deal of research and writing on group therapy and to a lesser extent on marital and couples therapy, it is individual psychotherapy that has stimulated the most research and to which most conclusions are addressed.

Psychotherapy has increasingly come to be defined as a health-related activity and has thereby come under the purview of third-party payers and political bodies. Cost containment concerns have placed increasing pressures on practitioners to justify their procedures and to demonstrate that they are effective. This, in turn, has led to increasing emphasis being placed on those who conduct psychotherapy research to demonstrate the value of these procedures in ways that have scientific credibility.

II. Theoretical Models of Individual Psychotherapy

It has been estimated that there are over 400 different theories of individual psychotherapy. However, most of these fall within five general classes.

Cognitive psychotherapy models of intervention focus on identifying specific problems and changing the processes and mechanisms by which patients evaluate themselves, others, and their environments. A central assumption of this model is that beliefs rather than facts determine how one will evaluate one's own behavior, remember the past, and anticipate the future. If one's beliefs are distorted and inaccurate, then one's evaluations and memories will be distorted as well. Moreover, one may develop behavioral or emotional disturbances in which the behavior and feelings, too, are inappropriate to one's present situations. Distortions and misperceptions of events are assumed to be at the root of or associated with many problems that impair daily functioning. Cognitive psychotherapy applies methods that encourage re-inspection of these assumptions and the application of rational analysis to correct distortions and cognitive errors. This type of treatment focuses on directly altering one's symptoms through a process that involves the rational and realistic appraisal of situations and the application of thoughtful and systematic problem solving strategies.

Behavior therapy models of individual treatment focus on immediate events and consequences. Symptoms are thought simply to reflect patterns of learning that are cued by the presence of evoking environmental stimuli. That is, behavioral models eschew the use of mental or biological events as explanations for behavior. They look for both causes and consequences within the person's immediate environment or in the concomitant occurrences of sequential cues that progress to more remote consequences. The focus of such treatments is on the development of new skills and on repeated exposure to aversive stimuli leading to extinction of behaviors

that are excessive and repetitive. In this model, the therapist is a guide and instructor rather than a philosopher and healer. Indeed, postulations of illnesses are thought to obfuscate the factors that support and reinforce dysfunctional and disturbed behaviors.

Interpersonal psychotherapy models emphasize that all behavior, whether problematic or adaptive, occurs within a social context. That is, they focus on social and intimate crises such as loss and expected loss, transitions to new social environments, skills to navigate social expectancies and demands, and mediating the competing expectancies and desires that emerge when one enters into relationships with other people. This form of treatment assumes that there are a finite number and type of interpersonal problems that relate to such conditions as anxiety and depression. Interpersonal treatment involves identifying the problematic interpersonal patterns, creating understanding of the interpersonal nature of one's problems, learning to anticipate when problems will emerge, gaining a meaningful understanding of one's own behavior, and developing skills of communication and assertion that can be applied in competitive environments. The therapist assumes an authoritative role in directing the patient through a process of identifying and exploring the nature and causes of one's problems and directs the patient in a process of selecting and using effective procedures for ameliorating these problems and developing improved interactions with others.

Psychodynamic/psychoanalytic psychotherapy models are widely varied but are bound by a common emphasis on the indirect relationship between behavior and environment. That is, disturbed behavior and feelings are thought to reflect internal conflicts rather than current events. The conflicts are symbolized by symptoms and are thought to derive largely from primitive experiences that predispose patients to continue to reenact certain dysfunctional patterns of behavior in a vain effort to obtain a resolution in the present for a conflict whose nature is out of awareness and whose genesis is in the past. Thus, in contrast to other models, neither immediate situations nor dysfunctional thoughts cause disturbance. Indeed, these situations and thoughts are thought to more likely be the consequences of the individual's effort to resolve conflict rather than the causal agents of psychopathology. That is, current behaviors and situations may reflect the disturbance that is caused by the turmoil of inner struggles between contrasting impulses and wishes. Usually, the nucleus of these inner conflicts is kept unconscious by innate efforts to protect one's self from painful

awareness. Thus, the patient does not acknowledge, understand, or know the motivation behind behavior. Improvement is thought to relate to the development of insight and awareness, uncovering these unconscious processes, and becoming aware of how past experiences and filial needs, rather than current demands and exigencies, are determining one's current behavior.

Experiential psychotherapy models focus on problems that are associated with the failure to integrate emotional experience with either thoughts or behaviors. They adopt the viewpoint that from traumatic experience and interpersonal crises early in life, individuals learn ways to protect themselves from experiencing strong emotions. These defensive patterns typically involve separating one's self from one's emotional state and learning to be oblivious to personal emotional cues. Overreliance on rationality, on action and "doing," rather than on feeling and awareness is thought to arise when social forces encourage one to lose sight of inner experiences or to distort and suppress emotional drives and experiences. Experiential treatment is based in the here and now of immediate experience. It endeavors to identify current feelings and to bring these into high relief, often magnifying and enhancing these experiences in order to encourage emotional processing. In this process, the therapist attempts to foster the integration of emotional, behavioral, and cognitive life.

Experiential treatments strive to keep patients in the emotional present rather than retreating to thoughts of the past or future. They encourage patients to learn to tolerate strong feelings without withdrawal, attempting to help them remove their internalized, socially imposed sanctions against such feelings.

III. THE EFFECTS OF INDIVIDUAL PSYCHOTHERAPY

A. Models and Theories

Scientific research over the past 40 years confirms that individual psychotherapy is an effective method for initiating personal change and reducing feelings of unhappiness, stress, and conflict. Its effects are substantial and compare well to alternative treatments for emotional problems, such as psychoactive medication. In recent years, considerable attention has turned to efforts to identify which of the many available models and theories of treatment yield positive effects among different patient groups. Research on these various

models or types of psychotherapy indicates that substantial improvements are associated with their use—relief can be reliably achieved in various kinds of symptoms and problems.

Among the most widely accepted methods and models, those based on cognitive-behavioral, behavioral (e.g., exposure therapy), and interpersonal therapy principles have been most consistently identified as being effective. Models that have received some, but less, support from research, include those that are constructed around psychodynamic principles and emotional awareness or emotion-enhancing therapy (e.g., experiential therapy). Cognitive therapies have been identified as especially effective for treating depression, anxiety, general distress, chemical abuse, and specific anxiety disorders (e.g., obsessive-compulsive disorder, agoraphobia, panic disorder). Behavior therapies are identified as effective for treating depression, psychophysiological disorders (e.g., headache, rheumatic disease), and habit control problems (e.g., smoking, drug/alcohol abuse, enuresis, etc.). Experiential therapies are identified as effective for depression and relationship problems. Interpersonal therapy is identified as being effective for treating depression and eating disorders. Psychodynamic therapies are considered useful for depression, chemical abuse, and social distress.

B. Specific versus Common Contributors to Change

In his classic treatise on *Persuasion and Healing*, Jerome Frank defined psychotherapy as a form of interpersonal influence that involves (1) a healing agent in the person of the therapist, (2) a patient who seeks relief of his or her suffering from the healer or healing agent, and (3) a healing relationship comprised of a circumscribed, more or less structured series of contacts between the healer and the sufferer in which the healer attempts to bring about relief.

By restricting his definition of psychotherapy to these three elements and excluding specific mention of any of the myriad procedures and therapeutic models used by therapists to effect recovery or improvement, Frank underscored what has become a major point of controversy in the field. Namely, does the use of particular psychotherapeutic models and procedures add benefit to that which is obtained from a supportive and caring psychotherapeutic relationship alone? The essential controversy embodied in this question can be distilled to a conflict between those who attribute healing to the use of specific techniques and procedures (i.e., specific “antipathogenic” psychotherapeutic inter-

ventions) and those who attribute psychotherapeutic healing to the effects of a supportive, caring, and evocative therapeutic relationship in its own right—a medical versus a humanistic view of change.

Adherence to a medical analogy has resulted in the admonition that practice be restricted to the use of interventions that have been supported by scientific research. Scientists who look for the differences among psychotherapeutic treatments have advanced and published lists of effective treatment brands and have identified various diagnostic conditions for which each brand of treatment is considered to be effective. However, this line of investigation may oversimplify the difficulty of garnering evidence of efficacy on the 400+ different models of psychotherapy that are currently practiced in contemporary Western society. Restricting practice even to the 150 or so treatments that have been scientifically supported would mean that much of the service that is currently provided in hospitals and clinics throughout the world would have to be discontinued. Furthermore, even if society were to embrace this view and undertake a systematic study of these various treatments, the results may tell us very little about some of the more important and powerful contributors to treatment gain. Research strictly based on fitting brands of treatment to diagnoses of patients will tell us very little about the various modes and formats through which psychotherapy is applied and virtually nothing about the contributions of important nondiagnostic patient qualities and individual therapist variations.

To those who emphasize the similarities among treatments, rather than the differences, such lists of brand-name models inappropriately imply that there are more differences among the various models than have been consistently demonstrated. The qualities that contribute to the development of a healing relationship and those that dictate the specific use of different treatments may have little to do with the patient's diagnosis or the brand name of the treatment provided. By extension, many authors suggest that focusing on differences among brands and models of psychotherapy discourages research on ways both to enhance the presence of therapeutic relationships and to blend interventions across therapeutic models.

Many of these same authors suggest that the effort to identify certain brands of treatment that fit with patients who are identified only by diagnosis would both require that therapists learn many different and frequently contradictory treatment models and that clinicians could only treat a limited and perhaps insignificant number of patients—those who comply with certain inclusion and exclusion criteria.

The use of a medical analogy and the corollary assertion that practice should be restricted to empirically supported treatments applied within the confines of patient samples on which they have been systematically tested is one way to increase the credibility of mental health treatment in a political world. It reflects an effort to place psychotherapy on a parallel with medical treatments for diseases—effective treatment depends on accurate diagnosis, and once diagnosis is established, one should select and apply a treatment that has been scientifically demonstrated to be safe, practical, and effective in the treatment of that condition. From this perspective, the field would do well to consolidate around a uniform effort to find or develop specific procedures that work with particular kinds of problems and conditions.

Working from this viewpoint, clinicians and researchers alike are continuing to develop new theoretical models and technical methods of intervention, with the implicit assertion that these specific techniques and procedures are responsible for the effects of treatment, either positive or negative. This point of view has generated hundreds of theoretical constructs and causal inferences that describe the nature of effective psychotherapy. Each of the resulting theories and procedures vies for the status of being “most effective.”

Controversies between those who attribute change to the elements that are common to all treatments and those who attribute change to specific and unique treatments that derive from certain brands of treatment are not unique to psychotherapy. The past decade has seen the emergence of similar conflicts in the general area of health and medicine as well. Placebo effects, expectancy, hope, and other constructs are implicated in the treatment of a wide array of medical and health conditions and compete for effectiveness with active drugs, surgery, and other interventions that are based on contemporary notions of illness. Clearly, whatever else is working, both physical health and emotional/behavioral well-being rely more than most would acknowledge on the forces of interpersonal persuasion, expectation, faith, and relationship, and less than some would wish on the specifics of pathology-based treatments.

In contrast to the specific treatments approach, the common factors viewpoint focuses on the interpersonal qualities that are correlated with change rather than with the technical ones. Scientists from this camp point out that virtually no direct comparison of one legitimate treatment against another yields any meaningful differences between them. Most who review this latter body of literature conclude that “all have won and all must have prizes.” From the bulk of existing

data, it is not scientifically sound to conclude that there are any treatments that are uniquely effective. To many of these scholars, it is the ubiquitous qualities of support and caring within the patient–therapist relationship that are seen as signals in evoking change in all of these treatments. Proponents of the common factors model consider these relationship qualities to be relatively independent of the specific procedures and techniques used—they are based largely on the nature of the relationship or the bond that develops between patient and therapist. That is, common factors proponents conceptualize a healing relationship as one that instills hope, facilitates communication, conveys safety, and is imbued with the patient’s respect for, and trust of, the therapist.

These two viewpoints color how one perceives the extant research literature. For example, investigators who seek to identify specific treatments that work best with patients who carry different diagnostic labels are gratified by evidence that some treatments may produce substantially better effects among patients with different disorders than various comparison treatments or control groups. However, these same investigators tend to ignore the abundance of evidence indicating that all treatment studies produce essentially equivalent results. At the same time, researchers who believe that all treatments owe their effects to common interpersonal processes find their viewpoint reinforced by evidence that relationships and alliances are consistently related to outcomes but ignore the absence of direct evidence of a causal (rather than simply a correlational) relationship between alliance and outcomes. These investigators see the similarity of outcomes among different psychotherapy models as evidence for the causal nature of common factors, but no studies have been published that clearly demonstrate such a causal chain. For example, alliance may simply be a consequence of change rather than a cause of change.

It is certainly persuasive to look at the consistent correlation that exists between treatment qualities and outcomes, and to conclude that the many diverse therapeutic procedures that are effective all exercise their effects through the medium of improving the patient’s sense of safety, comfort, and support. Thus, it is popular to conclude that therapists who provide safety, while being collaborative and supportive, are likely to produce good effects regardless of the specific procedures or theories used. Such a conclusion lacks the necessary scientific support to conclude that the observed correlation is the result of a causal chain of events. It is equally plausible that change itself may cement and

foster warm and caring relationships, for example. It is also scientifically unjustified at present to conclude that some treatments are better than others.

Out of this awareness has emerged a third group of individuals within the individual psychotherapy movement who have attempted to integrate the opposing views of therapeutic specificity and therapeutic commonality. Members of this third group hold that the principal reason treatments don't show significant differences is that they have been tested on groups that are too homogeneous. They observe that within any treatment, there are some patients who get better, some who get worse, and some who fail to change. This pervasive pattern constitutes strong evidence that undisclosed patient factors are interacting with treatments. These scientists also hold that most research fails by attending only to therapy or relationship factors, and they assert that patient qualities themselves as well as the fit between patient qualities, and the procedures used also contribute to outcome. Indeed, they assert that patient qualities, therapy procedures, treatment relationship, and the fit or match between patient and treatment qualities are likely to make independent contributions to treatment benefit and that if relevant patient and matching qualities could be identified, the accuracy of predictions and the power of treatments could be substantially improved.

Contemporary research provides some evidence that while no specific procedure holds a mean or average advantage over others, there are some patient characteristics that mediate or moderate the effects of treatment, moreover, while the therapeutic relationship is very important, it may be more or less important depending on a variety of patient proclivities and the psychotherapeutic techniques utilized. Integrative and eclectic psychotherapy models accept the assumption that at least some interventions from widely different models are equally appropriate for some symptoms, some people, or some occasions. These models also assume that all treatment models are inappropriate for some people and that different people may benefit from different treatments. Some of these models simply blend two or more theories to make one new theory that is compatible with the techniques from more than one theoretical position. Other models attempt to directly identify patient markers that will indicate when to use different procedures and techniques of treatment, each representing different broad-band models.

Relatively new approaches within integrative and eclectic field have directed attention away from deriving finite lists of either theories or techniques, asserting that

integration is best achieved by identifying cross-cutting principles that govern behavioral change in any of several different individual therapy formats. These latter approaches attempt to develop prescriptive treatment programs based on trait and statelike characteristics that the patient brings into the treatment relationship. Research is accumulating to support this point of view and to suggest that cross-cutting principles and discriminative use of different treatment procedures tend to enhance treatment outcomes. At present, these three points of view are yet to be reconciled. Moreover, the diversity of viewpoint and of research interpretation embodied in these views underlie the presence of other cardinal issues in the field of individual psychotherapy.

C. Lesser Issues in Individual Psychotherapy

As individual psychotherapy begins its second century as an accepted treatment for emotional, behavioral, and mental disorders, it is faced with a variety of complex and difficult problems. These problems are largely occasioned by threats to the credibility of this form of treatment.

I. The Proliferation of Psychotherapy Models

In the past three decades, the sheer number of available and practiced psychotherapies has grown exponentially, now reaching several hundred. All or at least most of these theories purport to offer both an explanatory model of psychopathology and a model of treatment change. In almost all theories, the model of psychopathology, incorporates an explanation of normal behavior by invoking developmental and situational factors, as well as an explanation of deviance by invoking pathogens and insidious precipitators of disorder and disease. The explanations extend to all disorders and identified conditions, and, if they exclude a causal explanation of any type of psychopathology at all, it is an explanation of those disorders that are judged to be outside the influence of interpersonal persuasion methods. Thus, all theories undertake to explain virtually all behaviors and to develop concepts that can fit all persons. Although psychotherapists may be comfortable with this breadth, it does not instill great faith in the idea that psychotherapists really know what produces change and what is healing in the patient-therapist exchange. Those within the managed health care environment who are in charge of assigning treatments to patients are likely to find the process of distilling the truly effective treatment from among 400 or so theoretical descriptions rather daunting they may

conclude that a theory that explains everything really explains nothing.

Even among clinicians, the proliferation of theories and models may be taken as an indication that none of the models really works well. Clinicians are likely to develop new models when old ones don't work. Certainly, the fact that the highest percentage of clinicians identify themselves as being "eclectic" supports the view that no one theory is satisfactory. It is no wonder that psychotherapy has lost credibility both among patients and among managed health care providers, both of whom seem to believe that the various models and methods are interchangeable—there is no real or meaningful difference among them. Thus, a patient is recommended for or seeks psychotherapy for a condition or symptoms like depression; patients rarely seek a specific type of psychotherapy. In the rare instances in which a patient does seek a particular kind of therapy, typically one in which he or she has become familiar through friends or through reading, these treatments are likely to be rather exotic or unusual therapies. Predominantly, patients seem to view the particular therapist as being more important than the theoretical model from which he or she practices.

2. Criteria of Effectiveness

One of the major controversies in the field is how treatment effectiveness should be judged. Many psychologists believe that the best test of the worth of a psychotherapeutic treatment is in the observations of the clinician who exercises judgement and forms an opinion based on his or her theories of psychological disturbance and the elements that facilitate change. Such opinions, however, are by their nature very subjective; they cannot be reliably replicated, and their validity is highly suspect.

The usual criteria by which a treatment is judged to be effective is based on how persuasive, sincere, and articulate a clinician may be. These factors determine how effective a therapist is in persuading fellow clinicians to adopt his or her philosophy and perspective about psychotherapy. Political and legal criteria of a treatment's value are equally subjective and rarely focus on what the actual impact of the treatment is at the level of the patient's problems. Factors such as treatment cost, number of people accessed, popularity, and acceptance among peers are all considered in these criteria and frequently take precedence over actual effectiveness at altering symptoms and resolving problems.

In North America, as health care companies continue to struggle with the cost containment of mental

health services, managed health care has increasingly turned to more objective methods of assessing whether a treatment is appropriate. Some professional groups have emphasized the need for a scientific standard by which to judge a treatment's worth and have suggested certain research-informed standards by which to assess effectiveness.

By far the biggest obstacle to developing a uniform, research-based standard of care is that most contemporary approaches to treatment have not been subjected to empirical test. Nonetheless, a number of well-developed efforts have been made to translate the available research into standards of care or guidelines to direct practitioners. These guidelines typically specify the priority of various models and identify which ones among them have achieved empirical support through scientific research. A continuing obstacle to the implementation of these guidelines involves the sheer number of treatment models available.

Recognizing that it is difficult for clinicians to learn several different theoretical models and that often these guidelines are overly rigid, some authors have argued for a set of standards that emphasize empirically derived principles of psychotherapeutic change rather than either techniques or whole theories. This approach identifies various principles of selecting and applying treatments that are sensitive to ways in which patients differ from one another in their receptivity to different techniques, models, or therapeutic styles. It also emphasizes the need to customize the treatment to each patient, usually by mixing and fitting specific interventions or general styles to defined patient characteristics.

3. Integration of the Science and Practice of Psychotherapy

In these several ways, research findings are becoming more central to clinical practice, though this merger is frequently mandated by law and policy rather than being the result of a voluntary effort. Moreover, without a clear standard for assessing the scientific standing of various models of intervention, whatever merging or integration does occur is difficult to evaluate.

One of the most enduring and complex problems facing the practice of individual psychotherapy is the way in which scientific and clinical observers come to integrate their findings. This problem is complicated both because clinicians who practice psychotherapy and scientists who evaluate it have very different belief systems and perspectives. These differences underlie many of the disputes over the criteria by which to evaluate effectiveness and undermine the credibility of the treatment

itself. Some of the differences that exist between scientists and practitioners are embodied in what kind of research methodologies are most valued. Scientists have tended to value studies of efficacy, whereas practitioners tend to value studies of effectiveness.

Efficacy studies are typically characterized by the use of a highly defined sample of patients, a well-trained cadre of clinicians, random assignment to well-structured and specific treatments, and systematic measurement of outcomes. They contrast with effectiveness studies, which are often less controlled, with more typical samples of therapists and patients, clinical assignment procedures, and less systematic treatments and measures. Although these labels represent the end points of control and generalizability in psychotherapy research, there is ample reason to believe that the distinction between them is more arbitrary than real. Efficacy studies frequently use complex, clinically representative samples, real therapists, and clinically meaningful measurements, whereas effectiveness studies often include random assignment and controlled treatments. In the final analysis, the critical question is the clinical utility of research, by whatever method it is conducted.

Perhaps a more important factor in keeping scientists and practitioners apart is that within both the camp of practitioners and the camp of scientists, there are many factions. In this chapter, we have already pointed to the many different clinical theories that guide treatment, but equally problematic is the fact that scientists themselves have disparate interpretations about what contemporary research tells us.

At the present time, there is no well-accepted way to translate research findings directly into practice or for researchers to be very responsive to clinician opinions and needs. Some argue that a new model of research is needed that adequately addresses the problems of practice. This model would systematically include clinical as well as research perspectives in treatment.

IV. SUMMARY

Over the 100 plus years since it emerged as a formal professional activity, psychotherapy has proven itself to be both popular and effective. Individual psychotherapy is by far the most widely researched and practiced, and it sets the general standard of efficacy and effectiveness by which other approaches can be assessed.

With the popularity of individual psychotherapy has come a burgeoning number of practitioners representing various professional backgrounds and types of

training. Moreover, there has been an exponential growth in the number of theories used to describe the psychotherapeutic process and to guide one's work. Research has demonstrated that some of these approaches are effective, but most psychotherapeutic practices do not rely on scientific research for justification. Clinician experience and impressions are the most frequently used yardsticks by which to judge when treatment is effective and is working. However, this situation seems to be changing, and contemporary political movements and health care programs are recognizing the need to identify which treatments are effective and which ones are not. This movement has introduced a number of changes in the field of psychology. It has brought increasing pressure on clinicians to justify their practices in terms of research findings, and this development has placed more emphasis on making research that is clinically applicable.

As a result of changes in the health care environment, the disparities within the field of psychotherapy research as well as those between science and practice are becoming more apparent. New models are needed and are developing, both for making research more applicable and for applying research findings to the task of directing the course of treatment.

of confidentiality. This article provides a description of the components of informed consent and methods of obtaining valid consent. Next, the article discusses the legal and ethical bases of the concept. Finally, a review of the available research on ways of obtaining informed consent and the impact that written forms have on the therapy process is provided.

GLOSSARY

confidentiality The ethical (and often legal) requirement to restrict disclosure of client information outside the therapy sessions.

mandated reporting of child abuse The legal requirement in all 50 states that psychologists report to authorities reasonable suspicion of physical, sexual, and/or emotional abuse of a child under the age of 18.

reasonable patient standard The prevailing standard employed when determining the amount of information to provide to clients in order to obtain consent for treatment. Although it is not clearly defined, this standard requires clinicians to provide as much information as a reasonable patient would desire.

Clinicians have an ethical and often legal obligation to obtain consent from clients prior to treating them. In order to obtain valid consent, clients must be fully informed regarding the nature of psychotherapy, including, for example, the potential benefits and risks of treatment, alternative treatments available, and limits

I. DESCRIPTION OF INFORMED CONSENT

Initially, informed consent was a medical concept applying only to physicians and surgeons. The concept was circumscribed, requiring only that doctors tell patients the type of treatment recommended. Within the medical community, the concept eventually was expanded in scope, requiring physicians to give patients enough information about different available treatments so that patients could make educated decisions as to whether to accept a particular form of treatment. More recently, the concept has been incorporated into other disciplines, such as psychology.

As it applies to psychotherapy, the current doctrine of informed consent requires a client to be informed of the potential benefits and risks of the contemplated treatments, the expected prognosis with and without treatment, and any possible alternative treatments. Barring exceptions such as emergency treatment, a person cannot be given therapy without his or her informed

consent to such procedures. Underlying the concept of informed consent is the principle that allowing a client to make an informed decision respects that person's autonomy and self-determination.

Valid consent implies that the client agrees to treatment intelligently, knowingly, and voluntarily. Intelligence, sometimes referred to as competency, is defined as a client's capacity to comprehend and evaluate the specific information that is offered, whereas knowledge is defined as a client's ability to appreciate how the given treatment information applies to him or her specifically. Finally, the voluntary element suggests that a client's consent may not be coerced or enticed by the treating agent. All three elements must be present in order to consider consent truly informed and valid.

The first element of competency or intelligence is a difficult concept for two reasons. First, there has been considerable debate over how much information should be given to a client to allow him or her to make an informed decision. Second, the concept is often difficult to assess with child clients.

Regarding the debate over the extent of information provided, historically there have been two standards employed to determine whether the client has received adequate information. The first is a professional standard, which requires that the amount of information provided to a client be what other professionals in the community typically provide. The professional standard has been criticized for being somewhat paternalistic, in that clinicians determine the extent of the information that is provided to clients. The second standard is the reasonable patient standard, which requires the professional to give as much information as a reasonable patient would desire to make treatment decisions. The major problem with this standard is the difficulty in quantifying the exact amount of information a reasonable patient would desire. This standard does, in addition, put the onus squarely on clinicians to provide information, even when not requested by a particular client. In recent years, the reasonable patient standard has been the prevailing model.

Regarding child clients, it should be noted that the right to give consent is a legal one that is based on a client's presumed ability to understand the information given. In general, only adults are considered able to understand treatment information and to be legally competent to give consent. In many states, minors are not legally competent to give consent; instead, consent for treatment must be obtained from a legal guardian or parent. However, some state statutes give minors limited rights to consent to treatment. For example, in Oregon, state law allows children 14 years of age and older to give

valid consent for outpatient mental health treatment without the consent of parents. Other states' statutes recognize the mature minor exception, granting minors near the age of majority or mature enough to understand and weigh treatment options the right to consent to treatment. Regardless of state law, it is important to involve even young children in the process of obtaining consent. Despite the fact that state laws often do not recognize their capacities, research has found that even young children may be capable of understanding and weighing treatment options. Given these findings, clinicians should endeavor to obtain assent to treatment from children ages 7 and older. The term assent does not imply legal consent; however, it suggests that young children should be given relevant treatment information and asked whether or not they wish to participate in treatment. If a child does not want to participate in treatment, despite parental consent, ethical principles dictate that the clinician should consider the best interests of the child. Such a dilemma would involve considering and respecting the child's autonomy while recognizing the legal authority of the child's parents.

Although providing information about treatment is necessary to ensure a person's consent is done intelligently, it is not sufficient to obtain informed consent from a client. In addition, a client's knowledge or ability to appreciate that the material is relevant to him or her specifically must be assessed. In order to ensure that a client fully appreciates the information provided, a clinician must regularly question the client's comprehension of the material. One way of assessing comprehension is to ask a client to repeat, in his or her own words, treatment information that was presented previously. Only with a reasonable appreciation of the information will consent to treatment be considered valid. By the reasonable patient standard, clinicians bear the responsibility of ensuring that clients understand and appreciate the treatment information given.

Finally, in order to satisfy the requirement that consent be given voluntarily, no undue pressure may be placed on the client by the treating agent. For example, clinicians should avoid promising miraculous and timely cures; they should also avoid offering financial incentives for participating in treatment. To ensure the voluntary element necessary to valid consent, clients must be told that they can withdraw from treatment at any time.

The limits of informed consent should be noted by clinicians. Obtaining informed consent does not provide permission to clinicians to perform illegal or unethical acts. For example, a therapist cannot justify sexual acts with a client by claiming that informed consent for these

acts as part of treatment was obtained from the client. In other words, there clearly are limits on those things to which a client can validly consent.

Given the three elements of valid consent, it should be clear that obtaining informed consent is not a one-time incident but instead is an ongoing process throughout treatment. Several authors have suggested that clinicians adopt a process model rather than an event model of informed consent. Ongoing discussions with clients throughout the treatment process may be necessary to ensure that they have sufficient opportunities to ask questions and have information clarified. At a minimum, there are two discrete times during the therapy process when informed consent should be obtained: at the initiation of therapy and when particular treatments are proposed.

At the initiation of therapy, clinicians should provide general information on the nature and process of therapy to potential clients. Informed consent for treatment generally should be obtained at the beginning of the very first session, prior to obtaining potentially sensitive information, conducting assessments, or implementing any treatment techniques. The following information should be given at the initial session to assure informed consent. First, clients should be told the qualifications of the therapist and any supervision that is required. Second, clients should be told the limits of confidentiality (e.g., mandated reporting of child abuse) and general client rights (e.g., the right to withdraw from therapy at any time). Finally, clients should be told logistical information, such as scheduling practices and fee structures.

In addition to general information on the nature of therapy, the informed consent process should continue when specific treatments are proposed. At this time in the therapy process, clinicians should provide information on the purpose of the proposed treatment, any possible discomforts or harms, and any potential positive benefits. In addition, clients must be told about alternative treatments available and the possible risks and benefits of these treatments. Finally, clients must be told that no treatment is an option and must be informed of the possible consequences of opting out of treatment.

It is imperative that clinicians document this ongoing process of obtaining informed consent. The first major point of documentation is at the first session. At that time, clinicians are advised to employ a written information sheet that is read and signed by the client. Although there are many variations of this form, it should be written in plain language free of jargon or legalistic phrases and should contain the information

necessary for the client to make an informed choice regarding whether or not to participate in therapy. However, it should be noted that a signed informed consent form is not enough to demonstrate knowledge, one of the three elements of informed consent. To document client knowledge, clinicians should include in a progress note any client questions or statements that indicate that the client has a full appreciation of the information given. The second major point of documentation is when specific treatment techniques are proposed. At that time, clinicians should carefully document in progress notes the treatment options presented to the client and any questions asked by the client. Standard of care issues now dictate that clinicians should determine which treatment to employ by reading available literature and using empirically supported treatments. If a clinician decides to employ an unusual or experimental treatment, he or she should thoroughly document that the client has been fully informed about the nature of the experimental treatment and the possible risks and benefits. In addition, the clinician should document that the client was given information about standard treatments.

The documentation requirements ensuring valid consent may become more time-consuming when clinicians conduct family or couples sessions. In those instances, informed consent should be obtained from all participating members at the initiation of therapy and throughout the treatment process. In addition, progress notes should document that discussions have been held regarding any issues that are unique to family or couples sessions. For example, clinicians should discuss with all family members how to handle difficult confidentiality issues faced when more than one client is in the room and should document these discussions in the progress notes.

II. LEGAL AND ETHICAL BASES OF INFORMED CONSENT

Several legal cases illustrate the importance of obtaining informed consent. The first major legal statement of the need for consent occurred in the 1905 case of *Mohr versus Williams*. In this case, the plaintiff used a physician for performing an unauthorized surgical operation. While the plaintiff did consent to an operation on her right ear, the physician instead performed an operation on her left ear, as he had found the left ear to be more in need of treatment once the surgical procedures had commenced. Following the operation, the

plaintiff claimed that she had not previously experienced any difficulty with her left ear but that she currently was having trouble hearing out of that ear. The court found in favor of the plaintiff and stated that a surgical operation by a physician upon the body of his patient is unlawful when performed without either the express or implied consent of the patient.

In 1914, the case of *Schloendorff versus the Society of New York Hospital* expanded on the requirements for informed consent. The court stated that a patient must be apprised of the potential benefits and major risks of any proposed treatment, as well as the available alternative treatments. However, the court did not give specific guidance on how much information is sufficient. A later case, *Canterbury versus Spence* (1972), appeared to support the reasonable patient rather than the professional standard of information provision. The court in this case stated that physicians have “a duty to impart information which the patient has every right to expect.” Since this 1972 case, physicians have been considered to have an affirmative duty to impart as much information as a reasonable patient would require, regardless of whether a particular patient asks for such information.

It is clear from the above brief review that case law has supported obtaining informed consent for medical procedures. However, courts have not directly addressed whether or not informed consent is applicable to typical psychological or counseling services. Likewise, state statutes that address the concept of informed consent have typically addressed only physician obligations to obtain consent. Currently, all states have statutes mandating some type of informed consent procedures for physicians and psychiatrists. Not every state, however, clearly specifies that psychologists or other mental health providers must obtain informed consent for psychological treatments. For example, Oregon law on informed consent states only that physicians and surgeons must obtain informed consent for treatment, with no mention of any such obligation on the part of psychologists. On the other hand, Colorado and Indiana statutes mandate that psychotherapists obtain informed consent. Other state legislatures currently are considering bills requiring psychologists to obtain informed consent prior to treatment. It appears that the recent increase in legislative activity stems from controversy surrounding therapy techniques designed to activate repressed memories. These techniques supposedly help adults recover or unlock previously repressed or forgotten memories of childhood sexual abuse. Critics claim that these techniques result in false memories rather than true memories of abuse and that the techniques lack a scientific

basis. Critics have introduced legislation requiring psychologists to inform clients of the scientific basis of all treatment techniques, as part of their efforts to reduce the use of repressed memory techniques. Clearly, clinicians should be aware of the statutes in the states in which they practice, as laws regarding informed consent for therapy vary across state lines.

Regardless of whether state statutes or case law mandate that clinicians obtain informed consent prior to mental health treatment, ethical codes of conduct typically dictate that clinicians apply the concept of informed consent with all clients. For example, the ethical codes developed by the American Psychological Association (APA) and the American Counseling Association (ACA) contain sections dealing with informed consent. In the APA code, Principle 4.02 states that psychologists must obtain informed consent by using “language that is reasonably understood by participants.” If a client is a child or otherwise unable to give consent, psychologists must obtain consent from the legal guardian. In addition, psychologists must provide information to a child or other legally incompetent person and obtain assent from that person. The overarching principle espoused in ethical principles is that clinicians must consider the client’s best interests, autonomy, and self-determination.

Clinicians should be aware that not obtaining valid consent prior to treatment places them in a precarious position. Due to ethical principles requiring informed consent, a client may file an ethical complaint with the state licensing board for a clinician’s failure to obtain valid consent. Complaints regarding lack of informed consent may be based on the three areas discussed previously: lack of competence to consent to treatment, lack of voluntary consent, or lack of sufficient information. To be found in violation of the ethical code, a psychologist must only be found to have neglected standard and reasonable informed consent procedures. It is not necessary for the client to have been harmed due to the psychologist’s negligence for a clinician to be found in violation of the ethics code. In egregious cases, the result may be suspension or loss of the license to practice psychology in that state.

In addition to an ethical complaint, clinicians who neglect to obtain valid consent from clients may find themselves facing a civil lawsuit. Despite a lack of case law directly addressing the concept of informed consent for psychological services, it is only a matter of time until such a suit is filed. In contrast to an ethical complaint, the client in a civil suit must show, among other things, that the client was harmed by the clinician. To win a suit based on a failure to obtain informed

consent, the client must prove all of the following five things: (1) that the risks involved with a therapy should have been disclosed; (2) that the risks were not disclosed; (3) that the risks materialized; (4) that the materialized risks resulted in injury; and (5) that the client would not have accepted the therapy if he or she knew of the risks involved. It is true that such lawsuits are uncommon and difficult to prove currently. However, the rise of empirically supported treatments may increase the frequency of complaints made by clients who did not receive information and full disclosure regarding such treatment options. Injury or harm may be demonstrated by a client who incurred expenses while participating in an ineffectual therapy for a long period of time, when a more time-efficient and empirically supported therapy was available but was not disclosed to the client. In our increasingly litigious society, clinicians should be aware of the growing possibility of legal liability for failure to obtain fully informed consent.

III. RESEARCH ON INFORMED CONSENT PROCEDURES

There has been little research conducted on the process or effects of obtaining informed consent. The limited research that is available has addressed three main areas: prevalence of informed consent procedures, optimal methods of obtaining informed consent, and effects of informed consent procedures on client disclosure or attendance.

First, research has not supported the idea that all clinicians employ some form of consent procedure. As stated previously, consent procedures include utilizing a written informational form and documenting ongoing discussions with the client. As recently as 1993, Daniel Somberg, Gerald Stone, and Charles Claiborn found that only 60% of psychologists reported utilizing any type of consent procedure with all clients. Thirty-seven percent of the remaining psychologists stated that they did not employ informed consent procedures with all clients due to believing that such procedures were irrelevant, while 16% stated that they often simply forgot to obtain informed consent.

As should be clear from previous sections, the use of both written forms and ongoing discussions with clients is encouraged. Research has found that the sole use of written forms to convey information on the therapy process and treatments has increased over the past two decades. However, research does not support the exclusive use of a written informational form as a method of

obtaining valid consent. There are two major problems with sole reliance on such forms. First, researchers have found that the average length of consent forms doubled from 1975 to 1982, in order to include more information about client rights and confidentiality. Second, the written forms typically employed generally require that the reader have at least a college education. One study found that the average readability of consent forms was grade 15.7 (third year college level), while some reached grade 17+ (postgraduate level).

Given the increasing length and complexity in such forms, it is important to ask whether the typical client can comprehend such information. It is possible that longer and more detailed forms, while covering all of the required consent elements, are primarily utilized to protect clinicians against ethical complaints or lawsuits rather than as a way to educate and inform clients. Clearly, understanding is an important element in giving informed consent; without it, a signature on an informational form is not valid. Although not directly addressing clinical or treatment forms, a 1994 study by Traci Mann on the understanding of research informed consent forms is relevant. Overall, Mann found that longer consent forms inhibited the amount of information retained by participants. Mann concluded that research participants often agree to engage in studies that they do not understand, which belies the whole idea of informed consent. His findings imply that long, complex consent forms should not be employed with clinical clients.

An alternative to employing detailed informed consent forms is a procedure suggested by Mitchell Handelsman and Michael Galvin in 1988. These authors developed a question sheet that includes a list of commonly asked questions. This sheet also instructs potential clients that they have a right to ask any or all of these questions to their therapist. Handelsman and Galvin directed that some of the questions must be answered by the therapist even if not asked by the client; examples of such questions that therapists are ethically obligated to discuss with clients would be those dealing with confidentiality and the general nature of treatment. However, the remaining questions are left to the discretion of the client, respecting the right of clients to not be given information that is not wanted. It may also encourage the use of a process format of obtaining informed consent, rather than a single event model. To date, no studies have been done investigating the level of client retention of information presented in such a format.

Several studies have examined the effects of informed consent procedures on the therapy process, with most of the research examining the effects of

written informational forms. Clearly, some clinicians have been reluctant to employ informed consent procedures, particularly written forms, on a regular basis. The primary concern may be that the use of legalistic forms and terms is detrimental to the establishment of a therapeutic relationship. In other words, informed consent procedures, particularly written forms, may create a negative impression of therapy in general and the therapist specifically. It is also possible that clinicians are concerned that too much information on the limits of confidentiality may deter clients from revealing important but sensitive information. However, in general, the literature does not support these negative effects of informed consent procedures; instead, research has found primarily positive results from the process of obtaining informed consent.

In regard to the therapeutic relationship, in 1990 Mitchell Handelsman surveyed 129 undergraduate students regarding their impressions of a hypothetical therapist. Holding level of experience of the therapist constant across conditions, Handelsman varied the amount of written information provided to survey participants. In all conditions, participants were provided minimal written information about the therapist, including his educational background and years of experience. In the first condition, participants also were provided the question sheet. In the second condition, participants were given a legal disclosure form, outlining client rights, limits to confidentiality, and other information often considered part of informed consent procedures. Finally, in the third condition, participants were given a brochure that provided general information to commonly asked questions (e.g., What is the difference between a psychologist and a psychiatrist?). Based on the information provided, participants were asked to complete a questionnaire regarding their impressions of the hypothetical psychologist. Overall, Handelsman found that the use of more written information increased participants' positive judgments of therapists' experience, likeability, and trustworthiness, in addition to their likelihood of referring the therapist to others. This study suggested that written information, whether disclosed in a more legalistic document or through a question sheet, may improve therapist ratings. The study was not able to conclude that the question sheet was more beneficial than the legal disclosure form.

In a separate study in 1990, Mitchell Handelsman surveyed 137 undergraduate students to assess whether varying level of therapist experience would affect the previously established positive impact of legal disclosure forms. For this study, half the participants received the legal disclosure form; the other half received both the

legal disclosure form and the question sheet. In addition, therapist level of experience varied. In the first condition (the low-experience condition) participants were told that the hypothetical therapist was recently licensed within the past year. In the second condition (the moderate-experience condition), participants were told that the therapist had been practicing for at least 9 years. Finally, in the third condition (the high-experience condition), participants were told that the therapist had been in practice for 19 years. Overall, Handelsman found that participants rated experience highly. However, with more information provided, the less experienced therapist was rated more highly. Handelsman's findings suggest that adding more written information in the informed consent process improves client ratings, particularly with less experienced therapists.

In 1993, Therese Sullivan, William Martin, and Mitchell Handelsman conducted a survey of 124 undergraduate psychology students to further investigate the impact of information on ratings of clinicians. Participants were assigned to one of two conditions. In both conditions, participants were given a hypothetical transcript of a first therapy session. In the first condition (informed consent transcript condition), the transcript was accompanied by a written consent form and included discussion of confidentiality, alternative treatments, and risks and benefits of therapy. In the second condition (control transcript condition), no written form accompanied the transcript and no discussion on informed consent issues was included. Following presentation of materials, all participants were asked to complete a questionnaire regarding impressions of the therapist. The authors found that the combined presentation of oral and written information positively impacted therapist ratings.

To date, only one study has found any negative effects of written forms on client impressions of therapists. In 1992, Mitchell Handelsman and William Martin found that male adult clients reported lower ratings for therapists who provided written informed consent forms than no information at all. However, the forms employed in this study were difficult to read, as they required at least a 10th-grade reading level, had complex sentences, and were single-spaced. As previously reported, less readable forms are likely to be misunderstood by clients. It appears from this study that therapist ratings also suffer from complex information forms.

As the above brief review demonstrates, the limited research that has been done appears to support the idea that informed consent procedures improve client ratings of therapists. Further research has examined

whether informed consent procedures affect client behaviors in therapy, such as termination rates and the frequency of disclosures of sensitive information.

Termination and no-show rates of clients at a counseling center of a state university were examined in 1995 by Patricia Dauser, Suzanne Hedstrom, and James Croteau. In the partial disclosure condition, participants received only the counseling center's standard written information, including the services provided at the clinic, limits of confidentiality, length and frequency of sessions, and the client's right to terminate treatment. In the full disclosure condition, participants received the standard written form as well as written materials containing more detailed information. Specifically, participants were told the name of the assigned therapist, the therapist's experience and typical treatment procedures, anticipated positive results of therapy, possible risks, potential alternatives to therapy, fee structure, the name of the therapist's supervisor (if applicable), and the name and number of the state licensing board. Overall, the authors found no differences between the two conditions in no-show or termination rates during the course of therapy, suggesting that more information does not negatively affect client attendance.

The results of research on the impact of informed consent procedures on client disclosures have been mixed. In recent years, legislation in most states has mandated that certain information revealed by clients (e.g., child abuse, imminent harm to others) be disclosed to authorities. This legislation is based on the idea that society has more of an interest in preventing harm than in protecting client confidentiality. Informing clients of the limits of confidentiality is a standard part of most informed consent procedures. Some studies have found that warning clients of the limits of confidentiality reduces client disclosures, whereas other studies have found that it has no impact. As an example, Daniel Taube and Amiram Elwork examined rates of disclosure of sensitive information in 1990. These authors assessed 42 adult outpatient clients regarding level of self-disclosure following either minimal information on confidentiality limits or full information regarding this topic. The authors found that information on confidentiality limits does reduce self-disclosure for some patients in some circumstances. In particular, more informed clients did not admit to as many child punishment and neglect behaviors, nor did they admit to as many socially unacceptable thoughts and behaviors as the minimally informed group. The authors suggested that legislation on mandated reporting of certain client information may not achieve its intended aim of

protecting society and may also hinder the therapy process. Due to conflicting findings in the literature, further research is needed to clarify the impact of informed consent procedures on client disclosures.

IV. SUMMARY

Obtaining informed consent of all clients is an ethical requirement for psychologists. In addition, it is likely that psychologists will increasingly be legally required to obtain informed consent prior to treatment. Informed consent is valid only if given intelligently, knowingly, and voluntarily. The reasonable patient model is now the standard of care, suggesting that clinicians must take the responsibility for initiating dialogues with clients regarding consent issues. An ongoing, process model is advisable, rather than a single event model that relies exclusively on a written informational form. Both written forms and continual discussions are helpful, as long as the client understands these basic areas: nature of therapy in general, limits to confidentiality, treatment techniques available, and the risks and benefits of potential techniques (including the option of no treatment).

Research has found that not all therapists currently utilize informed consent procedures, believing it may be irrelevant or even harmful to the therapeutic relationship. In general, research has supported the positive effects of providing more information to the client prior to treatment. For example, research has found that increased information appears to improve client ratings of clinicians. Although not directly studied, it is possible that providing more information to clients reduces the risk of exploitation of clients by informing them of rights and expectations. In addition, it is possible that utilizing informed consent procedures may align client and clinician expectations of therapy, resulting in a better therapy outcome, as well as fewer lawsuits or ethical complaints for clinicians. Clearly, further research should be conducted on these hypotheses.

It should be noted, however, that research has not been uniformly positive as to the effects of informed consent procedures. When long or complex written materials are utilized, client comprehension suffers. Also, research is mixed on the effects of informed consent procedures on client disclosure of sensitive information. At least one study has found that disclosure of sensitive material may be inhibited when more information on the limits of confidentiality is provided to clients. Further research on this issue is needed to clarify the extent of client censoring of sensitive materials.

theoretical integration The most conceptually complex form of psychotherapy integration, in which the underlying theories of personality and psychopathology are synthesized and are the foundation of a new therapeutic approach.

This article will introduce the reader to progress in the area of psychotherapy integration. This is a new and exciting subdiscipline in the field of psychotherapy. It is concerned with using and combining the most effective elements of psychotherapy theory and practice in ways that accentuate the power of integrated psychotherapies to help a wider range of patients, with a broader spectrum of problems, to change.

GLOSSARY

assimilative integration A system of psychotherapy integration that depends largely on one approach but that incorporates concepts and methods as dictated by clinical necessity. These new elements are transformed to fit into the primary approach.

common factors That group of variables that have been found to be the effective ingredients of most psychotherapies.

common factors integration The combination of therapeutic approaches based on the ability of particular methods to deliver the desired common factor of change.

psychodynamic A synonym for psychoanalytic, it refers to unconscious motivations, perceptions, emotions, and conflicts that determine behavior, and to forms of psychotherapy that emphasize these factors.

psychotherapy integration The combination of techniques and/or concepts from two or more psychotherapeutic approaches into a single method of psychotherapy.

technical eclectic The most pragmatic and common form of psychotherapy integration, in which interventions are matched to patient characteristics, symptoms, and problems on the basis of research findings and clinical knowledge.

I. DESCRIPTION OF TREATMENT: A HISTORICAL AND CONCEPTUAL OVERVIEW OF PSYCHOTHERAPY INTEGRATION

From the earliest foundations of modern approaches to psychotherapy, practitioners and students of psychotherapy have been extraordinarily unwilling to learn from systems of psychotherapy other than their own. Each school of psychotherapy has developed in a state of isolation from the other schools. This state of segregation within the field of psychotherapy has had dramatic and important effects. It has led to unwanted

hostility between adherents of the various psychotherapeutic schools, and to efforts to dismiss out of hand the ideas and methods of competing approaches without systematic study or intellectual consideration. This self-imposed therapeutic “apartheid” also has prevented psychotherapists and patients from benefiting from clinical and theoretical innovations introduced by colleagues who are loyal to other psychotherapeutic approaches. Michael Mahoney argued in 1985 that these schisms in the field were political in nature and did not reflect clinical reality, which indicated that none of the therapeutic schools could claim to be vastly superior to any other.

This stubborn isolationism in the field of psychotherapy stands in contrast to the fact that psychotherapists have always been interested in, and long have attempted to use, new developments in the natural and social sciences, philosophy, theology, the arts, and literature. A small group of scholars and clinicians have been able to cross sectarian lines and have countered the segregation of the various schools of psychotherapy. These integrationists have aimed at establishing a useful dialogue among members of the various sectarian schools of psychotherapy. Their goal has been the development of the most effective forms of psychotherapy possible. The integration of therapies involves the synthesis of the “best and brightest” concepts and methods into new theories and practical systems of treatment.

Integrative forms of psychotherapy vary greatly depending on the particular version that is being considered, yet all share one common goal and purpose. Integrative psychotherapies are the result of the synthesis of theoretical concepts and clinical techniques from two or more traditional schools of psychotherapy (such as psychoanalysis and behavior therapy) into one therapeutic approach. It is hoped and assumed that this therapeutic synthesis will be more powerful and will be applicable to a wider range of clinical populations and problems than were the individual models of psychotherapy that formed the basis of the integrated model.

Histories of early efforts at integrating compiled by Marvin Goldfried and Cory Newman in 1992, and by Jerold Gold in 1993, identified scattered but important contributions as early as 1933, when Thomas French argued that concepts from Pavlovian models of learning should be integrated with then current psychoanalytic insights. In 1944 Robert Sears offered a synthesis of learning theory and psychoanalysis, as did John Dollard and Neal Miller in 1950, whose translation of psychoanalytic concepts and methods into the language and framework of laboratory-derived learning principles was a watershed event.

Early clinical efforts at integrating behavioral and psychoanalytic interventions in a single case were introduced by Bernard Weitzman in 1967, in 1971 by Judd Marmor, and by Benjamin Feather and John Rhodes in 1973. These clinical efforts demonstrated that unconscious factors in a patient’s psychopathology could be ameliorated through the use of behavioral methods, along with traditional psychodynamic exploration and interpretation.

In the past two decades a number of important integrative approaches to psychotherapy have been developed. In 1977 Paul Wachtel published a groundbreaking book that advocated an integration of psychoanalytic theory with social learning theory, and in which he demonstrated ways in which clinicians could effectively use behavioral and psychoanalytic interventions with one patient. This integrative approach received enormous attention within the behavior therapy and psychoanalytic communities, and was followed by other efforts at promoting a dialogue between clinicians of various orientations, as well as a relative torrent of articles and books that focused on integrative topics. In 1984 Hal Arkowitz and Stanley Messer published an edited volume in which prominent behavior therapists and psychoanalytic therapists discussed and debated the possibilities of extensive integration of the two systems.

In 1992 John Norcross and Marvin Goldfried published a handbook that presented a variety of fully developed integrative systems of psychotherapy. This effort was followed in 1993 by a volume edited by George Stricker and Jerold Gold in which an even greater number of integrative models was presented, and the clinical utility of psychotherapy integration was explored with regard to a variety of clinical problems and populations. These volumes illustrated that integrative models were no longer focused exclusively on the synthesis of psychoanalytic and behavioral systems. Newer integrative efforts have combined humanistic, cognitive, experiential, and family systems models with each other and with psychoanalytic and behavioral components in ever more sophisticated combinations and permutations. Process-experiential psychotherapy, an innovation introduced by Leslie Greenberg, Laura Rice, and Robert Elliot in 1993, and acceptance and commitment therapy (ACT), described by Steven Hayes, Kirk Strosahl, and Kelly Wilson in 1999, are important examples of integrative approaches that rely heavily on the integration of humanistic and experiential approaches with cognitive-behavioral therapies. Similarly, an integrative model that blended existential,

humanistic, and narrative therapies was described in 1999 by Alphonse Richert.

These psychotherapeutic systems have received increasing attention on the part of clinicians and researchers alike, and have become established and viable alternatives to traditional schools of psychotherapy.

In 1992 John Norcross and Cory Newman identified eight variables that have encouraged this rapid proliferation of integrative psychotherapies after decades during which these efforts were scanty. These included (1) The ever-increasing number of schools of psychotherapy; (2) a lack of clear-cut empirical support for superior efficacy of any school of therapy; (3) the failure of any single theory to adequately explain and predict pathology, or personality and behavioral change; (4) the growth in number and importance of shorter term, focused psychotherapies; (5) greater communication between clinicians and scholars that has resulted in increased willingness to, and opportunity for, experimentation; (6) the intrusion into the consulting room of the realities of limited socioeconomic support by third parties for long-term psychotherapies; (7) the identification of common factors in all psychotherapies that are related to outcome; and (8) the development of professional organizations, conferences, and journals that are dedicated to the discussion and study of psychotherapy integration.

II. THEORETICAL BASES OF PSYCHOTHERAPY INTEGRATION

A. Modes of Psychotherapy Integration

The three most commonly discussed forms of integration are technical eclecticism, the common factors approach, and theoretical integration.

1. *Technical Eclecticism*

This is the most clinical and technically oriented form of psychotherapy integration. Techniques and interventions drawn from two or more psychotherapeutic systems are applied systematically and sequentially. The series of linked interventions usually follows a comprehensive assessment of the patient. This assessment allows target problems to be identified and identifies the relationships between different problems, strengths, and the cognitive, affective, and interpersonal characteristics of the patient. Techniques are chosen on the basis of the best clinical match to the needs of the patient, as guided by clinical knowledge and by research findings.

a. Multimodal Therapy The most influential and important integrative approach that is representative of technical eclecticism is multimodal therapy, described by Arnold Lazarus in 1992 and studied extensively by him and many others since that time. Multimodal therapy was derived from Lazarus's experiences as a behavior therapist, and particularly from his follow-up studies of patients who relapsed after seemingly successful behavioral treatment. His research and clinical experience indicated that most behavioral problems had more extensive psychological and social causes and correlates than then current behavior therapy had addressed. Seeking to expand the range of his ability to work in a more "broad spectrum" way, Lazarus arrived at a multimodal, or broad-based, eclectic therapy.

Multimodal therapy is organized around an extensive assessment of the patient's strengths, excesses, liabilities, and problem behaviors. Upon completion of this assessment, that patient's clinically significant issues are organized within a framework that follows the acronym of the *BASIC ID*: Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal relations, and Drugs (or biology). As the firing order or causal sequence of variables in the *BASIC ID* is identified, interventions are selected and are implemented. More microscopic *BASIC ID* profiles of discrete or difficult problems and of components of a firing order can be attempted once the initial, global assessment and interventions are completed.

Lazarus states that he prefers to use methods that have been demonstrated through empirical tests to be effective with specific problems and skills, and his theory and technical strategies are more heavily aligned with social learning theory and with cognitive-behavior therapy than with any other therapeutic school. However, in his broad-spectrum approach, he often includes imagery work, techniques drawn from couples and family therapy, gestalt exercises and some affective and insight oriented interventions.

b. Systematic Eclectic Psychotherapy This system of psychotherapy integration was described by Larry Beutler and Amy Hodgson in 1993. This is an empirically informed system in which a thorough assessment of the patient is followed by the prescription of techniques, if available, that have received the most research validation for efficacy with that specific clinical profile. When such research-based matching is not possible, techniques are selected according to accumulated clinical findings drawn from the literature and from the experience of the individual therapist. Beutler and Hodgson choose therapeutic interventions by considering the

interaction of three variables: the stage of involvement in psychotherapy that the patient has reached; the necessary change experiences for which the patient is prepared; and the dominant aspects of the patient's immediate clinical status. Clinical techniques can be matched with four psychological spheres that are assessed on an ongoing basis: overt dysfunctional behavior, faulty thinking, inhibitions of affective and sensory experience, and repressed unconscious conflict. Therapists who work in this framework are free to draw on interventions from any existing system of psychotherapy ranging from psychoanalytically oriented interpretations, to experiential, emotional work, to efforts at modifying thoughts and overt behaviors.

2. Common Factors Approaches to Integration

Common factors integration starts from the identification of specific effective ingredients of any group of therapies. This way of thinking has its origins in the 1936 paper by Saul Rosenzweig, who argued that all therapies shared certain effective ingredients of change, despite their overt ideologies and technical procedures. Also critically important in this area is the work of Jerome Frank, who in 1961 suggested that all systems of psychological healing share certain common, effective ingredients, such as socially sanctioned rituals, the provision of hope, and the shaping of an outlook on life that offers encouragement to the patient. Integrative therapists who rely on common factors concern themselves with the task of identifying which of the several known common factors will be most important in the treatment of each individual. Once the most salient common factors are selected, the therapist reviews the array of interventions and psychotherapeutic interactions to find those that have been found to promote and contain those ingredients. The integrative therapies that result from this process are structured around the goal of maximizing the patient's exposure to the unique combination of therapeutic factors that will best ameliorate his or her problems.

a. Transtheoretical Psychotherapy The most important and widely accepted integrative psychotherapy that exemplifies the common factors mode is transtheoretical psychotherapy, described by James Prochaska and Carlos DiClemente in 1992. In this system, the therapist selects intervention techniques after three patient characteristics are assessed. These are the change mechanisms or common therapeutic factors that are required, the stage of change at which the patient seeks help, and the level of change that is necessary. Prochaska and Di-

Clemente identified 10 possible change factors that operate in the entire range of the psychotherapies, including consciousness raising, self-liberation, social liberation, counterconditioning, stimulus control, self-reevaluation, environmental reevaluation, contingency management, dramatic relief, and helping relationships. Each of these factors is linked to particular therapeutic interventions, although most therapies contain only 2 or 3 of the 10. The concept stage of change refers to the patient's readiness and motivation to change. Five stages have been identified, including precontemplation (the patient is not actively considering change), contemplation (consideration of change without current readiness), preparation, action, and maintenance. Depth of change refers to the sphere of psychological life in which the targeted problem is located, including situational problems, maladaptive thinking, interpersonal conflicts, family conflicts, and intrapersonal conflicts. The trans-theoretical therapist selects interventions that will have maximal impact at the desired level of change, will be consistent with the patient's readiness for change, and will convey the highest level of exposure to the most powerful change factors.

b. Common Factors Eclectic Psychotherapy Sol Garfield described in 2000 another influential integrative model that is grounded in common factors research. Garfield integrates interventions from a variety of psychotherapies, with the aim of providing the patient with a number of positive experiences and skills. The common factors that guide Garfield's selection of therapeutic techniques include an empathic, hope-promoting therapeutic relationship; emotional release or catharsis; explanation and interpretation; desensitization; reinforcement; confrontation of problems; provision of new information and skills; and time as a healing factor.

3. Theoretical Integration

Theoretical integration refers to the most complex and sophisticated mode of psychotherapy integration. Psychotherapies that are theoretically integrated rely on the synthesis of concepts of personality functioning, psychopathology, and psychological change from two or more traditional systems. These integrative theories explain behavior and internal experience in cyclical, interactional terms, by looking for the ways in which environmental, motivational, cognitive, and affective variables influence and are influenced by each other. Perhaps the best known version of theoretical integration is a form of psychotherapy that is so well established that it is recognized only rarely as integrative:

cognitive-behavior therapy. As described by Marvin Goldfried in 1995 in an important work on psychotherapy integration, cognitive-behavior therapy is based on a theory of psychopathology and of personality change that is greater than the sum of its behavioral and cognitive parts. This expanded, integrated theory guides the therapist in the selection and use of interventions that are drawn from each school of therapy.

The systems of psychotherapy that are based on theoretical integration use interventions from each of the component theories, and lead to original techniques that may be added to the technical repertoire of the originating therapeutic schools. At times, the clinical efforts suggested within a theoretically integrated system substantially may resemble the choice of techniques of a technically eclectic model. The essential differences may lie in the belief systems and conceptual explanations that precede the clinical strategies selected by the respective therapists. Theoretical integration goes beyond technical eclecticism in clinical practice by expanding the range of covert and overt factors that can be addressed therapeutically. Subtle interactions between behavioral and interpersonal experiences and internal states and processes can be assessed and targeted for intervention from a number of complementary perspectives. Expected effects of any form of intervention in one or more problem areas can be predicted, tested, and refined as necessary. This conceptual expansion offers a framework in which problems at one level or in one sphere of psychological life can be addressed in formerly incompatible ways. That is, the therapist might target a problem in cognition not only to help the patient to think more adaptively, but to promote change in interpersonal behavior, or to rid the patient of a way of thinking that maintained powerful unconscious feelings.

a. Cyclical Psychodynamics Paul Wachtel introduced the most important and influential integrative approach that exemplifies theoretical integration in 1977. This system is known as cyclical psychodynamics and was the first psychotherapeutic model in which psychodynamic theory and therapy were integrated completely with other systems, including especially behavioral theory and behavior therapy techniques. The integration of psychoanalytic and behavioral theories led to the integrative theory that posited that human beings are influenced by unconscious factors that reflect their ongoing perceptions of significant interpersonal relationships. Further, these unconscious issues were seen as maintained and reinforced by the responses of the persons with whom the patient was interacting.

With this cyclical theory as a foundation, Wachtel pioneered the viewpoint that those clinical issues that were the typical concern of psychodynamic therapists could be addressed in therapy through the use of behavioral techniques such as desensitization and assertiveness training. Wachtel argued convincingly that these active behavioral interventions could reach and change unconscious conflicts, fantasies, and depictions of the self and of other people, and as such were useful within a psychodynamically informed psychotherapy. In an updated work on cyclical psychodynamics that was published in 1997, Wachtel expanded his integrative approach to include concepts and methods that were drawn from family systems therapy and gestalt therapy.

b. Cognitive-Analytic Therapy Cognitive-analytic therapy was developed by Anthony Ryle in his role as a consulting psychiatrist in the British National Health System, and has been described in two books that were published in 1990 and 1997. Cognitive-analytic therapy is a theoretical and technical integration of psychoanalytic object relations theory with schema-based cognitive theory and therapy. Ryle found that it was possible to reconceptualize psychoanalytic concepts as the unconscious images of self and of others in explicit, cognitive terms. This theoretical integration allows the cognitive-analytic therapist to introduce and to emphasize the use of cognitive techniques for the purpose of actively modifying these depictions of the self and of other people that exist outside of the patient's awareness but that exert powerfully negative influence on the patient's behavior, symptoms, and relationships.

c. Assimilative Integration A particular subset of theoretical integration that has been the focus of much recent interest is assimilative integration. This way of thinking about psychotherapy integration was introduced into the literature in 1992 by Stanley Messer. Messer suggested that many integrative approaches could best be termed assimilative due to the impact that new techniques have on the existing conceptual foundation of the therapy. As therapeutic interventions are used in a context other than that in which they originated, the meaning, impact, and utility of those techniques are changed in powerful ways. Essentially, these interventions (such as psychodynamic interpretation used by a behavior therapist) are assimilated into a different model and thus are changed in meaning and in impact. In his discussion of assimilative integration of psychotherapies, Messer pointed out that all actions are defined and contained by the interpersonal, historical,

and physical context in which those acts occur. As any therapeutic intervention is an interpersonal action (and a highly complex one at that) those interventions are defined, and perhaps even re-created, by the larger context of the therapy. Therefore, a behavioral method such as systematic desensitization will mean something entirely different to a patient whose ongoing therapeutic experience has been largely defined by psychodynamically oriented exploration, than that intervention would mean to a patient in traditional behavior therapy.

George Stricker and Jerold Gold introduced an influential version of assimilative integrative psychotherapy into the literature in 1996. This integrative approach is one in which the basis for the therapy is traditional psychodynamic exploration. Most of the therapeutic work is carried out through the usual psychoanalytically oriented techniques of clarification, confrontation of defenses and resistances, and interpretation of unconscious conflict and of transference phenomena. However, there are frequent occasions during which an intervention that originated in cognitive, behavioral, or experiential therapy will be introduced into the treatment. Even though these interventions may seem identical to those used by therapists from those other schools, the assimilative nature of this therapy means that the intention, meaning, and potential impact of these interventions will differ, reflecting the basic psychodynamic foundation of the therapy. As an example, when a common behavioral intervention such as assertiveness training is assimilated, it is chosen as much for its ability to bring unconscious conflicts about anger into awareness for the patient as it is for its behavior benefits. Similarly, the use of a cognitive restructuring technique may help a patient to lessen his or her resistances to therapy by reducing anxiety, as well as helping that person to learn a more adaptive way of thinking.

III. RESEARCH ON INTEGRATIVE APPROACHES TO PSYCHOTHERAPY

Research on systematic eclectic psychotherapy as described by Beutler and Hodgson has yielded promising empirical support for the effectiveness of matching patient characteristics and specific therapeutic interventions. Larry Beutler, Paulo Machado, David Engle, and David Mohr conducted an important study of this approach to integrative psychotherapy in 1993. These authors reported that when depressed patients were assigned randomly to three different forms of psychotherapy, two patient characteristics were crucial in predicting the effectiveness of the different therapies.

As predicted, cognitive therapy was most effective for those patients who externalized responsibility for their depressions, while those patients with an internal locus of control showed the greatest improvement in the insight-oriented, focused expressive psychotherapy. Patients with higher levels of defensiveness and with greater resistance to authority were helped most by a self-directed therapy.

In 1999 James Prochaska and John Norcross summarized the research literature concerned with the effectiveness of technically eclectic psychotherapies. Although they were appropriately concerned with the limitations of the methodologies used in many of these studies, Prochaska and Norcross concluded that this approach had, on average, a moderate to large effect size and performed better than control therapies in about 70% of the studies that were located.

The transtheoretical model of psychotherapy and its basis in the stages of change in psychotherapy as described by James Prochaska and Carlos DiClemente in 1992, has been studied extensively. These studies, summarized by Carol Glass, Diane Arnkoff, and Benjamin Rodriguez in 1998, have demonstrated the maximized effectiveness of psychotherapies that include interventions that are drawn from several different dimensions of psychological life, as does our model. These studies impressively support the idea that technique serves the patient best when interventions are matched to the patient's immediate clinical need and psychological state.

Clinical trials of integrative psychotherapies that synthesize psychodynamic formulations and exploration with active interventions have yielded preliminary but positive results. For instance, the integrative, interpersonal psychotherapy for depression developed by Gerald Klerman, Myrna Weissman, Bruce Rounsaville, and Eve Chevron in 1984 has outperformed medication and other psychological interventions in a number of studies. Haim Omer, writing in 1992, offered empirical support for integrative interventions that heighten the patient's awareness of his or her participation in psychotherapy, thus improving the impact of the basic exploratory stance of the psychotherapist. Carol Glass, Brian Victor, and Diane Arnkoff pointed out in a 1993 publication that several systems of integrative psychotherapy, such as the "FIAT" model (Flexible, Interpersonal orientation, Active, and Teleological understanding) have been demonstrated, albeit in limited numbers of studies, to outperform either strictly psychodynamic or cognitive-behavioral interventions.

Anthony Ryle reported in 1995 that short-term and long-term versions of cognitive analytic therapy (CAT) have been found to be more effective than

purely psychodynamic or behaviorally oriented approaches. Perhaps the most impressive and important collection of studies of integrative psychotherapy that compare the synthesis of two or more approaches with traditional therapies have been carried out by David Shapiro and his colleagues at the Sheffield Psychotherapy Project. Shapiro and Jenny Firth-Cozens reported on this work in an important paper published in 1990. These workers studied the impact of two sequences of combined psychodynamic and cognitive-behavioral therapy: dynamic work followed by active intervention or vice versa. They found that the greatest gains were made, and the smoothest experiences of treatment were reported, by those in the dynamic-behavioral sequence. Patients in the behavioral-dynamic sequence more frequently deteriorated in the second part of the therapy, and did not maintain their gains over time as often as did patients in the other group.

An integrative approach to treating agoraphobia that combines behavioral, systemic, and psychodynamic theories and techniques was evaluated by Diane Chambless, Alan Goldstein, Richard Gallagher, and Priscilla Bright in 1986. These authors found that their integrated model led to marked or great improvement for almost 605 of the patients. Specific treatment effects included lessened avoidance, depression, social phobia, and agoraphobic symptoms, and enhanced assertiveness for their subjects. When this treatment was compared to standard drug therapy and to behavior therapy, the patients treated with the integrated therapy had a much lower dropout rate than either of the other therapies.

Another theoretically integrated approach that has been tested empirically is process-experiential therapy, an integration of principles and methods derived from client-centered, gestalt, and cognitive therapies that was described in 1993 by Leslie Greenberg, Laura Rice, and Robert Elliot. This therapy has been found to be more efficacious than control therapies such as standard behavior therapy. The effectiveness of this integrative model has been demonstrated with individuals on a short-term basis for problems such as anxiety and depression. Glass, Arnkoff, and Rodriguez pointed out in 1998 that a version of this approach that had been adapted for use with couples also has been demonstrated to be more effective than standard control measures.

Dialectical behavior therapy (DBT) is an integrative psychotherapy aimed at alleviating borderline personality disorder. Marsha Linehan described this approach to this disorder in 1987. DBT integrates skills training, cognitive restructuring, and collaborative problem-solving from cognitive-behavior therapy, with relationship elements (such as warmth, empathy, and unconditional

positive regard) from client-centered therapy, and with aspects of psychoanalytic works as well. Borderline personality disorder is recognized by most clinicians as among the most difficult forms of psychopathology to treat, yet DBT has gained wide acceptance among clinicians in recent years, due in great part to the research support for its effectiveness. Glass, Arnkoff, and Rodriguez reported that patients who received DBT demonstrated better treatment retention, had fewer suicide attempts and episodes of self-injury, fewer hospitalizations, decreased anger, greater social adjustment, and more improved general adjustment when compared with those who received standard therapies. These results were maintained over a 1-year follow-up period, and were replicated in a second study.

The first psychotherapeutic approach that has been demonstrated empirically to be effective for treating chronic depression (dysthymic disorder) is an integrative model developed by James McCullough in 2000. This psychotherapy is known as CBASP, for the systems that it synthesizes: Cognitive, Behavioral, Analytic, and Systems psychotherapies. CBASP has been found to be as or more effective as antidepressant medication and traditional forms of psychotherapy in alleviating the symptoms and interpersonal problems involved in chronic depression. As importantly, its results are more enduring and more resistant to relapse than are other treatments.

IV. RANGE OF PATIENT POPULATIONS AND ISSUE OF DIVERSITY

Marvin Goldfried, an early, influential advocate of psychotherapy integration, summed the dilemma of the psychotherapy patient in a cartoon that he included with an article published in 1999. Goldfried's cartoon shows a therapist and patient shaking hands, with two thought bubbles above the head of each person. The therapist is seen to be thinking, "I hope he has what I treat!" while the patient silently worries, "I wonder if he can treat what I have?"

Integrative approaches to psychotherapy would seem, at least in theory, to be uniquely suited to the needs of patients with diverse backgrounds and problems. The problem highlighted by Goldfried may best be avoided by employing an integrative outlook. The hallmark of effective integration is the flexibility of the therapist and the therapeutic approach, and the overriding concern for the individuality of the patient. Unlike many traditional psychotherapeutic systems and schools, wherein the patient is made to fit into, or to

conform with, the therapist's preconceived notion of what works for whom, the integrative therapist tries to tailor the therapy to meet the needs and characteristics of the patient.

Similarly, it would be difficult to think of a specific psychological disorder or patient population for which integrative approaches could not be considered. Since the cornerstone of psychotherapy integration is using the best of what works, any therapeutic approach to any problem may, at least in theory, be improved by the addition of active ingredients from other models.

Presently there exist a number of important contributions to the literature on psychotherapy that are concerned with improving the lot of patients from diverse backgrounds. Sheila Coonerty demonstrated in 1993 that an integrative model of psychotherapy that combines behavioral and psychodynamic elements could be used successfully in the treatment of school-aged children. Mary Fitzpatrick published in 1993 the application of a similar integrative model to the problems of adolescents. Iris Fodor introduced into the literature in 1993 an integrative therapy that was designed particularly for the needs of female patients. Fodor's model integrated concepts and methods from gestalt therapy and cognitive-behavior therapy with feminist theory and therapy. Many integrative therapists have focused on improving the effectiveness of family therapies by adding elements from other schools of psychotherapy. Among the more influential approaches of this type are William Pinsof's integrative family therapy, published in 1995, which assimilated behavior, cognitive, and psychoanalytic methods into family therapy, and Mary Joan Gerson's 1996 integration of psychoanalytic and family systems therapies.

In 1993 Anderson Franklin, Robert Carter, and Cynthia Grace described an integrative approach to psychotherapy with Black African Americans in which issues of race and culture were synthesized with clinical concepts and methods. These authors illustrated how an understanding of the adverse social and cultural factors in American life that shape African American identity development and family structure can be integrated with a variety of therapeutic approaches within a systems framework. Nicholas Papouchis and Vicky Passman, also writing in 1993, described an integrative model of psychotherapy specifically designed to meet the needs of geriatric patients. These authors described how the cognitive deficits, personal losses, and physical illnesses that often afflict the elderly make the traditional psychodynamic therapist less accessible to many older people. However, Papouchis and Passman

pointed out that the judicious integration of structured cognitive-behavioral techniques into a psychodynamically oriented psychotherapy may be used effectively by this population, allowing these patients to benefit from the curative factors contained in both approaches.

A number of integrative psychotherapists have explored the ways in which an integrative perspective can be helpful in extending the reach of Western psychotherapies to other sectors of the world. These contributions collectively demonstrate the cultural sensitivity and respect for indigenous traditions, meanings, and ways of life that must be part and parcel of any effective psychotherapy. Articles by Sylvester Madu and Karl Pelzer, both of which appeared in 1991, described integrative therapeutic systems that synthesized several Western therapies with traditional African modes of healing. Both of these writers noted that the openness and flexibility of integrative therapies made these approaches more likely to be able to accommodate the cultural necessities of African life than were standard forms of treatment. Willi Butollo published in 2000 a report of an integrative therapy that he had developed while working in refugee camps in Bosnia during and after the civil war and ethnically motivated atrocities that occurred in the Balkans. Butollo's approach synthesized elements from humanistic, interpersonal, psychodynamic, and cognitive-behavior therapies, and was found clinically to be extremely effective in helping trauma survivors to recover from posttraumatic syndromes.

Integrative therapists have been concerned with expanding the effectiveness of psychotherapy to include politically and economically disenfranchised individuals. In 1989 Paul Wachtel expanded his pioneering integration of psychoanalysis and behavior therapy by focusing on the economic, political, and societal factors that lead to psychopathology. Wachtel then expanded his clinical methodology to include intervention in these areas.

In 1990 Jerold Gold described an integrative therapy that was aimed at helping institutionalized inner-city children and adolescents recover from the mixed impact of individual psychopathology, family dysfunction, and social problems such as divorce, poverty, drug abuse, malnutrition, and substandard housing. Gold's synthesis of psychodynamic, family systems, and behavioral methods also included a strong emphasis on understanding and utilizing the cultural framework within which each patient lived, and posited for the therapist the role of social and political advocate when appropriate.

Integrative psychotherapies have been applied successfully to a wide range of clinical syndromes and patient

populations. Anxiety disorders and related conditions such as panic disorders and phobias are the focus of at least three integrative models. As noted above, Diane Chambless and her colleagues demonstrated in 1986 that an integrative treatment model for agoraphobia was highly successful in alleviating that difficult condition. Barry Wolfe described an integrative approach to anxiety disorders that has been highly influential since it appeared in print in 1992. Wolfe proposed a developmental model for anxiety disorders in which unconsciously processed experiences of self-endangerment are established and maintained during traumatic interpersonal experiences. Wolfe demonstrated how an integration of imagery, behavioral, experiential, and interpersonal techniques could be used to treat this disorder. Another integrative therapy for anxiety disorders was published in 1993 by Jerold Gold, who based his integrative model on a synthesis of concepts and methods from attachment theory, behavior therapy, and humanistic therapy. Obsessive-compulsive disorder was targeted for treatment by R. Harris McCarter in 1997. This author based his approach on a combination of behaviorally oriented exposure techniques with psychoanalytic interventions that were aimed at enhancing the patient's ability to regulate his or her internal emotional experience.

Depression, in its acute and chronic manifestations, has been the focus of much effort on the part of integrationists. We have already encountered the integrative, interpersonal psychotherapy for depression developed by Gerald Klerman, Myrna Weissman, Bruce Rounsaville, and Eve Chevron in 1984. In 1992 Hal Arkowitz presented an integrative approach to depression that exemplified a common factors model. In 1993 Adele Hayes and Cory Newman wrote about an integrative model for depression that allowed the therapist to intervene with techniques drawn from behavior therapy, cognitive therapy, experiential therapy, interpersonal therapy, psychodynamic therapy, and biological psychiatry. As discussed earlier, the most effective therapy for chronic depression that has been introduced to date is the integrative CBASP model that was described by James McCullough in 2000.

Other integrationists have turned their attention to more severe disorders that often are impervious to the effects of traditional psychotherapies. One of the most important examples of this work was discussed earlier in this article, that being Marsha Linehan's dialectical behavior therapy for borderline personality disorder. Anthony Ryle wrote in 1997 of his successful attempt to treat borderline and narcissistic disorders with cognitive analytic therapy. Other important integrative models

that have been applied to severe psychopathology include Mitchell Becker's treatment for organic disorders that he wrote about in 1993; the integrative therapy for bulimia proposed by David Tobin in 1995; Nicholas Cummings' integrative psychotherapy for substances abusers, reported on in 1993; and integrative therapies for schizophrenia discussed by David Hellcamp in 1993 and by Giovanni Zapparoli and Maria Gislon in 1999. Finally, integrative models have made inroads into areas such as health psychology, as discussed by Robert Dworkin and Roy Grzesiak in 1993. These authors described an integrative psychotherapeutic approach to the treatment of chronic pain that combined the behaviorally oriented procedures of biofeedback, hypnosis, and relaxation with psychodynamic exploration and medical interventions.

V. CASE EXAMPLE

This brief case report is drawn from the author's practice and exemplifies aspects of theoretical, assimilative integration and an instance of technical eclecticism. It overlaps to a large degree with other integrative approaches but cannot be assumed to illustrate exactly the many approaches that have been discussed in this article.

Mr. X was a 35-year-old single man who had entered psychotherapy suffering from dysthymic disorder of several years' duration. He was seen in weekly psychodynamic psychotherapy sessions. As the therapy unfolded the unconscious determinants of Mr. X's depression were explored and were interpreted to him. It became clear that Mr. X had never gotten over the dissolution of his relationships with his parents, which had occurred when the patient was in his late twenties. At that time he had abandoned a lucrative career in the financial industry to become a high school teacher. This decision was highly satisfying to him on an emotional and interpersonal level, but was experienced by his parents as a major disappointment and betrayal. After trying to "mend fences" and receiving only continued anger and criticism from his parents, Mr. X had stopped seeing and speaking to them.

As far as the patient was aware, he had gotten over his hurt, anger, and longing for contact with and approval from, his family. However, as his dreams, free associations, and reactions to the therapist were explored, it became apparent that he was stuck in a process of interrupted mourning for his parents. In this state he was beset by helpless rage at his mother and father, guilt and shame at having hurt them, and an unrealistic hope that

they would one day come to love and accept him for his choice. All of these emotions were kept outside of his awareness through active defensive processes, among which was the unwitting decision to turn his anger against himself. The outcome of these unconscious attacks on himself was to feel sad, listless, and depleted, and to be constantly plagued by self-critical thoughts and images.

Interpretation of these unconscious processes and emotions helped to gain some distance and relief from his self-critical, attacking stance, but he was still unable to feel the anger and longing that he agreed intellectually seemed to be at the core of his depression. At this point, a period of cognitive restructuring was begun, with two goals: first, to further alleviate the patient's suffering, and second, because it was assumed that the presence of these thoughts continued to turn Mr. X's anger at his parents back toward himself to externalize his anger. The use of the cognitive intervention to test this was typical of assimilative integration, as it involved using a technique from cognitive therapy in order to promote change at a psychodynamic level.

As Mr. X became increasingly successful at countering his self-critical thinking, his depressive symptoms improved significantly. He began to have longer periods during which his self-esteem was maintained. As importantly, he began to recognize that the internal stimuli for his self-criticism often were dimly perceived reminders of his parents, and he began to fully feel the anger that their rejection still evoked in him. It seemed that the integration of cognitive restructuring had in fact accomplished its assimilative goal of reaching and making more accessible to the patient previously disavowed, unconscious emotional conflicts.

As Mr. X gained more access to his anger and feelings of rejection, his guilt and sense of failure diminished greatly. However, he also experienced a powerful upsurge of longing for his parents and for their love and approval. These feelings led him to contact them, but he was rebuffed in a cold and cruel way when he refused to give into their demands to return to his old job. This experience was, of course, entirely disheartening to the patient, but did help him to recover a series of memories from his childhood, all of which were concerned with his inability to satisfy his parents' demands for academic, social, and athletic success on his part. These memories echoed his present-day experience in their emotional tone of longing for love, and of feeling essentially unlovable because of his inability to attain it from his parents.

Mr. X explored these memories, emotions, and the connected image of himself as unlovable, for a number

of weeks without much progress. Remembering the success he had had with the introduction into the therapy of cognitive techniques, Mr. X asked the therapist if there might be another way to approach these issues. The therapist suggested that Mr. X might try using the empty chair technique. This method originated in gestalt therapy and involves speaking to an imaginary person whom the patient imagines is sitting in a chair in the therapist's office. This technique has been found empirically to be highly effective in helping people with "unfinished business" in this case, with Mr. X's incomplete mourning and with his longing for parental approval and love that did not seem possible to obtain. This prescriptive matching of an effective technique with a specified problem is typical of technical eclecticism, but in this case it also has an assimilative purpose. The therapist hoped that any unconscious factors that were maintaining the patient's longing could become more accessible by having Mr. X interact with the images of his parents in the sessions. As Mr. X spoke with the imaginary figures in the empty chair he was able to experience his need for love and approval in an expanded way, and found that this catharsis left him sad but comforted at the same time, with a lessened sense of need. He also became aware that he had always blamed himself for his parents' coldness and criticism. His dialogue with them helped him to become more aware of their intrinsic emotional limitations, and to separate his sense of worth and of being lovable from their inability to love. Again, the integrative technique had been successful at two levels, in this case at the experiential level for which the method had been designed, and at the psychodynamic level for which it had been integrated in an assimilative mode.

After about 11 months of therapy, Mr. X had freed himself of his dysphoric mood, but had begun to experience frequent bouts of anxiety that bordered on panic. It became clear that he also suffered from significant social anxiety that had been disguised and warded off by his depression.

Attempts to explore Mr. X's anxiety symptoms, and to identify the situational precipitants or the psychodynamic meanings of these symptoms, were fruitless and frustrating. Mr. X felt helpless and incompetent during these discussions, and the therapist eventually began to consider these interactions as constituting a transference repetition of some past relationship in which Mr. X's distress had been responded to with a lack of concern or competence on the part of a significant other. The therapist then suggested a change of tactics: the introduction of cognitive-behavioral techniques that were aimed at relaxation, anxiety management, and self-soothing.

These techniques were employed for a number of simultaneous purposes. The first purpose was to address the clinical situation and to enable Mr. X to master his anxiety and to gain a new level of comfort when faced with anxiety. Second, these active interventions were a way to move the therapy past this stalemate, and thus to resolve the resistances involved in the patient's anxiety symptoms without addressing those resistances directly. Attempts to explore and interpret the unconsciously motivated, resistive nature of the patient's anxiety had led only to Mr. X feeling criticized, ineffective, and "stupid," and to a perception of the therapist as hostile and demeaning. Finally, the therapist hoped that by actively helping Mr. X to lessen his anxiety, the patient would have an immediate (corrective emotional) experience of being valued and cared for that would illuminate and correct the negative enactment in which patient and therapist were caught.

As Mr. X became more capable of managing his anxiety he also became more aware of the interpersonal precipitants of these symptoms, and was better able to explore the warded-off meanings as well. Most important, patient and therapist were able to reestablish a positive working alliance and to explore fruitfully the past relationships, particularly with Mr. X's father, in which Mr. X's pain and fear had been met by indifference and ridicule. As he stated, "By showing that you cared how I felt and that you were willing to help in an accepting way, you proved how different you are from my father. That allowed me to see and feel how hurt and angry I am at him for how he made fun of me when I was scared, and how I expect that, and get it from others now."

This case example demonstrates the ways in which interventions from another therapeutic system can be assimilated into psychodynamic therapy, changing the meaning and impact of that intervention, and eventuating in psychodynamic and interpersonal changes that would not be anticipated in the original (here, cognitive-behavioral and experiential) systems. The active interventions led to the reduction of painful symptoms and the acquisition of new skills, but also to a radical shift in the patient's defenses, transference situation, and his understanding of his psychodynamics. Most important, the active provision of help led to the establishment of new and benign ways of perceiving himself

and important people in his life, which became the bases for hopefulness, a sense of self-worth, and a newly independent, grief-free, way of life.

VI. SUMMARY

Integrative approaches to psychotherapy blend together techniques and ideas that are drawn from the widest possible ranges of schools of psychotherapy. The goal inherent in these approaches is maximizing the patient's exposure to those factors that induce change. As such, integrative approaches represent an attempt to develop and apply, custom-fitted, broad-spectrum psychotherapies that will meet the needs of the majority of patients.

Among the many useful integrative approaches there are a number that synthesize psychoanalytic, cognitive, and behavioral features. Others emphasize the integration of humanistic and experiential therapies with more active approaches, while still a third group has focused on the combination of family systems and integrative models. Some integrative therapies are empirically tested and are guided by data, while others reflect clinical wisdom and experience.

GLOSSARY

cognitive behavior therapy (CBT) A treatment which focuses on the patient's internally based cognitions in an effort to relieve symptoms, change behavior, and ease suffering.

content affect Refers to the dominant feeling experienced at the time of a significant event.

defense mechanisms Psychological structures that assist in the modulation of internal conflicts in order to achieve harmony, both internally with demands and prohibitions, and externally with social reality and individual desires, needs, and wishes.

ego strength A term broadly referring to the ability to modulate and balance internal needs and wishes with external reality. Sometimes the term is simply used to refer to the ability to withstand threats from the external world and to modify the external world.

here and now A term that refers to present, ongoing active events in interpersonal relationships, in contrast to fantasized future or past presentations.

interpersonal incidents Descriptions by the patient of specific interactions with a significant other.

interpersonal inventory A brief description of important people in a person's life, which include the amount and quality

of contact, problems in the relationship, and expectations about the relationship.

interpersonal psychotherapy (IPT) A time-limited treatment that focuses on interpersonal relationships as a means of bringing about symptom relief and improvement in interpersonal functioning.

maintenance treatment The explicit agreement to continue treatment and contact at a "lower dose" than the agreed upon for active treatment.

process affect Refers to the emotion experienced by the patient as he or she is describing to the therapist events surrounding the cause of the affect.

transference The feelings and attitudes brought about towards a person in the present that stem from unconscious feelings and attitudes derived from a relationship with a person in the past.

treatment contract The conscious and explicit understanding between the therapist and the patient, which includes the number, frequency, and duration of sessions, the clinical foci of treatment, the roles of the patient and therapist, and the planning for contingencies such as illness, lateness, missed sessions, and acceptable and unacceptable contact for out of session and off hour emergencies and behavioral expectations, such as substance abuse.

Interpersonal psychotherapy (IPT) is a time-limited treatment that focuses on interpersonal relationships as a means of bringing about symptom relief and improvement in interpersonal functioning. This article will describe the fundamental characteristics of IPT, the

theoretical basis of the treatment, and will detail several of the therapeutic interventions used in IPT.

I. TREATMENT DESCRIPTION

A. Introduction

IPT is a time-limited, dynamically informed psychotherapy that aims to alleviate patients' suffering and improve their interpersonal functioning. IPT focuses specifically on interpersonal relationships as a means of bringing about change, with the goal of helping patients to either improve their interpersonal relationships or change their expectations about them. In addition, IPT also aims to assist patients to improve their social support network so that they can better manage their current interpersonal distress.

IPT was originally developed in a research context as a treatment for major depression, and was codified in a manual developed by Klerman and colleagues in 1984. Since that time, a great deal of empirical evidence supporting its use has accumulated. As clinical experience with IPT has increased, its use has broadened to include both a number of well-specified *Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (DSM-IV) diagnoses and the treatment of patients presenting with a variety of interpersonal problems.

IPT is based on both empirical research and clinical experience. Rather than being a static and codified treatment, IPT is designed to incorporate changes that improve the treatment, as additional data and clinical experience accumulate. Instead of being applied in a strict "manualized" form in which the clinician is required to follow precisely a treatment protocol, clinicians using IPT are encouraged to use their clinical judgment to modify the treatment when necessary in order to provide maximum benefit for their patients. The practice of IPT should be based on equal measures of empirical research, clinical experience, and clinical judgment.

B. Characteristics of IPT

IPT is characterized by three primary elements: (1) IPT focuses specifically on interpersonal relationships; (2) IPT is time limited as an acute treatment; and (3) the interventions used in IPT do not directly address the transference relationship.

1. Interpersonal Relationships

Interpersonal psychotherapy is based on the concept that interpersonal distress is linked with psychological

symptoms. Thus the foci of treatment are twofold. One focus is the difficulties and changes in relationships that patients are experiencing, with the aim of helping patients to either improve communication within those relationships, or to change their expectations about those relationships. The second focus is helping patients to better utilize their social support network so that they are better able to deal with the crises that precipitated their distress.

Interpersonal psychotherapy therefore stands in contrast to treatments such as cognitive-behavior therapy (CBT) and psychoanalytically oriented psychotherapy. In contrast to CBT, in which the focus of treatment is the patient's internally based cognitions, IPT focuses on the patient's interpersonal communications. In contrast to analytically oriented treatments, in which the focus of treatment is on understanding the contribution of early life experiences to psychological functioning, IPT focuses on helping the patient to improve communication and social support in the present. Past experiences, although clearly influencing current functioning, are not a major focus of intervention.

Interpersonal psychotherapy seeks to resolve psychiatric symptoms rather than to change underlying dynamic structures. Although ego strength, defense mechanisms, and personality characteristics are all important in assessing suitability for treatment, change in these constructs are not presumed to occur in IPT. The question that should drive the therapist's interventions is, "Given this particular patient's personality style, ego strength, defense mechanisms, and early life experiences, how can he or she be helped to improve here-and-now interpersonal relationships and build a more effective social support network?"

2. Time Limit

The acute phase of IPT is time-limited. In general, a course of 12 to 20 sessions is used for the acute treatment of depression and other major psychiatric illnesses, and a contract should be established with the patient to end acute treatment after a specified number of sessions. Clinical experience has shown that having a definitive endpoint for therapy often "pushes" patients to make changes in their relationships more quickly. The time limit also influences both patient and therapist to focus on improving the patient's interpersonal functioning in current relationships.

Although empirical research is limited to controlled treatment studies in which weekly treatment is provided and then abruptly stopped, clinical experience has clearly demonstrated that tapering treatment over time is more effective. In other words, weekly sessions may be used for

6 to 10 weeks, followed by a gradual increase in the time between sessions as the patient improves, such that weekly sessions may be followed by biweekly and monthly meetings. Although acute treatment should be time-limited, both empirical research and clinical experience have clearly demonstrated that maintenance treatment with IPT, particularly for recurrent disorders such as depression, should be provided to reduce relapse risk. Maintenance IPT must be distinguished from the acute phase of treatment in IPT, and a specific contract must be negotiated with the patient for the maintenance phase.

3. The Interventions Used in IPT Do Not Directly Address the Transference Relationship

The third characteristic of IPT is the absence of interventions that address the transference aspects of the therapeutic relationship. It is readily acknowledged in IPT that transference occurs; it is a universal phenomenon in all psychotherapy. However, although in IPT the therapist's experience of transference is used to provide information about the patient and his or her interpersonal relationships, the transference relationship is not addressed directly. To do so detracts from the focus on symptom reduction and rapid improvement in interpersonal functioning that is the aim of IPT, and also typically leads to a longer course of treatment than is required for IPT. The goal in IPT is to work with the patient quickly to solve his or her interpersonal problems before problematic transference develops and becomes the focus of treatment.

Although the transference is not directly addressed, the use of transference in IPT to assess the patient's attachment style and to understand the patient's interpersonal functioning is crucial. The use of transference to formulate questions about the patient's interpersonal relationships outside of therapy is also important. The transferential experience should be used by the therapist to formulate hypotheses about the patient's interpersonal difficulties, and to ask questions about how the patient asks others for help, ends relationships, and reacts when others are not responsive to his or her needs. These questions are directed outside of the therapy relationship, however, to current interpersonal relationships.

As an illustration, consider a patient who forms a dependent relationship with the therapist. The patient may manifest this dependency as difficulty in ending sessions, calls to the therapist between sessions, or in more subtle pleas to the therapist for help or reassurance. This transferential relationship should inform the therapist about several aspects of the patient's functioning: (1) The

patient is likely to have similar problems in relating to others; (2) the patient is likely to have difficulty in ending relationships; and (3) the patient has likely exhausted others with the persistent dependency. A hypochondriacal patient would be an excellent example of this kind of behavior, manifested in the ways described.

Further, the transferential experience should be used by the therapist to predict potential problems in treatment, and to modify the therapy accordingly. For instance, the therapist might hypothesize that the patient's dependency may be a problem when concluding treatment, and may begin discussing the ending of therapy much sooner than with less dependent patients. The therapist should also strongly encourage a dependent patient to build a more effective social support network, so that the patient's needs are more fully met outside of therapy rather than fostering a dependent or regressive relationship in the therapy itself. Appropriate modifications would also be made with patients who are avoidant or who manifest other personality characteristics.

C. Treatment Process

IPT can be divided into assessment (described later), initial sessions, intermediate sessions, treatment conclusion, and maintenance treatment phases. During each, the clinician has a well-defined set of tasks to accomplish. Undergirding these therapeutic tasks and techniques is the stance taken by the therapist. Clinicians should be active and maintain the focus of therapy. The therapist should also be supportive, empathic, and strongly encouraging, and should make every effort to convey a sense of hope to the patient and to reinforce his or her gains.

1. Initial Sessions

During the initial sessions of IPT (usually the first one or two meetings following the general assessment) the therapist has three specific tasks. These are (1) to conduct an interpersonal inventory; (2) to work collaboratively with the patient to determine which problem areas will be the focus of treatment; and (3) to develop a treatment contract with the patient.

The interpersonal inventory is a brief description of the important people in the patient's life, and for each includes the amount and quality of contact, problems in the relationship, and the expectations about the relationship. These descriptions need not be exhaustive; those that become treatment foci will be revisited in detail later. The purpose of the inventory is to determine which relationships to work on, and to gather further

information regarding the patient's attachment and communication patterns.

Once the inventory is complete, the patient and clinician should mutually identify one or two problem relationships on which to focus. The therapist should frame the patient's problem as interpersonal, and should give specific examples of the way in which the problem fits into one of the four problem areas: grief and loss, interpersonal disputes, role transitions, or interpersonal sensitivity.

Establishing a treatment contract is an essential part of IPT. In general, the contract should specifically address (1) the number, frequency and duration of sessions, which in general will be about 12 to 20; (2) the clinical foci of treatment; (3) the roles of the patient and therapist, particularly the need for the patient to take responsibility for working on his or her communication between sessions; (4) contingency planning: issues such as missed sessions, lateness or illness; and (5) acceptable conduct: contact out of hours, emergencies, and behavioral expectations such as substance use.

Because of the injunction in IPT to limit discussing the transference relationship directly, the contract must serve as a rock solid point of reference for both patient and therapist. Thus when contract violations occur, the therapist can remind the patient that both had initially agreed on certain guidelines for therapy, and that the patient, by failing to meet his or her responsibility, is in essence minimizing the benefit of the treatment. The therapist would then proceed to ask questions about similar behavior outside of the therapeutic relationship.

2. Intermediate Sessions

During the intermediate sessions of IPT, the patient and therapist work together to address the interpersonal problems identified during the assessment. In general, work on these issues proceeds in the following order: (1) identification of a specific interpersonal problem; (2) a detailed exploration of the patient's perception of the problem, including communication patterns and expectations about the relationship; (3) collaborative brainstorming to identify possible solutions to the problem; (4) implementation of the proposed solution; and (5) reviewing the patient's attempted solution, with positive reinforcement of the changes made and discussion of refinements to be carried out.

The tasks of the therapist in the intermediate sessions of IPT are to assist the patient in discussing his or her problematic interpersonal relationships, and to attend to the therapeutic relationship. In addition, the

therapist must actively work to maintain the focus of therapy, rather than encouraging or allowing the patient to talk about peripheral issues.

Once a specific issue is identified, the therapist should encourage the patient to describe his or her perceptions and expectations about the relationship problem. Whether it is a problem in communication or a matter of unrealistic expectations, the patient and therapist work collaboratively to brainstorm and identify possible solutions. The patient is responsible for attempting to implement the agreed upon solution, and to provide feedback regarding the attempted solution and its results at the next session. The therapist and patient then review these results and make modifications as needed.

A number of solutions can be considered in IPT. For instance, a change in communication to a style that is more direct may be of help with a dispute. A change in circumstances, such as a change in location or in employment, may be of benefit during a role transition. Changes in expectations, with a movement toward other social support, are also viable options. In IPT, however, the endpoint of therapy is not simply insight; it is change in communication, behavior, and social support that leads to symptom resolution.

3. Completing Acute Treatment

Acute treatment with IPT comes to an end as specified by the therapeutic contract. There are both theoretical and practical reasons for keeping acute treatment with IPT time-limited. The time limit is very effective in generating change, as it often compels patients to work more rapidly on improving communication skills and building more effective social networks. In addition, the time limit influences both patient and therapist to focus on acute symptoms rather than on personality change. Moreover, to extend IPT beyond the acute time frame may lead to the development of problematic transference, as the relationship between patient and therapist assumes greater importance.

On the other hand, the success of therapy is also dependent on the patient's belief that the therapist is committed to helping the patient, and that the patient's needs supercede other considerations. The IPT therapist should prioritize helping the patient ahead of satisfying the dictates of a manualized protocol. Consequently, if extending the therapy beyond the number of sessions initially agreed upon is clearly in the patient's best interest, then it should be extended. The apparent conflict between maintaining the therapeutic contract and extending sessions when needed can be resolved by renegotiating a new treatment contract with the patient. Clinical judgment should be used to make such a decision.

Clinical experience with IPT strongly suggests that the best clinical practice is usually to extend the interval between sessions once the patient is in the recovery stage of acute treatment. Rather than continuing to meet weekly, the patient and therapist may choose to meet biweekly or even monthly toward the end of treatment. This gives the patient further opportunities to practice communication skills, to reinforce the changes that have been made, and to develop more self-confidence while remaining in a supportive relationship, all of which facilitate better and more stable functioning.

As the primary goals of IPT are symptom relief and improvement in interpersonal functioning, the specific aims of treatment conclusion are to foster the patient's independent functioning and to enhance his or her sense of competence. The therapist is still available should a future emergency arise, but the expectation is that the patient will quite capably function independently.

4. Maintenance Treatment

Rather than using the traditional psychoanalytic model in which "termination" is a complete severing of the therapeutic relationship, concluding acute treatment with IPT does not signify the end of the therapeutic relationship. In fact, in IPT it is usually agreed that there will be therapeutic contacts in the future, and provision is specifically made for these. Clinical experience, theory, and empirical evidence all make clear that IPT should be conceptualized as a two-phase treatment, in which a more intense acute phase of treatment focuses on resolution of immediate symptoms, and a subsequent maintenance phase follows with the intent of preventing relapse and maintaining productive interpersonal functioning. Therefore, the therapist should specifically discuss future treatment with the patient prior to concluding therapy. A specific contract should be established with the patient for the specific alternative for the provision of maintenance treatment that is chosen. Options include specifically scheduling maintenance sessions at monthly or greater intervals; concluding acute treatment with the understanding that the patient will contact the therapist should problems recur; or planning to have the patient contact another provider in the future. Decisions about how to structure future treatment should rely on clinical judgment.

In essence, IPT follows a "family practice" or "general practitioner" model, in which short-term treatment for an acute problem or stressor is provided until the problem is resolved. Once resolved, however, the therapeutic relationship is not terminated; as with a general practitioner, the therapist makes himself or her-

self available to the patient should another crisis occur, when another time-limited course of treatment can be undertaken. In the interim, the therapist may choose, like a general practitioner, to provide "health maintenance" sessions periodically. There is no compelling clinical or theoretical reason to come to a complete termination with most patients in IPT, while the data clearly support the benefit of maintenance treatment.

D. Techniques and Therapeutic Process

It is the focus on extra-therapeutic interpersonal relationships rather than any particular intervention which characterizes IPT. Not surprisingly, given its psychodynamic roots, IPT incorporates a number of "traditional" psychotherapeutic methods, such as exploration, clarification, and even some directive techniques. While there are no techniques which are actually forbidden in IPT, all should be used in the service of helping the patient to modify interpersonal relationships.

More important than any techniques, however, is the establishment of a productive therapeutic alliance. Warmth, empathy, genuineness, and conveying unconditional positive regard, though not sufficient for change, are all necessary for change in IPT. Without a productive alliance, the patient will flee therapy, an obstacle which no amount of technical expertise can overcome.

A primary goal of the IPT therapist should be to understand the patient. If the patient does not perceive that the therapist is truly committed to doing this, the patient will not readily disclose information, will not feel valued as an individual, and will not develop a meaningful relationship with the therapist. Working to understand the patient should always take precedence over any technical interventions. Further, all IPT interventions should be therapeutic; the ultimate value of an intervention is the degree to which it helps the patient. Techniques should not be used simply because they are included in a manualized protocol; the benefit to the patient should guide the interventions used in treatment.

1. Nonspecific Techniques

Nonspecific techniques are generally understood as those that are held in common across most psychotherapies. Examples would be the use of open-ended questions, clarifications, and the expression of empathy by the therapist. These techniques play a crucial role in IPT, as they serve to help the therapist understand the patient's experience, convey that understanding to the patient, and to provide information regarding the genesis

of the patient's problems and potential solutions to them. Techniques such as problem solving with the patient, giving directives, and assigning homework can also be used judiciously in the service of facilitating interpersonal change.

2. Communication Analysis and Interpersonal Incidents

The analysis of the patient's communication patterns is one of the primary techniques used in IPT. The therapist's task is to assist the patient to communicate more clearly what he or she wants from significant others. Communication analysis requires that the therapist elicit information from the patient about important interpersonal incidents. Interpersonal incidents are descriptions by the patient of specific interactions with a significant other. If the identified dispute results in a pattern of fighting between spouses, the therapist might ask the patient to "describe the last time you and your spouse got into a fight," or to "describe one of the more recent big fights you had with your spouse." The therapist should direct the patient to describe the communication that occurred in detail, re-creating the dialogue as accurately as possible. The patient should describe his or her affective reactions as well as both verbal and nonverbal responses, and describe observations of his or her spouse's nonverbal behavior.

The purpose of discussing an interpersonal incident is twofold: (1) to provide information regarding the miscommunication that is occurring between the parties; and (2) to provide insight to the patient about the unrealistic view that the problem is intractable. The goal in working through an interpersonal incident is to examine the patient's communication so that maladaptive patterns of communication can be identified. The patient can then begin to modify his or her communication so that his or her attachment needs are better met.

3. Use of Affect

The more the patient is affectively involved in the issues being discussed, the greater the motivation to change behavior or communication style. Consequently, one of the most important tasks for the IPT therapist is to attend to the patient's affective state. Of particular importance are those moments in therapy in which the patient's observed affective state, and his or her subjectively reported affect, are incongruent. Examining this inconsistency in affect can often lead to breakthroughs in therapy.

Affect can be divided into that experienced during therapy (process affect) and that reported by the patient to have occurred in the past (content affect). Con-

tent affect refers to the predominant affect experienced at the time of a significant event. For instance, a patient might describe feeling "numb" at the time of the death and funeral of a significant other. Process affect, on the other hand, refers to the affect experienced by the patient as he or she is describing to the therapist the events surrounding the loss. The same patient, for example, might describe a "numb" feeling at the time of the funeral, but when describing the event to the therapist might be in tears, and feeling sadness, or perhaps anger. When met with this incongruence in affect, the therapist can focus directly on the discrepancy between content and process affect. In other words, when the report the patient gives about how he or she felt during an interpersonal event is different from the affect he or she is exhibiting during the session, it should be noted by the therapist and explored further.

4. Use of Transference

Transference is a universal occurrence in all psychotherapies, and plays an extremely important part in IPT. However, in contrast to longer-term psychodynamic therapies, information gleaned from the transference that develops during IPT, although an important source of data, is not typically a point of intervention.

By observing the developing transference, the IPT therapist can begin to draw hypotheses about the way that the patient interacts with others outside of the therapeutic relationship. Sullivan coined the term "parataxic distortion" to describe this phenomena: The way in which a patient relates to the therapist in session is a reflection of the way in which he or she relates to others as well. Attachment theory also supports the idea that individuals tend to relate to others in a manner that is consistent both across relationships and within relationships. Thus the transference or parataxic distortion recognized by the clinician provides a means of understanding all of the other relationships in the patient's interpersonal sphere.

Using these data, the therapist can then begin to draw conclusions about the patient's attachment style and problems in communicating to others. The therapist should ask questions to confirm or disprove these hypotheses. For instance, if the therapist notes that the patient tends to be deferential in therapy, hypothesizing that the patient tends to be the same way in other relationships is reasonable. The therapist may want to ask about the experiences (or difficulties) that the patient has had in confronting others, or in dealing with rejection. Similarly, if the patient behaves in a dependent manner during therapy, the therapist may ask about

how the patient maintains relationships, or about experiences the patient has had in ending relationships.

The key difference between IPT and transference-based therapies is that the IPT therapist should avoid making transference comments, and particularly interpretations, about the therapeutic relationship. As long as a reasonably positive transference is maintained, therapy can proceed without the need to focus on it. The therapist should focus instead on the here-and-now problems in the patient's extratherapy interpersonal relationships. With well-selected patients, keeping the therapy short-term allows the therapist to assist the patient to solve his or her interpersonal problems before the transference becomes intense, and as a result, becomes the new focus of therapy.

E. Interpersonal Model

1. Problem Areas

IPT focuses on four specific interpersonal problem areas: grief and loss, interpersonal disputes, role transitions, and interpersonal sensitivity. Psychosocial stressors from any of the problem areas, when combined with an attachment disruption in the context of poor social support, can lead to interpersonal problems or psychiatric syndromes. Although these categories are useful in focusing the patient on specific interpersonal problems, it is important to be flexible when using them. Rather than "diagnosing" a specific category, the problem areas should be used primarily to maintain focus on one or two interpersonal problems, particularly as the time available in IPT is limited. Because the interpersonal problems experienced by patients are all derived from the combination of an acute interpersonal stressor combined with a social support system that does not sufficiently sustain the patient, effort should always be directed toward improving the patient's social supports as well as addressing the specific problem.

a. Grief and Loss. Grief in IPT can best be conceptualized as a loss experienced by the patient. In addition to the death of a significant other, a loss such as divorce may be seen by the patient as a grief issue. Loss of physical functioning, such as that following a heart attack or traumatic injury, may also appropriately be considered in the grief problem area.

The therapist's tasks are to facilitate the patient's mourning process, and to assist the patient to develop new interpersonal relationships, or to modify existing relationships to increase social support. Although new or existing relationships cannot "replace" the lost rela-

tionship, the patient can reallocate his or her energies and interpersonal resources over time.

Several strategies are useful in dealing with grief issues. Primary among these is the elicitation of feelings from the patient, which may be facilitated by discussing the loss and the circumstances surrounding it. The use of process and content affect may be quite useful. Often the patient will initially describe the lost person as "all good" or "all bad," and be unaware that this idealization (or devaluation) covers other contradictory feelings. Grief issues commonly involve layers of conflicted feelings surrounding the lost person, and assisting the patient to develop a "three-dimensional" picture of the lost person, including a realistic assessment of the person's good and bad characteristics, is a helpful process in the resolution of the grief.

This same process can be used for other losses as well, such as the loss of a job, a divorce, or loss of physical functioning. In such instances the patient will also need to grieve the loss, and to move toward establishing new social supports. Encouraging patients to develop a more realistic view of their loss is helpful as well.

b. Interpersonal Disputes. The first step in dealing with interpersonal disputes is to identify the stage of the conflict, and to determine whether both parties are either actively working to solve the problem, have reached an impasse, or have reached a point at which dissolution is inevitable. Successful treatment does not necessarily require that the relationship be repaired. Resolutions to the conflict may be to modify the relationship, to modify expectations about the relationship, or to exit the relationship. The important point is that the patient makes an active and informed decision about the relationship.

A primary goal of treatment is to assist patients with interpersonal disputes to modify their patterns of communication. Patients may become locked in patterns of communication with others that result in misunderstanding, or in cycles of escalating affect. The therapist can assist the patient to communicate his or her needs more clearly and productively, rather than provoking hostile responses. The therapist should model direct communication to the patient, and may engage the patient in role playing to reinforce the new communication. Although IPT is generally an individual therapy, inviting a significant other to therapy for several conjoint sessions can be an invaluable way to observe the communication *in vivo*, and to begin to help the couple to make changes in their interactions.

C. Role Transitions. Role transitions encompass a huge number of possible life changes. Included are life cycle changes such as adolescence, childbirth, and decline in physical functioning, and social transitions such as marriage, divorce, changes in job status, and retirement. Typical problems include sadness at the loss of a familiar role, as well as poor adaptation or rejection of the new role. Role transitions often result in the loss of important social supports and attachments, and may require new social skills.

The therapist should assist the patient in moving from his or her old role, which includes assisting the patient to experience grief over the loss, often using some of the techniques described for dealing with grief issues. It is crucial to help the patient to develop a realistic and “balanced” view of the old role, including both positive and negative aspects. Assisting the patient to develop new social supports is also essential.

d. Interpersonal Sensitivity. There are some patients who either because of personality traits, avoidant attachment styles, or other factors, may have problems with poor interpersonal functioning. “Interpersonal sensitivity” refers specifically to a patient’s difficulty in establishing and maintaining interpersonal relationships. Patients with interpersonal sensitivities often require a different approach than is utilized with patients who have better social skills.

Patients with interpersonal sensitivities may have few, if any, interpersonal relationships to discuss in therapy. Relationships with family members, although they may be quite disrupted, may be some of the only relationships the patient has. The therapeutic relationship may also take on greater importance, as it too may be one of the patient’s only relationships. The therapist should be prepared to give feedback to the patient regarding the way he or she communicates in therapy, and may utilize role-playing to practice skills with the patient. In addition, the therapist should assist the patient to get involved in appropriate social groups or activities in the community. Above all, the therapist and patient must keep in mind that the therapy is not designed to “correct” the social difficulties, but rather to teach the patient some skills to build new relationships, and to relieve his or her acute distress.

II. THEORETICAL BASIS

IPT is grounded in attachment theory, which as described by Bowlby among others, rests on the premise

that people have an instinctual and biological drive to attach to one another. When crises occur, individuals seek reassurance and care from those important to them. Interpersonal communication is intrinsic to this process, and individuals who cannot effectively ask for care, and consequently cannot obtain the physical and psychological care they need, will suffer as a result. When interpersonal support is insufficient or lacking during times of stress, individuals are less able to deal with crises and are more prone to develop psychiatric symptoms.

Bowlby described three different types of attachment styles that drive interpersonal behavior. Secure attachment describes individuals who are able to both give and receive care, and are relatively secure that care will be provided when it is needed. Because securely attached individuals are able to communicate their needs effectively, and because they are able to provide care for others, they typically have good social support networks. Thus they are relatively protected from developing problems when faced with stressors.

Anxious ambivalent attachment, in contrast, is a style in which individuals behave as if they are never sure that their attachment needs will be met. Because of this, such individuals believe that care must be sought constantly. Such individuals often lack the capacity to care for others, since their concern about getting their own attachment needs met outweighs all other concerns. Consequently, they have a relatively poor social support network, which in combination with their difficulties in enlisting help, leave them quite vulnerable to interpersonal stressors.

Individuals with anxious avoidant attachment typically behave as if care will not be provided by others in any circumstances. As a result, they avoid becoming close to others. The paucity of their social connections, along with their tendency to avoid asking for help during times of crises, leaves these individuals quite prone to difficulties.

In essence, attachment theory states that those individuals with less secure attachments are more likely to develop psychiatric symptoms and interpersonal problems during times of stress. A persistent belief that care must be constantly demanded from others, or that care will not be provided by others, typically leads insecurely attached individuals to have more difficulty in asking for and maintaining social support during times of crisis. Severe disruptions of important attachment relationships, such as the death of a significant other, also lead to an increased vulnerability to psychiatric symptoms.

Interpersonal psychotherapy also follows the biopsychosocial model of psychiatric illness, resting on the

premise that psychiatric and interpersonal difficulties result from a combination of interpersonal and biological factors. Individuals with a genetic predisposition are more likely to become ill when stressed interpersonally. On this foundation rests the individual's temperament, personality traits, and early life experiences, which in turn are reflected in a particular attachment style. The attachment style may be more or less adaptive, and has effects on the person's current social support network and his or her ability to enlist the support of significant others. Interpersonal functioning is determined by the severity of current stressors in the context of this social support.

Interpersonal psychotherapy is therefore designed to treat psychiatric symptoms by focusing specifically on patients' primary interpersonal relationships, particularly in the problem areas of grief, interpersonal disputes, role transitions, and interpersonal sensitivity. This is done by helping the individual to recognize and modify his or her communication patterns, which has a threefold effect. First, it leads to more effective problem solving, as conflicts can be more directly addressed. Second, it improves the patient's social support; communicating in a way to which others can more readily respond will more effectively meet the patient's attachment needs. Third, these improvements in communication and in conflictual relationships, and improved social support, help resolve the interpersonal crisis and result in symptom resolution.

III. APPLICATIONS AND EXCLUSIONS

The purpose of conducting an assessment is to determine when IPT should be used, and to whom it should be applied. The assessment may take several sessions to complete. It is only after the assessment, and the determination that the patient is suitable, that IPT should formally begin.

During the assessment, the therapist should evaluate the patient's attachment style, communication patterns, motivation, and insight. Assessment of DSM-IV diagnoses should also occur. IPT should not, however, be restricted only to patients with DSM Axis I diagnoses; it is quite suitable for patients with a variety of interpersonal problems such as work conflicts or marital issues. In fact, because patients without major psychiatric illness often have more secure attachments and better social support networks, they are usually able to utilize IPT very effectively.

Special attention should be paid to patients diagnosed with personality disorders. Those with cluster A disor-

ders including paranoid, schizoid, and schizotypal personality disorders may be unable to form effective alliances with their therapists in short-term therapy, whereas those with severe cluster B disorders such as narcissistic, histrionic, borderline, and antisocial personality disorders may require more intensive therapy than can be provided in an IPT format. However, many patients with depression or anxiety superimposed on a personality disorder may benefit a great deal from short-term therapy with IPT if the focus is on the treatment of the depression or anxiety rather than on personality change.

The assessment should include an evaluation of the patient's attachment style. This should consist of information about the patient's perception of his or her patterns of relating to others, and an evaluation of the patient's past and current relationships. Questions regarding what the patient does when stressed, ill, or otherwise in need of care are particularly helpful. The patient should also be queried about his or her typical responses when asked to assist others.

The patient's attachment style has direct implications regarding his or her ability to develop a therapeutic alliance with the therapist and the likelihood that treatment will be beneficial. Those patients with more secure attachment styles are usually able to form a more productive relationship with the therapist, and because of their relatively healthy relationships outside of therapy, are also more likely to be able to use their social support system effectively. Individuals with more anxious ambivalent attachments can usually quickly form relationships with their clinicians, but often have difficulty with the conclusion of treatment. Those with anxious avoidant attachments may have difficulty trusting the therapist. Consequently, when working with anxious avoidant patients, the therapist may need to spend the initial sessions working on developing a productive therapeutic alliance, waiting until a good alliance is established before moving into more formal IPT work.

The therapist should also use the assessment to forecast and plan for problems that may arise during therapy. For example, because patients with anxious ambivalent attachment styles often have difficulty in ending relationships, the therapist may modify his or her approach by emphasizing the time-limited nature of the treatment, and by discussing the conclusion process earlier. Significant others may also be included in sessions more frequently to ensure that therapeutic dependency does not become a problem. When working with avoidant patients, the therapist should plan to spend several sessions completing an assessment, taking great care to convey a sense of understanding and empathy to the patient.

The therapist should conduct an assessment of the patient's communication style. The way in which the patient communicates his or her needs to others has profound implications for the therapeutic process, as well as for the likelihood that the patient will improve with therapy. The therapist should directly ask the patient for examples or vignettes in which a conflict with a significant other occurred. Patients who are able to relate a coherent and detailed story are likely to be able to provide the narrative information necessary to work productively in IPT. Insight can also be judged by noting the way in which the patient describes an interaction, and the degree to which the other person's point of view is accurately represented.

In general, patients who have characteristics that render them good candidates for all of the time-limited therapies will be good candidates for IPT. These include motivation, good insight, average or better intelligence, and sufficient ego functioning. Other characteristics specific to IPT include (1) a specific interpersonal focus of distress, such as a loss or interpersonal conflict; (2) a relatively secure attachment style; (3) the ability to relate a coherent narrative; and (4) a good social support system.

IV. EMPIRICAL STUDIES

Interpersonal psychotherapy has been demonstrated to be efficacious in a number of research studies; at present, with the exception of cognitive therapy, IPT enjoys more empirical support than any other form of psychotherapy. Since the initial studies of IPT in 1979 by Klerman, Weissman, and colleagues, IPT has been demonstrated to be efficacious with a number of depressed populations, including depressed geriatric patients, depressed adolescents, depressed patients who are HIV-positive, and patients with dysthymic disorder. IPT has also been used for both postpartum and antenatal depression. In addition, it has been tested with patients in the depressed phase of bipolar disorder and with eating disorders.

Largely because of the success of the early efficacy studies, IPT, along with CBT, was chosen as a comparative psychotherapeutic treatment in the National Institute of Mental Health Treatment of Depression Collaborative Research Program (NIMH-TDCRP). Both were compared to treatment with imipramine and with placebo over 16 weeks. IPT was found to be superior to placebo, and was equal to imipramine and CBT for mild to moderate depression. Neither psychosocial treatment was as effective as imipramine for severe depression. The

consensus from the NIMH-TDCRP study is that IPT and CBT are effective for mild to moderate depression, but that antidepressant medication should remain the gold standard treatment for severe depression.

Another major study evaluating IPT involved maintenance treatment of patients with recurrent depression. Acutely depressed patients who had suffered at least three prior episodes were treated with a combination of imipramine and IPT over 16 weeks. Patients who recovered were then assigned to one of five maintenance treatments: (1) imipramine alone; (2) imipramine plus monthly IPT; (3) monthly IPT alone; (4) monthly IPT plus placebo; and (5) placebo alone. The patients were then followed for 3 years.

Mean depression-free survival time was significantly longer for those patients who received imipramine alone or imipramine plus IPT. Over 3 years, the mean time before relapse of depression was about 120 to 130 weeks for patients who received imipramine with or without IPT as an adjunct. The patients who received IPT alone or IPT plus placebo had a mean survival time of about 75 to 80 weeks. Although significantly better than the mean survival of patients who received only placebo (roughly 40 weeks), treatment with IPT alone was not as beneficial as treatment with maintenance antidepressant medication. The current consensus is that recurrent depression should be treated with maintenance antidepressant medication, with IPT a viable alternative for patients who do not want or who cannot tolerate medication.

Currently IPT is being investigated for use with social phobia and somatization disorder. The use of IPT has also been described with groups, couples, and in a family practice setting. Excellent reviews of this research can be found elsewhere.

The research on IPT clearly demonstrates its efficacy as a time-limited treatment for acute depression, and as an effective alternative to medication for patients with recurrent depression. Further, there are numerous studies that suggest that IPT may be efficacious for patients with a variety of DSM-IV Axis I disorders.

V. SUMMARY

Interpersonal psychotherapy is characterized by three essential elements: a focus on interpersonal relationships, a contract that specifies a time limit for therapy, and the use of interventions that focus on relationships outside of therapy rather than on the transference relationship. Attachment theory undergirds the approach used in IPT, and the attachment style of the patient

should instruct the therapist about the patient's suitability for treatment, prognosis, and the potential problems that may arise in therapy. Further, the patient's attachment style should inform the therapist about the ways in which the therapy can be modified.

Interpersonal problems and psychiatric symptoms are conceptualized within a biopsychosocial framework. An acute interpersonal crisis, such as a loss, interpersonal dispute, or a difficult life transition, creates problems for patients for two reasons: (1) Their interpersonal communication skills within their significant relationships are not adaptive; and (2) their social support network is not sufficient to sustain them through the interpersonal crisis. IPT proceeds by helping patients to communicate their attachment needs more effectively, to realistically assess their expectations of others, and to improve their social support. This should help resolve interpersonal problems and relieve psychiatric symptoms.

The conduct of IPT is based on a three-point foundation. First, the practice of IPT rests on empirical research. Second, the practice of IPT reflects clinical experience. Finally, and most important, the practice of IPT includes the use of clinical judgment: The therapist

must recognize the unique nature of the relationship with the unique individual with whom he or she works, and must always place the needs of the patient above a strict adherence to a manual. Given these foundational supports, IPT is an efficacious, effective, and extremely useful clinical approach to interpersonal problems.

GLOSSARY

genetic History of the individual encompassing both biological influences, the temperamental givens in birth and development, and the prior influences of environmental nurture and stressors.

internalization Process by which the new knowledge conveyed by the interpretation becomes syncretic with the person's expanded sense of self.

interpretation Technique for reformulating the many competing and conflicting modes of thought from the multiple developmental epochs of the mind.

I. INTERPRETATION: A DEFINITION

Interpretation is a basic process in psychoanalysis and psychotherapy by which old information of the patient is translated into a new syntax of self-understanding by a therapist. It is a fundamental element of the process of psychological healing. The act of interpretation simultaneously promotes psychological repair and is the mode for bringing about psychological change in the individual. It is a technique by which one individual, the psy-

chotherapist or analyst, plumbs the unconscious mind of the analysand or patient with the purpose of bringing to light new cognitive connections, new feeling states, and new perspectives on human relationships. Interpretation involves a reformulation of the affected mind to address the defensive intellectualizations, rationalizations, and denials of fact and outer reality that have been erected by individuals to salvage and preserve their limited and compromised sense of identity and being, such as it is. Interpretation connects the latent and manifest meanings that reside in a person's psyche as they emerge in the context of a special therapeutic relationship. This relationship consists of transference of past history on the part of the patient onto his or her image of the therapist and countertransference empathic referencing of this transference on the part of the therapist. Interpretation provides a medium and context for further objectification of the individual's subjective experience, leading to an increase in capacities for insight, self-analysis, and self-interpretation. On another level these shifts in reflection are accompanied by new senses of self and identity in relation to others. When it works well interpretation brings about incrementally and occasionally dramatically a new language of self in a new key.

II. WHY INTERPRETATION?

To understand interpretation and its fundamental role in the therapeutic action in dynamic treatments,

psychotherapy, and psychoanalysis it is first necessary to review some central concepts about the growth and functioning of the mind. The brain provides the biological engine of the mind. Dysfunctions of the brain can readily translate into disorders of the mind. The mind is also capable of its own disorders apart from neurophysiology that are related to its often imperfect attempts to synthesize the conflicting types of information that it is presented with and the divergent modes by which it processes that information. For instance, one of the great paradoxes of human existence involves the presence of a sense of both mindedness and mindlessness in our psychology. The evolution of mankind's capacities for consciousness, self-awareness, and self-reflection are central aspects of what separates *homo sapiens* from other organisms. The human capacity for thought that extends beyond the immediate neural responses to stimuli for the purposes of obtaining pleasure, release, or avoiding unpleasure is present and developed in humans as in no other species. The capacity for mental activity that goes beyond the immediate and relatively fixed response to signal forms of activity adds variety to human behavior and to the possibility of thinking about things.

We have a potential and actual psychology that we share, communicate, and talk about in myriad ways. Many organisms may use signs and signals to communicate. These occur without a sense of memory and foreknowledge and the mutually reinforcing transfer of information and intellect that we both observe and infer in humans. In the realm of feelings and affective life, while flight and/or fight provides a foundation of basic organismic and affective responses, the dimension of time adds complexity, depth, and layers of feelings and shared understanding. The apprehension of a dangerous or painful future becomes the foundation for a complex of anxieties and is something that humans share. The memory of a noxious past in the form of depressive dread is part and parcel of human existence in a world of psychological infinitude that continues through and beyond time. We possess minds that meet, diverge, that are lost and found but that are nonetheless capable of thinking about a self or other selves through a unique medium that we call psychological mindedness.

The other part of the paradox of mindedness that I referred to earlier is mindlessness. Mindlessness in psychoanalytic terms represents preconscious and unconscious realms and aspects of our minds that are typically "lost" or unknown. We conceptualize the disavowed "mindless" unconscious as originating in our psychological prehistory. It emerges as part of the earliest psychological stirrings and questings of the infant-

organism. As such it contains all the contradictions and conflicts of the organism's attempt to derive a structure and function of thought from rudimentary physical and psychological experience. In Freud's original terms we come to conceptualize this first infant area of psychological strata as primary process thought. Primary process thought is an "unminded" mode of thinking about perceptions that we think are experienced by the infant and are reported by the adult as occurring in a relatively monadic context. There are few social referents in this realm. It is a way of perceiving that will eventually give way through experience, learning, socialization, and neuropsychological maturation to the dyadic mindedness and organized cognition of secondary process thought.

The toll on the developing brain of managing these divergences of mind and consciousness is that certain modes of thought and experience are relegated to unconscious mental functioning. This is the price to be extracted for resolving conflicts between one part of the mind and another. We describe this as intrapsychic conflict resolution. This mode may also be active in resolving conflict between the psyche and forces or beings in the outer world, what we refer to as interpsychic conflict resolution. Both forms may be, and often are, sequestered in the "mindless," disavowed regions of unconscious thought although each area of conflict may also have its derivatives in consciousness.

The result of such syntheses is that we split our consciousness in our waking state and to some lesser extent in our sleeping state. We must think and act as though we know what we are doing and responding to in its entirety even when, in fact, we know only a portion, sometimes only a small portion, of the picture of perception and response. If our responses become stereotypic with fixed outcomes that seem not to benefit from experience and learning, we categorize such responses as "neurotic." Neurosis is a quality of experience that is driven more by the need to appease the internal psychic economy of the individual than it is geared to benefiting from novel experiences and attaining a newer and better adaptation of inner and outer worlds. What in the optimum sense should be a part of mindedness becomes instead coopted by conflict resolution that leads to repetitive behaviors and circular modes of thought. Thus the child who has been severely abused and neglected by a parent may continue to encounter such a parent in his many relationships throughout life as though to work out through repetition the trauma of the early parental catastrophe. Such neurotic modes affirm a mindless frozen psychological state in which

what is unconscious dictates mental outcome rather than facilitating new levels of mentation and psychological organization. In the example just given that would mean having the psychological flexibility to move on to appreciate and appropriate the new opportunities for nurturing and nontraumatic mothering in later life figures or thought.

The therapist is the agent necessary to make interpretations and shed new light on dim repetitions. Such interpretations are delivered in a value-neutral manner except insofar as they carry with them an investment in the patient acquiring increasing self-perspective and making a psychological recovery. To cite another example, the power of an individual's anger may be blocked from perception and expression, or, conversely, it may be expressed in overly strong and inappropriate ways. In either case the person is unable to face the threat that anger poses. They may feel either paralyzed in the first instance or defeated by their own rage in the second. They require interpretation of what they are unaware of through the medium of a significant and trusted other to be able to link up all levels of the neurotic feeling state that has brought with it either such an overabundance or a paucity of action.

We equate "healthy" psychological development with a wholeness of consciousness; one that admits to opposites, similarities, ambiguities, and divergent lines of thought. We look for flexibility, adaptability, and the capacity to ride through life's inevitable conflicts so as to arrive at some sort of stability and interpenetration of conscious thought with unconscious fantasy that enlarges and deepens the individual's engagement with inner and outer worlds. The need for interpretation is always there, but healthy individuals are less blocked and more able to provide meaningful reformulations of everyday events. They are able to learn from their experience and the experience of others without the aid of special pleadings of special agents.

To approach the matter of interpretation from a somewhat different direction, in the ideal, because we are capable of empathy, putting oneself in the mind of another, there exists the possibility of psychological healing. The prototype for this experience is the mother's psychological work in intuiting and inferring the affective and cognitive state of her nonverbal infant and then taking the necessary steps physically or psychologically to remedy its distress. If the child was cold and wet, warmth and dryness would be the soothing response. This response would permit the infant to identify such a state, not from the affective perspective of anxiety and helplessness, but with the anticipation

and optimism that the ministrations of another are correct, timely, and will bring relief. Ultimately this would allow for the development of the capacity for self-soothing through the process of internalization. If the infant is fearful of separation from the mother or the presence of strangers, the mother's adoption of a calm stance through verbal tone, words, and actions will eventually increase the child's sense of security in the mother's availability and protectiveness. Such interpretive understanding translates into the child's taking in the mother's loving presence. If things go wrong in such situations the child will end up afraid of anxiety and distrustful of the adult's abilities to understand and remedy their fear of the strange. Over time the infant becomes more able to take in, to internalize, the mother's empathic actions. This eventuates in the ability to consciously and unconsciously soothe and care for themselves in situations of potential estrangement or physical discomfort.

This empathic paradigm is the cornerstone of psychological healing. By means of it, one participant, the therapist, listens and observes another person, the patient, in distress and infers and interprets the hidden and unconscious elements that have led them to repeatedly hit the same mental block as in their love and work lives.

In 1901 Freud originally introduced the technical lynchpin of interpretation in his classic work *The Interpretation of Dreams*. In its initial guise in his attempts to treat hysteria, interpretation involved a "Rumpelstiltskin" sort of technique in which deep understanding by the therapist was converted into memory of genetic events that were expected to magically change the patient's symptomatology. In most versions of the fairy tale "Rumpelstiltskin" if the princess whom Rumpelstiltskin has given a baby can guess his name she may keep the baby and he will vanish. In his treatment of hysterics Freud had started from the notion that as a group hysterics suffer from their reminiscences. His remedy was to go to the heart of their problems and with his profound powers of intuition wrench into consciousness the unconscious amnesic event that was causing the hysteric's symptoms. This would lead to their cure. In this early theory, by finding the "gnome" of their neurosis and labeling it would cause it to vanish.

By 1901 Freud had progressed to the point past labeling the trauma to using the interpretation of dreams as the agent of therapeutic action by which what was unconscious in the manner of unacceptable wishes and impulses was made conscious. Thus he articulated the unconsciously dominated nature of dreams and the light

that their interpretation could shed on the neuroses of everyday life and what had amounted to, heretofore, the individual's mindless domination by their unconscious. The interpretation of a person's dreams was conducted mainly in the context of their own personal meanings and metaphors. The previous historical emphasis had been on dreambook and cookbook kinds of understanding of generic dream symbolism. Inherent in such an approach was a grammar of dream symbolism that attributed meanings to symbols on an abstract basis that was divorced from the possibility that the dreamer might have developed idiosyncratic meanings of their own for the objects and dynamics encountered in their dream life. The analysis of a dream is an example par excellence of the proposition regarding healing that resides in the phenomenon of interpretation. It is the rare individual, and Freud was certainly one, who can interpret the multilayered meaning of one's own dream. To arrive at such meanings usually requires two minds and the convergence of the unconscious "mindlessness" of both parties. The exercise involved in this meeting with another mind may allow the dreamer to eventually carry on the work of dream interpretation independently, just as the exercise of analysis may set the stage for future self-analysis.

In the early era of id psychology, interpretation enjoyed a decade's reign during which it was considered "the royal road to the unconscious" and thus the avenue of therapeutic cure. As the subsequent development of analysis has borne out, innovations expand the range of treatment but they also reveal the shortcomings of the current dominant technique and point toward areas in need of further theoretical clarification. This heyday established the subsequent niche of dream interpretation in analytic technique but it also uncovered its shortcomings. Practitioners began to realize that id psychology with its emphasis on the understanding of forbidden wishes and desires located in the deep unconscious could only bring the treatment dyad so far. There were obvious limitations to its general treatment effectiveness. Other factors of therapeutic significance emerged that came to be categorized in terms of self and object relations. In order to promote the further understanding of symptom and character it became necessary to subject the person's internalized images of others as well as their actual social relations to interpretive attention. Although the initial premise still holds that the work of interpretation is to uncover hidden meanings and occult connections, the potential residence of such meanings took on more global consideration in personality functioning. Areas may be encountered in object relations, ego psychology, and in relation to the defensive activi-

ties of the ego, not to mention in relation to the meanings that reside in the unconscious conscience, that are subject to first the therapist's and then the therapist and patient's interpretive scrutiny.

III. WHAT GETS INTERPRETED?

There are now considered to be many dimensions to interpretation. It can be seen as a process that may extend through many aspects of space and time. Freud initially emphasized the temporal and historical aspects of interpretation. The earliest form of interpretation tended to have a genetic emphasis. That is, the ideal interpretation attempted to link up the individual's current difficulties functioning and the many "mindless" factors throughout life that had contributed to the difficulties and were being actively expressed through them. This approach aimed at positing as the nidus for a symptom an event that was either unconscious or not clearly conscious in its recall. "Your arm became paralyzed because you were in conflict about using it to strike your father" would be one such example. If presented in the proper emotional setting, this would expose the noxious forbidden element of trauma. It is brought into consciousness in a more fully and clearly focused manner that allows the individual a better view of the regressed elements of his or her history that his or her mind had hitherto deemed too painful or too awful to acknowledge. This is a technical point that has been emphasized many times by Loewald in his modern reformulation of psychoanalysis.

In an overall sense psychoanalysis is an ally of memory. This is the case to the extent that one of the goals of psychic exploration is to provide the individual with a fuller sense of the historical truth of his or her life as it courses back and forth through memory and time. Ernst Kris conceptualized the therapeutic process as an activity in which the personal myth of the individual is gradually replaced with a sense of conviction about the affective and experiential elements of a life that is both more compelling and more coherent than the one that had been woven into the fabric of their neurosis. Paradoxically adolescence, a period that often holds vivid memories, is also one in which the pressure of interpretation will yield a significantly altered story line through the reconstructions that inevitably accompany a dynamically founded treatment. A not uncommon statement might be "we can now understand your sense of dominance and distance with females during your teenage years as an outgrowth of several early stinging

rejections by girls that became coupled with your own deep anxieties about sexual and emotional intimacy. This seems quite consonant with the manner in which you have kept me (your therapist) at a distance. It has also manifested itself in the conflicts of intimacy that you have attempted to defend yourself against by seeing me as sexually threatening and at the same time emotionally withdrawn.” The interpretation presented here *en bloc* would in all likelihood be parceled out over time, eventuating in this summary interpretation. Such ideas when introduced in a timely fashion with a tactful tone of voice should lead over time to a gradual acceptance, acknowledgment, and further elaboration of the interpretive premise. This may lead over time to an equanimity that comes from possessing a sense of an apt and resonant relation to both inner and outer realities. It may be even more enhancing in introducing a larger acceptance of the objective and subjective mix of fantasy and fact that constitutes such “realities.” Human experience being what it is, a state of relative equanimity is just that, and although neurotic difficulties may have been fixed, the mind is never fixated in any healthy state. We will always struggle to process our experience in a manner that updates our realities at the expense of our personal myths.

The upshot of any interpretation may be quite varied. The patient may respond with immediate recognition, what Ralph Greenson termed the “aha” phenomenon. Alternatively the reaction may be vague resistance, either in response to the sense of criticism that every interpretation inevitably conveys, or as a function of the partial nature of the interpretation. On the therapist’s side of the treatment process or the couch, the reaction may be “oi vay!” The therapist, with or without reaction from his patient, immediately registers the vast error in his interpretation. When errors of interpretation occur, necessarily unavoidable but hopefully rarely, they require acknowledgment on the part of the analyst. Perhaps this would mean an apology, depending on the circumstances and the content of the errant ideas. Following this there should be a moving on to more fully understand how the patient interpreted the misunderstanding on the part of the therapist. For some patients it is the therapist’s grace in responding to an incorrect interpretation rather than his or her acumen that saves the day. In addition there is currently developing an added appreciation that such spontaneous moments may reference memory and events that are beyond the usual realm of interpretation in declarative memory. They may bring in elements from the “noninterpretive” realm of nondeclarative memory for attention and objectification.

In addition to the dimension of time there is a metaphorical dimension by which interpretations extend through the layers of mind and consciousness, from surface to depth. In addition to placing the spotlight of interpretation on elements involving group and interpsychic dynamics of social relations and control, the operations of the ego per se need at times to be an object of attention. It is not only the conflicts that the ego works to control but also the workings of the ego as an organ of synthesis and adaptation and as a partner or hostage of conscience that needs to be taken into consideration.

In a stepwise fashion a series of interpretations may lead to a complex revision of the patient’s sense of world and self. New and novel choices begin to appear in the mind’s eye. Fresh ideas presented in the proper sequence can lead to paranoia evaporating over time, to be replaced by a less anxious, more confident, and less reactive sense of self. “Originally your independence in childhood served you well, given the discontinuities in care that you experienced with your mother and your need to put some space between the two of you. You sensed at several levels of awareness that she could not accept you for who you were. This left you with confusions about dependency and now in your work and in your love life this cloak of alienated independence that you cover yourself with serves to keep you apart from others and unfulfilled in terms of your self-esteem. You end up not safe, as you intended, but anxious and never fully relaxed or satisfied. Yes, your escape is swallowed up by anyone and anything but also you are never able to fully be yourself with another.” Such a revisionist approach spans areas of history, defense, self-configuration, and neurotic adaptation while pointing the way toward a potentially less defended and restricted person with a more fulsome nature. Such interpretive syntheses may only be possible toward the end of an analysis when there is a fairly firm sense that all the facts are in and available for tally.

As the previous examples have indicated most interpretations follow from the content of the patient’s thoughts, the subject matter of their consciousness. There are exceptions in which the process of associating becomes coopted by predominantly defensive dynamics. We are then confronted with the paradoxical situation that speaking one’s mind serves mainly to cloud and obscure one’s more cogent thoughts and feelings. This defensive maneuver was initially identified in relation to dreams where the telling of the dream became so elaborated and extended that there was no time or opportunity for its deeper examination and interpretation. The supposedly cooperative and compliant dreamer pro-

duced too much of a good thing and in the process defeated the central purpose of dream analysis. This profusion of information without the opportunity for comment or interpretive scrutiny may occur in the course of any string of associations. At those instances the content of the patient's communication becomes less interesting than the quality and the process of the associations as they exhibit more of the quality of an action. When a torrent of words drowns out the facts contained in the stream of associations, a comment acknowledging the diversion of words from meaning is indicated. "The pressure and volume of your words and speech, while seeming to communicate a great deal, actually confuses me and makes it more difficult to understand what is going on in you. I wonder if there is some anxiety behind your words that we need to examine?" This might be one among many possible comments that the therapist could make in such a situation.

A current associational emphasis that is popular among some therapists is that of "close process monitoring." This technique expands the usual emphasis in any treatment, the ebb and flow of verbal material toward or away from areas of conflict and concern. The defensive nature, particularly with regard to matters of aggression, is given a predominant focus. Comments and questions leading up to interpretive statements are restricted to here and now observations that call patients' attention to shifts in their train of thought away from more affectively loaded material. This often involves bringing to light hostile and aggressive thoughts and feelings about the analyst that the patient is consciously suppressing and unconsciously censoring.

IV. TIMING AND SCOPE OF INTERPRETATIONS

The timing and scope of an interpretation has everything to do with how successful or effective an interpretation is. It is also critical if the therapist's activity at a particular point is gauged toward building to a broader interpretation. Some treatments may hinge upon the proper and timely application of a very limited number of interpretive comments. Selecting the right moment when idea, emotion, and resistance is at a proper pitch is key. The therapist's ease in understanding and delivering a properly timed formulation is also a significant factor in its successful reception by the patient. Much of an interpretation's effectiveness is contingent on how much data, both affective and cognitive, the therapist has at his or her disposal. This may

be a factor in setting apart analysis from most psychotherapies. In an analysis, with its greater frequency and often intensity of meetings, we anticipate that there will be less use of guesswork and intuition and a more refined processing of the unconscious into conscious thought. Therapists of different professional persuasions and different temperaments will vary widely in how much they rely on empathy and intuition in their interpretive activity. In Kleinian analyses and in briefer forms of psychotherapy the therapist may rely more heavily on "deep" intuition-rich verbal interventions to shortcut the defensive activities of the ego and get right to the heart of the matter. This is more in accordance with the technique of the early days of id analysis as opposed to current fashion that draws more on a constant assessment of object relations and the quality of the ego's defensive activity to determine how to proceed in a stepwise manner toward id interpretation.

Some versions of interpretation are met with immediate approval or disapproval. Depending on the quality of the therapeutic alliance, positive or negative, collaborative or combative, the degree to which an interpretation will be accepted for further internalization may be immediately apparent. At other times the impact of an interpretation is apparent only over time in the context of the further elaboration and working through of associations and defenses. This may be particularly the case when working with children, whose response to interpretations may appear minutes, hours, or days later. Children's responses may also show up in their play in apparent wide displacement from the therapist's words.

Central to determining what is healthy collaboration and what is neurotic compliance is the degree to which interpretations open up new avenues of information for inquiry and exploration. A premature interpretation may be greeted by a range of responses: incredulity at the therapist's cognitive lapse, confusion and self-blame, or the therapist may find himself the target of a withering attack of invectives and humiliation. Of course, it is impossible to assess the impact on the patient of tactfully delivered words until they are spoken. If the patient's reaction needs to be redressed with regard to the transference or countertransference elements elicited by an interpretive comment, that will require time and an open mind by both parties. Some patients are well-versed in contemporary or past therapeutic techniques and apply them easily and at will. They are also often too smart by half, bending their energies to making interpretive points before the therapist does. The quantity of clarifying comments is also important. Too many interpretations may cause them to fall on deaf ears. At

other points such comments will only be received according to the criticism that is inherent in them. If that is the case the interpretive activity either has no effect or it has a negative countertherapeutic impact. Traumatically sensitized patients are more prone to experience the therapist's words almost literally as being struck by a cudgel or raped. These concrete, physically referenced reactions can be taken up as defensive reactions of one sort or another.

A tilted relationship is one aspect of any therapy in which a psychological "expert" is helping a psychologically in need "patient." There is always the risk and danger that the interpretations will be perceived as a manifestation of the analyst's legitimate or illegitimate authority. Likewise they may be taken as evidence by the patient of the therapist's investment in the power politics of the situation. If that happens, boredom and impatience on the part of either member of the therapeutic dyad may come to supplant the fervor of self-other exploration. If the patient is mainly reacting to suggestion and is in the process of succumbing to the analyst's need to be the authority, the treatment process will come to feel more and more predictable, stereotyped, and static. If there are narcissistic issues on the part of the analyst or analysand that are not accessible to insight and clarification then stalemate, breakdown, or a compromised therapeutic process is inevitable. In these occasional situations unanalyzed rage in the patient or therapist may lead to stultification or truncation of the treatment.

The scope of interpretations has become much more varied and vast as the varied and vast capacities of the human mind have become more accessible to understanding. It ranges from interpretations of content, process, and defense to the sorts of overarching historical and genetic interpretations on which this aspect of technique was founded. In the case of defense analysis, attention is drawn to largely unconscious mechanisms that restrain the patient in speaking his or her mind. These may be in place to avoid coming across to the therapist as too active, too passive, too involved or needy, or too affect ridden, to mention a few of the conditions of defense. Interpretation of the mythic history of the individual may possess a particular power if used sparingly and precisely, identifying and appreciating the compulsive and repetitive aspects of historical experience without taking up camp in the past at the expense of existential frame in the here and now. Care should be taken not to develop a historical mantra that becomes yet another version of the personal myth or that distracts or displaces in an exaggerated and unwar-

ranted fashion from pressing dynamic issues in current-day experience.

There is as yet no agreed on objective standard for interpretation in the field. We are left with an activity that is still more art than science. The crucial element in interpreting is that it should always contain a question mark and rarely an exclamation point. It should indicate both what the analyst knows or thinks he or she may know as well as extending an invitation to the patient to provide further data from all levels of the mind to extend the interpretive moment to a clearer conclusion. As is continually emphasized, the overall treatment alliance is an essential part of therapeutic efficacy. In some instances the process of collaboration is as much or more important than the self-knowledge that emerges from it. At times it is not what is said that is most pertinent. At its core, self knowledge, including the growing ability to auto-interpret, should cause the distinction between what the therapist perceives and anticipates of the patient and what the patient's understanding of themselves is, to be subject to more and more overlap. The other's understanding of one's self should become ever more one's self-awareness and self-acceptance.

At the point in a treatment where there are no new issues left to interpret and explore there should be an emerging sense of completion and wholeness to complement the feeling that what has been available for resolution and reformulation has, by and large, been apprehended. To put it another way, in the ideal therapy, a time of mourning, celebration, and parting emerges that signifies that a maximum (for the moment) of self-understanding and self-acceptance has been achieved. It is not the completion of a life's story but rather the end of a chapter in the life of an individual when the need for another to understand one's self has reached a developmental conclusion. This is much as the need for a child to have understanding and defining parents wanes with the ending of adolescence. The self-understanding that comes from interpretation has been internalized and "knowing thyself" in the universal (and idealized) dimensions of love and work has been optimized. For many this will include knowing that at some future time they may come again to be beyond their psychological depth. In addition to having a better sense of when they have reached the limits of self-help, they will be able to interpret their own need to once again rely on the help and interpretive powers of a therapist. Ultimately an open mind with better access to, and reciprocity with, conscious and unconscious mindedness should be the endpoint of interpretation.

GLOSSARY

abreaction A cathartic release of pent-up affect usually associated with trauma.

ensor Synonymous with the term of repressive barrier anthropomorphosized in order to dramatically make the point of the fact of repression.

compromise formation The synthesis created by conflicting mental components.

defense The counterforce opposing the expression and emergence into consciousness of socially unacceptable or otherwise problematic biological and somatic urges.

instinctual drives Mental/somatic entities which are the mental representation of somatic stimuli.

intrapsychic conflict The basic psychoanalytic idea that almost all mental phenomenon and psychologically mediated behavior are the product of opposing mental forces or structures.

latent content An aspect of the dream that deals with underlying or repressed thoughts stimulated by the day's activity and seeking expression.

libidinal drive The tendency of the psychological structure seeking the satiation of biological needs, as well as psychological needs, for affiliation and merger.

manifest content Refers to the aspect of dreams that are expressed clearly and directly within the dream.

multiple functions The almost universal tendency of certain defenses to serve multiple functions at the time of their use.

primary process A mode of thinking in which logical and formal relations between mental contents are absent and there is a press for immediate gratification of pleasurable needs. Contraindications exist without difficulty. Temporal considerations are irrelevant.

psychic energy An imprecise term referring to the economic work or resource required on the part of the individual to accomplish a certain act or invest a psychological structure with capacity.

reality principle The tendency for an organism to orient itself to practical social dictates and requirements.

repression A form of defense in which unacceptable urges and materials are kept outside the realm of consciousness.

repression barrier The psychological structure that separates the contents of the system unconscious from the preconscious system by a defense and the function of the censor.

resistance A form of defense specifically oriented towards keeping certain thoughts and ideas out of the talk between analysis and analysis.

secondary process functioning Refers to a mode of functioning in which logic, temporal relationships, and social and physical reality predominate as principles.

sexual drives Refers to drives emanating from specific bodily areas and following a development timetable, which have a pressure, an aim, an object, and a source.

structural model The psychoanalytic model developed by Freud that hypothesized the existence of three basic psychological structures that embody and mediate between

the demands of external social reality and internal, biologically based, instinctual needs.

structures Psychological constructs of drive, representation, motivation, and function that exist to carry out psychological work and integrate various domains of mental functioning.

superego The agency within the structure model that is responsible for determining ideal social reality and measuring various aspects of the individual's function in relationship to this reality.

system conscious (CS) A set of structures oriented towards conscious and explicit experience.

system preconscious (PCS) Refers to the existence of psychological material that can be made conscious and has not attracted enough repression to render it incapable of being known consciously.

system unconscious (UCS) Refers to the psychological and biological structures that press for expression and satiation and are not capable of consciousness.

topographical model The model of the mind developed by Freud that postulates the existence of conscious and unconscious mental processes separated by repressive barrier.

transference The tendency for all people to "transfer" feelings, attitudes, and relationships more appropriate to a specific person in the past of the individual to some other analogous, present, and active social relationship.

The concept of intrapsychic conflict, also called internal conflict, psychic conflict, or neurotic conflict, is central both to the psychoanalytic theory of mind and the application of that theory to differential treatment strategies. This concept refers to the basic psychoanalytic thesis that almost all mental phenomena and psychologically mediated behavior are the result of opposing mental forces or structures. Thus, symptoms, personality structure, fantasies, emotions, and so on reflect the synthesis of more basic mental components. This synthesis of these conflicting mental components is referred to as a compromise formation. Psychoanalysts assume that virtually all complex mental acts are compromise formations designed to allow the maximum possible gratification of the conflicting components with the least possible mental pain. Intrapsychic conflict and its subsequent compromise formations are ubiquitous and not inherently pathological. Rather they are understood as essential aspects of the human condition. Thus, psychoanalysis has traditionally been viewed as a psychology of intrapsychic conflict. Conflict and compromise formations are pathological only when they lead to excessive inhibition of key human urges, when they give rise to excessive anxiety and/or depression, when they cause excessive inhibition of important psychological functions, when they lead to ex-

cessive self-destructiveness, or when they bring the individual into excessive conflict with his or her environment. Mental health occurs along a continuum in terms of intrapsychic conflict. Conflict and compromise formation move from the healthy to the unhealthy parts of the continuum as they interfere in one's life in the previously listed ways.

I. AFFECT—TRAUMA MODEL

Psychoanalysis' theory of mental functioning, and the technical implications drawn from it, has evolved over the past 100 years. Each phase in that evolution has defined the conflicting elements of the mind differently and derived different technical precepts from those definitions. Freud's first stage of thinking occurred between the mid-1880s and 1897. The psychological model that he developed during those years is commonly referred to as the affect-trauma model. While trying to understand the etiology and treatment of neurotic symptoms, Freud emphasized the role of environmental trauma and subsequently pent-up charges of affect. Essentially Freud said that neurotic symptoms derived from internal conflict between the individual's conscious moral standards and distressing affects or ideas that were incompatible with these precepts. In general, trauma, usually of a sexual nature, was understood to overstimulate the individual to a degree that an intense charge of affective energy developed. This affective charge was defended from consciousness to avoid the unpleasant feelings generated by it running counter to conscious moral standards. Damming up of affect occurred and became expressed in disguised ways through neurotic symptoms. Oftentimes symptoms would develop years later when a current event stimulated memory traces of early events that had not been experienced consciously as fully traumatic at the time they occurred. In these situations a conflict was postulated to arise between what was repressed as a child and the adult's current moral standards. During this earliest stage of psychoanalytic theorizing, the strategy of treatment revolved around helping the patient to remember the traumatic event and to cathartically release the pent-up affect associated with it. Freud called this cathartic release *abreaction*. In this way the pathological impact of intrapsychic conflict was thought to be overcome.

II. TOPOGRAPHIC STAGE

By 1897, however, Freud was finding this understanding of psychic conflict unsatisfactory and the

treatment results from it disappointing. Thus, his topographic stage of theorizing was developed over the next 26 years as his understanding of intrapsychic conflict underwent radical revision. Perhaps most importantly, several events, including Freud's own self-analysis, led him to shift his focus away from memories of actual childhood sexual traumas and their related affects as a significant component of intrapsychic conflict. Instead Freud came to the conclusion that most of his patients' memories of childhood sexual seductions were, in fact, disguised unconscious wishes. These wishes had to be disavowed because they conflicted with other components of the mind, resulting in a false belief that an actual sexual trauma had occurred during childhood. The recent furor over the false-memory syndrome speaks to how slow nonanalysts have been to realize the intensity and ubiquitousness of childhood sexual wishes and the defenses against them.

During this second phase in the development of his thinking, Freud defined and elaborated his concept of libidinal drive as a key component of intrapsychic conflict. He introduced the concept of instinctual drive as a mental-somatic construct, defining it as a mental representation of somatic stimuli. The sexual drives had a pressure, an aim, an object, and a source. The source referred to a part of the body imbued with sexual energy, following a developmental timetable. These sources became synonymous with the stage of development at which they were primary—hence, the oral, anal, phallic, and genital stages of development. Inherent in this idea of a sexual drive following a developmental timetable was Freud's notion of libido or psychic energy. That is, this energy was postulated to arise in the somatic sources of the sexual drive and to provide the impetus for the mind to work. Freud maintained his belief in the importance of the sexual drive and its underlying energy, even when he ultimately rejected the topographic model in 1923.

Freud's topographic stage of thinking involved far more than the realization that childhood sexual wishes and fantasies exerted a profound impact on mental functioning into and through adulthood, however. That is, he had to explain the reason that patients experienced and reported such wishes as memories of actual occurrences. Furthermore, he needed to explain why such memories (in reality, fantasies) emerged only during treatment. These issues required the introduction of a counter force to becoming aware of such wishes or fantasies—that is, defense. During this stage in his model building, Freud used the term “repression” synonymously with defense. Repression did not refer to any particular type of defense mechanism but to the

gamut of ways in which the mind could render a wish, thought, fantasy, or memory unconscious. It represented the work of the ego or self-preservative instincts that had as their aim the preservation of the individual.

Freud's topographic model did far more than redefine the conflicting elements of the mind. It also attempted to chart out the organization of the mind and to map the main components through which internal conflict was actualized. Thus, three systems or layers of the mind were described: (1) the system Unconscious (UCS); (2) the system Preconscious (PCS); and (3) the system Conscious (CS). These three systems were structures, each with its own type of mental contents, and each characterized by qualitatively different modes of functioning. Essentially these structures or stratas of the mind were viewed as the mind's attempt to harness the instinctual drives so that the individual could adapt to reality. Were the instinctual drives and wishes to succeed in their push for conscious awareness and discharge, the individual would experience unpleasant feelings as well as potential danger. During this era of Freud's thinking all sorts of mental phenomena including jokes, slips of the tongue, dreams, as well as neurotic symptoms were understood to involve a conflict between instinctual wishes and the mind's counter forces occurring within and between these mental strata.

The UCS was viewed as the deepest strata of the mind and the repository of instinctual drives and wishes, always pushing for conscious expression. This system is characterized by a very primitive mode of functioning or thinking that Freud called the primary process. In this mode of functioning, logical and formal relations between mental contents are absent. Contradictions exist without difficulty, temporal considerations are irrelevant, and so on. What Freud called the pleasure principle dominates. Drives and wishes push for discharge, gratification, and relief of tension without consideration for anything but pleasure. It is important to distinguish this system UCS from the descriptive term unconscious. Contents of the system UCS are kept unconscious through a repression barrier; that is, active amounts of psychic energy are used to keep the contents dynamically unconscious. In contrast, descriptively unconscious mental contents might be outside of conscious awareness only because attention is not directed at them. Were attention to be focused on them, they would become conscious. No defensive force is exerted against this possible occurrence.

This distinction becomes relevant when defining the system PCS. The contents of this system are also unconscious but only descriptively so. They are capable of becoming conscious once attention is focused on them.

Thus, Freud initially located the active censor or repressive barrier that kept dynamically unconscious content out of consciousness at the boundary between the system UCS and PCS. Intrapsychic conflict occurred first at this juncture. This barrier allowed the system PCS to function according to what he called the secondary process in which logical reason and moral concerns characterize the relationship between its mental contents. The reality principle predominates so that any discharge of instinctual drives or wishes has to be filtered, altered, and/or disguised to make it compatible to reality logic and the individual's moral standards. Freud eventually explained that the system PCS modified drive impulses at all levels on their way through the system to the system CS. Thus, repression or defense no longer became conceptualized as a static barrier occurring between the systems UCS and PCS. Instead unconscious wishes are continually transformed during their traversal of the system PCS and had to pass by a second censor at the boundary between the systems PCS and CS. Intrapsychic conflict could occur at any step along the way. To pass muster and get past the censor unconscious drive laden wishes have to be disguised—what psychoanalysts labeled drive derivatives. Only such derivatives can be allowed into the system CS to be discharged.

The system CS was described by Freud as on the mind's surface. All its mental contents are conscious, although only a limited range of contents can be attended to at any moment. Perception occurs in this system as does attention. Thus, the system CS receives input from both the deeper recesses of the mind as well as from the external environment. To become aware either of mental contents from inside or perceptual stimuli from without, the system CS has to invest what was called attention cathexis, that is, to invest content or stimuli with psychic energy that has become neutralized of its sexual and/or aggressive drive qualities. As with the system PCS, the contents of the system CS follow the reality principle and are characterized by secondary process functioning.

This stage of Freud's thinking in which internal conflict was viewed as occurring between the instinctual drives of the system UCS and the censorship and defenses of the system PCS continues to be important because all of Freud's papers on clinical technique were written during this era. For example, he formulated the important clinical concept of transference during this era and emphasized the importance of analyzing dreams. Dream analysis became synonymous with psychoanalytic technique during this stage as Freud de-

scribed dreams to be the royal road to the Unconscious. Vestiges of this theoretical understanding of internal conflict continue to appear in modern day clinical literature because Freud never reformulated his theory of technique when he gave up this model in 1923. This failure to recast his theory of technique has impeded the development of modern-day thinking about technical matters as many analysts and nonanalysts alike seem to operate therapeutically out of an outdated understanding of mental functioning and conflict.

For example, the clinical dictum that psychoanalytic technique should aim to raise unconscious mental content to consciousness is still regarded by many as the means by which psychoanalysis cures despite it being overly simplistic and at odds with how most contemporary psychoanalysts understand the mind to work. But during the topographic era, Freud believed that one only had to make the patient aware of his or her unconscious sexual and, later, aggressive wishes derived from childhood in order to overcome the symptoms and/or character traits for which treatment was being sought. Resistance to analytic treatment at this stage was thought to reflect solely the operation of the defense mechanisms in the clinical encounter. That is, resistance was the patient's defensive attempt to protect against the analyst's attempts to make the analyst aware of unconscious wishes. Resistance analysis meant that one had to overcome the resistance so as to allow the patient to gain access to the recesses of the Unconscious. This formulation led to didactic if not coercive practices such as telling the patient that he or she was in a state of resistance with the implicit, if not explicit, idea that he or she should stop doing so. Such an approach has led many nonanalysts as well as analysts of more modern schools to criticize classical analysis as coercive and controlling.

III. TRANSFERENCE

In this theoretical vein, Freud introduced the concept of transference as a clinical phenomenon arising within the analytic situation. Originally Freud viewed transference as the displacement of unconscious wishes and fantasies about past individuals in the patient's life onto the person of the analyst. He first viewed such transference as an obstacle to making the unconscious conscious, but later came to view it as an ally in the work. That is, transference allowed the analyst to see the unconscious wishes, feelings, thoughts, and so on, and to bring them to the patient's conscious awareness.

But during this stage of thinking, too often, the emphasis was placed on demonstrating to the patient the unconscious wishes or fantasies about historical objects rather than on understanding the reasons that such contents had to be disguised or on the analyst's actual contributions to the patient's transference perceptions.

IV. DREAM ANALYSIS

Dream analysis also took priority during this era of psychoanalytic theorizing. Given the dream's latent content about unconscious wishes, the analysis of dreams took high priority in guiding the analyst's decisions about where to intervene. The prevailing theory of analytic cure, making what was unconscious conscious, led the analyst to interpret the unconscious or latent content of the dream to the patient. In particular, this approach to dream analysis focused on remembering or reconstructing the experiences and fantasies of childhood. At the same time, the defensive use of dreams to avoid other less comfortable mental contents received short shrift. So did the attempt to understand why a childhood drive-laden experience or fantasy had to be expressed through dreaming rather than remembered and experienced more directly. Such distinctions about whether to give dream analysis particular priority in determining analytic interventions or whether to regard the dream as just one of many types of mental content that can serve multiple purposes continues to be debated in the literature and serves, in part, to distinguish those analysts who continue to practice from a primarily topographic perspective from those who have integrated Freud's structural model and more recent advances in psychoanalytic thinking into their theory of technique.

V. STRUCTURAL THEORY

By 1923, Freud felt obliged to change his model again, first through his important book, *The Ego and the Id*, and then with *Inhibitions, Symptoms, and Anxiety*, published in 1926. These two volumes are considered to define the structural theory of psychoanalysis, a model which once again shifted the conceptualization of intrapsychic conflict. Essentially, theoretical inconsistencies in the topographic model along with the problem of how to formulate the newfound clinical phenomenon of unconscious guilt led Freud to revise his understanding about what sort of conflicts gave rise

to mental phenomena. The terms conscious, preconscious, and unconscious remained in psychoanalytic theory but only as adjectives describing the nature of mental contents or processes. They no longer referred to strata or organizations of the mind.

Instead an explicitly tripartite model with the mind composed of three separate structures—id, ego, and superego—was described. The use of the term structure is a metaphor that refers to enduring patterns and configurations of mental processes that show a slow rate of change. That is, they are theoretical abstractions that have proven valuable clinically and can be inferred from behavior or mental content. The id is the structure that most closely approximates Freud's early concept of the system Unconscious. It involves mental representations of the twin instinctual drives of libido and aggression, operates according to the pleasure principle, and is organized according to the rules of the primary process. Freud conceived of the ego as developing out of and retaining roots in the id while the later ego psychologists such as Heinz Hartmann described the id and ego as differentiating out of an originally undifferentiated matrix. Regardless of its origins the ego is described as the mental structure that balances and mediates the pressure of the id drives and superego and integrates them with the need to adapt to the demands or pressures of the external world. As such it operates toward the goal of preservation of the individual. Thus, it involves multiple functions, the most important of which, in regard to intrapsychic conflict, is defensive functioning. At times it helps the id to gratify its drive impulses and, at other times, it exerts defense against them in order to adapt to the external world. Intrapsychic conflict occurs at such times. Because successful defenses must always allow some drive discharge, the ego facilitates the development of compromise formations.

The third structure, the superego, was added by Freud to help explain unconscious guilt. It is the internalized representation of parental values and prohibitions—in essence a conscience as well as an ego ideal. Conflict among these structures—structural conflict—was seen by Freud as the genesis of all subsequent mental phenomena. In this model, still used by many if not most American psychoanalysts, the genesis of symptoms or character traits is as follows. An id wish or impulse runs into conflict with an internal or external prohibition, which threatens the ego with a variety of unpleasurable situations causing signal anxiety or depression. This signal affect stimulates defensive functioning, which leads the ego to find a compromise formation that allows for some id gratification while also

preventing the impulse from becoming manifestly conscious; the compromise formation also assuages the prohibitions of the superego. Symptoms and character traits are examples of such compromise formations as are other mental phenomena. Besides the intersystemic conflicts that can develop between these structures, intrasystemic conflicts also occur. These conflicts involve clashes between mental contents of the same structure, for example, between incompatible ideals in the superego or between opposing drive wishes in the id.

VI. TECHNICAL IMPLICATIONS

Only in the past 20 years have psychoanalysts begun to systematically revise their theory of technique to implement the implications of this new understanding of mental functioning and intrapsychic conflict. Expanding the ego's unconscious awareness of intrapsychic conflict has become the focus of clinical technique based on the assumption that such ego expansion will bring mastery. No longer are resistances viewed as obstacles to making the unconscious conscious. Instead the importance of understanding the reasons for resistance is emphasized as is an awareness that the occurrence of resistance can be used as an opportunity to teach the patient how to observe the manifestations of unconscious conflict as they occur in his or her free associations.

Increasingly the importance of addressing the conscious ego and intervening at the surface in a way that the patient's ego can grasp and observe is seen as more important than deep interpretations of id content. Psychoanalysts now assume that unconscious id content will emerge into consciousness under its own impetus as the anxieties and threats that motivate the ego to

defend against them are understood. Self-analysis—the ability to continue to observe and analyze such resistances to full consciousness—is now a goal of technique and a definition of a successful analysis, as we accept that intrapsychic conflict never disappears. Instead psychoanalysis aims to increase ego mastery over such conflicts with the assumption that conscious awareness and understanding of such conflicts will lead to compromise formations that are more adaptive and less restrictive. Thus, contemporary structural theory promulgates an approach to analytic technique that studies all facets of intrapsychic conflict rather than giving therapeutic priority to one of them. As such it can be viewed as a comprehensive approach to analysis.

job-finding Viewed as a chain of responses from the initial step of identifying a job lead, each of the steps being taught and supervised in the Job Club session, rehearsed, and actually put into practice under the supervision of the Job Club instructor.

I. THEORETICAL BASIS

The Job Club method is based on established principles of learning similar to those used in behavior therapy and by applied behavior analysis for treating psychological problems. The process of job-finding is viewed as a chain of responses from the initial step of identifying a possible job lead, each of the steps being taught and supervised in the Job Club session, rehearsed, and actually put into practice under the supervision of the Job Club instructor. Also included are modeling (imitation), self-recording of each of the job-seeking behaviors, progress charting, and “homework” assignments for out-of-session behaviors. The same rationale governs the conduct of the Job Club instructor

analogous to that of the therapist in behavior therapy; specifically, the Job Club instructor constantly reinforces the job seeker using descriptive praise that designates the specific behavior being praised. The instructor is always positive, praises any action in the direction of the final goal of obtaining a job, never criticizes, and directs attention to future constructive actions rather than past difficulties.

The program takes place in a group for reasons of cost/benefit but also to obtain group support including finding job leads for each other, transportation assistance (car pools), and assigning each job seeker a partner such that they work in pairs with the partner providing a role model, reminders, and assistance, thereby having each person receiving continuous individual assistance while still functioning in a group.

Also similar to behavior therapy, the Job Club program is highly structured with standardized forms and scripts that are individualized for each person.

II. EMPIRICAL STUDIES

Prior to 1975, many types of job-finding programs were being promoted and used, such as those relying on “Job Development,” or subsidized priming (such as the G.I. bills), or motivational seminars, interview rehearsal, and public employment agency listings of openings by employers. Controlled evaluation of all of these programs using the accepted scientific require-

ment of a randomly assigned control group was absent, similar to the situation that had existed previously in medicine and clinical psychology.

In 1975 my colleagues and I, as part of an Illinois research group (see Further Reading) conducted the first controlled evaluation using the Job Club method to help normal job seekers to obtain jobs. The result was that in 3 months 92% of the Job Club members had obtained jobs compared with 60% of those in the comparable wait-listed control group.

In 1979, the Job Club program was evaluated with job seekers who had severe job-finding handicaps: former mental patients, retardation, prison records, physically handicapped, and other such difficulties. As compared to a control group of similar job seekers who were given a motivational and information counseling program, 95% of the Job Club members obtained jobs versus 28% of the information counseling members. In 1980, the Job Club method was evaluated in a controlled study with chronic welfare recipients by the U.S. Department of Labor. The results were that twice as many job seekers enrolled in the Job Club obtained jobs than did those counseled by the agency's existing program.

Since that time the Job Club has been evaluated by many different controlled studies, all of which have found the method to be more effective than any of the alternatives with which it has been compared. More specifically, the Job Club has been found effective in different studies with high school students, the elderly, the visually impaired, the intellectually handicapped, the chronically mentally ill, unemployed professionals, deaf people, workforce programs, physically handicapped, state hospital patients, halfway house and outpatient mental patients, alcoholics, drug addicts, those with psychiatric disorders, criminal offenders, and in several foreign countries.

The Job Club method also has been found empirically to decrease depression and to increase feelings of self-efficacy, indicating its value in improving one's psychological state as well as in obtaining employment.

III. DESCRIPTION

A. Setting

The job seekers meet as a group—preferably 8 to 12 persons in a room equipped with a large table for ease of writing. These should be several telephone lines and an extension phone for each primary phone such that

the assigned “buddy” and instructor can listen to all calls made. The facility also provides a copy machine for résumé copies, secretarial assistance for typing résumés, daily copies of the help wanted advertisements in the local newspapers, and several copies of the Yellow Pages telephone directory. The room also contains a file of job openings uncovered by previous and current club members. A bulletin board displays for each member a visually conspicuous record in histogram form of the (1) number of telephone calls, (2) number of letters written, and (3) number of interviews obtained; these serve as a progress chart.

B. Schedule

The members attend each day for 2 weeks, arranging interviews during half of each day and attending the interviews during the other half of the day. The second half of the day after the first 2 weeks is attended by all those members who have not yet obtained a job during the first 2 weeks. The local telephone calls, photocopying, postage, stationery, and secretarial assistance are provided without cost to the job seekers. A new group can start every 2 weeks.

C. Initial Session

During the initial session, the members briefly introduce themselves to the group and identify what type of work they have had and hope to obtain. A written form is circulated on which members list their telephone number, address, and any transportation needs. This list is photocopied and distributed to all and arrangements are made to assist those with transportation needs. Each person is paired off with a “buddy” to work together. An explanation of the program and its record of successes is provided. The members are instructed to attend any interviews arranged in the sessions that day and all future days.

D. Specific Procedures

1. Job finding is treated as a full-time job; as stated, half of each day is spent in the Job Club office, and the remainder of the day is spent attending interviews.

2. Personal sources of job leads. Because surveys have consistently shown that the initial job leads for two-thirds of jobs obtained were first identified by a friend, relative, or acquaintance, the Job Club makes a systematic effort to contact those persons and not to rely primarily on published job listings.

3. Supplies and services. As noted above, the program provides all supplies and services necessary for the job seeker without cost. The actual cost to the agency has been found to be very slight relative to the usual cost of a job-finding person.

4. Group support. Members are instructed and prompted to assist each other with transportation, obtaining job leads for others and providing mutual encouragement and advice.

5. Buddy. Each member is paired with a "buddy" to provide each other with assistance. The buddy is given a checklist to record the other buddy's phone contacts with potential employers; they review the checklist recordings together.

6. Positive personal and social attributes. In addition to work skills, the Job Club approach stresses the communication of positive personal and social attributes. The job seeker is shown how to identify these attributes and how to stress these attributes during an interview, in the job resume, and when first contacting a potential employer to arrange an interview.

7. Open letters of recommendation. The job seekers are taught to obtain open letters of recommendation that can be given to interviewers and possible employers at the time of initial contact to maximize the initial positive impression.

8. Interview rehearsal. The program has each job-seeker rehearse being interviewed using common questions asked by job interviewers and is given written material describing how such questions might best be answered for maximum benefit.

9. Interview behavior reminder checklist. The program provides instruction and a checklist of behaviors to be considered in interviews, such as proper posture, eye contact, arranging a call-back date, handshake at start and end, describing positive personal attributes, and so on. The completed checklist is reviewed the next day with the Job Club instructor.

10. Assistance by family. The program sends a letter to the family (spouse, parent, or significant other) providing suggestions as to how they can assist the job seeker, such as by actively seeking job leads, providing needed transportation, relieving the job seeker of household activities that would interfere with Job Club attendance, providing encouragement, assistance in typing or letter writing, and so on. Surveys have shown that family members are typically a source of productive job leads.

11. Counselor individual attention. In order to provide the job seeker with continuing feedback, advice, and support in spite of the group setting, the counselor

follows a "continuous rotation" rule in which the counselor observes each club member in systematic rotation, spending no more than about 1 minute per club member. The counselor examines the forms being filled out, listens briefly if needed on the extension phone to job seeker calls, praises for efforts made (e.g., number of leads collected), and gives brief instruction as to what to do until the next counselor contact. This procedure plus the "Buddy" procedure described earlier provides continuous feedback and support.

12. Telephone book. The "Yellow Pages" of the local telephone book is used as a major source of job leads in the session. Because companies are conveniently listed by the type of business, the job seeker contacting those businesses will know if they are likely to utilize the job seeker's skills. As noted above, surveys have consistently shown that jobs were obtained from contact with nonpublicized sources.

13. Current job leads leading to new leads. Because personal contacts have been found to be the most frequent source of productive job leads, job seekers are taught (and supervised in session) to request additional leads from any contact person who has no positions immediately available; this situation occurs often in the telephone book contact, with friends, or at the termination of unsuccessful interviews.

14. Auto transportation is often a problem for job seekers possibly because of insufficient funds, or relative lack of public transportation in rural areas. As noted in "Group support" earlier, the club members are encouraged to assist these members with this need. Also as noted previously in "Assistance by family," family members are sent a letter urging them to supply auto transport to interviews and indeed to the Job Club location as well as to the job site when a job is obtained.

15. Telephone as initial contact. Rather than using actual "drop-ins" as a method of contacting potential employers, which usually allows 2 to 4 contacts per day, the Job Club arranges for the telephone to be used as the initial contact to arrange an interview. The telephone contacts can be made under supervision in the Job Club session and in great number.

16. Number of sessions. The goal of the Job Club is to obtain employment for all (100%) of the job seekers. If a fixed number of sessions are allowed, the most needy or job handicapped are likely to remain unemployed. Therefore, the Job Club program allows and encourages continued attendance until a job is obtained. Even after a job is obtained, the members are encouraged to return if they again become unemployed. This continual access

is logistically made possible by having the continued access members meet in the afternoon each day, while new members meet in the morning hours, with a new group starting in the morning every 2 weeks. After the 2 weeks, the members attend in the afternoon. In practice, past club members attend only occasionally, usually to use the copy machine, or telephone, or to obtain postage or typing assistance, but this continued availability appears very important in assuring the most difficult-to-place persons that they will not be abandoned.

17. Multiple sources of job leads. Surveys reveal that productive job leads result from many sources, primarily from personal contacts, but also about a third from various public announcements. The Job Club accordingly emphasizes primarily the personal sources (see "Personal Sources of Job Leads" earlier), but also common public announcements that are obtained by visits to a local public service employment agency, and announcements in newspapers' help wanted advertisements and professional and trade newsletters.

18. Personal orientation of résumé. In recognition of the great role played by personal attributes, the résumé does not only chronicle the Job Club members' job-relevant experience but also positive personal attributes of the job seeker, such as being "a team player," a "leader," "dedication to one's employer," "motivates the employees reporting to him," "needs no supervision," "well-liked by customers and fellow employees," and so on, whichever attributes honestly apply to the specific job seekers. These personal attributes are noted and emphasized in the interview as well.

19. Type of job applied for. In recognition of the diversity of skills of a given job seeker, they are encouraged to apply for more than one type of position (grant writer as well as English teacher, for example) and also to list the diversity of their experiences that may not be evident from the listing of their work history, such as being multilingual, computer proficient, organizing groups for community service, or club projects leader.

20. Structured job-seeking schedule. The job seeker is given preprinted forms and taught by the counselor to use them to arrange each day's activities with regard to interviews (date, time, name of interviewer, address, telephone number, etc.), call-backs after an initial inquiry or after each interview, persons to contact for possible leads, and so on. By structuring each day's activities the job-seeker's job search is focused, organized, and full-time.

21. Job Seeker Progress Feedback. A major problem in the job search is the discouragement and loss of motivation that results when no job placement has resulted from one's initial efforts. To help overcome this prob-

lem, the program provides feedback to the job seeker via a visual display on the wall of the room depicting separately how many interviews, telephone calls, and letters were completed by the job seeker since the start of the research. Also on the wall is a chart showing how the probability of success increases as the number of interviews increases, as determined by the results of all previous Job Club members. A job seeker's attention is directed to this chart as feedback on how his or her efforts are increasing the probability of success even though no placement has yet been obtained.

22. Counselor's style. The counselor's style is consistently positive, never criticizing or pointing out shortcomings or errors in carrying out the specific steps of the search. Rather, the counselor praises all progress and all efforts, even the fact of attendance. To address any omissions or errors, the counselor follows a "future-oriented" style, describing to the client what changes or additions might be made in future efforts to improve the chances of success.

IV. SUMMARY

The Job Club method is a program for assisting job seekers to obtain employment that has been found effective in several controlled outcome studies. It requires an experienced counselor as the leader and functions in a group format. The members do not passively listen to suggestions, but rather are actively engaged and supervised in the job search during each session by obtaining job leads and arranging interviews. The sessions continue for each job seeker until he or she obtains a job or discontinues attendance. The results of this intensive program has been that more than 90% of the attendees obtain employment. The program is based on the principles of learning and motivation embodied in the psychological body of knowledge known as behavioral psychology, which emphasizes rehearsal and functional improvement.

GLOSSARY

(Archetypes are preceded by asterisks. Some are also correlated [*in brackets*] to characters in the popular film series “Star Wars,” as these were deliberately designed by George Lucas to represent Jungian archetypes.)

active imagination A practice whereby imagery is deliberately engaged as though one were participating in one’s dreams while awake. [*As when Luke “feels the Force.”*]

amplification Used chiefly as a method of dream interpretation, whereby the therapist explicates a patient’s dream by relating those myths, legends, fairy tales or otherwise archived symbol, images, and stories that seem most pertinent to the dream.

analysis (Jungian) The formal designation given Jungian psychotherapy within the Jungian world, reflecting Jung’s early role in the development of (Freudian) psychoanalysis. However, the practice of Jungian therapy is very unlike that of classical psychoanalysis.

* **anima** A personified representation (imago) of the undeveloped feminine potential in a man. [*Princess Leia*]

* **animus** A personified representation (imago) of the undeveloped masculine potential in a woman. [*Han Solo*]

archetypal (Jungian school) Followers of James Hillman. Hillman considers there to be no “Self”—and no “self” ei-

ther. His school focuses on literary elaborations of archetypal motifs rather in the spirit of Lacan and of deconstructionist literary criticism. He terms his approach “archetypal psychology.” While much admired throughout the Jungian world, it has no formal structure (e.g., training methods, programs, or institutes). It may be thought of as being focused on the technique of amplification, narrowly and for its own sake.

archetype An innate, latent nucleus of personality predispositions conforming to a consistent set of attitudes, ideas, emotions, and behaviors. Symbolically represented as the stereotyped characters of myth, fable, and literature.

classical (Jungian school) Followers of Jung’s original formulations. The classical school is emphasized in this article and relates Jungian analysis as less a form of therapy than a modernized Gnostic spiritual discipline: a sacred journey or quest to achieve full realization of the Self. [*Luke Skywalker is the hero of the quest*]

* **collective unconscious** The various archetypes; the innate preformed structure of the psyche.

developmental (Jungian school) Followers of Jung whose primary interest is in practical therapeutics. Formerly termed the “clinical” school, which is more accurate. However, it is also true that this school assumes that adult personality develops largely on the basis of childhood developmental process. The classical school is more interested in adult developmental changes while the archetypal school considers development a “fantasy.”

extraversion One of two fundamental orientations of a person. The extravert directs interest and adaptive effort chiefly toward the outer world and other people.

Gnosticism A perennial religious philosophy that identifies God (or a god) with an interior state of “illumination” available only to initiates. Gnostic strains accompany the

mystical practices of most religions. Gnostic variants of Christianity have always been the chief source of heresy in the Church's view. [*The Jedi Knights*]

* **Great Mother** A personified representation (imago) of on the one hand the experience of being comforted and nurtured, and on the other, of being terrifyingly vulnerable to the withdrawal of same.

individuation process The process of achieving "wholeness," wherein all competing aspects of the personality are accepted, integrated and harmonized. Marked by the appearance of the Self, and by subjective states of a religious or spiritual character.

inflation Hypomania.

introversion One of two fundamental orientations of a person. The introvert directs his interest and adaptive efforts chiefly toward the inner world and himself.

mandala A term from Buddhist iconography, these are complex images whose basic structure consists of a circle subdivided into four major quadrants, and further subdivided or inscribed with complex, highly symmetrical, often recursive designs. Mandala-like imagery represents the Self and is expected to emerge spontaneously in dreams and visions as the sign of a successful individuation process.

personal unconscious Jung's term for what Freud called the unconscious (i.e., repressed material) in contrast to archetypes, that are presumed never previously to have been conscious.

psychoid A necessarily ill-defined term that refers to the puzzling mind-brain interface.

* **Self** The entirety of the personality encompassing both consciousness and the unconscious; an experienced unity of all archetypes; the endpoint of the individuation process. Often felt subjectively as the presence of God and so symbolized in dreams, visions, and in cultural products. [**The Force*]

* **shadow** A personified representation (imago) of the personal unconscious. [*Darth Vader*. But the "dark father" is not typical.]

synchronicity The relatedness of two events solely on the basis of their meaning to an individual, in the absence of any possible direct or indirect causal relation. This relatedness was held by Jung to be in some sense objective, however, and not merely in the mind of the individual(s) perceiving the meaning. Pathologically: ideas of reference.

* **trickster** A personified representation (imago) of a capacity for paradox, and concealed wisdom, messenger to the gods. [*C3PO and R2D2*]

types A set of innate personality predispositions on three orthogonal axes.

* **wise old man** A personified representation (imago) of a capacity for spiritual insight and experience. Leads to the Self [*apart from their ears, Joda looks exactly like Jung*.]

I. INTRODUCTION

Jungian therapy ("J_analysis") is a face-to-face psychoanalytic psychotherapy based on psychodynamic

principles elaborated by the Swiss psychiatrist Carl Gustav Jung (b. July 26, 1875, Kesswil, Switzerland; d. June 6, 1961, Küsnacht) after his break with Freud and classical psychoanalysis around 1912. In sharp contrast to the early psychoanalytic model of the mind restricted to instinct, drive, and defense, Jung postulated an innate, irreducible, and thus additional psychic need to apprehend meaning and to express it symbolically. This need most commonly generates a religious impulse that cannot in every case be derived from (nor need always be a defense against conflict with) the biological drives. When ignored or blocked, this need can produce not only unhappiness, but psychological distress and eventually overt symptoms. Jung considered the now-widespread dismissal of religion as driven less by rational disillusionment than by hubris.

Classical Jungian therapy therefore aims at promoting an "individuation process," marked by an individually determined interior experience of a markedly mystical character. Jungian scholarship incorporates and interprets a vast, world-spanning body of mythological, religious, mystical, and occult references. Jungian ideas are widely embraced within artistic, literary, religious, and pastoral circles, but remain largely peripheral to academic psychology and psychiatry.

Jung anticipated many later trends: "ego-psychology," which defines, and focuses treatment toward expanding a defense-free domain of the ego; the ideas of Otto Rank, who similarly focused on free will; Heinz Kohut with his emphasis on a "self" developed out of "normal narcissism"; Hans Loewald's re-evaluation of regression as not merely restorative but creative; and Abraham Maslow's notion of "self-realization." Today's easy blending of "new age" psychotherapy and spirituality likewise parallels Jung's approach—and was in large part fostered by it.

II. DESCRIPTION OF TREATMENT(S)

A. Historical Backdrop

It took about 1000 years for European culture to consolidate around a relatively uniform body of Christian, creedal beliefs. That this would happen was by no means a foregone conclusion. The main competitors to early and medieval Christianity formed a group of philosophies and theologies loosely called "Gnostic." They shared with each other, and with many Eastern religions, the view that the goal of spirituality was a

form of personal “illumination,” a specific state of mind, if you will.

Jung considered his “analytic psychology” to be a modern reformulation of these same ancient Gnostic principles. The mass return to these ancient mysticisms that marked the 1960s was therefore unsurprisingly characterized as well by a sudden upsurge of interest in Jung. (Timothy Leary applied to the C. G. Jung Institute of Zürich in 1971 but was rejected.)

Jungian psychology arose within an unusually gifted, accomplished, and eclectic circle of continental scientists, artists, poets, writers, and theologians who gathered around the person of Jung (see, for example, the proceedings of the Eranos Conferences of the 1930s and 1940s). Most shared with Jung a deep hunger for the mysterious and a visceral dislike of the rationalism and materialism that they considered Freudian psychoanalysis to embody—indeed, modernism altogether. But they were also too sophisticated for the fading religiosity of pre-World War I Europe.

They were seekers, an intellectual elite that heralded the new-age spirituality that would explode in populist form worldwide two decades later. As Jung conceived it, “analysis” should stimulate the “Self” to emerge, heralded by imagery associated with God (dreams; induced visions called “active imaginations”) and accompanied by the unique emotions attending divine revelation. This “individuation process,” hence classical Jungian therapy itself, therefore has a markedly spiritual—specifically Gnostic—cast.

Nonetheless, Jung had a strikingly open mind toward what we now call “biological psychiatry.” In the mid-1950s he chaired the First International Congress on Chemical Concepts of Psychosis, having formulated a prescient biochemical theory of schizophrenia—in the same book in which he first outlined his *religiously* based objections to Freudian psychoanalysis. Freud had specifically appointed Jung his “prince and heir,” and as Jung was a rising young psychiatrist assigned him the task of “conquering for psychoanalysis the psychoses,” as Freud himself had the neuroses, by showing that psychotic imagery, like dreams, consisted of the same infantile conflicts, in disguised form, as in neurotic fantasy. But Jung concluded otherwise: Psychotic imagery was a rigidified self-portrait of innate, biologically foundational brain processes. They were on this genetic basis universal, and did not arise from the idiosyncratic conflicts of an individual mind. Such imagery was accessible in normal states as well, mystical and creative ones in particular; their emergence and fixedness in psychosis was due neither to spiritual development nor creative genius but rather, he guessed, to a

destructive toxin. To treat all such imagery as born of neurotic conflict at once grossly underestimated both art and religion and grossly overestimated both the neurological integrity of a brain affected by psychosis and the power of psychoanalysis as a treatment method. Empirically, if not strictly speaking scientifically, Jung was well ahead of his time on both points.

Jungians after Jung have been keen students of other schools of psychotherapy—object relations theory, the ideas of Heinz Kohut, Gestalt therapy, for example, even classical psychoanalysis—as much as they have been keen students of religion, both new and old. However, those Jungians most interested in other schools of therapy tend not to be the ones most interested in religion. This difference in “culture,” as it were, underlies the major divisions in the Jungian world, markedly enough so that conferences in the 1970s and 1980s explicitly addressed the conflict between a second-generation “clinical” camp and Jung’s first generation of followers. The clinical practices of the former are scarcely distinguishable from the clinical practices of any well-trained, psychodynamic psychotherapist, even if the language they use is different.

By the 1980s, yet a third strand in Jungian thought and therapy had developed, largely under the influence of James Hillman, whose talents and approach to treatment are chiefly literary, with a strong “deconstructionist” cast. Whereas Jung and his early followers sought a form of enlightenment as symbolized by the emergence of a unitary “Self,” Hillman and his followers pursue rather a never-ending process of poetic interpretation and story-telling whereby any (and every) firm belief save one can ultimately be “seen through,” as they put it: deconstructed not into a set of socially inculcated self-serving biases, but into a set of transcendental self-serving illusions (“gods”). Whereas Jung made an explicit analogy between the “Self” and God (or to a Gnostic Christ), Hillman makes an explicit analogy between his “archetypal psychology,” and the god Hermes, messenger among all the gods—and trickster to their self-importance.

The sole firm belief opaque to Hillman’s archetypal psychology is, of course, the firm belief that any and every firm belief can ultimately be “seen through,” the belief on which depends the trickster’s own self-importance.

These three Jungian camps have now acquired more or less formal names: the “classical,” “developmental,” and “archetypal” schools, respectively. (No school wants not to be called “clinical.”) A brief analysis of the same case as approached by representatives of each of the schools may be found in *The Cambridge Companion to Jung*, and

an excerpted web version at <http://www.iaap.org/articles/ccj3approaches.html>. What follows is a synopsis of classical, hence distinctively Jungian, psychotherapy.

B. Classical Jungian Therapy

1. Format

Jungian therapy (“Jungian analysis”) is conducted face-to-face. Jung believed that the “neutrality” of the classical psychoanalyst was undesirable—because largely illusory. He was the first to argue for a more “personal” form of psychotherapy in which the mixing of the patient’s problems and biases with those of the therapist would be accepted as a virtue. Treatment sessions last about an hour and take place no more than three times weekly, more typically once or twice.

2. Process

Classical Jungian therapy has two chief components: dream interpretation and “active imagination.” Dream interpretation begins immediately; active imagination is a method usually employed later.

a. Dream Interpretation The Jungian approach to dream interpretation uses two main techniques: association and amplification. To associate to his dream, the patient freely expresses, without censorship, any thoughts that the imagery brings to mind. In contrast to classical psychoanalytic technique, however, Jungian-style association is interrupted, not free. It is akin to the limited association Jung asked of his subjects in his early word-association studies: Once a link is established by the patient between an element of the dream and some aspect of the patient’s life—past or present—the therapist encourages him or her to set that element aside and associate to other aspects of the dream. Jung insisted that while associations eventually lead toward a patient’s familiar conflicts (which he called “complexes”) they wandered away from the specific meaning of the dream to which they were tethered. Inevitably, the lack of new information will lead both therapist and patient to devalue dream interpretation. Over the years, this is exactly what has happened in most schools of psychoanalytic psychotherapy. On the other hand, those classically trained Freudians in whose hands dream-interpretation remains a vital art (and those patients who have likewise learned its vitality) invariably interrupt free associations in precisely the way Jung argued they should—a matter more of common sense than of deep theoretical distinction. Jung’s rather overly sharp argument with free association also reflects the relatively limited role played by

conflict, repression, and compromise in the (early) Jungian psychodynamic theory of symbol and symptom formation, hence in the classical Jungian approach.

For both practical and theoretical reasons, in the early stages of a classical Jungian treatment, dream interpretation consists in teaching the patient (by commentary, not directive) how to make plausible links between the elements of the dreams and their personal concerns. Early on, the dreams are expected to be of the kind familiar to most psychotherapists: fleeting, fragmentary, often confusing.

Patients are encouraged to keep careful records of their dreams, and to note their responses both to the dream imagery itself and to any of the personal material evoked by the dreams. They are likewise encouraged to express both the dreams and their responses in plastic form: drawing, painting, poetry, story-telling, music, even dance, as the patient is inclined. For perhaps two years, a classical Jungian analysis may consist of little else but attention to dreams.

Over time, it is anticipated that the character of the dreams will subtly change. From reflecting a more or less self-evident preponderance of personal problems and concerns expressed in idiosyncratic images composed largely of memory traces, the dreams will begin to become more mysterious—harder to link to personal experiences—and will take on a more general character. More fable-like, such “big dreams” employ the universal characters of myth and legend: heroes, villains, monsters, kings, queens, princes and princesses, fantastic landscapes. They are also more likely to unfold as full-scale dramas, with a coherent structure. This kind of imagery is termed “archetypal,” by which Jung meant to indicate at once their common and their fundamental nature. He considered these figures, and the dramas they engaged in, to be the intrapsychic representation of the innate structure and dynamic of the human psyche, the “images of the instincts.” Out of the inherent repertoire of such dramas (aspects of brain function that presumably evolved as discrete patterns of adaptive response to being a human being in a typical human setting), the ones that are individually emphasized in each person reflect the psyche’s deepest response to particular challenges constructed from the common, evolved responses of the human species to like challenges. Variations in this response unique to each individual’s specific genetic background may be evident as well, especially if these reflect relatively long-term adaptational pressures that affected many ancestral generations.

Once criticized as dangerously racist, such notions tend nowadays to be taken for granted in evolutionary

medicine—as for example in the strong genetic pigment correlations and statistically near-perfect north–south geographic gradient in the distribution of seasonal affective disorder. Group differences in innate brain-based response patterns attenuate, naturally, as the human gene pool becomes increasingly mobile and admixed. It should be said, however, that the classical Jungian therapist attributes to these patterns a transcendent meaning that goes beyond purely biological explanations.

b. Active Imagination Once a patient has begun to experience “big dreams,” they are encouraged to take their expressive engagement with the material a step further. The patient will be guided to converse with the dream figures in imagination. The goal is to achieve a state of mind akin to certain forms of meditation that utilize explicit visualization. These meditative practices can be found worldwide and are detailed, for instance, in Jewish Kabbalistic, medieval Christian-contemplative, Tibetan Buddhist, and Chinese Taoist texts, *inter alia*. When successful, the visualized dream characters are experienced as holding up their end of the conversation, as it were, on their own, not as being invented by the patient in the way that an author invents dialogue.

On the other hand, it is not uncommon for authors (indeed, anyone experiencing creative inspiration) to feel that certain ideas appear spontaneously. But the purpose of “active imagination” is not artistic but rather to learn from whatever the “characters” themselves have to say. “Active imagination” is a state of dissociation, cultivated for constructive purposes rather than for defense. Arguably, it has much in common with classical free association. The major difference between active imagination and free association—and between individuals drawn to the one and those drawn to the other—may precisely be the well-known individual differences in dissociability. The temperament of Jungians, both patients and professionals, may therefore tend on average to be more expressive, sentimental, and “hysteroid”; of Freudians, more restrained, intellectual, and “obsessive.” An older parallel distinction is that between the romantic and the classical types. In sum: That which Freudians dichotomize by the abstractions “hysteria” and “obsessionality,” Jungians poeticize as the enmity of Apollo and Dionysus.

3. Individuation

In any event, not everyone has a knack for active imagination. Those who do are considered to have the essential skill for the “individuation process.” Utilizing active imagination as its chief vehicle, the Jungian analysand may now undergo a lengthy series of imagi-

native encounters with the major “archetypes.” These appear as larger-than-life beings of mythic proportion and (in the meditative state) so real as to engender intense emotional response. The therapist’s role at this stage is two-fold: First, to ensure that the emergence of this archetypal material is paced so as to minimize the risk of “inflation” (hypomania); and second, to guide the analysand toward literature that “amplifies” the meaning of the emerging themes.

Jung’s own autobiography remains the best example in the literature of such a state, and of the difficulty of discriminating among deliberate active imagination, psychotic hallucination, and extreme dissociation. There are some individuals who are able to engage in active imagination but who should not, because of its potentially destabilizing effects.

In a successful individuation process, the encounter with the archetypes greatly expands the individual’s sense of meaning and purpose in life, and their flexibility in adaptation. Potentials previously unrecognized and untapped may be awakened, and aspects of the personality that had lain fallow may now be cultivated and incorporated, yielding greater “wholeness.”

Jung believed that such an expansion of the personality was marked in dreams and active imagination by the spontaneous appearance of symbols of the “Self.” These are images whose basic geometric format is the quartered circle (“mandala”). They are strikingly similar to symbols utilized worldwide to represent God; in polytheistic cultures, the highest god; in Gnostic religions, the union of all gods.

The symbol system Jung considered closest to that which emerges in modern patients was that of the alchemists. Their journey to all the planets, their “sublimation” of lead through various metals to gold, their quest to unite ever higher-level opposite elements to form the Philosopher’s Stone: All symbolized the transformation of personality by the progressive encounter with and integration of the “lesser” gods within to form the “Self”—hence the capitalization.

The ideal classical Jungian individuation process is expected to traverse the following stages: (1) Integration of the “personal unconscious,” or “shadow,” loosely equated with the unconscious as defined in psychoanalysis; this prepares the individual for integration of the “collective unconscious,” that is, the archetypes; to wit (2) the “anima”—unrealized feminine aspects of a man, or “animus”—unrealized masculine aspects of a woman; (3) the “Great Mother,” the embodiment of everything maternal, both nurturing and engulfing, as nature herself can be; (4) the “Wise Old Man,” the embodiment of “spirit”; (5) the “Self,” an overarching union of all of

these, that is at once the superordinate representation of God and the foundation of individual identity (as in the equation of Atman and Brahman in Hindu mysticism; or of Christ and the person in orthodox Christian theology).

Individuation itself is a never-ending process. Jung considered the ignition of the process in therapy, and at least some substantial experience of the “Self,” to be the goal of therapy. With the acquisition of a sense of meaning and higher purpose in life, symptoms may be expected either to disappear or, if not, to have taken on the kind of meaning that allows them to be accepted as a gift rather than a hindrance.

III. THEORETICAL BASES

In classical Jungian therapy, practice and theory are intimately intertwined. A common criticism of Jungian therapy is that it amounts to the indoctrination of the patient in a specific quasimystical worldview. The classical Jungian would sharply deny that this is criticism; Jung and many of his followers explicitly consider the individuation process to be a modern equivalent to antique rites of initiation into the cult and doctrine of certain gods and/or goddesses. But he would balk at “indoctrination.” A central tenet of Jungian theory is that the “initiatory” sequence of archetypes emerges spontaneously from within the patient, rather than being overtly or covertly taught. Similarities to any external sequences arise because of innate predispositions that underlie the symbol-making potential of the human brain.

Evolution suggests that the brain should develop predispositions to apperceive experience according to common if flexible categories and patterns (like the newborn whose mouth conforms, without instruction, to the negative space of a human nipple). Fully formed “images” per se need not be embedded innately for common forms to emerge widely. Nor can simple commonality of experience account for all the overlap in imagery: Even motherless infants hunger for her expected presence. (This particular line of reasoning led to a rapprochement in the United Kingdom between followers of Jung and of Melanie Klein.)

A. Biology versus Spirit in Jungian Therapy

Against this one may argue that Jung developed Jungian therapy not empirically but much as did Freud: out of a lengthy attempt to define himself, free from serious outside accountability, with patients

turning into followers, and with data from all. The importance and plausibility of the archetypal hypothesis notwithstanding, the vast body of Jungian writing detailing “archetypal imagery” in case studies can provide no compelling supportive evidence for it. Today’s Jungian therapists are therefore far less likely to assume that something is archetypal just because it looks like it.

What exactly is an innate structure of the psyche? Jung’s revolt against Freudian reductionism led to Jung’s claim that there is a “level” of the psyche deemed “psychoid,” that is at once both instinctive and transcendent. Critics argue that this is a mere assertion and that the concept “psychoid” is ill-defined. In effect, Freud argued that society strikes a never-wholly successful compromise between animal desires and a wholly pragmatic civility, religion of any kind serving to enforce the precarious dominance of the latter. Jung argued that society need strike no such balance, since in the form of spirituality he advocates desire and civility become one; only organized religion is a problem in stifling both spirituality and instinctive gratification.

The religious instinct, Jung thus argues, is real, not a defensive pose taken up by one of the animal instincts to help us avert our gaze from its true intent. Like any instinct, it has an underlying nervous system physiology that is relatively invariant among all human beings. Hence, its patterns of expression, and the sequence of maturational steps it follows, are similarly invariant. It may be ignored, as may any other instinctive drive, but only at significant cost: a sense that life is ultimately meaningless. On the other hand, Jung argued, spirituality that defines itself as unconnected to instinct tends to become sterile and unfulfilling, a criticism he leveled without cease at Christianity.

A dominant Eastern model for the individuation process in early Jungian circles (in the 1930s) was therefore Kundalini Yoga, a form of mystical practice in whose original (Tantric) form enlightenment could be achieved via the sacred sexual union of the male and female practitioners. The corresponding Western model was, again, alchemy, the symbolic content of which was explicitly sacred-sexual, the “union of opposites” depicted as the explicit sexual conjugation of a naked king and queen; and the practice of which involved a male alchemist and his “mystical sister” (*soror mystica*) working together in sacred precincts of the “laboratory.”

In the classical Jungian model of therapy as individuation, an intense mutual emotional entanglement of analyst and analysand was anticipated and cultivated. As in psychoanalysis, these emotions are termed “transference”

and “countertransference,” but they are not interpreted as the emergence of long-repressed infantile longings whose original objects are found in the family. Rather, they are understood as the awakening of never-before experienced longings whose proper objects are divine.

To penetrate into the depths of the psyche in a classical Jungian analysis is therefore meant to be a profoundly spiritual journey whereby the tension between material drives and spiritual longings are resolved by their union. Such a journey has importance beyond the resolution of an individual’s personal conflicts: To achieve in any significant measure a “union of matter and spirit” is to contribute to the building of a new explicitly post-Christian spiritual epoch. In light of modern culture-wide sentiments it is remarkable that Jung and his followers elaborated all these ideas well before World War II.

B. The Structure of the Psyche

1. *Conscious versus Unconscious*

For Freud the unconscious is primarily a set of primitive, unacknowledged desires that to remain out of sight require an ever-expanding construction of mutually reinforcing false ideas, self-serving attitudes, and conveniently filtered, distorted and, as needed, invented, memories. But such freedom from self-knowledge demands an exhausting vigilance. Psychoanalytic treatment therefore consists largely of a tactful undermining of this vast defensive fortress. Treatment releases the energy invested in defense for other “constructive” purposes.

To that aspect of the unconscious that is more than what has been repressed psychoanalytic theory did once accord a place—Freud recognized that some dream images, for example, represented “vestiges” of an early stage in the (biological) evolution of brain function. But as the term “vestige” suggests, he considered this material of little practical significance. It is rarely even mentioned anymore.

Jung’s dislike of psychoanalytic theory, and of Freud’s worldview, follows rather directly. Freud’s insistence that all human activities are but distorted variations of material, instinctive drives—that “higher meaning” is therefore nothing but cheesecloth veiling the bleak truth of reality—seemed to Jung much like what the alchemists called “the universal solvent.” In its attack, it excepts nothing: not even the beaker supposed to contain the solvent; not even, therefore, psychoanalysis itself. In such a bleak view, there are no “constructive” purposes in whose service all that freed energy can be

placed without some new illusion to sustain it. “Sublimation” therefore is not sublime, it is merely the “highest” form of defense against reality.

For Jung, by contrast, the structure created by repression is the trivial and uninteresting aspect of the unconscious (the “personal unconscious”). What Freud considered a mere vestige, Jungians view as the essential, inherited anatomy of the psyche, and by virtue of its link to spirit, the pathway toward higher meaning. Jungians argue that meaninglessness is a priori pathogenic, and to train people to accept it is to induce, not alleviate, both psychological and societal disorder. The Nazis succeeded, Jung argued, because they offered Germans meaning, whereas Weimar deprived them of it. The power of his simple insight—that no one accepts meaninglessness—was severely compromised by Jung’s own early flirtation with Nazi ideology.

The repressed material of the personal unconscious may need to be dealt with first, but the individuation process proper will only begin when material from the deeper levels of the collective unconscious begins to emerge. This deeper material is not considered to be a disguise for otherwise unacceptable but perfectly expressible thoughts and feelings. The mythic imagery is treated rather as genuine metaphor—that is, the best possible representation of profound states of mind otherwise inexpressible. The repressed material of the personal unconscious and the innate archetypes of the collective unconscious are related in that personal conflict, hence repression, develops only around matters that are of inherently profound import.

2. *Archetypes*

The infant is born hard-wired to form an attachment to a specific kind of external object. Later, to this latent expectation there becomes associated a specific set of sensory impressions. But the innate representation can never adequately be embodied by any real experience or memory. Instead, the mind, when released from the criticisms of rationality, will creatively weave together—from memory and from imagination—whatever fragments it needs to paint a portrait of the hidden, never before “seen,” yet more “real,” more deeply longed-for and feared “Great Mother,” the “archetype” against which all human mothers—indeed, all women—are subtly going to be judged; and against which they subtly judge themselves.

Religion and therapy come together in this model when the compulsive philanderer, say, realizes that not only is he pursuing his mother in the guise of other

women (the personal unconscious at work), but that his disappointment in his mother arises less from her flaws as a person than from his previously unacknowledged longing for a Mother of the sort not ever available in earthly form (an element of the collective unconscious). The latent, preformed imago of “mother” Jung called the “Great Mother” archetype. A family of archetypes constitutes the basic structure of the human psyche. Such a viewpoint has much in common with later “object relations” psychoanalytic theory except that for Jungians, “introjects” do not come from the outside—they begin within, are projected outward onto more or less suitable objects, and only then reintegrated.

Many Jungian archetypes have obvious parallels in typical human experience and so lend themselves to a more standard psychoanalytic or object-relations reinterpretation: Perhaps images of the “Great Mother” are energized not by innate, universally human expectations but by experiences that are universal, or nearly so, subjectively processed. (The Jungian model is closest to an interactionist model.) But other archetypes are not so easy to reinterpret this way. For example, the so-called trickster figure, common to many folk religions, and especially to shamanism, was the veritable patron god of alchemy in the form of Hermes (Mercurius). Why jokes, trickery, adolescent mischief-making, chicanery, and even outright duplicity should have so honored a place in certain forms of spirituality is hardly self-evident—unless one starts with the assumption that all such “higher” pursuits are cons.

3. The “Self”

The hermetic mysticisms of antiquity guided the seeker along a more-or-less well-known path toward a distinct state of illumination. The state is represented by a plethora of metaphors; the path likewise. But a common feature of most metaphors for the path is that of a synthesis of some sort: Initiation consists of the controlled identification with, incorporation of, and disidentification from a sequence of gods (“metabolized introjects”). The journey to each of the planets (named after the gods) is one such metaphor; the progressive transformation of base metals (lead) to noble ones (gold) is another (with each metal associated with a planet and a god). Hermes guides the soul on its planetary peregrination; Mercurius guides the alchemist in the progressive “sublimation” of the metals. As each “god” is encountered, identified with, and disidentified from, it is integrated to form a larger nucleus of personality that Jung called the “Self.” Although experienced within, it is experienced as larger and other than one’s personal identity.

4. Personality Types

Jung also authored the widely accepted distinction between “introversion” and “extraversion.” He considered these traits as defining an important and universal dimension of human personality—an axis along which everyone tends toward a characteristic position that forms their most comfortable way of relating to the world. Jung extracted two other independent such axes as well: one defined by a polar contrast between “thinking” and “feeling”; the other by a polar contrast between “sensation” and “intuition.” The eight types thus defined seem at first glance to have a rather forced symmetry. But of all of Jung’s theoretical constructs, his typology has earned the most research-based confirmation.

A careful study of Jung’s ideas about the archetypes and the collective unconscious on the one hand, and of his typology on the other, reveals very little compelling connection between them—they could easily be developed as two entirely different models of the psyche.

There is one critical point of contact, however, with respect to the concept of introversion. When he at first accepted Freud’s plan that he should conquer the psychoses for psychoanalysis, Jung spoke of the essential problem in psychosis as being that of “narcissism”—the turning away from relationships to a solipsistic world of inner gratification. Freud’s understanding was that this turning away was regressive and defensive—that the healthy capacity to spurn narcissism had been acquired by the psychotic and then split off (a defensive “vertical split in the psyche,” as Freud would later characterize it when indirectly responding to Jung’s abandonment of psychoanalytic theory), a variant of repression.

But eventually, Jung came to two very different conclusions: First, as noted before, that however it may first have been initiated, the profound entrenchment of psychosis was due not to psychological defense and resistance, but by a serious biochemical defect. The second conclusion was that narcissism per se was more than an early stage in psychic development and more than a defensive regression to that stage: It was a normal, natural, and absolutely critical component of the psyche at all stages of life, and perhaps especially necessary in later maturity in particular. That is why when he broke from Freud over just this issue, Jung ceased using the word narcissism and replaced it with “introversion.”

When Jung rejected/was ejected from the psychoanalytic movement, a nascent psychodynamic understanding of healthy narcissism was ejected as well. The mutual bitterness of this parting ensured that it would take Jung’s followers a good 50 years to accept the importance of the “personal unconscious,” and that it

would take Freud's followers the same 50 years to produce and accept the ideas of a Heinz Kohut and of related forms of self psychology.

C. Science or Religion?

Most people are unaware of this, but many major mainstream American churches have tacitly but extensively made of Jungian theory a new theological foundation. (This is especially true, for example, of the Episcopal church in general and of the female religious orders of the American Catholic church.) In many cases the incorporation of Gnostic and pagan themes is remarkably explicit given the flat contradiction between the Hebrew and Christian scriptures, on the one hand, and the Gnostic heretics to whom Jung explicitly relates his own ideas. To the extent that religions have felt that they need to justify themselves on psychological grounds—theology proper apparently being passé—they have frequently therefore become agents for the widespread social acceptance of Jungian psychotheological ideas, although these are rarely recognized for what they are. Jungian theory and therapy thus exerts an extraordinary cultural influence both via formal religion and informal post-sixties' spirituality.

Yet Jung also exerted an important influence—one that continues to grow—on arguably the most fundamental of the hard sciences, namely physics. Mathematical physicists with a keen interest in quantum mechanics cite certain Jungian ideas regularly in their writings. A few of the more prominent names include Christopher Isham, professor of theoretical physics at Imperial College, London, and Henry Stapp of the Theoretical Physics Group at Berkeley, Harald Atmanspacher of the Max Planck Institut and Kalervo Laurikainen at CERN. On the brief back flap biography of his *Lectures on Quantum Theory: Mathematical and Structural Foundations* Isham specifically mentions his interest in “the work of C. G. Jung,” and on the cover, the letter “o” in “theory” is replaced by a snake biting its tail—the “ouroboros”—a favorite symbol of Jung's that he often interpreted as referring to a mysterious wholeness of everything that evades causality. This is no accident.

In the late 1920s and early 1930s Jung developed a theory of “synchronicity,” the idea that events unrelated by any causal chain were nonetheless related via meaning, not merely as an invention of imagination, but objectively. Astrology, for example, claims that stellar arrangements as happen to be seen on earth, and perceived as forming images drawn from earthly expe-

rience (e.g., Scorpio the scorpion), influence both behavioral tendencies and chance events in the life of selected individuals, and that this influence is uniquely symbolized by the constellation's image.

The kernel of astrology is not the idea that stars influence people—one could contrive some chain of physical events, however farfetched, that might effect such an influence; perhaps some as-yet-to-be-discovered radiation, for example. What is nutty is rather the claim that the nature of the effect is reliably characterized by the earthly image to which in two dimensions an impossibly widely separated three-dimensional array of stars happen to conform—only for the moment!—and merely in someone's imagination.

Ideas of this sort strike most scientists as absurd beyond mention, but they have formed an important part of classical Jungian practice: Jung's daughter provided astrological charts for many new students at the C. G. Jung Institute in Zürich—not officially, to be sure, but wholly accepted; lectures on tarot and palm reading are unexceptional; divination via the I Ching has long held an especially esteemed place in classical Jungian practice. In his autobiography, Jung provides a number of examples where he would interpret an incidental event that occurred during a treatment session just as he would a dream reported by the patient—as when once a bird flew into the room. Synchronicity, in short, has never been a mere cognitive foible of classical Jungian therapy; it has been central to it.

But physicists (a minority, to be sure) of varying rank, from modest to the very best, find in “synchronicity” a rather startling analogy to certain bizarre features of quantum mechanics (e.g., “entanglement”), wherein two particles appear to function as though they were one, with an instantaneous orchestration of behavior between them, no matter how widely separated, and even backward in time: Neither causality nor physical interaction (e.g., forces) is involved. Out of early quantum hypotheses Einstein brilliantly drew such behavior as an inevitable consequence, hoping thereby to demonstrate their absurdity. But all subsequent experiments, over 80 years, have instead validated their reality. Physical reality as understood by the very foundations of physical science is exactly as Einstein said quantum mechanics describes it, a description he considered so absurd as to be its own self-evident impossibility proof. Yet so it is.

Marcus Fierz, an eminent Swiss physicist whose brother became a Jungian analyst and founder of the Jungian inpatient psychiatric facility Klinik am Zürichberg, assisted Jung with later corrections to the statistics

in Jung's astrology paper. The corrections erased any statistical significance in the supposed correlations between constellations and psychology. Between hard modern science that does indeed unveil a mysterious universal correlation among subatomic particles everywhere, and Jung's unsuccessful attempt to statistically correlate astronomical orbits with human fantasy, there is a huge gulf—which Jung dismissed.

Having found that a better statistical analysis nullified his hypothesis, he changed his hypothesis. Synchronistic relations occur within statistical fluctuations, he then claimed, not in excess of them as do causal associations. By contrast, the physical relations created by entanglement are detected precisely in their violation of classically expected statistical results. It may be plausibly argued, therefore, that however poetic the analogy between modern physics and a Jungian model of psyche, there is no real connection whatsoever. How is it then that so many eminently qualified scientists have taken Jung's ideas, amateur statistics and all, so seriously? Is there something about the Jungian theory of synchronicity that should perhaps not be dismissed out of hand?

The answer is a qualified "yes," and arises out of an aspect of Jungian theory and history that is often alluded to but has yet to be fully clarified: The personal relationship and collegial interchange between Jung and one of the very greatest of the founders of quantum mechanics—Wolfgang Pauli. Within their relationship Jungian theory, practice, and history unite.

In 1904, Einstein had been Jung's dinner guest: "These were very early days when Einstein was developing his first [i.e., special] theory of relativity..." Jung recalled. "I pumped him about his relativity theory. I am not gifted in mathematics. I went fourteen feet deep into the floor and felt quite small." Nonetheless, says Jung, "...it was he who first started me off thinking about a possible relativity of time as well as space, and their psychic conditionality."¹

Fifteen years later, in the early 1920s, Wolfgang Pauli was at work on the mathematics of "spin," a quantum phenomenon whose utter mysteriousness even today remains to be fully fathomed. Among other things, spin ensures that two identical particles with the same (half-integer) spin will tend to avoid each other—not via any force propagating at the speed of light, but by fiat, instantaneously, everywhere in the universe and probabilistically, as though orchestrated by some gentle

omnipotent conductor who merely urges—and who leaves no physical trace of his existence.

For electrons—the foundational instance of such a spin-bearing particle—these probabilities conform to the mathematical relations of three intersecting rings, rotating about three perpendicular axes with a common center, but with some twists: Each ring may rotate simultaneously in both possible (opposite) directions. By the laws of classical physics (including those in which Einstein firmly believed) such "superpositions" are completely impossible—like one object being in two places at the same time; and to return to its original position, a ring must complete two identical rotations (a fact that is beyond human visualization). But superpositions do, in fact, exist. Recently, objects large enough to be seen by the naked eye have been made to exist simultaneously in two places at once. And on the fact that two-rotations-equals-one depends every diagnostic MRI scan ever taken. Furthermore, the speed of rotation for each ring, in either direction, was quantized—it could assume only discrete values, like pulses or rhythms, giving spin values what we might call "clock-speeds," that in multielectron systems are determined by certain special powers and inverse powers of 2.

Pauli's initial success in 1924 delineating these relations would win him standing as one of the very greatest of the founders of quantum mechanics, the 1945 Nobel prize, and on that occasion an unsurpassed accolade by Einstein, who designated Pauli his "spiritual son" and successor as director of the Institute for Advanced Studies at Princeton.² The strange relations of spin—now termed the Pauli Exclusion Principle—are directly responsible for the current explosion of quantum technology, including such astounding feats as quantum teleportation, quantum computation, and the emerging field of "spintronics."

But even this understates the matter: "There is no one fact in the physical world which has a greater impact on the way things *are* than the Pauli Exclusion Principle. To this great Principle we credit the very existence of the hierarchy of matter ... which makes possible all of nuclear and atomic physics, chemistry, biology and the macroscopic world that we see" (theoretical particle physicists Ian Duck and E.C.G. Sudarshan).

¹ Before their estrangement, Freud had publicly deemed Jung his "spiritual son *and heir*." The infinitely nuanced, unfailingly courteous Einstein, friend to Freud, and knowing of the true relationship between Pauli and Jung, gave Pauli his love with no strings attached. Quantum theory was Einstein's permanent *bête noir*.

¹ Jung, C. G.: *Letters*, Vol. 2, p. 108.

But Pauli had also been wrestling with a profound twofold despair. In 1927 his mother poisoned herself after discovering that Pauli's father's was having an affair with a much younger sculptress whom he later married; and his scientific genius had early on led him to a deep estrangement from Catholicism. "I am baptized 'antimetaphysical,'" he wrote, "instead of Catholic." (To safeguard his rise in the professoriate at the University of Vienna in the 1890s, Pauli's Jewish father converted to Catholicism—much as today a conversion to leftism is *de rigueur*; near the end of his life Pauli seems to have made something of a return to his father's abandoned faith.) In May 1929 Pauli formally left the Catholic church and in December 1929 a beautiful and seductive cabaret performer married the lovesick physicist, even though he was her second choice. In 1930 she abruptly abandoned him and quickly married her first choice.

Pauli had by no means been happy with his 1924 formulation of spin, whatever his colleagues thought. "My nonsense is conjugate to the nonsense which has been customary so far," he wrote. Yet in 1927, the year that his mother killed herself, he fully satisfied himself with respect to spin, inventing the three famous "Pauli matrices," mathematical representations of the doubly valued quantum spin, one for each spatial axis. In anguish, regardless, Pauli drank heavily and provoked humiliating public quarrels until, at his father's urging, he consulted Jung.

Jung repeatedly claimed that he never "formally analyzed" Pauli because he found Pauli's natural psychological capacity so great ("He even invented active imagination for himself...") and because Jung was intent on studying and presenting Pauli's dreams as objective evidence for his theory of the collective unconscious, archetypes, individuation, the Self and the relationship of these to alchemy: "Now I am going to make an interesting experiment to get that material absolutely pure, without any influence from myself, and therefore I won't touch it," Jung stated. Instead, "[a]t the end of the year I am going to publish a selection from his first four hundred dreams, where I show the development of one motif only." Pauli was officially treated by Dr. Erna Rosenbaum who, since she was "a beginner," Jung "was absolutely sure she would not tamper."

Nonetheless, Jung supervised Rosenbaum's work and met weekly at noon with Pauli to discuss and interpret Pauli's dreams: "[H]e was doing the work all by himself," for 3 months, Jung says, but "for about 2 months, he had a number of interviews with me. ... I did not have to explain much."

In 1935, Jung discussed 400 of these dreams as the 1937 Terry Lectures in Psychology and Religion at Yale. They form the evidentiary backbone for all his volumes on alchemy. At Yale, Jung asserted that "the dreams I am going to relate ... represent an entirely uninfluenced natural sequence of events" and that in these dreams, his "well-educated intellectual" (and at the time anonymous) subject "worked out (among other matters) the problem of perpetual motion, not in a crazy way but in a symbolic way. He worked on all the problems which medieval philosophy was so keen on."

The climax of the series was not a dream, however, but a "visual impression" that "sums up all the allusions in the previous dreams." Jung called it "a turning point in the patient's psychological development ... in the language of religion—a conversion." The visual impression was (in Pauli's words, as quoted by Jung):

There is a vertical and a horizontal circle having a common center. This is the world clock. It is supported by the black bird. The vertical circle is a blue disc with a white border divided into $4 \times 8 = 32$ partitions. A pointer rotates upon it. The horizontal circle consists of 4 colors. On it stand 4 little men with pendulums, and round about it is laid the ring that was once dark and is now golden formerly carried by 40 children. The world clock has three rhythms or pulses. (1) The small pulse—the pointer on the blue vertical disc advances by $1/32$. (2) The middle pulse—one complete rotation of the pointer. At the same time the horizontal circle advances by $1/32$. (3) The great pulse—32 middle pulses are equal to one complete rotation of the golden ring.

Jung refers to this vision as the "perpetuum mobile," and provides 64 pages of world religious commentary on it, representing it as the spontaneous emergence of the Self. Thereafter, Jung says, Pauli "became a perfectly normal and reasonable person. He did not drink any more, he became completely adapted and in every respect normal. ... He had a new center of interest." In 1934, Pauli discontinued his sessions with Rosenbaum and married that same year, for life.

Never in his many discussions of this prototypical vision does Jung mention Pauli's successful matrix model of three quantized spin axes, which this visual impression obviously reproduces; nor the admix of feelings over his personal losses (the black ring turning golden once again; the blue and white motif that Jung related to Mary, the Mother of God in Catholicism, but not to Pauli's own lost mother). Indeed, the particular problem that the Pauli Exclusion Principle solved was how and why the first four "magic" numbers of the periodic

table arise: 2, 8, 18, and 32. Pauli was widely known to have continued his problematic drinking long after.

However weakened Jungian theory may be by the lack of evidence from one of its chief sources, and in spite of the fact that throughout their ensuing friendship Pauli made his own doubts clear about many of Jung's scientific claims, Pauli made no bones about his personal debt to Jung. He had wanted Jung to test "synchronicity" against the rigors of statistical evidence; Jung refused. When urged by colleagues not to damage his reputation by later copublishing a book with Jung, Pauli nonetheless insisted: "For there comes the time when I must give documentary evidence of what I owe this man."

IV. EMPIRICAL STUDIES

Only very recently has any attempt been made to assess the value of Jungian treatment with due consideration to the fundamentals of experimental design. Numerous presentations on outcome have been delivered at Jungian conferences by Dr. Seth Rubin of the Society for Psychotherapy Research, and the first peer-reviewed article was published in 2002 in the *Journal of Analytical Psychology*.

However, a German Jungian society has published on the web and in print an extensive, lengthy, and independently funded study with attempt at controls and a clear delineation of its own limitations and weaknesses. This study found that "Even after 5 years, ... improvement in the patients' state of health and attitude ... resulted in a measurable reduction of health insurance claims (work days lost due to sickness, hospitalisation days, doctor's visits and psychotropic drug intake) in a significant number of the patients treated ... [with] long-lasting effects on the patients' psychological well-being. [However], there are numerous major methodological problems with these data including the lack of comparison sample, the non-representativeness of the sample, the unreliability of pre-treatment data, the high rate of attrition, the need for multi-variate statistics, and uncertainty about the actual treatments offered."

V. SUMMARY

C. G. Jung has exerted an enormous and steadily growing influence on modern culture, especially as the "search for meaning" has taken on special urgency in light of the triumphs of scientific materialism. Transplanted via anal-

ogy from physics to psychology, the seminal ideas of the theoretical physicist Wolfgang Pauli profoundly influenced Jung's theory of the psyche. Although greatly helped by Jung the person, and deeply grateful to him, Pauli predicted what has in fact happened: That for an era bereft by science of religion, Jungian theory would ultimately prove more worthy as a philosophy than as a strictly scientific model of psychology.

Jungian therapy is therefore most distinct when aiming its therapeutics primarily at the development of a spiritual life. Its practitioners root themselves theoretically in a model they find personally congenial and that provides for them, as it were, a larger myth within which to lead a meaning-infused life. In practice, the evidence for and against the comparative efficacy of a specifically Jungian treatment method is no better than for any other method—or worse. Given the many different approaches that have arisen among the various Jungian schools—and within them—a good argument can be made that the parameters defining Jungian therapy will surely evade adequate denotation, but that individuals who identify themselves as Jungian therapists do as good a job on the whole as do those who do not. There is no doubt that many individuals deliberately seek Jungian therapy for what the term "Jungian" connotes and that Jungian therapists favor a style of communication that is comfortable for such individuals.

GLOSSARY

bridging Language that associates current thoughts and feelings with historical events or previous experiences. For example, “Is this a familiar feeling?” and “You said when she yelled at you the thought ‘I am such a loser’ popped into your head. Is that a new thought or is it a familiar one?”

clarification Clarifications are questions (or statements with the inflection of a question) that serve to confirm the perspective of the client. During instances when the client is vague, clarifications are used to encourage more description or explanation in order to bring clarity to the session. Importantly, a clarification can also be a way to convey an understanding of the client’s situation or perspective.

confrontation Noticing, and bringing the client’s attention to, events, behaviors, or content that are inconsistent with the goal of progress or change. Mixed messages, aloof behavior, and inconsistent remarks are examples of content that are typically confronted.

counterassumptive A counterassumptive statement is used to manage the working distance between the client and therapist. It targets the assumption of the client and counters it without arguing with the client. For example, when the client says “tell me what I should do” the therapist can respond with a counterassumptive instead of arguing or

fusing the client’s request (“It isn’t obvious to me either ... I wish I knew”).

description There is an important distinction between inference and description. Describing behavior is generally less threatening than inferring something from the client’s behavior. “It doesn’t look like you like your kids” is an inference and “when you talk about your kids your face becomes more constricted and strained” is a description.

dichotomous questions Presenting a choice between two statements is a dichotomous question. “What feels more true to you ... that you are angry or that you are afraid?”

edification Educating the client is an essential variable in the change process. Explanations regarding the etiology and causes of various problems, imparting treatment options, developing new skills, and Socratic discussions, are all examples of edification in counseling.

exclamations Exclamations are used to convey an active empathic stance. “Wow!,” “How awful!,” and “Outstanding!” are expressions that either convey an understanding regarding the intensity of a given situation, or welcome clients to experience something they are currently holding at an emotional distance.

extensions When clients constrict content and have difficulty acknowledging what might be obvious emotional dimensions of their life experience, the therapist can take an active empathic stance and state it for the client. This very delicate and advanced skill is used as an invitation to delve further into emotional content. For example, the client says “I am lonely” and when there is a reasonable amount of certainty, the therapist can use an extension “and it has been this way for a long time.”

horizontal questions Horizontal questions are used when the therapist wants the focus to stay on the emotional and

relational aspects of a client's experience. When the client makes a sensitive and personal self-disclosure, the therapist can respond either vertically (which focuses on the informational level of content) or can respond horizontally. "Now that you have told me this, what are you thinking?" or "What was happening right before you told me this?" are examples of horizontal questions.

imperatives A statement that elicits a specified action. "Tell me what you're thinking" or "Say the first thing that comes to mind when I say 'airplane'."

interpretations An interpretation is a well-timed and carefully constructed explanation of the client's experience, disorder, or interpersonal context. In most instances, this is where the theory of the therapist emerges. The primary difference between an interpretation and a clarification is that the interpretation introduces a new perspective to the client (it is the therapist's perspective).

minimal encourager These are sounds and statements that encourage the client to continue in a monologue. "Mmm," "uh huh," and "ooh" are examples of minimal encouragers designed to keep the process going without undue interference.

open-ended question A question that cannot be answered with a "yes or no" or single word response. "What did you do on your vacation?" as opposed to "Did you have a nice vacation?"

paraphrasing Putting the client's description into different words as a means of conveying an understanding of the client's thoughts and experiences.

performatives Statements that are also actions. "I do" in a wedding binds the individual in a commitment, a compliment like "That looks nice" has the effect of making the recipient feel good, or the therapist saying "I have confidence in your ability to handle this" is intended to instill a sense of self-efficacy.

probes These are statements and questions designed to elicit more information regarding a specific area of content. "I'm thinking you must have had a good reason to start drinking again after all the things you have been through" is a probing statement and "Why did you start drinking again?" is a probing question.

reflection Rephrasing or restating the emotional or affective part of the client's statement. Many therapists rely on reflections as a way of expressing empathy and acceptance of the client.

reflexive questions Posing questions that put the client in a position to consider new perspectives or alternatives. Reflexive questions start off with statements like "What would happen if..." and "Let's say you were assertive with your boss, what would you expect to happen?"

strategic questions Tactful use of strategic questions is an option when the therapist observes the need for more direct challenges. Strategic questions are often corrective and imply a desired outcome. "What keeps you from doing your own grocery shopping at this point?" and "Something

stops you from speaking out about this to your boss (with the inflection of a question)" are examples of strategic questions.

summarizing Rephrasing the client's utterance as a means of clarifying and conveying an understanding of the client's disclosure.

verdictives These are performative statements that serve as verdict or implicit declaration. "I think you can handle this" or "It is necessary to deal with this" are verdictives.

vertical questions Interviewing often requires a number of questions regarding the client's history, family structure, educational background, and other facets of the individual's personal life. Vertical questions are designed to elicit information and logical details. When a client discloses something very personal, the therapist can either address the informational aspects of the disclosure (via vertical questions like "How long?" and "When?") or can focus on the emotional and personal aspects of the revelation (see horizontal questions).

I. INTRODUCTION

Throughout this encyclopedia, there are descriptions of specific psychological theories and novel techniques of therapy that set various orientations apart. In spite of numerous differences expressed by the respective denominations in psychotherapy, there is one common element that very few would dispute; the essential use of language as a mechanism of change. In the short time psychotherapy has existed, the field has evolved into a craft with its own language, conversational rules, and social structure. Although the process of therapy is more than word selection and phrasing, there is a growing accumulation of verbal strategies designed to assist the therapist through a number of situations and contexts. This article is a review of the actual verbal "tools of the trade" that serve as the staple of most therapeutic approaches.

II. EVOLUTION OF THERAPEUTIC LANGUAGE

The systematic use of conversation for therapeutic purposes is not a new concept. As far back as Hellenic Greece, rhetoricians were employed to challenge the logical errors of melancholic "patients" in order to effect a more positive outlook on life and to find solutions to problems. The Greek formulation of mental processes paved the way for the use of persuasion, motivational conversations, and encouragement, as a healing form.

In spite of the historical dominance of mystical and spiritual formulations of human suffering, it is clear that very few “lost faith” in the use of a confidential and abiding relationship to produce behavioral changes or to render assistance to those who needed it. Even the priests of the middle ages were purveyors of a healing conversation in the form of confession. This sacramental ritual included many facets of modern psychotherapy. A confidential setting, self-disclosure, focus on behavior change, and a redemptive relationship are all elements in common with the secular practice of psychotherapy. It was not until the “age of enlightenment” that the intellectual formulations of mental illness and human suffering returned to mainstream Western thought. As the ideas and attitudes shifted away from the more mystical views of mental disturbance, the medical field advanced concepts that served as the precursors to psychotherapy as we know it today. Importantly, the more humane and optimistic views posited by Tuke, in Great Britain, and Rush, in the United States, encouraged treatments based on rational and scientific formulations of mental illness and set the tone for the next century.

A culmination of theoretical contributions led to the ultimate invention of psychotherapy; however, psychoanalysis was the first type of therapeutic conversation to emerge as a discipline. By the time of Freud’s death in 1939, psychoanalysis had developed an assortment of well-defined pragmatic verbal strategies. The verbal activity of the contemporary analyst is largely centered around the sequence of free associating, confronting, clarifying, interpreting, and “working through” material as it emerges in the session. In essence, the psychoanalyst’s artful use of language creates a process of unencumbered exploration while striking a delicate balance between defensive self-preservation and a desire to access the troubling source of the individual’s problem or neurosis. With a strict sense of restraint and economy, the analyst uses a series of prompts and other linguistic devices of language to accumulate enough data or material to form an interpretation. In many ways, it is initially a process of collecting pieces to a puzzle and then it proceeds to an interpretation, at which point the therapist actually attempts to put the pieces together. The interpretation brings to light connections that were, at one time, outside of the individual’s awareness. With each insight, the individual is equipped to reallocate psychological resources previously dedicated to the unresolved intrapsychic conflict. Freud described the process as two travelers on a train with one looking out the window and describing what

is on the landscape and providing details about the scenery. The other traveler is blindfolded, but is able to explain details and impart meaningful information regarding the countryside as they pass through. This one-sided and slow deliberation was unprecedented in terms of a social structure and seminal with regard to the development of therapeutic language.

The psychoanalytic approach to treating psychological and emotional problems was a dramatic departure from the “bootstrapping” and “advice giving” mores of the time. Society began to accept the notion that emotional suffering and mental illness was often too complex to resolve with simplistic solutions. Along with the changes in attitude came a rapid succession of new therapies, as well as more lively debates about what “active ingredients” of therapy make it effective.

Although psychoanalysis solidified the presence of the “talking cure” in the twentieth century, a proliferation of therapeutic approaches would lead to an expansion of ideas regarding therapeutic language. There was a notable transition from the “free floating” and nonintrusive stance of the psychoanalyst to a more active and broadly applied use of the therapeutic relationship. A new taxonomy of language developed around a number of core concepts in psychotherapy that included a collection of therapist behaviors and types of utterances. Therapeutic orientations began to offer ideas regarding language usage and presented techniques that were based on their respective theories of change. Whether it be insight, a corrective emotional experience, or an in-depth exploration of an important aspect of the client’s life experience, clinicians and theorists were discovering how to make these types of conversations occur.

The new faces of therapy expanded well beyond the original constraints imposed by “psychodynamic” theory. Albert Ellis broke through the vales of neutral distance with his often blunt and usually directive approach to dialogue in his rational emotive therapy (now rational emotive behavior therapy). Conversely, Carl Rogers placed considerable importance on a nonjudgmental and supportive collaboration in his person-centered therapy. Mirroring techniques, passive empathic statements, and an emphasis on genuine dialogue, are all activities advanced by Rogers as “facilitative” therapist behaviors. Fritz Perls demonstrated a number of creative strategies that intensified the emotional experience in therapy, including cathartic techniques such as the “empty chair” where the client engages in a role-played conversation with an imagined person. Aaron T. Beck and his colleagues established a

method of “collaborative empiricism” in his cognitive therapy approach. His method included the use of the Socratic method, engaging the client in a scientific inquiry using questions, and persuasive challenges to problematic thought processes and perceptions. The interpersonal theorist Harry Stack Sullivan attended scrupulously to the impact of his wording and phrasing on his patients and lectured extensively on the importance of deliberate syntax. His well-regarded work on interviewing and therapeutic processes articulated minute differences between well-constructed therapist statements and poorly constructed ones. Milton Erickson was widely known for his creative use of language and his effective use of metaphors. The full spectrum of contributions to therapeutic language is a vast and voluminous subject; however, it is clear that developments in therapeutic language have come from a multitude of sources. Close examination of the various techniques and approaches reveal a field that is willing to integrate new ideas and to learn from one another. The rapid growth of “integrative” and “eclectic” therapeutic movements is testimony to the widespread recognition of the need for the creative application of a variety of tools, rather than strict adherence to a narrow and dogmatic view of change.

III. THERAPEUTIC COMMUNICATION

The cornerstone of most therapeutic approaches centers on the mutual participation in a special type of conversation, a conversation that is implicitly different from everyday discourse and that is unique in terms of structure and content. The “way” the therapist phrases something, the timing of a given response, even the selection of words, have become a recognizable form of social interaction. The cliché “How does that make you feel?” may be the best known of the therapist’s staples; however, the skilled therapist is capable of applying many more proprietary tools of the trade to help the client. Historically, it is clear that the development of therapeutic approaches was largely dependent on recognizing what worked in different situations. The remainder of this article focuses on the actual verbal behavior of the therapist, how language changes within different contexts of the process, and what the therapist hopes to achieve with different types of verbal responses.

Much of what we know about language in psychotherapy comes from the field of “process research.” Studies of the actual behavior as well as *in vivo* observa-

tions of different forms of therapeutic communication have resulted in a reliable taxonomy of words and behavior that are unique to psychotherapy relative to everyday conversation. The seminal research of Clara Hill, William Stiles, Sol Garfield, Kenneth Howard, Carl Rogers, Larry Beutler, Leslie Greenberg, Michael Patton, Robert Russell, Hans Strupp, David Orlinsky, and numerous others, elevated the level of description from vague and theoretically laden inferences, to measurable entities. The content and scope of process research attends to complex variables within the session such as therapist intentions, types of utterances or “verbal response modes,” probabilities of therapist responses within different contexts, conversation analysis, semantics, “good moments,” and other interpersonal variables related to positive outcomes. The collective findings of this type of research have had a direct influence on the therapeutic terminology, the validity of outcome studies that use process measures to assess treatment integrity, and training. The glossary provides an overview of therapist statements, as well as the typical contexts in which they are used. Ultimately, these tools make it possible to engage the client in a conversation that is markedly different from other forms of social support, help, or advisement.

The fields of anthropology and “conversation analysis” observe that in most interpersonal contexts and cultures, verbal interactions fall into fixed patterns that are predictable and orderly. When people abide by these social tenets, it contributes to a sense of cooperation, safety, and compatibility. Even minor infractions of these rules can lead to anxiety, perceived disturbance, interpersonal distance, conflict, or the interpretation of rudeness. For example, a self-disclosure of emotional pain or suffering will typically lead to consolation, commiseration, or supportive comments. Beyond that point, however, intuitive signals cause one or both speakers to change the topic away from the delicate subject matter and on to a subject that is not so sensitive. Subsequently, a concern about intrusiveness or a fear of intensifying the person’s emotional pain can effectively thwart a therapeutic conversation. Conversely, it is understood, even expected, that the collaborative relationship between the client and the therapist is in effect to talk about things that are difficult to share and to address issues beyond the normal scope of everyday conversation. Therapists develop the ability to depart from the social restrictions that limit the course and depth of everyday conversation with implicit permission to abandon conventional patterns of conversation in order to engage the client in a

unique and constructive process. Probing questions, long silences, interpretations, *in vivo* descriptions of behavior, and clarifications, are but a few verbal events that are rarely observed in most other interpersonal contexts. This relatively new type of dialogue employs a variety of illocutionary strategies in order to promote positive movement in the therapy process. Therapists-in-training learn to use a variety of verbal strategies that have known effects on the direction of the session and that are introduced as a means of meeting identified therapeutic goals. Specific roles are adopted (e.g., teacher, redemptive listener, a guide through the healing process, motivational speaker, and persuader) to engage the client in different types of therapeutic interactions. In whatever the context, the skilled therapist relies on the systematic use of language to ensure the best chance of a positive outcome.

The appropriateness and quality of any therapeutic response is dependent on the situation at hand. Although there are over 400 identified "orientations" of psychotherapy, the conversation of therapy is fairly uniform when considering context. There is an initial greeting, then a brief gathering of information, a subsequent exploration or delving into more detail, and then a "winding down" period. Each session follows a general trend and provides a "frame" that guides the therapist's responses. Take, for instance, the statement "I feel bad." Again, the type of therapist response will depend significantly on when or in what context the statement was made. If it occurs early in the session, the therapist may ask questions, or direct the client to elaborate, as a means of establishing a focus, or to determine the context of the client's reported experience (e.g., "Tell me what has been happening" or "What has happened since our last session?"). The same statement, "I feel bad", elicits a different set of therapeutic responses when it occurs further into the therapeutic hour. It is notable that most of the "treatment"-oriented techniques occur during this part of the therapy session. It is not unusual for the therapist to use techniques to intensify the client's emotional experience or engage the client into a deeper exploration of content. Therapist empathy becomes more finely tuned and is accompanied by a due amount of encouragement, even pressure, to work through difficult material. Clients are sometimes guided through a courageous process of facing dreaded material, conquering personal demons, and are systematically exposed to fears and stimuli that provoke escape and avoidance. When the client says, "I feel bad" toward the end of the session, the constraints of time affect the therapist's response. The same disclo-

sure might require attention to coping strategies that the client can use between sessions (e.g., "What do you expect to happen to this feeling later today? or "Do you think it would be helpful to go over some of the coping strategies we have discussed previously to get us through the week?"). The therapist will also summarize the session with relevant information, new insights, or present an objective view of the possibilities in the future. It follows then, that the quality of any given response depends significantly on the context in which it occurs.

The therapist is also mindful of "timing" a statement or question appropriately and is poised to respond to opportunities for positive movement. When to exert pressure and when to back off, is an hourly challenge that is largely determined by the readiness and competence of the client. Premature exploration often leads to flight responses or other types of resistance such as restricting content, dominating the session, attempts to change the therapeutic arrangement, and emotional withdrawal. An absence of exertion or movement can lead to meandering and even apathy. In both cases, there is a risk of a negative effect. One poignant example of this comes from an intake conducted by a seasoned psychologist working with a woman struggling to bond with her adopted child. She reported feeling repulsed by her new son's attempts to be close to her. At one point during a description of her son, she displayed a look of disgust and made a gesture that signified "go away." After observing the intensity of her emotion, the psychologist asked, "Is this a familiar feeling?" It did not take long to realize that the question thrust her into a dissociative state. Her history of abuse had yet to be disclosed to anyone and they scrambled for 2 hours using standard grounding techniques to get back to the "here and now." Although this kind of "bridging" question was not a bad one, the timing was clearly premature. If the same question occurred several sessions later, it may have resulted in a more fruitful outcome. Thus, it is not simply what the therapist says that makes a difference, it is also what the therapist chooses not to say. At any given moment, the therapist is considering options, restraining his or her own impulses, and choosing one response over another, based on what has the best chance of leading the conversation in a direction that will help the client.

For better or worse, each utterance has the potential of affecting the course and experience of the conversation. The study of pragmatics examines the interpersonal effect of phrasing and syntax. Each statement has a probability of influencing the direction and nature of

the subsequent utterance. When the therapist makes a statement or asks a question, it is often “goal-directed” and made with specific intentions. For instance, if therapists believe that creating a “here-and-now” experience is important to therapeutic success, then they will ask questions differently than if they are interested in gathering basic information. Instead of the therapist asking “So what was it like in your house growing up?” the therapist might set up the question with a present tense like “It is 6 o’clock in the evening at your house when you were growing up ... what is happening around you?” This type of phrasing is more likely to be “experienced” than the past tense questioning.

Depending on the goal of a given session, the therapist will pose questions and initiate dialogue with a fair amount of attention to probability. Starting the session with “O.K., where is a good place to start today?” produces a different direction or set of responses than “So tell me about your week.” An even more predictable outcome can be generated with a statement like “Last time we were talking about your relationship with your brother and how he was the prized son.” In each case, the therapist uses language to shape the course and emotional depth of the session.

Mindful of the multiple layers of therapeutic communication and the known effects of certain types of statements, the therapist mentally juggles a variety of options and then selects a response according to the immediate goals of the session. An example of how the therapist considers the probable effect of one type of utterance versus another is observable in instances when the client discloses a closely guarded secret. After the disclosure, the therapist can ask “vertical” questions designed to generate information about the historical and factual aspects of the secret. “How long ago did this happen?” or “What makes you think that?” are examples of vertical questions. However, the skilled therapist might decide to prioritize strengthening the therapeutic relationship over gathering information. In this event, the therapist could ask a “horizontal” question such as “What was it like to say that?” or “Tell me what you were thinking before you told me this.” Horizontal dialogue changes the focus from the content of the disclosure to the client’s experience of therapeutic relationship. When a delusional patient discloses a fear of an “FBI plot” to assassinate him, the therapist can respond with at least two routes of exploration. It is tempting to assess and treat the delusion or psychosis; however, the seasoned therapist recognizes the tenuous nature of the therapeutic relationship with this type of problem. Subsequently, since the notion of an FBI plot

is frightening to the patient, empathic language and supportive comments are appropriate responses. “Approximating” statements make it possible to express an understanding of the fear without endorsing the belief. “If I were convinced the FBI intended to kill me it would be very frightening and I wouldn’t know who to trust” is different than “If I were in your shoes I would be very frightened.” The therapist will attempt to side with the fear and express an understanding of the experience before attempting to confront the delusion. When it is time to confront the delusion directly, it is prudent to phrase the probe in a manner that elicits a description, rather than a belief. “What are you seeing that convinces you that this is happening?” leads to a description of external events and “Why do you think this is happening” generates a response depicting thought processes and theories. Therefore, the therapist can minimize problematic exchanges and lower the chances of exacerbating the patient’s delusion with carefully crafted phrasing.

Countless situations are navigated and managed with the deliberate use of language. Although there is not a “right way” to respond to every situation, there are responses that have better probabilities of success than others.

IV. LANGUAGE AND THE THERAPEUTIC RELATIONSHIP

The therapist is also monitoring the quality and strength of the therapeutic relationship. Freud was the first to recognize the intense bond that forms when two individuals embark on the therapeutic journey and others have concluded that this is one of the most critical dimensions to successful therapy. It is necessary to establish intimacy and trust before the therapist employs any deep probes or challenges. In order to keep the focus on the client it is necessary to discard the most common means of achieving interpersonal intimacy, namely two-sided self-disclosure. When people pursue personal relationships, they willingly collaborate in a “do as I do” process that is proportional and rhythmic. When we meet someone for the first time, we often attempt to achieve a level of intimacy and comfort by beginning a search for things in common. “Where are you from?” “Where did you attend college?” and “What do you do for fun?” are questions that lead to a point of excitement when people find a mutual domain of experience or interest (i.e., “Me too!” or “Oh really, I have a friend at that university. Perhaps you know her...”).

With emotionally and deeply personal information the implications of disclosure are more threatening. As the layers of self-protection peel away, there is a lingering state of vulnerability until the other responds with either an affirmation or a similar unveiling of personal content. Intimacy in psychotherapy is different. Client disclosures are met with expressions of understanding, empathy, and prompts to continue rather than reciprocal self-disclosures. Empathic sounds (e.g., “uh huh,” “hmmm,” and “oh”) and positive nonverbal gestures serve to encourage, even invite the client to discuss sensitive material if it is needed.

The seminal work of Carl Rogers emphasized the importance of creating a strong alliance between the therapist and client. To be in “sync” with clients and to reflect an understanding of their experience is a necessary condition of therapy. Conveying a genuine interest in the individual, as well as making an effort to understand the client’s emotional experience, or empathy, is the cornerstone of a functional therapeutic relationship. Upon disclosing the horror of a traumatic event, the client sees and hears indications of empathy and a human response. A grimace or the sound of a quiet gasp serves to encourage, even prompt the client into further exploration. Rogers emphasized the nonintrusive and tentative stance of “passive empathy” as a means of establishing a safe and “facilitative” environment. Although the therapist is encouraged to monitor (and even express) his or her own personal reactions within the therapeutic process, there is a clear separation between the therapist’s experience and the client’s reported experience. Instead of “me too” statements, the therapist attempts to acknowledge and validate the client’s view of the world. Once the therapist is confident about the level of “intersubjectivity” or degree of shared knowledge, the therapist can tread carefully into the client’s space. Sometimes it is a matter of expressing or conveying an “experience of the client’s experience,” but also verbalizing thoughts and feelings that the client is reluctant to admit. Therapy is brimming with opportunities for this type of connection. For example, as an exhausted and anxious single mother describes all of the activities and obligations that she encounters on a daily basis, the therapist can use a passive empathic statement such as, “That must be overwhelming” or he or she can choose an active empathic statement such as, “Wow, when I think of doing all of that I feel overwhelmed.” In either case, the therapist uses empathy to fortify the therapeutic alliance and create a safe place for therapy to occur.

The therapeutic relationship is also subject to periods when it shifts into altered states. During the course

of therapy, Freud noted that patients would develop a distorted view of the patient–analyst relationship. Frequently, the patient would transfer thoughts and feelings associated with parental figures to the analyst. It became evident to Freud that this phenomenon, which he labeled “transference,” was an opportunity to work through unresolved conflicts of the patient’s childhood. Harry Stack Sullivan expanded on the notion of transference with his concept of “parataxis,” which included feelings about people in general rather than just parental figures. Nonetheless, when these feelings emerge in the therapy session it presents some opportunities for positive movement. The therapeutic dyad can serve as a microcosm of other relationships and facilitate an opportunity to work through pervasive issues that exist in the individual’s social milieu.

Hostility, seductiveness, submissiveness, and dominance are all examples of behavior addressed in the safety of the therapeutic environment. In these cases, the therapist must establish and manage a “working distance.” In his book *Making Contact*, Harvard psychiatrist Lesten Havens describes working distance as “being alone together” in a state of “noninvasive closeness.” The instincts of the client might compel him or her to submit too readily to the will of the therapist, rebel against the therapeutic process, or to take over the process with his or her own preferred form of dominance. Language moderates imbalances created by these polar movements and prevents the therapist from colluding with the client’s attempt to derail threatening but constructive movement. The seductive client may attempt to draw the therapist out of a neutral stance by appealing to the personal needs of the therapist. After disclosing in provocative detail, a sexual dream about the therapist and then conveying current sexual feelings, the therapist is saddled with the task of redirecting the focus without rejecting the client. When the client moves toward the therapist in this way, the use of horizontal questions such as “What is it like to tell me about these feelings?” can create an objective moment. A statement such as “It says a lot about the trust we have established that you are able to talk about this with me. You can speak openly about these feelings and know, with confidence that I will not betray you by changing our relationship in that way” is a “performative” (see glossary) statement that declares the status of the relationship. If the client exhibits embarrassment or regret, a counterassumptive statement such as “One thing I will ask is that the next time you have a dream like that about me could you give me a full head of hair and rippling stomach muscles?” This statement counters the assumption that

the client did something wrong by disclosing the dream, but also reaffirms the safety of the therapeutic setting.

Managing the working distance involves keeping a perspective and thinking of these events in terms of data instead of personal dilemmas. Harry Stack Sullivan referred to a state of mind called “participant observer.” Like the ethnographic researcher, the therapist is both experiencing and studying the situation. Instead of treating challenging situations as a problem, the therapist observes the behavior and assesses the degree to which the behavior is likely to be a problem in the individual’s daily life. Using the example of the seductive client, rather than thinking about how appealing the therapist must be to elicit such feelings, the therapist considers the possibility that this behavior is a maladaptive response to psychological intimacy. The socially anxious client sometimes projects hostility or aloofness as a way of creating a safe distance from people whom they perceive as a threat. The therapist subdues the initial experience of rejection and, again observes the behavior as important data. By use of description, as well as carefully constructed questions, it is possible to capitalize on the emergence of the behavior and offer an opportunity that literally does not exist in any other setting. The therapist can offer “objective” feedback about potentially problematic behavior without an obligation to apologize or repair the relationship.

In addition to dealing with the challenges of direct “focal messages” or the literal content of any given utterance, there are “metamessages” that are equally important. Metamessages are the implicit messages that are not typically acknowledged as a message, but have a profound impact on the conversation nonetheless. If, for instance, a client pleads to the therapist “Just tell me what to do” the therapist has a few options. One common response to this type of plea is to refuse the request with an explanation. “It wouldn’t be appropriate for me to tell you what to do in this case” or “This is your life and I think you are in the best position to make a decision of this importance.” The focal messages in this case are “no” and “It isn’t a good idea to tell you what to do.” However, one of the metamessages might be perceived as “I am withholding my advice” and “I probably do have the answers but it is against the rules to tell you.” In spite of the reasonable focal content, these metamessages could result in resistance, problems in the therapeutic alliance, and unnecessary arguments. One way to counter this

metamessage would be to use a statement such as “I wish I knew what the right way to handle this would be . . . it is not obvious to me either” (which is a “counterassumptive” statement). This response counters the assumption that the therapist knows what is best for the client and, for whatever reason, chooses to keep from the client, and sends another message acknowledging the complexity and difficulty of the client’s situation.

V. SUMMARY

Psychotherapy resides in our culture as a widely accepted and specialized form of communication. The psychotherapist shapes the process by using a unique combination of verbal tools and well-placed responses to the client. Importantly, statements are selected on the basis of the known effects of specific devices or techniques, and are utilized as a means of meeting an identified therapeutic goal. The therapist adopts specific roles such as teacher, redemptive listener, a guide through the healing process, motivational speaker, and persuader, and engages the client in different types of therapeutic interactions. In whatever the context, the skilled therapist relies on a deliberate use of language to ensure the best chance of a positive outcome.

GLOSSARY

adjudicate Refers to the process whereby differences and conflicts within the justice system are heard and settled.

confidentiality The right of a patient to have any information or communications made during the course of treatment and evaluation to be held in strict confidence unless authorized to be divulged.

due process The process whereby the rights of parties in a conflict are assiduously protected in the settlement of that conflict. Due process generally entails the opportunity to know and examine one's accusers and the chance to present one's own case in defense of an accusation.

HIPAA Health Insurance Portability and Accountability Act of 1996, which is federal law intended to rectify a variety of conflicting state laws concerning health related issues. It has stringent confidentiality protections.

privilege Refers to disclosures made in court or for legal reasons and is an exception to the general rule of evidence of the justice system, in which every member or party to a conflict has a right to every other person's evidence.

There are both ethical and legal underpinnings to the confidential relationship between a psychotherapist and a patient. Confidentiality here refers to the right of a patient to have communications, made during the course of evaluation or treatment, held confidential absent express or implied authorization. Although confidentiality is not absolute, and may vary with the professional qualifications of the therapist, it remains a core value for mental health professionals and patients.

A variety of professionals may fulfill the role of psychotherapist. Physicians specializing in psychiatry and psychoanalysis have the ability to prescribe medication for their patients in addition to performing psychotherapy in its varied forms. Clinical psychologists with master's or doctorate degrees have special training in administering and interpreting psychological testing as well as clinical training in psychotherapy. Other licensed professionals who conduct psychotherapy are social workers and nurses with master's or doctorate degrees. In addition there are marital and family counselors and the clergy.

Psychotherapy involves disclosures of the most personal nature, including wishes, fears, dreams, fantasies as well as detailed disclosures regarding one's personal, educational, legal, employment, social, sexual, and family history. This information is important, not just for the isolated facts and psychological symptoms, but also to learn how the person deals with stress and conducts personal and intimate relationships. This data is needed for accurate assessment and diagnosis, as well

as treatment. The style and process by which the information is disclosed by the patient/client is also revealing of personality traits and cognitive styles of dealing with the inevitable stresses of daily life. It is not uncommon for a psychotherapist to be the recipient of information that has never been shared by the patient with anyone else. Unless there is some assurance of confidentiality, it is unlikely that individuals would be as open or free about making disclosures, especially as there remains a significant stigma associated with mental disorders and their treatment.

I. CONFIDENTIALITY AND PRIVILEGE

Confidentiality protections are derived from a variety of sources. The oldest derives from professional and ethical codes. Since the fourth century BCE, the Hippocratic Oath has required that physicians respect the confidentiality of patient communications:

And whatsoever I shall see or hear in the course of my profession, as well as outside my profession, in my intercourse with men, if it be what should not be published abroad, I will never divulge, holding such things to be holy secret.

Professional organizations, such as the American Medical Association (AMA), since early in its history, have been concerned with the importance of confidentiality. The current code of medical ethics has a section on confidentiality:

The information disclosed to a physician during the course of the relationship between physician and patient is confidential to the greatest possible degree. The patient should feel free to make a full disclosure of information to the physician in order that the physician may most effectively provide needed services. The patient should be able to make this disclosure with the knowledge that the physician will respect the confidential nature of that communication. The physician should not reveal confidential communications or information without the express consent of the patient unless required to do so by law.

The American Psychiatric Association (APA) publishes for its members *The Principles of Medical Ethics* with special "Annotations Especially Applicable to Psychiatry." Members are required to follow the basic AMA principles as well as the APA Annotations. The APA

principles state that psychiatrists must "respect the rights of patients, colleagues, and other health professionals, and that they must safeguard patient confidences within the constraints of the law." The guidelines on confidentiality also tell psychiatrists that they "may release confidential information only with the authorization of the patient or under proper legal compulsion. The continuing duty of the psychiatrist to protect the patient includes fully apprising him/her of the connotations of waiving the privilege of privacy." Other therapists are also bound by ethical codes to keep information within the therapeutic relationship confidential. The American Psychological Association, in its *Ethical Principles of Psychologists and Code of Conduct*, informs therapists that "safeguarding information about an individual that has been obtained by the psychologists in the course of his teaching, practice, or investigation is a primary obligation of the psychologist." The National Association of Social Workers (NASW) also has a code of ethics with an elaborate confidentiality section. Section 1.07c states in part

Social workers should protect the confidentiality of all information obtained in the course of professional service, except for compelling professional reasons. The general expectation that social workers will keep information confidential does not apply when disclosure is necessary to prevent serious, foreseeable, and imminent harm to a client or other identifiable person.

All clients must be informed by the social worker of the limits of confidentiality in a given situation. The American Counseling Association requires its members to adhere to a code of ethics that has a full section on confidentiality. Counselors must respect their clients right to privacy and avoid illegal and unwarranted disclosures of confidential information.

The concepts of confidentiality and privilege are related but separate. Privilege laws, strictly speaking, only relate to disclosures made in court whereas confidentiality statutes govern therapist's obligations outside the courtroom. Privilege is an exception to the general rule that the justice system has a right to every person's evidence. Confidentiality is both an ethical and legal duty that protects a patient from unauthorized disclosures of protected information. At this point all states and the federal courts recognize important confidentiality and privilege protections in the psychotherapist-patient relationship. At the same time statutes and courts have created numerous exceptions to the confidentiality/privilege rights.

By far the most influential rationale for recent privilege law is the traditional justification enunciated by Dean Wigmore. Essentially utilitarian in nature, this justification asserts that communications should be privileged only if the benefit derived from protecting the relationship is important enough to society that it outweighs the detrimental effect on the search for truth. In particular, Wigmore set out four conditions for the establishment of a privilege:

1. The communications must originate in a confidence that they will not be disclosed.
2. This element of confidentiality must be essential to the full and satisfactory maintenance of the relation between the parties.
3. The relation must be one which in the opinion of the community ought to be sedulously fostered.
4. The injury that would inure to the relation by the disclosure of the communications must be greater than the benefit thereby gained for the correct disposal of litigation.

The evolution of the privilege concept in law is helpful in understanding its current role for psychotherapists. The rule that an advocate could not be called as a witness against his client existed in Roman times. It is unclear whether the Roman tradition influenced the Anglo-Saxon attorney–client privilege, but English recognition of the privilege goes back at least to the reign of Elizabeth I. The purpose of the privilege was to prevent the attorney from being required to take an oath and testify against his client. Later, it was also considered that such testimony against one to whom loyalty was owed would violate the attorney’s honor as a gentleman. Thus, the original justification for the privilege was nonutilitarian. Accordingly, the attorney, rather than the client, held and asserted the privilege. Today the privilege is the prerogative of the client. The client, not the lawyer, holds the privilege. The client has the ultimate authority to raise or to waive the privilege. In addition to the attorney–client privilege under English common law there was also a spousal privilege and, until the Reformation, a clergy–communicant privilege.

The physician–patient privilege did not exist under the English common law, and physicians were expected to testify as any other witnesses in court proceedings. In the United States, a New York court first recognized the clergy–communicant privilege in 1813. In 1828, New York also became the first state to grant a testimonial privilege to communications between a doctor and patient. This permitted a patient to prevent a physician

from testifying about information relevant to the patient’s treatment that was divulged to the physician in his professional capacity. The psychological counseling privilege has gained recognition since the 1950s, and more recently the privilege has been extended to cover other therapists and sexual assault counselors. Around 1970 there were some efforts by psychiatrists to assert the privilege in their own right. Psychiatrists argued that the patient could not fully understand what they were agreeing to when they signed a release of information. Only the analyst could understand the full implications of the disclosures made in therapy. Courts were by and large not sympathetic with this argument and have clearly held that it is the patient’s privilege and is not the prerogative of the therapist.

By 1996 all 50 states and the District of Columbia had enacted some form of psychotherapist privilege. Federal courts, however, did not accept the privilege. In 1972 the Chief Justice of the Supreme Court transmitted to the Congress proposed rules of evidence for the federal courts that had been formulated by the Judicial Conference Advisory Committee and approved by the Judicial Conference of the United States. The proposed rules defined nine specific testimonial privileges, including a psychotherapist–patient privilege. Congress rejected this recommendation in favor of Rule 501, which was more general and authorized federal courts to define new privileges by interpreting “common law principles ... in the light of reason and experience.”

Until 1996 only a few federal jurisdictions adopted a limited form of a psychotherapist privilege. Others rejected it entirely. Because of these conflicts in the federal courts the U.S. Supreme Court agreed to hear the case of *Jaffee v. Redmond*. Mary Lu Redmond was the first police officer to respond to a “fight in progress” call at an apartment complex in Illinois. As she arrived two women ran toward the squad car saying there had been a stabbing in one of the apartments. Officer Redmond relayed the information and requested an ambulance. As she was walking to the entrance of the building several men ran out, one waving a pipe. Two other men then burst out of the building, one chasing the other and brandishing a butcher knife. He disregarded her repeated commands to drop the weapon, and Redmond shot him when she believed he was about to stab the man. He died at the scene, and people came pouring out of the building, and a threatening confrontation followed before other officers arrived. A suit was filed against the officer claiming excessive force. There was conflicting testimony from the victim’s relatives claiming that he was unarmed and that she drew her gun immediately on exiting the squad

car. After the shooting Redmond saw a clinical social worker for 50 sessions. The plaintiff sought access to the therapy notes concerning the sessions in their cross-examination of Officer Redmond. The district judge rejected Redmond's assertion that the contents of the therapy notes were protected under the psychotherapist–patient privilege. Neither the therapist nor Redmond complied with the order to release the notes. The judge instructed the jury that they could presume the notes would have been unfavorable to Redmond, and the jury awarded approximately \$550,000 in state and federal claims.

The U.S. Supreme Court majority opinion concerning this case held that confidential communications between a licensed psychotherapist and her patients in the course of diagnosis and treatment are protected from compelled disclosure under Rule 501 of the Federal Rules of Evidence. They explicitly recognized and extended the privilege for psychiatrists and psychologists to licensed social workers. They noted that there would be situations in which the privilege must give way, for example, if a serious threat of harm to the patient or to others could be averted only by means of the disclosure by the therapist.

In spite of the importance of the recognition of a psychotherapist–patient privilege, it is important to be aware that the patient's privilege is not absolute. There are several exceptions to both the psychotherapist–patient privilege and confidentiality statutes. The patient waives the right to confidentiality when he or she places his or her mental condition into issue in civil litigation, the so-called patient-litigant exception. This is permitted to allow the defendants to explore a patient's prior history to confirm that the current mental condition was related to the claimed injury and had not been present before. Since *Jaffee*, courts continue to differ about the breadth of this exception. The most frequent examples are plaintiff's claims in civil cases for emotional distress damages or in suits under the Americans with Disabilities Act in which a party's mental condition may be part of the case. Some courts have held that where a patient merely alleges "garden variety" emotional distress following an injury and not a specific psychiatric disability or unusually severe distress, this has not been deemed sufficient to waive the psychotherapist–patient privilege. However, there is wide variation in individual rulings. A waiver is frequently deemed to apply when parents cannot agree in custody disputes regarding who is best able to care for the child. In many jurisdictions, statutes also exclude the use of the privilege in involuntary civil commitment proceedings.

The dangerous patient exception to the privilege was explored in a case where a man was indicted for threatening to kill the president. The defendant moved to exclude from evidence his prior statement to a psychiatrist that he "wanted to shoot Bill Clinton." The government argued that under the *Jaffee* exception the privilege was not available, and the trial court agreed. On appeal the Tenth Circuit rejected the broad claim that the privilege does not apply in the criminal setting but remanded the case for an evidentiary hearing "to determine whether ... the threat was serious when it was uttered and whether its disclosure was the only means of averting harm to the president when the disclosure was made." If serious and the only means for averting harm then the privilege would not be available. On remand, the District Court heard from the psychiatrist that the man had been discharged to his father's care after his hallucinations of killing the president had stopped and he was stabilized on antipsychotic medication. Three days later the psychiatrist learned that the man had left the father's home, and his whereabouts were unknown. Concerned that he would again stop his medication without supervision, the psychiatrist now concluded that he posed a "serious threat" but commitment was not an option because he had disappeared. The Secret Service was concerned that he had money to travel and had once before been investigated for similar threats. Based on this evidence the court denied the defendant's motion to exclude the disclosure to his psychiatrist. Neither the trial court nor the appellate court considered whether the disclosure, designed to prevent a future harm, should be admissible in a subsequent criminal prosecution.

California has an evidentiary rule permitting this type of disclosure, which has led to psychiatrists and psychologists being called to give evidence of aggravation in capital sentencing hearings after making a *Tarassoff* warning that ultimately failed to protect a victim. The prosecutor was interested in showing long-standing hostility and premeditation by use of this testimony. Other state courts, without this rule of evidence, have refused to let such testimony into evidence.

Other exceptions to confidentiality include reporting laws, such as those relating to communicable diseases; child abuse and neglect; chronic health problems affecting safety to drive; disabled physicians; elderly abuse; and mentally retarded abuse. Most states also permit disclosures, without patient consent, when therapists wish to consult with other professionals for the purpose of diagnosis and treatment, when decisions need to be made regarding hospitalization of the patient, or when the patient poses a risk of harm to self or others.

There are also special rules that come into effect when the work setting or facility has developed specific guidelines. For example, correctional institutions, employee assistance programs, and the military all have additional exceptions to confidentiality. Prison wardens generally require, as a work rule, that any information regarding escapes or escape plans are not confidential and require disclosure to security staff. In employee assistance programs, some information concerning work performance issues may be available to the employer. Commanding officers in the military frequently must be told certain information that would be confidential in other settings. Such special settings frequently require a therapist to learn about and then inform the patient of any limitations on confidentiality that may be applicable.

There have not been many cases brought against psychotherapists for inappropriate breaches of confidentiality reaching appellate levels of review. Many explanations have been offered to account for this small number. The standard of care is not as clearly defined as in other areas of medicine, and causation and damages are hard to prove. There is rarely a physical injury, and courts have been reluctant to make awards for purely emotional damages. Patients may also be reluctant to file cases and expose their mental history in public. It is also possible that many cases settle before reaching open court. Nonetheless a small number of cases have reached public attention, and some are instructive.

In 1986 Diane Wood Middlebrook was writing an authorized biography of Anne Sexton, an American poet. Although Sexton had left detailed instructions regarding most of her papers including some therapy notebooks and a few tapes, her psychiatrist, Dr. Martin Orne, released 300 tapes after obtaining the permission of Sexton's daughter and literary executor, Linda Gray Sexton, to allow the biographer to review the tapes. The release of the tapes evoked great consternation from both literary and psychiatric circles. One professional called his actions a "betrayal of his patient and profession." Others felt the family's wishes did not matter and that confidentiality should survive a patient's death. Dr. Orne believed that the patient would have been eager to have the material reviewed. Eventually charges of an ethics violation were brought against Dr. Orne and adjudicated by the American Psychiatric Association. Ultimately a decision was reached that no ethical violation occurred. Although no lawsuit was filed, the situation illustrates the high sensitivity to these issues as well as the vulnerability of psychotherapists to ethical complaints.

Some liability for disclosures has been founded upon "breach of contract." In *Doe v. Roe* a psychiatrist and her psychologist husband wrote and published a book about a wife and her late husband eight years after the couple terminated psychotherapeutic treatment with the psychiatrist. The book reported extensive details of their lives with verbatim quotations on the feelings, fantasies, and thoughts of both husband and wife concerning the marriage that was breaking up. The therapist claimed that she had obtained verbal consent during the course of therapy. The suit was brought for breach of contract and in tort, for a violation of the confidentiality statute between physician and patient and for invasion of privacy. The court held that the defendant psychiatrist had entered into an agreement with her patients to provide medical care, and although not an express contract, the court stated that the physician impliedly covenants to keep in confidence all disclosures made by the patient concerning the patient's physical and mental condition "as well as all matters discovered by the physician in the course of examination or treatment." The court noted that patients would bring out "all manner of socially unacceptable instincts and urges, immature wishes, perverse sexual thoughts—in short the unspeakable, the unthinkable, the repressed." The psychologist husband who was a co-author was not in a contractual or physician-patient relationship with the plaintiff but the court held him equally liable as a co-violator.

The courts have used a similar means to hold non-physician therapists to a standard of care encompassing confidentiality. In *Mississippi State Board of Psychological Examiners vs. Hosford*, a psychologist was suspended from practice by the state board for revealing confidential information about his patient. The patient and her husband had sought a treatment for marital difficulties. The psychologist voluntarily and unilaterally revealed information about the wife in a subsequent divorce and custody action to the husband's attorney and signed an affidavit attesting that the wife was not a competent parent. This disclosure was made without a court order requiring disclosure. The Mississippi Supreme Court reviewed the American Psychological Association's Ethical Principles, the psychologist patient privilege, and a "public imperative that the psychology profession as a whole enjoy an impeccable reputation for respecting patient confidences" when the psychologist appealed the decision of the licensure board. The suspension was upheld.

The complexity of the psychotherapist-patient privilege and the Fifth Amendment were illustrated in a case

that arose on an Indian reservation and thus was heard in federal court. D. F. was a troubled 13-year-old adolescent who was admitted to a residential treatment program at a county mental health center. Over the course of 6 months she received very conflicting messages about the confidentiality of her statements made to center staff. She was suspected of harming two infant cousins who had died within a short time of each other. While at the center she was repeatedly encouraged by staff to write and discuss her abuse of young children to gain better ward privileges. At the same time some of the staff were in close communication with Protective Services and the FBI. The staff could never reach consensus about their role and responsibilities. Finally, after more than 6 months on the unit, she confessed. She was arrested and charged with second-degree murder. When the government attempted to introduce her confession, the defense argued that it was not voluntary. The admission into evidence of a confession that was not voluntary, within the legal meaning of the word, violates due process. The court found that the therapists were acting more like "state actors" (police) than they were therapists as they were directly communicating with law enforcement, and thus the confession was determined to be coerced and inadmissible. The staff never clearly defined their role as caregivers with a duty to look after the patient's best interests. Had they done so they would have thought of suggesting that she have a lawyer appointed to attend to her legal problems as well as obtaining legal guidance for the staff.

II. ACCESS TO ONE'S OWN MEDICAL RECORDS

Traditionally, medical records were considered the property of the physician or therapist and thus were under his or her full control. As recently as 1975 a woman, who had signed a contract to write a book about her own experiences as a patient, wished to read her psychiatric records. The New York court, at that time, had no difficulty in upholding the hospital's right to refuse such access. This rule has been altered as the vast majority of states have passed right-of-access laws permitting patient access to their own medical records. Generally, however, these laws allow therapists a limited ability to restrict access where there are reasonable grounds for a judgment that access would be harmful to the patient.

III. "DUTIES TO THIRD PARTIES" OR WHEN CAN VICTIMS OF A PATIENT'S VIOLENT BEHAVIOR HOLD THE PSYCHOTHERAPIST ACCOUNTABLE?

Prior to the mid-1970s psychotherapists had little exposure to lawsuits from individuals who were injured by their patients. This generally was limited to cases of (a) harm by a patient to other patients on an inpatient unit, or (b) negligent discharge from inpatient facilities that resulted in harm to families or strangers within a short period of time from the discharge. This was based on a common-law principal that imposed a duty on the person having custody of another to control the conduct of that person. This common law principle is stated in Restatement of the Law, Second, Torts § 320

one who is required by law to take or who voluntarily takes the custody of another under circumstances such as to deprive the other of his normal power of self-protection or is subject him to association with persons likely to harm him, is under a duty to exercise reasonable care so to control the conduct of third persons as to prevent them from intentionally harming the other or so conducting themselves as to create an unreasonable risk of harm to him, if the actor

1. Knows or has reason to know that he has the ability to control the conduct of the third persons, and
2. Knows or should know of the necessity and opportunity for exercising such control.

As written this would not seem to apply to outpatients in psychotherapy.

A. The Tarasoff Case

In 1969 a case arose in California that substantially expanded the duty of care for psychotherapists. The facts are interesting, and although a jury (because of a settlement prior to trial) never heard the case, it has become a landmark case for psychotherapists. Prosenit Poddar was a 25-year-old Bengalese Indian student at the University of California in Berkeley when he murdered another student, 19-year-old Tatiana Tarasoff. Why he killed this young woman he "loved," but barely knew, gradually emerged. Poddar had risen with amazing success through the Indian educational system. In the 1960s he was one of a small number of

Indian students chosen because of his intellectual abilities to pursue graduate-level study in United States in the field of electronics and naval architecture. He grew up in a tiny village in a remote area of India. His upbringing was so the distant from that of Western society that when he first attended the University in India, his friend Farrokh Mistree had to teach him how to eat with a knife, fork, and spoon and had to explain plates to him. He was a member of the lowest caste in India, the so-called untouchables. During his first year in the United States he did quite well academically. His friend Mistree then joined him in the states but was able to adapt much more quickly to U.S. culture. In the fall of 1968, during his second year, Poddar met Tatiana Tarasoff at an International Students' Organization folk dance. She talked, danced, and flirted with him. She told him of her background, being born in Shanghai of Russian parents, moving to Brazil and then the United States. She was studying languages at a local college and liked to practice at the International House where Poddar was living. She was outgoing and friendly with many of the foreign students but gradually Poddar's interest in her increased, and he told his friend Mistree of his powerful attraction. He did not understand how her behavior, that seemed more than friendly to him, was compatible with spending time with other male students. His friend explained that he thought her interest was genuine but probably only casual.

At a New Years Eve party, he was alone with her in an elevator. It was a festive occasion, and people had been drinking. Impulsively she kissed him for the New Year. He was stunned, as he had never had physical contact with a woman other than his relatives. He almost immediately fled to tell his friend of the new development. In the months that followed he became increasingly upset by her inconsistent behavior. He installed microphones in his room to record their conversations both on the phone and in person. His friend suggested that he end the relationship because it was interfering with his work. He did so, but a month later she called and said she missed him. Within a month he was again uncertain, and in an effort to clarify the situation, he proposed marriage. She did not accept but also did not clearly refuse. Shortly afterward he again confided to his friend that Tatiana's friends were now laughing at him. "Even you, Mistree," he said, "laugh at my state. But I am like an animal, I could do anything, I could kill her. If I killed her, what would you do?" He began to stay in his room for days. He told fellow students that he would like to blow up the house where she lived with

her brother and parents. They persuaded him that it was not possible but did not say anything to warn anyone or call the police.

In June, Tatiana returned to Brazil for the summer, but nothing changed for Poddar. His friend suggested that he see a doctor, set up the appointment, and accompanied him. After the initial interview the psychiatrist placed him on antipsychotic medication and set up weekly appointments with a psychologist. During the summer months Poddar became friendly with Tatiana's brother, Alex, spent time with him, and planned to share an apartment with him in the fall. He began to fantasize about rescuing Tatiana from a contrived situation so she would understand the depth of his affection for her. When he told his friend Mistree that he planned to buy a gun to effect this plan, Mistree called the therapist and told him that Poddar planned to stop therapy and buy a gun. The psychologist consulted with the psychiatrist, and they decided that Poddar needed to be hospitalized. Because of peculiarities in California commitment law the psychologist wrote a letter to the University police requesting their assistance in hospitalizing Poddar. Shortly thereafter the Berkeley campus police found Poddar in his new apartment with Alex and interviewed him there. Poddar denied he had a weapon and denied any specific threats although he acknowledged that there had been a difficult relationship between him and the young woman. The police warned him to stay away from her and left without taking any other action. Tatiana's brother Alex was present during interview and knew that the threats were related to his sister but he did not take them seriously and did not report them to his family. When the head of the clinic reviewed the case, he ordered the therapist to destroy the letter to the campus police requesting hospitalization.

Tatiana returned in September, and Poddar overheard her recounting a summer affair to her friends. He began to follow her around. He then purchased a gun, perhaps to carry out his plan of rescuing her from a disaster situation. He consulted with Alex about what would be the best way to approach his sister but Alex recommended that he stay away from her and that it was all over and best forgotten. Poddar insisted that he must talk with her, but Alex told him not to go over to his parent's house, as his father was quite hot tempered. Poddar then made several efforts to see Tatiana at the house. After her mother turned him away, he returned in midafternoon before anyone else came home. As he left his apartment, he slipped a kitchen knife as well as the gun into his pocket as protection against her angry

father. When she answered the door he tried to explain his need to talk with her and forced his way past the closing door. Tatiana screamed, pushed him away, and started to run away. He fired at her scream and followed her. He took the knife from his pocket as they plunged together through the kitchen door. Within minutes he dialed the phone number of the Berkeley City Police stating that he thought he had killed someone. Poddar was charged with first-degree murder. He pled insanity and diminished capacity. Although all experts agreed with the diagnosis of paranoid schizophrenia, the jury found Poddar guilty of second-degree murder. He was sent to California state prison. Five years after he had begun serving a sentence, the California Supreme Court issued its decision; overturning the jury verdict on the grounds the trial judge had given inadequate instructions on diminished capacity to the jury. Rather than retry him, a deal was struck. Because he had already served 5 years, if the state would agree to release Poddar from prison; his attorney personally guaranteed that Poddar would return immediately to India and would never come back to the United States.

Alongside the criminal case, *Tarasoff v. Regents of the University of California* also ended with a settlement. Tatiana's parents sued the University of California and the therapists for the wrongful death of Tatiana. They included a complaint that the psychiatrist's failure to warn them or Tatiana of the danger that Poddar posed to the family was a legal cause of action. Because the trial court dismissed the causes of action as groundless it was appealed to the California Supreme Court on their legal adequacy. After the Court rendered its first decision holding that psychotherapists had a duty to warn potential victims of their patient's threats and that the campus police could be found liable for a failure to warn Tanya, a rehearing was requested although such requests are almost never granted, it was in this case. The second decision reaffirmed but modified the original decision. It required therapists to "protect" intended victims, rather than just "warn" them and absolved the police from any liability. Although the Court expressed concern about the confidentially issues raised by psychiatrists and other mental health professionals, they concluded in both decisions "The protective privilege ends when the public peril begins." The major holding of the case was that the therapists could not escape liability on the grounds that Tatiana was not their patient. The Court held:

When a therapist determines, or pursuant to the standards of his profession should determine, that his patient presents a serious danger of violence to another, he

incurs an obligation to use reasonable care to protect the intended victim against such danger. The discharge of this duty may require the therapist to take one or more of various steps, depending upon the nature of the case. Thus it may call for him to warn the intended victim or others likely to apprise the victim of the danger, to notify the police, or to take whatever other steps are reasonably necessary under the circumstances.

Justice Mosk, in a concurring opinion (meaning that he agreed with the holding but not the legal reasoning), agreed that under the limited circumstances of this particular case, Poddar's therapists had a duty to warn Tatiana. Although Mosk believed the therapists' duty had been satisfied by warning the campus police, he considered this a factual matter to be raised by the defense on remand and did not dissent on this basis. He dissented from the majority's use of the term "standards of the profession." What standards? Psychiatric opinions of future violence were inherently unreliable. "The majority's expansion of that rule will take us from the world of reality into the wonderland of clairvoyance."

Justice Clark, in dissent, was concerned about the pressure on psychiatrists to protect themselves.

Now, confronted by the majority's new duty, the psychiatrist must instantaneously calculate potential violence from each patient on each visit. The difficulties researchers have encountered in accurately predicting violence will be heightened for the practicing psychiatrist dealing for brief periods in his office with heretofore nonviolent patients. And, given the decision not to warn or commit must always be made at the psychiatrist's civil peril, one can expect most doubts will be resolved in favor of the psychiatrist protecting himself."

Because the case settled prior to trial, there was no discussion or expert opinion of what warnings or protective action were possible or appropriate in the above circumstances.

Although California went on to clarify the meaning of the principle in later decisions to cover only identifiable victims, other jurisdictions disagreed and expanded the scope of the decision. The broadest interpretation occurred in 1980 in the case of *Lipari v. Sears Roebuck & Co.* There, a patient fired a shotgun in a crowded nightclub, blinding a woman and killing her husband. There were no advance warnings to his therapists, and he never threatened any specific person. He did make clear that he was unhappy with his treatment. While still in treatment at the V.A. day care center he purchased a shotgun at Sears, but told no one on his treatment team. He terminated treatment 3 weeks later. One month after the

termination he entered the nightclub. The Nebraska District Court allowed the plaintiffs to proceed in their lawsuit against the hospital. The court held it was for the jury to decide whether the therapist knew or should have known of the patient's dangerous propensity. It did not matter that the victims were not identifiable. The Court rejected the limitation to identifiable victims and focused on the foreseeability of the act.

A Vermont case extended the liability to situations where only damage to property was involved. In that case a patient informed his master's-level counselor that he intended to burn down another person's barn.

The duty has also expanded in some jurisdictions to the area of a patient's erratic driving. In one case a man diagnosed with paranoid schizophrenia, and with an extensive history of depression, self-mutilation, and noncompliance with neuroleptic regimens, was confined following his excision of his left testicle. One day prior to the expiration of his commitment he was observed driving dangerously on the hospital grounds. His commitment was not renewed, and he was released to outpatient follow-up. He promptly threw away his medication and resumed use of street drugs. Five days later he ran a red light at excessive speed and hit a vehicle, injuring the driver. She filed a suit, charging the state with negligent treatment by failing to recommit him or releasing information, regarding his violation of probation conditions. The court adopted the foreseeability standard from *Lipari* to hold that a psychiatrist has a duty to take reasonable precautions to protect anyone who might foreseeably be injured by the patient's drug-related problems. This line of cases requires therapists to protect victims from their patients' negligent behavior rather than just intentional harmful acts.

An interesting variant occurred in another California case where the question arose as to whether a therapist has to make a warning if the potential victim is already aware of the danger. In *Jablonski v. U.S.* the victim was the defendant's common-law wife, Melissa Kimball. Ms. Kimball was fully aware of her husband's violent tendencies in view of his prior beatings of her and his attempted rape of her mother. His more recent behavior included threatening the mother-in-law again. His psychiatrist recommended a voluntary hospitalization, which he refused. Prior psychiatric records from the V.A. were not obtained that would have revealed homicidal ideations toward his former wife. His wife brought him back for a second visit but the physicians felt that although he was potentially dangerous due to his antisocial personality he was not presently committable.

Two days later he attacked and murdered his common-law wife. The victim's daughter claimed the psychiatrists were negligent by failing to warn her mother of her husband's foreseeable danger. The court agreed. "Warning Kimball would have posed no difficulty for the doctors, especially since she twice expressed her fear of Jablonski directly to them. Neither can it be said ... that direct and precise warnings would have had little effect." The reasoning of the Court seemed to be that, even though others had suggested she stay away from him, a warning from a doctor carries greater weight and might have influenced the victim.

Almost all jurisdictions have adopted some form of the *Tarasoff* duty, either through case law or by statute. Some courts have reasoned that this duty to protect third parties should be imposed because of the therapist's control over the patient, while others have taken a modified approach by broadening the therapist's duty to warn all foreseeable victims. Some have limited liability to specific identifiable victims or to a class of identifiable victims (e.g., children). A minority of jurisdictions has declined to recognize the obligation altogether, especially for outpatient therapists (Florida, Virginia, and Texas). The American Psychiatric Association has proposed model legislation to better define the nature of the liability as well as what actions are sufficient to fulfill the duty. They suggest language to include "actual" or "real" threats as well as identifiable victims. They also suggest that hospitalizing the patient or making reasonable attempts to notify the victim and calling the police is sufficient to satisfy the duty. This model statute was adopted in some 22 states with variations in wording.

There were many concerns that this decision would have dire effects on the psychotherapeutic relationship. Some felt that psychotherapists would be deterred from treating potentially violent patients or that patients would be deterred from seeking therapy. Others thought that patients would be less likely to share violent fantasies or that once a warning was issued the therapy would end as in the *Tarasoff* case. Subsequent studies and experience, however, have failed to confirm these fears. Psychotherapists have and should increase their use of consultation in potential *Tarasoff* cases, which is a useful step in planning carefully as well as averting liability.

Tarasoff and subsequent cases have defined and expanded the psychotherapist's obligations to victims of their patient's actions if they are deemed foreseeable. The challenge is how to maintain trust with patients while carefully assessing and evaluating risk of violence

to third parties. Therapists must then consider how best to protect potential victims as well as their patients by considering increased contact, medication, hospitalization, warnings, or other protective actions. Problems have arisen when past medical records have not been reviewed or past therapists have not been contacted.

By contrast when patients reveal information about past crimes most confidentiality statutes (except for child abuse reporting) do not permit disclosure by the therapist. Yet therapists, unlike attorneys who hear such information are generally more uncomfortable keeping such information confidential, especially if the crime is serious, and often wish to call law enforcement authorities. They are concerned that patients are using psychotherapy to “get away with a crime.” But for an expectation of confidentiality, patients would not disclose such information to therapists. In such circumstances a consultation with an attorney or knowledgeable colleague may be useful in reviewing duties and obligations.

IV. FEDERAL LAW AND REGULATIONS REGARDING CONFIDENTIALITY

Aside from comprehensive regulations regarding treatment of substance abusers in facilities receiving federal funding, the federal government has generally left confidentiality protections of medical information to the states. In 1996, however, Congress passed the Health Insurance Portability and Accountability Act (HIPAA). Concerns about the fact that more and more health care providers and plans are using electronic means of storing and transmitting health information caused Congress to attempt to develop privacy rules and to ask the Department of Health and Human Services (HHS) to provide regulations if there was no congressional action by August 1999. Congress did not act, and regulations were developed by HHS and went into effect in April 2001. Compliance is required by 2003. This Act covers all health care providers who have engaged in at least one standard electronic transaction or providers that use billing services that utilize electronic transactions as well as health plans. The Act distinguishes between consent and authorization. Consent must be obtained to release information for “treatment, payment, and health care operations” (TPO). Consent, in this context, is a general document that gives health care providers, who have a direct treatment relationship with a patient, permission to use and disclose all health information for TPO. Authorization is required for more specific releases of information. An authorization is a more cus-

tomized document that gives providers permission to use specified protected health information (PHI) for specified purposes, which are generally other than TPO, or to disclose PHI to a third party specified by the individual. Psychotherapy notes have received some special protections if they are kept separate from the rest of the medical record and are for the use of the therapist only. In general, disclosures of information will be limited to the “minimum necessary” for the purpose of the disclosure. This provision does not apply to the disclosure of medical records for treatment purposes because physicians, specialists, and other providers need access to the full record to provide quality care.

States that have more stringent confidentiality protections under local state laws (like those covering mental health, HIV infection, and AIDS information) are not preempted by HIPAA. These confidentiality protections are seen as setting a national “floor” of privacy standards. This law was not designed to resolve disputes between insurers and providers nor prevent subpoenas of records for court-related issues. HHS is beginning to issue “guidances” so that practitioners will be able to understand the regulations and their requirements.

V. BOUNDARY VIOLATIONS: PSYCHOTHERAPIST–PATIENT SEXUAL CONTACT

The boundaries of any relationship define how the parties ought to behave toward each other in their respective roles. In the psychotherapist–patient relationship, these boundaries are derived from professional ethical guidelines, cultural morality, and jurisprudence. Generally, boundaries include agreements relating to scheduled sessions; fee agreements; establishing “treatment goals” that are modified through negotiation; therapy sessions focused entirely on the client; an understanding regarding confidentiality and any limitations; and finally, no sexual contact or even social contact with patients, except when “overlapping [social] circles” render such contact unavoidable. The purpose of these limits is to create an atmosphere of safety and predictability within which the treatment can proceed. These guidelines have evolved from the psychoanalytic method of treatment. They have not been codified or updated to include current modes of treatment especially involving treatment of the seriously and chronically mentally ill in the public sector. This work does involve professionals in their clients’ lives especially when they live in supervised housing or are being delivered and administered medications in their homes or apartments.

Many of these patients or clients are also supervised and at times accompanied by staff to aid in shopping for food or clothes as well as helping with money management programs. Many of these behaviors have been deemed unethical when they have occurred in psychoanalytic-type treatment settings. Even within psychotherapeutic approaches, it has not been possible to articulate definitive guidelines, as most clinicians would agree that guidelines should be tailored to the particular requirements of the individual patient.

The fiduciary nature of the physician–patient relationship is fundamental to boundary setting and creates a covenant that controls the imbalance of power to ensure a safe and trusting relationship based on the patient’s needs. In essence, the physician guarantees that, within the therapeutic relationship, the patient can feel comfortable revealing intimate personal information without fear of exploitation.

Not all boundary crossings are equivalent to malpractice or substandard care. Many do not harm the patient or threaten the treatment. Helping a patient who has fallen or consoling a patient who has just been informed that a close relative has died are humane responses that should not be discouraged. There are situations where some behaviors may be inappropriate in some contexts but not in others, for example some touching of terminally ill, geriatric patients or HIV-infected patients. Both culture and context are important factors to consider in reviewing behavior.

Any sexual contact, however, has been increasingly viewed as an egregious violation of patient trust. Here, psychotherapists are seen as allowing personal interests to supercede those of the patient in a manner that may cause significant harm.

In cases involving breaches of confidentiality courts have been more willing to look at physicians’ ethical guidelines and fiduciary duties, than they have in cases involving physician–patient sexual contact. The courts’ inconsistency in applying the ethical standards and fiduciary aspects of the psychotherapist–patient relationship to sexual conduct remains unclear. Judicial unfamiliarity with the medical professions standards may reflect the inconsistent statements made by different professional organizations and the relatively late response of the American Medical Association to develop specific standards.

Like confidentiality standards, the ethical proscriptions against sexual contact between physicians and patients are long standing and were emphasized in the Hippocratic Oath that was codified around 460 BCE: “In every house where I come I will enter only for the good of my patients, keeping myself far from all intentional

ill-doing and all seduction, and especially from the pleasures of love with women or with men.”

Prior to 1990, the AMA recognized the potential for power abuse in the physician–patient relationships and declared “sexual misconduct” in the practice of medicine to be unethical. However, the code did not define “misconduct” and thus did not clarify what type of sexual conduct was proscribed. Today the code expressly provides that sexual contact that occurs concurrently with the physician–patient relationship constitutes sexual misconduct. Sexual relationships that predate the physician–patient relationship, such as sexual contact with a spouse, are an exception to this general rule. In most other cases the AMA has explained that sexual contact between a physician and patient is almost always detrimental to the patient and is unethical because the physician’s self-interest inappropriately becomes part of the professional relationship. Because a fiduciary relationship exists between a patient and a physician, physicians have obligations to act solely for the welfare of patients and refrain from engaging in sexual activity.

The American Psychiatric Association, in its annotations to the AMA Code for psychiatrists much earlier specified the possibility for exploitation of patients (1973—first edition of the Principles of Medical Ethics with “Annotations Especially Applicable to Psychiatry”): “The necessary intensity of the therapeutic relationship may tend to activate sexual and other needs and fantasies on the part of both patient and psychiatrist, while weakening the objectivity necessary for control. Sexual activity with a patient is unethical.” This policy was promulgated in the 1970s along with the suggestion that if therapy was ended but the subsequent relationship was exploiting the patient it too was unethical.

Other psychotherapeutic disciplines have similar codes. The ethical code for psychologists states that “Sexual intimacies with clients are unethical.” Likewise for social workers, “The social worker should under no circumstances engage in sexual activities with clients.” Similarly the ethical code for marriage and family therapists maintains, “Sexual intimacy with clients is prohibited.”

In one survey of psychiatrists in the 1980s, 7.1% of male and 3.1% of female psychiatrists admitted sexual contact with patients. In three surveys of psychologists, between 1977 and 1986, 12.1% of male psychologists and 2.6% of female psychologists reported sexual contact with patients. There are several indications that the incidence of sexual contact may be higher than admitted by therapists. For example, there were low return rates in some of the surveys, and some states have felony criminal penalties for such behavior. In one study, 63% of psychiatrists surveyed reported treating

at least one patient who had experienced sexual contact with another physician. In another study, 50% of psychologists reported treating at least one patient who had been sexually involved with a previous therapist.

Indeed, between 1976 and 1986, sexual misconduct was the most frequent cause of lawsuits against psychologists insured under American Psychological Association policies, accounting for 44.8% of all moneys (\$7,019,165.00) paid in claims. There is nothing to suggest that the incidence among the different mental health professionals differs greatly. In response to similar concerns, the American Psychiatric Association extended the prohibition from current patients to both current and former patients in 1993.

Problems abound in the implementation of remedies for victims of such misconduct and unethical behavior. There are now generally four avenues of redress and complaints can be filed simultaneously:

1. Traditional malpractice claim
2. Complaint to the state medical or professional licensing board
3. Criminal complaint
4. Ethical complaint to the professional association

A. Traditional Malpractice Claim

Health care professionals—including dentists, gynecologists, physicians, psychiatrists, psychologists, therapists, and medical technicians—spend millions of dollars purchasing medical-malpractice insurance from state, regional, and national liability insurers. For example, the St. Paul Fire & Marine Insurance Company, the largest medical-liability company in the nation, sells and renews thousands of medical-malpractice policies each year. The language appearing in St. Paul's medical-liability contracts is very similar to that appearing in legal-malpractice policies. Typically, the coverage provision states: "This agreement provides protection against professional liability claims which might be brought against you in your practice as a physician or surgeon. ... Your professional liability protection covers you for damages resulting from ... your providing or withholding of professional services."

For at least 30 years, St. Paul—as well as those professionals who were insured—has asked state and federal courts to decide whether St. Paul must defend professionals who allegedly seduced, battered, sexually assaulted, or molested their patients. As expected, St. Paul's defense has been consistent: These intentional injuries do not "arise out of" or "result from rendering professional services." The medical-liability carrier,

however, has not prevailed in every case, even though the third-party patients' allegations involved allegedly intentional acts excluded by St. Paul's insurance contracts. State courts have either refused, or failed to employ, various legal doctrines to help determine whether "deviant" physicians and medical technicians are "rendering professional services." Instead, these tribunals have permitted some generalized notion of public policy to influence whether some insurers must defend their insureds in cases involving sexual assault.

In one early case in 1977, *Hartogs v. Employer Mutual Liability Insurance Company*, Dr. Hartogs was a practicing psychiatrist. Under the guise of medical treatment, Dr. Hartogs administered "fornication therapy" to cure his patient's lesbianism. The patient received judgment for \$15,000.00 and Dr. Hartogs's insurer refused to pay the judgment on the grounds that the treatment did not constitute medical malpractice. They argued that sexual relations could not be considered a medical treatment. Dr. Hartogs brought an action against the insurer to recover his costs and expenses in defending the action, as well as the expenses incurred by him when he filed for bankruptcy to protect his property. As part of his argument for compensation, Dr. Hartogs noted that the jury had specifically found medical malpractice.

The court ruled that the insurer was not obligated to indemnify Dr. Hartogs for two reasons. First, the court held that a distinction should be drawn between medical malpractice in the mind of the patient, and medical malpractice in the mind of the doctor. The patient believed at the time that appropriate medical therapy was being administered. On the other hand, the doctor administering this treatment knew at all times that what he was doing was in no way pursuant to the doctor-patient relationship. As such, as between Dr. Hartogs and his insurer, his actions could not constitute medical malpractice.

Second, as a matter of public policy, the court would not allow itself to be used to enforce illicit or immoral or unconscionable purposes. The court held that to allow judgment in this type of case would be to indemnify immorality and pay the expenses of prurience. The Court did not deal with the question of how the plaintiff would collect judgment given that Dr. Hartogs had filed for bankruptcy.

On the other side of the same question, the issue of protecting the victim was focused on by the 1982 Michigan decision, *Vigilant Insurance Company v. Kambly*. In that case, Vigilant Insurance Company filed an action for relief, absolving it from liability under a professional insurance policy issued to a psychiatrist. The court's decision denied relief. In that case, Dr. Kambly

had induced his patient to engage in sexual intercourse under the guise of treatment. In its judgment, the court stated that there was no reason for distinguishing between this type of malpractice and others. The court noted that in each situation, the essence of the claim is the doctor's departure from proper standards of medical practice. In addition, the court found that allowing insurance coverage would benefit the patient, not the physician. Therefore, Dr. Kambly would not unjustly benefit from the determination that coverage existed.

The court further held that it was unlikely that the insured was induced to engage in unlawful conduct by relying on the insurability of any claims. Therefore, allowing insurance coverage would not induce future similar unlawful conduct by practitioners. In addition, the policy was not obtained in contemplation of a violation of the law. Finally, the court noted that there was a great public interest in protecting the interests of the injured party.

A number of insurers in the United States provide funding for a defense in sexual abuse cases but do not pay a judgment on a finding of liability. There is a problem throughout the lawsuit, however, that any settlement negotiations are complicated and restricted by the fact that the organization providing the defense is not ultimately responsible for paying the judgment. Many policies now either exclude or place liability limits (e.g., \$25,000) on policies for behavior or malpractice that stems from sexual interest or contacts.

The ethical guidelines in this area have also become the legal standard of care. Nonetheless, posttermination contacts continue to evoke much discussion in the clinical literature. Many allegations of abuse are based on allegations that transference continues after therapy ends. Transference, however, remains a complicated construct with multiple definitions. Freud initially used the concept to explain some of the irrational behavior of patients in treatment by the idea that feelings and other aspects of earlier relationships were "transferred" to the analyst who came to represent, often unconsciously, figures from the patient's past. Some therapists and treatment modalities do not accept or use the concept, while others believe that it exists in all therapies. Some psychoanalysts believe transference never ends and therefore taints any consent for posttermination relationships. This has led to conclusions that both former patients and patients are not capable of providing legally informed consent, even in the absence of a specific evaluation. A popular view of transference is that it refers to all feelings that arise between a patient and therapist. Others extend the concept to include all relationships, for example, a young woman falling in love

with an older man. Given this uncertainty, it is not surprising that courts have frequently misunderstood the concept. Even for those adopting a transference paradigm, there is a need to assess what role it may be playing. Patients continue to make many decisions while in treatment and posttreatment, and there is no literature to support global incapacity to do so just as a result of being in treatment.

B. Complaint to State Licensing Board

Another option available to victims is to file a complaint with the state licensing board regulating the offending therapist. Virtually all jurisdictions have licensure laws and codes of ethics that prohibit therapist-patient sexual contact and specify that such contact is grounds for discipline. The primary purpose of licensure laws is to protect the public from incompetent and unscrupulous therapists. As a general rule, state licensing boards are responsible for establishing and enforcing codes of ethics for the professions they regulate. In addition, most licensing statutes give the boards authority to refuse to grant a license to a therapist who has committed sexual misconduct or been found guilty of a felony involving moral turpitude. Furthermore, licensing boards also have authority to investigate ethical complaints and impose disciplinary sanctions.

Therapists accused of sexual misconduct are entitled to a hearing before disciplinary action is taken. Most complaints, however, are resolved without hearings through the use of negotiated settlements. If the complaint is not settled informally, and an administrative hearing becomes necessary, the burden of proof is low, a preponderance of the evidence (the standard of proof required in civil cases), and the rules of evidence are relaxed. In addition, although licensing board hearings are not as private and confidential as those of professional associations, they do provide less public exposure than civil trials.

From the victim's perspective, licensing board regulation has several positive aspects. First, most licensing boards do not impose a statute of limitations on the filing of complaints. In many cases, the statute of limitations is 2 to 3 years for a civil malpractice action. Therefore, disciplinary action by the licensing board may be the victim's only available remedy. Second, state licensing boards have a range of sanctions available to them. Most boards are authorized to discipline by warning, reprimand, censure, or probation. They may also suspend or revoke a license to practice.

C. Criminal Complaints

Several factors have led to the enactment of specific statutes criminalizing psychotherapist sexual misconduct. First, although some mental health professionals feel that the intensity of the therapist–patient relationship impairs the patient’s ability to consent to a sexual relationship with the therapist, courts have been reluctant to recognize this in criminal cases making it impossible to prosecute offending therapists under traditional sexual assault statutes. The second and more significant factor has been the public outcry and demand for specific legislation. In 1984, Wisconsin became the first state to enact a specific statute criminalizing psychotherapist sexual misconduct. At least 15 states have enacted some form of criminal penalty for psychotherapist or physician sexual misconduct, and most of these statutes have withstood constitutional challenges. The majority of these statutes impose criminal sanctions on therapists engaging in sexual contact while performing psychotherapy, defining those terms broadly enough to bring physicians within the scope of the statutes. Ten of the 15 statutes cover sexual contact both within and outside actual treatment sessions during an ongoing professional relationship. Two statutes apply to sexual contact outside the treatment setting only if the patient is emotionally dependent on the therapist, and two apply only to contact during therapy sessions or medical treatment or examination. All but one of the statutes applies a strict liability standard, expressly excluding consent as an affirmative defense.

Some private interest groups have argued that consent should not be eliminated as a defense in such cases because to do so “treats any person who consults a mental health professional as a child.” Eliminating consent as a defense, however, does not treat the patient as a child but merely recognizes that “competent individuals may be unduly influenced in special relationships.” Furthermore, as one commentator indicates, “patient consent to sex . . . is not the issue.” Rather, “it is the breach of fiduciary trust by the therapist who engages the patient in sex that is the appropriate focus of wrongdoing.”

Proponents of criminalization point to its deterrent and retributive value, its function as an alternative form of redress for patients inadequately served by civil or disciplinary avenues, and its potential for raising money via fines for both victim treatment and prevention programs. In reality, however, very few people file charges under these criminal statutes, suggesting that the disadvantages of criminal controls far outweigh the advantages.

Furthermore, prosecution is completely dependent on the victim’s willingness to come forward, and vic-

tims of physician sexual misconduct will be hesitant given the fact that a criminal conviction generally yields no monetary award, and the prosecutor, rather than the victim’s own legal advocate, maintains control over the case. In addition, the threat of criminal sanctions may have a chilling effect on both colleague reports and patient complaints, masking the significance of the problem and limiting the effectiveness of other controls. Moreover most malpractice insurance coverage excludes coverage for criminal acts, eliminating access to civil damages to cover the costs of necessary subsequent treatment.

Criminalization may, indeed, make it more difficult for the victim to prevail or negotiate settlements in civil suits, in that admissions will be less likely, and therapist assertions of Fifth Amendment rights may delay discovery in civil and administrative actions, pending completion of the criminal trial. In addition, criminal conviction offers little or no opportunity for rehabilitation. Finally, prosecutors face the higher reasonable doubt burden of proof and the limitations of strict rules of evidence. Given these barriers to prosecution, it is clear that criminal statutes, like civil actions, are inadequate in and of themselves to deal effectively with the problem of physician sexual misconduct.

D. Ethics Complaints to the Professional Association

Although many professional groups use professional licensing boards to adjudicate ethical violations, some professional organizations like the American Psychiatric Association (and the American Psychological Association and National Association of Social Workers) have procedures to adjudicate ethical complaints directly. If a complaint of unethical conduct against a member is sustained, that person can receive sanctions ranging from reprimand to expulsion from the association. A formal complaint has to be made in writing, and the ethics committee of the local district branch has the ability to appoint an ad hoc investigating committee to conduct an investigation and to render a decision. Due process requires that the accused member will be notified of a hearing by certified mail at least 30 days in advance. The notice includes the day, time, and place of the hearing. In addition, it includes a list of witnesses expected to testify, notification of the member’s right to representation by legal counsel (or another individual of the member’s choice), as well as notification of the member’s right to appeal any adverse decision to the ABA Ethics Appeals Board. In addition to sanctions the

district branch may also, but is not required to, impose certain conditions such as educational or supervisory requirements on a suspended member.

Patients are sometimes reluctant to file complaints, because they do not want any publicity of the details of their lives to become fodder for the press. But after years of what was termed a “conspiracy of silence,” several factors have changed the dynamics of reporting. First, as a result of both patient and women’s rights movements, patients feel less protective of and less intimidated by physicians and other professionals and are more willing to speak out. Increased awareness of sexual abuse, child abuse, date rape, clergy abuse, and therapist–patient exploitation has resulted in an increased focus on the healing professions. Professional organizations have also spoken out against these transgressions, developed training programs, and treatment programs for impaired professionals.

This section highlights a few of the major themes that have come under scrutiny over the past few decades. The factors that influence the practice of mental health professionals are an algorithm of a professional’s ethical, moral, and legal duties to provide competent care to patients. These duties are modified over time to reflect changing science, practice, and legal regulations as promulgated by courts, legislatures, professional organizations, and agencies that regulate professional practice. The mental health professional must learn to analyze clinical situations so as to know

how to balance sometimes conflicting values and rules so that proper care can be rendered to a patient.

GLOSSARY

dereflection A logotherapeutic technique to redirect clients' attention away from their problems to more positive aspects of their lives. It is built on the human capacity for self-distancing and self-transcendence.

existential analysis Developed by Viktor Frankl, it refers to therapeutic techniques that bring the hidden meaning of existence into consciousness.

logotherapy Developed by Viktor Frankl, it refers to a spiritually, existentially oriented therapy that seeks to achieve healing and health through meaning.

meaning-centered counseling and therapy Developed by Paul T. P. Wong, it focuses on the transformation of cognitive meanings as well as life's purposes. It integrates both cognitive-behavioral and narrative processes.

paradoxical intention A logotherapeutic technique to encourage the patient to do or wish to happen what the patient fears. It is built on the human capacity for self-detachment.

I. INTRODUCTION

This article will present an overview of Viktor Frankl's (1905–1997) logotherapy and existential analysis.

Known as the “Third Viennese School of Psychotherapy,” logotherapy was developed in the 1930s because of Frankl's dissatisfaction with both Freud and Adler.

Frankl accepts Sigmund Freud's concept of unconsciousness but considers the will to meaning as more fundamental than the will to pleasure. Existential analysis is designed to bring to consciousness the “hidden” meaning or spiritual dimension of the client.

Frankl received training in individual psychology from Adler. He differs from Adler because he focuses on the will to meaning, while Adler emphasizes social interest and the will to power. However, some of the basic concepts of logotherapy, such as freedom and responsibility, bear the imprint of Adler's influence.

A major difference between logotherapy and psychoanalysis is that both Freud and Adler focus on the past, while logotherapy focuses rather on the future—on the meanings to be fulfilled.

Although logotherapy and existential analysis tend to be used interchangeably or together as a single label, it may be helpful to recognize the following difference between these two terms:

Logotherapy means therapy through meaning, and it refers to Frankl's spiritually oriented approach to psychotherapy. *Existential analysis*, on the other hand, refers to the analytical therapeutic process involved in addressing the patient's spiritual, existential needs. To the extent that logotherapy makes the patient aware of the hidden meaning of existence, it is an analytical process.

Logotherapy is a distinct branch of existential–humanistic school psychotherapy, because of its focus on

the human spirit and “the meaning of human existence as well as on man’s search for such a meaning.” What sets Frankl apart from North America’s existential psychotherapy is his unconditional affirmation of life’s meaning. The main objective of logotherapy was to facilitate clients’ quest for meaning and empower them to live meaningfully, responsibly, regardless of their life circumstances.

Logotherapy was put to severe test in a very personal way between 1942 and 1945, when Frankl was committed to Nazi concentration camps. His experience in these camps was recorded in his best-selling book *Man’s Search for Meaning*. His personal triumph over unimaginable trauma has been the most compelling testimony to logotherapy. There are no other psychotherapists whose life and work are as inseparable as Frankl’s. He is logotherapy, and vice versa.

II. THE SPIRITUAL DIMENSION

It is not possible to practice logotherapy without understanding the human spirit or the spiritual dimension of human existence. According to Frankl’s dimensional ontology, human beings exist in three dimensions—somatic, mental, and spiritual. Spirituality is the uniquely human dimension. However, these different dimensions must be understood in their totality because a person is a unity in complexity.

A. The Defiant Power of the Human Spirit

One of the prepositions of logotherapy is that the human spirit is our healthy core. The human spirit may be blocked by biological or psychological sickness, but it will remain intact. The human spirit does not get sick, even when the psychobiological organism is injured.

According to Frankl, part of the human spirit is unconscious. When the human spirit is blocked or repressed, one experiences existential vacuum or neurosis. Existential analysis seeks to remove the block and brings to consciousness the will to meaning.

According to Joseph Fabry, the noetic dimension of the human spirit is the “medicine chest” of logotherapy; it contains love, the will to meaning, purpose, creativity, conscience, the capacity for choice, responsibility, sense of humor, and so forth.

The defiant power of the human spirit refers to people’s capacity to tap into the spiritual part of the self and rise about the negative effects of situations, illness

or the past. Paul T. P. Wong proposes that it may be more helpful for scientific and therapeutic purposes to conceptualize the human spirit as inner resources, which can come to one’s aid in coping with life stress.

B. Logotherapy and Religion

Frankl differentiates between spirit, spirituality, and religion. Spirit refers to one of the dimensions of humanity. Spirituality is manifest in a person’s quest for meaning. Religion encompasses the ultimate meaning, super meaning, as well as God. He clearly recognizes the importance of religion but is reluctant to be considered religious. He equates authentic religion with deep spirituality.

In an interview with Matthew Scully in 1995, when Frankl was already 90, he seemed to be more explicit about the important role of religion and faith in logotherapy. Frankl said:

I have come to define religion as an expression, a manifestation, of not only man’s will to meaning, but of man’s longing for ultimate meaning, that is to say a meaning that is so comprehensive that it is no longer comprehensible ... But it becomes a matter of believing rather than thinking, of faith rather than intellect. The positing of a super-meaning that evades mere rational grasp is one of the main tenets of logotherapy, after all. And a religious person may identify Supermeaning as something paralleling a Superbeing, and this Superbeing we would call God.

III. THE MEANING OF MEANING

The Greek word *logos* represents the word, the will of God, the controlling principles of the universe, or meaning. Dr. Frankl translates *logos* as meaning. Therefore, logotherapy means healing and health through meaning. But what is meaning?

A. Specific versus Ultimate Meaning

According to Frankl, there are two levels of meaning: (a) the present meaning, or meaning of the moment, and (b) the ultimate meaning or super-meaning. Dr. Frankl believes that it is more productive to address specific meaning of the moment, of the situation, rather than talking about meaning of life in general, because ultimate meanings exist in the supra-human dimension, which is “hidden” from us. He cautions

against addressing ultimate meanings in therapy, unless the client is openly religious.

Each individual must discover the specific meanings of the moment. Only the individual knows the right meaning specific to the moment. The therapist can also facilitate the quest and guide the client to those areas in which meanings can be found.

B. Meaning versus Value

In his earlier writings, Frankl often used meaning and value interchangeable. Fabry has clarified the difference between meaning and value:

We create unique relationships and accept unique tasks, face unique sufferings, experience unique guilt feelings and die a unique death. The search for meaning is highly personal and distinct. But millions of people have gone through situations that were similar enough so they could react in a similar way. They found what was meaningful in standard situations. They found universal meanings, which is the way Frankl defines values: "meaning universals."

Therefore, values are abstract meanings based on the meaning experiences of many, many individuals. Frankl believes that these values can guide our search for meaning and simplify decision making. For example, life can be made meaningful if we realize three categories of values—experiential, creative and attitudinal.

Traditional values are the examples of the accumulation of meaning experiences of many individuals over a long period of time. However, these values are threatened by modernization. Frankl believes that "Even if all universal values disappeared, life would remain meaningful, since the unique meanings remain untouched by the loss of traditions."

Implicit in all his writings, Frankl gives the impression that values, like Kant's categorical imperatives, are somehow universal, from which specific meanings flow. Thus, every experience of meaning involves the realization of some values. But these values may lie latent and need to be awakened or cultivated through existential analysis. This kind of reasoning may explain why Frankl insists: "The meaning of our existence is not invented by ourselves, but rather detected."

IV. BASIC TENETS

The logotherapeutic credo consists of freedom of will, will to meaning, and the meaning of life. These are the cornerstones of logotherapy and existential analysis.

A. Freedom of Will

Frankl realizes that "Human freedom is finite freedom. Man is not free from conditions. But he is free to take a stand in regard to them. The conditions do not completely condition him." Although our existence is influenced by instincts, inherited disposition, and environment, an area of freedom is always available to us. "Everything can be taken from a man, but ... the last of the human freedoms—to choose one's attitude in any a given set of circumstances, to choose one's own way." Therefore, we always have the freedom to take a stand toward the restrictive conditions and transcend our fate.

Freedom of will is possible because of the human capacity for self-distancing or self-detachment: "By virtue of this capacity man is capable of detaching himself not only from a situation, but also from himself. He is capable of choosing his attitude toward himself."

B. Responsibility and Responsibleness

With freedom comes responsibility. Joseph Fabry once said responsibility without freedom is tyranny, and freedom without responsibility leads to anarchy, which can lead to "boredom, anxiety, and neurosis." Frankl points out that we are responsible not only to something but also to Someone, not only to the task, but to the Taskmaster.

Frankl differentiates between responsibility and responsibleness. The former comes from possessing the freedom of will. The latter refers to exercising our freedom to make the right decisions in meeting the demands of each situation. "Existential analysis aims at nothing more and nothing less than leading men to consciousness of their responsibility."

C. Will to Meaning

Frankl considers the will to meaning as "the basic striving of man to find and meaning and purpose." The will to meaning is possible because of the human capacity to transcend immediate circumstances. "Being human is being always directed, and pointing to, something or someone other than oneself: to a meaning to fulfil or another human being to encounter, a cause to serve or a person to love."

Self-transcendence often makes use of the power of imagination and optimism. Self-transcendence is essential for finding happiness, which is not the end, but the by-product of trying to forget oneself. "Only to the

extent to which man fulfils a meaning out there in the world, does he fulfil himself.”

D. Meaning of Life

Every meaning is unique to each person, and each one has to individually discover the meaning of each particular situation. The therapist can only challenge and guide the patient to potential areas of meaning: creative, experiential, and attitudinal values.

According to logotherapy, we can discover this meaning in life in three different ways: (1) by creating a work or doing a deed; (2) by experiencing something or encountering someone; and (3) by the attitude we take toward unavoidable suffering.

Attitudinal values are especially important in situations of unavoidable suffering. Frankl claims: “This is why life never ceases to hold meaning, for even a person who is deprived of both creative and experiential values is still challenged by a meaning to fulfil, that is, by the meaning inherent in the right, in an upright way of suffering.”

V. EXISTENTIAL FRUSTRATION AND NOOGENIC NEUROSIS

Existential frustration is a universal human experience because the will to meaning can be blocked by external circumstances and internal hindrances. Existential frustration leads to noogenic neurosis or existential vacuum. According to Frankl, “Noogenic neuroses have their origin not in the psychological but rather in the ‘noological’ (from the Greek *noos* meaning mind) dimension of human existence.” Therefore, logotherapy is uniquely appropriate in dealing with existential neuroses.

Existential vacuum refers to general sense of meaninglessness or emptiness, as evidenced by a state of boredom. It is a widespread phenomenon of the twentieth century, as a result of industrialization, the loss of traditional values, and dehumanization of individuals. People may experience existential vacuum without developing existential neurosis. Many feel that life has no purpose, no challenge, no obligation, and they try to fill their existential vacuum with material things, pleasure, sex, or power, busy work, but they are misguided. Frankl believes that “The feeling of meaninglessness not only underlies the mass neurotic triad of today, i.e., depression-addiction-aggression, but also may eventuate in what we logotherapists call a ‘noogenic neurosis.’”

Suffering is not a necessary condition for meaning, but it tends to trigger the quest for meaning. Frankl has

observed that people are willing to endure any suffering, if they are convinced that this suffering has meaning. However, suffering without meaning leads to despair.

Logotherapists do not ask for the reason for suffering, but guide their clients toward the realization of concrete meanings, and choose the right attitudes. Often, logotherapists appeal to their clients to take a heroic stand toward suffering, by suggesting that unavoidable suffering gives them the opportunity to bear witness to the human potential and dignity.

Search for meaning is more likely to be occasioned by three negative facets of human existence: pain, guilt, and death. Pain refers to human suffering, guilt to the awareness of our fallibility, and death to our awareness of the transitoriness of life. These negative experiences make us more aware of our needs for meaning and spiritual aspiration. Neuroses are more likely to originate from our attempt to obscure the reality of pain, guilt, and death as existential facts. Logotherapy provides an answer to the tragic triad through attitudinal values and tragic optimism.

VI. LOGOTHERAPEUTIC TECHNIQUES AND APPLICATIONS

Frankl considers noogenic neurosis as the collective neurosis of contemporary Western society. The goal of logotherapy is to enable patients to discover their unique meanings and consider their own areas of freedom. In cases of psychogenic or individual neurosis, which may be treated by traditional psychotherapy or medication, logotherapy serves as a supplement and helps break the vicious cycles of neurosis.

According to E. Lukas, the four main logotherapeutic techniques are paradoxical intention, dereflection, modification of attitudes, and appealing techniques.

A. Paradoxical Intention

Frankl defines paradoxical intention as follows: “The patient is encouraged to do, or to wish to happen, the very things he fears (the former applying to the phobic patient, the latter to the obsessive-compulsive).”

This technique builds on the human capacity for self-detachment to break the vicious cycle, which traps people in psychogenic neuroses, such as phobia, anxiety, and obsessive—compulsive behaviour. Self-attachment enables the patient to adopt a new attitude, to stand back or laugh at the situation or self. In applying paradoxical intention, the therapist tries “to mobilize and utilize exclusive human capacity for humor.”

For the phobic patient, he has a “fearful expectation” that a particular symptom might occur, and his fear creates “anticipatory anxiety, which in turn brings about what the patient fears to happen. Thus “fear of fear” creates a “vicious cycle.” The most common reaction to “fear of fear” is “flight from fear,” and the phobic pattern is maintained by excessive avoidance. This vicious cycle is broken when “the pathogenic fear is replaced by a paradoxical wish.” As a result, the patient no longer avoids situations that create anxiety.

With phobic patient, paradoxical intention typically begins with self-detachment (often after invitation and persuasion). The second step is to ask the patient to develop a new attitude of not fearing but welcoming the symptoms. This typically results in a reduction of symptom, which allows therapist to work toward enhancing meaningful living.

In the case of obsessive–compulsive disorder, the patient fights against the obsessions or compulsions. However, the more he fights against these symptoms, the stronger they become. Again, a vicious cycle is created. To break this vicious cycle, the patient with compulsive hand washing because of fear of infection would be told to tell himself “I can’t get enough bacteria, I want to become as dirty as possible.”

According to D. Guttman, paradoxical intention has been used with increasing frequency with good results especially in treating clients who suffer from phobias and obsessive–compulsive disorder.

B. Dereflexion

Frankl developed dereflexion to counteract hyperintention (trying too hard) and hyperreflection (thinking too hard). Examples of hyperintention include trying very hard to fall asleep, excessively pursuing pleasure, happiness, or power. Addiction is a form of hyperintention.

Hyperreflection involves excessively monitoring one’s performance, and becoming very anxious about failure. Hyperreflection may turn everyday minor problem into catastrophes, and small obstacles into insurmountable hurdles.

This technique is built on the human capacity of self-distancing and self-transcendence. The clients are asked to redirect their attention away from their problems to more positive aspects of their lives. For example, instead of worrying about not being able to fall asleep, the client is asked to use the time to read a book or watch TV. Typically, the first step is to help clients to put some distance between themselves and their symptoms. Then, they are invited to use their defiant power

of the human spirit to transcend their present conditions and move toward positive activities. This will result in a reduction of symptom.

Joseph Fabry points out that by immersing ourselves in work or by choosing the right attitude, we can transcend not only external conditions but also ourselves. The goal of dereflexion is to help clients transcend themselves and move toward creative and experiential values.

C. Modification of Attitudes

It is used for noogenic neuroses, depression, and addiction by promoting the will to meaning. It can also be used in coping with suffering related to circumstances, fate or illness. Generally, the emphasis is on reframing attitudes from negative to positive. For example, the client may be asked: “Is there anything positive about the situation?” or “What freedom is still available to you in this situation?”

D. The Appealing Technique

These three logotherapeutic techniques are more likely to be effective, when the therapist appeals to the client’s defiant power of the human spirit. The therapist makes use of the power of suggestion and directly appeals to the client to change for the better, regardless of the client’s current circumstances, and physical–emotional condition. The therapist expresses trust in the client’s dignity, freedom, responsibility, meaning orientation, and potential for positive change.

Frankl claims that “Logotherapy is neither teaching nor preaching. It is far removed from logical reasoning as it is from moral exhortation.” However, appealing often involves exhortation on the value of taking a heroic stand against suffering. For example, a nurse suffered from an inoperable tumor and experienced despair because of her incapacity to work. Frankl tried to appeal to her sense of pride and moral obligation to her patients:

I tried to explain to her that to work eight or ten hours per day is no great thing—many people can do that. But to be as eager to work as, and so incapable of work, and yet not be despair—that would be an achievement few could attain. And then I asked her: “Are you not being unfair to all those sick people to whom you have dedicated your life; are you not being unfair to act now as if the life of an invalid were without meaning? If you behave as if the meaning of our life consisted in being able to work so many hours a day, you take away from all sick people the right to live and the justification for their existence.

E. The Socratic Dialogue

In Socratic dialogue, the therapist facilitates the client's discovery of meaning, freedom, and responsibility by challenging and questioning. The dialogue may begin with a struggle between client and therapist but should never become negative.

According to Paul Welter: "Socratic questions need to be asked that stretch the thinking of the client. This requires careful listening to find the circumference of the client's thought." Another consideration is that counselors need to know the moment when silence is more curative. Often silence occurs when the clients reflect on the deeper meanings of words from the counsellors.

F. Family Logotherapy

J. Lantz has applied logotherapy to help the client family discover the meaning of opportunities within the family through social skills training, Socratic questioning, and existential reflection. According to E. Lukas, meaning-centered family therapy helps the family focus on meaningful goals rather than the obstacles; consequently, family members learn to overcome the obstacles to pursue meaningful goals.

G. The Therapist–Client Relationship in Logotherapy

Frankl tends to emphasize partnership between therapist and client in the quest for meaning. According to Lantz, logotherapeutic practice is based on the following assumptions: (a) commitment to authentic communication by the therapist, (b) the therapists' communication of essential humanness, and c) the therapist's ultimate concern being similar to that of the clients.

VII. RECENT DEVELOPMENTS

In the past 15 years, Dr. Frankl's classic logotherapy has been elaborated and extended by Alfred Langle and the International Association of Logotherapy and Existential Analysis (*Gesellschaft fur Logotherapie und Existenzanalyse*). This Viennese society (GLE-Wien) is parallel to Viktor-Frankl-Institut–Scientific Society for Logotherapy and Existential Analysis (*Wissenschaftliche fur Logotherapie und Existenzanalyse*), also in Vienna.

According to A. Langle, existential analysis is now a full-fledged psychotherapeutic method, of which Dr. Frankl's logotherapy is considered its subsidiary branch.

Langle has applied existential analysis to cases of psychosocial, psychosomatic, and psychogenic disturbances.

Langle recognizes four fundamental preconditions for meaningful existence: (a) accept the situation, (b) find some positive value in the situation, (c) respond according to one's own conscience, and (d) recognize the specific demands of the situation.

He also postulates four types of fundamental human motivations:

1. The question of existence: I am, but can I become a "whole" person? Do I have the necessary space, support, and protection?
2. The question of life: I am alive, but do I enjoy it? Do I find it fulfilling? Do I experience a sense of abundance, love, and realization of values?
3. The question of the person: I am myself, but am I free to be myself? Do I experience validation, respect, and recognition of my own worth?
4. The question of existential meaning: I am here, but for what purpose, for what good?

Langle has developed additional methods, such as the biographical method of using phenomenological analysis to overcome unresolved past issues and the project analysis to elucidate areas that have proved to be a hindrance to one's life.

Joseph Fabry was largely responsible for introducing logotherapy to North America. Under his guidance and encouragement, Paul T. P. Wong has developed the integrative meaning-centred counselling and therapy (MCCT). It focuses on both the transformation of cognitive meanings as well as the discovery of new purposes in life. As an integrative existential therapy, it incorporates cognitive-behavioral interventions and narrative therapy with logotherapy.

GLOSSARY

- behavior therapy** Application of interventions based on an understanding of learning principles.
- effectiveness** The degree to which a treatment produces positive outcomes in the context in which treatment most often is sought (i.e., “real world”).
- efficacy** Demonstrations that an intervention improves psychological status in well-controlled, experimental studies.
- functional analysis of behavior** Isolation of proximate, contextual causes of problematic behavior and the tailoring of therapy protocols to reverse these causes once identified.
- multicomponent treatment strategies** Therapies that contain treatment elements that are based on behavioral and cognitive-affective processes.
- treatment integrity** Degree to which the implementation of a specific treatment matches the way it was conceptualized and intended to be employed.
- treatment manuals** Written materials that identify key concepts, procedures, and tactics for the delivery of a clinical intervention.

I. DESCRIPTION OF MANUALIZED BEHAVIOR THERAPY

A. Treatment Manual Description

In general, treatment manuals for psychological disorders are written materials that identify key concepts, procedures, and tactics for the delivery of a clinical intervention. Accordingly, treatment manuals are designed to help modify the variables and processes believed to produce, maintain, or increase the magnitude or frequency of problematic behavior. As is typical of treatment methods in general, there is considerable diversity in regard to the level of specification in a particular manualized therapy, which is contingent, at least in part, on the treatment strategy being employed. Despite this diversity, all manualized therapies provide rules and statements pertaining to how therapists are to prepare for treatment, describe what they should do during the session itself, and characterize how the process of therapy is to proceed over time. In the case of behavior therapy, which reflects the application of interventions largely based on an understanding of psychological learning principles, manuals serve to characterize the treatment process for persons with an identified psychological disorder.

At least initially, the primary aim of developing and implementing manualized behavior therapies was to improve the evaluation of particular treatment strategies and entire treatment programs. Within this context,

manuals served to specify (in abbreviated form) the nature of the treatment, and articulate (in detail) how it was to be delivered. In this way, researchers would have available a precise and standardized clinical methodology that could easily be used in the evaluation of a particular treatment's efficacy. In addition, manuals provided researchers with the opportunity to standardize training in a specific treatment to increase the chance that the therapy would be delivered in the manner designated by and consistent with the theoretical underpinnings of the approach. Today, the development and utilization of manualized behavior therapies reflect an important breakthrough in the larger history of developing and evaluating psychosocial treatments for behavior disorders.

B. Reasons for Treatment Manuals in Mental Health Work

With the advantage of hindsight, it is quite easy to identify a number of key reasons why manualized therapies originally emerged in the mid to late 1970s. Prior to having standardized treatment methods and procedures, researchers often were left "in the dark" in regard to how a particular treatment was delivered. In the best-case scenario, questions about the effects of a clinical trial could be directed at how well a particular treatment was delivered. In the worst-case scenario, it was possible to question whether a particular treatment was really delivered at all, or at least whether the key components of that therapy were implemented. Other types of common concerns were aimed at such issues as whether the therapy under investigation was delivered in a consistent fashion across study participants. Still other concerns were aimed at how well the results could be replicated across independent research sites. All the questions, and others similar to them, essentially reflect questions of treatment integrity. A prerequisite for adequately addressing questions of treatment integrity from a scientific standpoint is to have a methodology that identifies the treatment of interest, and guides one in a step-by-step manner in regard to how it should be delivered.

In more recent years, the development and utilization of manualized behavior therapies have exceeded the boundaries of research circles. Indeed, the use of manuals in clinical contexts with no clear research objectives has been spurred on by health care policy changes demanding that psychological services follow guidelines for relatively brief treatments that have an empirical basis for outcome. Thus, despite

the fact that manuals have helped to improve the quality of large-scale clinical trials in accordance with their original intended purpose, it is perhaps not surprising that they increasingly have been the subject of controversy and intense debate. In fact, the use of treatment manuals has called attention to clinical issues that strike at the very heart of what treatment should be considered clinically useful and in what contexts it should be implemented (e.g., controlled or real world settings).

II. THEORETICAL BASES OF MANUALIZED BEHAVIOR THERAPY

A. General History

At the time of inception of behavior therapy, the prevailing paradigm in clinical psychology was psychodynamic. Since that time there has arguably been a major paradigmatic shift from psychoanalytic approaches to behavioral approaches. This transition was based, at least in part, on the observation that psychoanalytic methods for treating behavioral disorders have not been consistently demonstrated to be superior to no treatment, placebo, or other treatment conditions. In contrast, investigations of behavior therapy have emphasized empirical scrutiny and quantifiable behavior change. As a consequence, behavior therapy applications have been widely recognized as being very successful for treating a wide variety of behavioral problems, ranging from anxiety disorders to developmental disabilities.

B. Function Oriented

Behavior therapy differs from other forms of psychological therapies in regard to its commitment to basic research and link with behavior theory. Specifically, behavior therapy is aimed at determining environment-behavior relations that either can explain the cause or maintenance of maladaptive behaviors individuals typically seek treatment for in clinical settings. Elucidation of these environment-behavior relations has emerged from behavioral research, most notably operant and classical conditioning. Congruent with the laboratory research on which it is based, behavior therapy focuses on the function rather than the structure of behavior. In the most general sense, structural analyses focus on how people behave (e.g., form of a

particular response), whereas functional analyses focus on why people behave (e.g., purpose of a particular response).

In a functional approach, behavior therapists attempt to explicate the relation between observable behavior and the contextual variables of the environment, particularly focusing on observable antecedents and consequences of behavioral responses. For example, if a child's recurrent tantruming in a school classroom is routinely followed by attention from the teacher, a behavior therapist might encourage the teacher to praise the child when the child is not tantruming and ignore the child when a tantrum occurs. Thus, tantruming behavior aimed at receiving attention is not reinforced, thereby changing the function of such responding. This process of assessment, called a functional analysis of behavior, is the core of behavior therapy approaches.

C. Idiographic Oriented

The other major theoretical component of behavior therapies is that they have historically been idiographic (i.e., individual) rather than nomothetic (i.e., group) approaches to assessing and changing behavior. Nomothetic approaches, by definition, focus on the identification of the commonalities and differences among traits and dispositions that occur within and between groups of people. Idiographic approaches, on the other hand, focus on variability in the behavior of a person over time and across situations. As such, a second aim of the functional analysis is to identify consistent sources of variance for a particular person presenting to the clinic with a specific behavioral problem.

Despite the uniformity among behavior therapists commonly perceived by the public, it is important to note that not all behavior therapists are alike. Indeed, there are different behavioral approaches, differing in specific aspects of their clinical approach and the focus of treatment. This diversity is reflected in the numerous terms that have been employed to describe this general therapeutic approach (e.g., applied behavior analysis, behavior modification, cognitive-behavior therapy). Although these various terminologies capture relative differences in one's specific approach, behaviorally oriented therapists are all committed to changing maladaptive behavior through a functional, idiographic-based assessment of specified target behaviors. Thus, even in the case of standardized treatment manuals that identify the major processes functionally related to a particular disorder, treatments are tailored to the individual—at least at the level of

practical implementation. Through this identification of the controlling variables, it has been possible to develop standardized treatment strategies that are based on behavior principles to alter problematic behavior. To achieve these goals, behavior therapists attempt to provide their patients with a new set of learning experiences that are in accord with positive behavior change within the patients' value system.

III. APPLICATIONS AND EXCLUSIONS

A. Empirically Supported Therapies and the Use of Treatment Manuals

There have a number of important developments within the behavioral health care that have come to shape the application of manualized behavior therapies. Perhaps most influential has been the push to establish empirically supported therapies for a variety of recognized psychological disorders. This movement has been at least partially in response to cost-containment efforts in the health care system in general and funding-related restrictions for behavioral health services specifically. For example, health care policy changes have strongly recommended, and in certain cases demanded, that psychological services follow guidelines for relatively brief treatments that have an empirical basis for positive outcome.

The movement to develop lists of empirically supported therapies for target populations defined by diagnostic categories has been pioneered by the Division 12 Task Force on Promotion and Dissemination of Psychological Procedures. The function of the task force has been to critically review the existing empirical psychological treatment literature in an effort to identify those psychosocial interventions that have shown promise in alleviating specific types of psychological distress. Once potential treatments are identified and agreed on, the task force communicates this information to the behavioral health community. The task of charting efficacious treatments is an ongoing process, as researchers are continuously examining therapies, refining their components, and assessing their utility across different populations, sites, and time periods (see Section IV). In all cases, the therapies that are evaluated by the task force have been manualized to facilitate the understanding and evaluation of the treatment's key concepts, procedures, and delivery tactics.

B. Behavior Therapy's Contributions to Standardization of Psychosocial Treatments

As behavior therapy always has been committed to empirical evaluation and time-efficient strategies, it is not surprising behavior therapists have been at the forefront of the major developments in the movement toward empirically supported treatments. In fact, behavioral and cognitive-behavioral therapies overwhelmingly top the list of empirically supported therapeutic interventions for a wide variety of disorders. In an illustrative example, the majority of empirically supported treatments can be considered behavioral in their theoretical foundations, content, and implementation procedures. For example, of the “well-established treatments,” 93% are considered “behavioral” in content and procedures.

Whereas behavioral interventions were largely based on operant and classical conditioning principles through the late 1970s, cognitive treatment strategies have been increasingly added to these therapies from the 1970s through the 1990s. This evolution of behavior therapy reflects the growing recognition that internal processes such as thoughts and language characterize many important aspects of psychological dysfunctions. As an extension, many clinicians believe that by directly targeting cognitive-affective processes, they can facilitate positive behavior change along a greater number of different response domains. Thus, it is not surprising contemporary behavioral interventions can be best described as multicomponent strategies that contain treatment elements that are based on both basic learning principles and more recent developments in experimental cognitive psychology (e.g., research on memory biases). Hence, most behavior therapies are now described as cognitive-behavioral treatments and compiled in multiple component treatment manuals. Although it is not entirely clear at this juncture to what extent specific therapy components contribute to treatment outcome and maintenance, available evidence suggests that both cognitive and behavioral components contribute to the overall positive outcome achieved by cognitive-behavioral treatment protocols.

C. Contemporary Issues Related to the Potential Limitations of Manuals

There have been a number of controversies surrounding the use of manualized treatments (e.g., flexibility of therapist in treatment delivery, creativity of therapist, reification of treatment to a fixed manner). All these in-

tensely debated topics differ in content but essentially rest on questions concerning the relative utility of manualized treatments as applied to “real-world” behavior problems. For the purposes of this article, only two of the most common concerns will be described.

1. Manuals as Standardized Treatment Strategies

Some scholars have suggested that manualized behavior therapy undermines and restricts clinical judgment of individual therapists in the practice setting. Manualizing treatments could be problematic because most clinicians are highly sensitive to the individual needs and characteristics of their patients. Furthermore, greater degrees of flexibility often are needed to deliver treatment in the “real world” relative to when the treatments are developed and initially tested in clinical trials conducted in research settings.

Yet, these concerns must be weighed against the background of a large body of evidence that suggests personal biases typically are worse or at the very least not better than statistical prediction based on scientific analyses of persons with the same or similar type of problem. Thus, manualized treatments, which generally are based on scientific testing of groups of people, guide therapists in implementing what research rather than clinical judgment suggests is the most clinically appropriate thing to do. It is becoming increasingly evident that the “truth” lies somewhere between a strict individually tailored relative to a strict manualized approach. Indeed, insofar as a clinician can modify a manualized treatment to help identify and target aspects of an individual's behavior that might interfere with the successful implementation of a proven manual, success rates should continue to improve.

2. Manuals as Treatment Strategies for Comorbidity

Another concern raised about manualized therapies is that they often are developed from studies involving patients with a homogenous diagnostic profile yet are implemented clinically on patients with multiple behavior problems (i.e., diagnostic heterogeneity). Recent research in such areas as the anxiety disorders has seriously challenged this concern, as in the vast majority of clinical trials using manuals, patients have high rates of psychiatric comorbidity. In addition, many of these patients have not responded to alternative treatment strategies in the past, and in this respect, can be considered “treatment refractory” or at least “treatment resistant.” Of further interest has been the finding that

some manualized behavior therapies have been found to produce clinical improvement in other not specifically targeted behavior problems.

Taken together, then, it may be more appropriate to suggest that the clinical effectiveness of manualized treatment will be partially a function of presenting problem, nature of comorbidity, and the specific treatment being employed. With the recognition that this is a complex problem in need of further systematic study, it will be critically important for future research to address the generalizability of manualized behavior therapies across different clinical populations and settings. Along these lines, increased attention to questions of effectiveness will assume an increasingly critical role in determining the relative clinical utility and generalizability of particular psychosocial treatments.

IV. EMPIRICAL STUDIES

A. General Treatment Development and Evaluation Model

Psychosocial treatment development and dissemination is based on the stage model used by the Food and Drug Administration for the approval of drugs. Briefly, there are three primary units, each reflecting different stages in treatment development. Stage 1 reflects technological refinement and pilot research aimed at developing theoretically based treatment strategies that can usefully be applied to a specific type of psychopathology. Stage 2 is concerned with demonstrating that a particular treatment can produce positive behavior change in a controlled evaluation. In addition, in Stage 2, research can be aimed at ascertaining the mechanisms of action for a particular treatment (i.e., how it works). Stage 3 is field research involving larger samples of patients for the evaluation of treatments that already have shown initial success in Stage 2.

B. Empirically Supported Treatment Manuals

The empirically supported treatment task force evaluates all manualized therapies according to their efficacy; that is, demonstrations that an intervention improves psychological status in well-controlled, experimental studies. This research differs slightly from questions of effectiveness, defined as the relative degree of utility of a treatment to produce positive outcomes in the context in which treatment most often is sought. Typically, large-

scale clinical trials are used to evaluate and demonstrate the efficacy of psychological interventions. Such evaluations are outcome oriented, that is, they typically are an evaluation of a particular type of therapy compared to some type of control group (e.g., placebo, other form of therapy), although a variety of different evaluation formats exist (e.g., series of single case studies).

The criteria for demonstrating efficacy are categorized as either “well-established treatments” or “probably efficacious treatments.” Although it is not possible to review the criteria for each of these domains in their entirety, well-established therapies generally have demonstrated superior outcome compared to a control condition (e.g., placebo) or another treatment on two separate occasions by independent investigators. In contrast, probably efficacious treatments generally indicate that a treatment is superior to persons who desire psychological treatment but are on a waiting list for such treatment.

In all cases, the evaluation process involves persons with a particular type of psychological disorder being randomly assigned to a specified treatment condition. For example, patients with panic disorder may either be randomly assigned to receive an “active” psychological treatment or separate treatments such as a medical drug or a placebo pill. In these trials, patients are then evaluated in a standardized manner over the same amount of time using the same types of clinically relevant outcome measures. Overall, these efforts allow one to determine whether a therapy can reduce psychological distress in both a statistically and clinically useful way.

V. CASE ILLUSTRATION

For purposes of this article, a clinical case presentation of an individual with panic disorder may help illustrate the use of a multicomponent treatment manual that is prototypical for other treatment manuals used for the majority of psychological dysfunctions.

A. Case Description

Sam is a 33-year-old married white male with a 10-month history of recurrent panic attacks. His panic attacks occur in an unpredictable and uncontrollable manner and last for approximately 2 to 15 min. Sam indicated that his panic attacks occur at least once every other day and involve chest pain, difficulty breathing, racing and pounding heart, increased sweating, and lightheadedness. As a result of these symptoms, Sam

believed he had cardiac disease. Due to the worry about the panic attacks, Sam had begun to avoid socializing with friends and family and declined professional opportunities to travel for his job as a computer programmer. After a thorough medical exam that found no indication of cardiac or other medical problems, Sam was referred to an anxiety disorders treatment center at a university hospital. After a psychiatric interview and testing, it was determined Sam suffers from panic disorder.

B. Manualized Therapy for Panic Disorder

We now discuss how Sam might be treated with a current well-established therapy for panic disorder and agoraphobia termed panic control therapy (PCT). This multicomponent cognitive-behavioral intervention is guided by the use of a treatment manual entitled *Mastery of Your Anxiety and Panic-II (MAP-II)* that articulates the procedures for PCT in a step-by-step fashion. Manual-based therapies like the *MAP-II* also include self-report and behavioral assessment tracking instruments that can be readily employed to evaluate treatment progress of individual patients across different time frames.

MAP-II contains a number of key components, including exposure to bodily and environmental situations associated with fear and panic, relaxation, and breathing retraining, as well as cognitive interventions. Briefly, exposure to interoceptive bodily events is achieved through exercises that produce somatic sensations that are similar to panic (e.g., head spinning, breathing through a straw). Situational exposure involves contacting feared environmental stimuli without escaping from them if panic symptoms occur. For instance, a person with panic disorder with agoraphobia who fears crowds might be asked to go to a shopping center and stay there for a specified period of time or until potentially high levels of anxiety have subsided. Relaxation training refers to exercises that serve to decrease base levels of autonomic arousal, as this decreases the likelihood of future panic attacks. Breathing retraining refers to having patients breathe diaphragmatically at a normal rate in an effort to optimize the balance between oxygen and carbon dioxide in the patient's blood. Cognitive strategies typically are aimed at (a) correcting misappraisals of bodily sensations as threatening, (b) helping patients to predict more accurately the future likelihood of panic attacks, and (c) helping patients to predict more accurately and rationally the likely consequences of panic attacks.

C. Treatment Process with Manual

Sam's treatment would most likely be conducted in an individual setting over a period of about 2 months. As is the case for most psychosocial interventions, the *MAP-II* first provides Sam with educational information about the nature, origin, and course of panic disorder prior to the application of specific intervention strategies. This information helps patients realize that they are "not alone" and communicates that professionals understand their specific type of problem. The second and ongoing step in Sam's *MAP-II* treatment would be to have him monitor both negative emotional experiences and stressful life events to facilitate the recognition and identification of environmental events that contribute to the occurrence of recurrent panic attacks. Identifying such negative life events makes the potential occurrence of panic attacks more predictable and perhaps controllable, thereby lessening their aversiveness.

Third, the therapist would train Sam in relaxation and breathing exercises and have him practice these exercises until he has acquired the skill of reducing and controlling bodily arousal. Throughout *MAP-II* therapy, the therapist is instructed to guide Sam in correcting maladaptive cognitive errors related to worry about the negative consequences of panic attacks. For example, during cognitive restructuring, Sam would be taught to reconceptualize his panic attacks as harmless events that occur in response to "natural" stressors. Finally, Sam would participate in repeated trials of interoceptive exposure, and if necessary, exteroceptive exposure exercises in both the clinical setting and his natural environment. Such exercises would be continued until such stimuli no longer elicit significant levels of anxiety. Therapy would be discontinued when Sam's condition improved to a level that he can adequately perform his life tasks and his psychological status has returned to a healthy level.

VI. SUMMARY

In summary, treatment manuals are written materials that identify key concepts, procedures, and tactics for the delivery of a clinical intervention. In this manner, treatment manuals are designed to help modify clinically relevant variables and processes involved with problematic behavior. Although manuals can be quite diverse, all provide rules and statements pertaining to how the therapist is to prepare for treatment, describe what they should do during the session itself, and characterize how the process of therapy is to proceed over

time. Manuals have greatly helped in efforts to improve the evaluation of particular treatment strategies by specifying the nature of the treatment and articulate how it is to be delivered. More recent, manualized behavior therapies have become apparent in clinical service contexts, calling attention to clinical issues that strike at the very heart of what treatment should be considered “clinically useful” and in what contexts it should be implemented (e.g., controlled or real-world settings).

An extension of the treatment utility issue has been the development of empirically supported therapies for target populations pioneered by the Division 12 Task Force on Promotion and Dissemination of Psychological Procedures. Testifying to the established place of manuals in contemporary clinical care, all therapies that are evaluated by the task force have been manualized so as to facilitate the understanding and evaluation of the treatment’s key concepts, procedures, and delivery tactics. Perhaps because behavior therapy has always been committed to empirical evaluation and time-efficient strategies, it is not surprising the majority of empirically supported treatments can be considered behavioral in their theoretical foundations, content, and implementation procedures. Although the use of manuals has been controversial in a number of respects, few would challenge the contention that they likely will retain in an important and influential role in continued evolution of psychological treatment in upcoming years.

others and that, in clinical practice, treatment outcomes can be improved by matching subgroups of patients with the therapy most suited to their particular needs using matching rules derived from previous experience.

GLOSSARY

alcoholism Alcoholism (also referred to as alcohol dependency) is an addictive disorder diagnosed by a series of specific DSM defined criteria such as, progressive loss of control over drinking, tolerance, withdrawal symptoms, continued drinking despite adverse consequences, narrowing of usual activities in favor of alcohol seeking.

clinical trial A clinical trial is a prospective experiment in which therapeutic interventions are evaluated. Desirable features which increase the rigor of the experiment include random assignment to treatment group, masking of clinician, research assessor and patient with respect to treatment assignment, and in the case of pharmacologic studies, use of matched placebo.

matching factors Matching factors are patient characteristics that affect outcomes differentially when two or more treatments are compared.

outcome predictors Outcome predictors are characteristics that influence the outcome of treatment across the board but do not have differential effects depending upon the type of treatment.

Patient-treatment matching is the concept that particular treatments may work better for some patients than

I. DESCRIPTION OF TREATMENT

Patient-treatment matching occurs when treatment is prescribed based on the needs of the individual patient, as contrasted with providing the same therapy to all patients with the same diagnosis. It has been suggested that triaging clients to treatments based on their particular needs and characteristics might significantly improve outcome. The potential of the matching hypothesis has been of particular interest in the treatment of alcohol use disorders, prompting researchers and clinicians to search for assignment rules to individualize selection of psychosocial treatments. The literature in this area spans several decades and includes small-scale studies, reports from a large multisite clinical trial, and examinations of underlying theory and clinical practice implications. It provides a useful example to illustrate the rationale and implementation of the matching hypothesis and is used as the model here. Although the focus here is alcohol dependency as the target for patient treatment matching interventions, the concept is relevant to other disorders and has been used to varying extents in numerous medical, psychiatric, and educational contexts.

In its most basic form, matching is done informally by providers when, based on their clinical judgment,

they provide treatment “tailored” to specific features of the patient and the patient’s disorder. Patients may also practice “self-matching” when they contribute to varying degrees to treatment decisions based on, for example, their beliefs about various treatments and what will benefit them, or other influences, such as availability of resources, advice from others, and so on.

However, the formal practice of matching in clinical and research settings is based on validated rules that link particular patient characteristics with certain treatments. Typical steps in the matching process are: (a) systematic assessment of patient characteristics and needs, (b) availability of specific matching rules, and (c) consistent assignment of patients to well-defined treatment in accordance with the specified matching rules. Ideally, the guidelines should be based on validated research, and patient outcomes should be monitored to determine the extent of improvement and if modifications are necessary.

In addition to matching patients with treatments, matching of patients to therapists has also been of interest and is reviewed by the Project MATCH Research Group in 1998 who concluded that therapist effects on treatment outcome may contribute more toward explaining the variance in outcomes than either specific treatments employed or baseline patient characteristics. Reporting on a study of therapist influence on treatment outcome conducted as a part of the multisite Project MATCH, they found that therapist effects did indeed exert an effect on treatment outcome as well as patient satisfaction with treatment. Interestingly though, most of the observed effects were due to “outlier” therapists whose clients tended to show poorer outcomes. They advise that future studies take into account the potential effect of “outlier” therapists.

Until relatively recently, matching to treatments for alcohol dependence has involved interventions of a verbal nature, such as behavioral therapies, counseling, and psychotherapy. Beginning in the 1990s, the development of medications that target neurochemical systems implicated in the addictive process have brought a new and promising approach to treatment of alcoholism. In addition to clinical trials evaluating the efficacy of these drugs, (both alone and in combination with verbal therapies) matching hypotheses have also been tested. As knowledge emerges on the neurochemical and neurogenetic determinants of alcohol addiction, the rationale is strengthened for hypothesizing that outcome may be improved when particular neuroactive medications are linked to certain patient characteristics of known biological basis.

II. THEORETICAL BASES

Interactions differ from predictors in that predictors affect the outcome of treatments in a similar way (Figure 1A). In contrast, interactions arise when the patient characteristic of interest has a differential effect on the treatments being compared (Figure 1B and 1C). Thus, the main effects of different treatments may suggest that they have similar benefits, however, analyses that examine the interactions between certain patient and treatment types may make differential benefits evident.

The idea of matching is not new, having first been proposed in the alcohol treatment area in 1941 by K. Bowman and E. Jellinek and is common to other fields such as psychiatry, medicine, and education. R. E. Snow in 1991 discussed aptitude-treatment interactions as derived from the educational psychology literature as a framework for research on individual differences in psychotherapy.

Matching came to be of interest to alcoholism treatment researchers when despite decades of outcome research no clearly and generally superior treatment(s) that could be considered the “magic bullet” of alcoholism treatment emerged. In parallel, thinking concerning the nature of alcoholism diversified and a view of the disorder as the end result of a complex interaction of factors—environmental, personal, interpersonal, and biological—competed with the predominant medical model of alcoholism as a unidimensional disease. It was suggested that perhaps the “one-size-fits-all” approach was inappropriate for alcoholism treatment. The notion that perhaps the missing ingredient in the treatment selection process was the matching of patient to treatment began to evolve.

The hypothesis was that perhaps the addition of matching could enhance outcomes above and beyond what could be accomplished by simply choosing generally effective treatments and paying attention to generic curative elements such as support, rapport, and communication from the therapist. This concept was fostered by about 40 studies published in from the 1970s through the 1990s suggesting that a variety of patient features—demographic, drinking relating factors, intrapersonal characteristics, and interpersonal factors—appeared to “match” with particular treatments.

III. EMPIRICAL STUDIES

A. Early Studies

Development of the experimental database pertaining to the patient-treatment matching hypothesis may

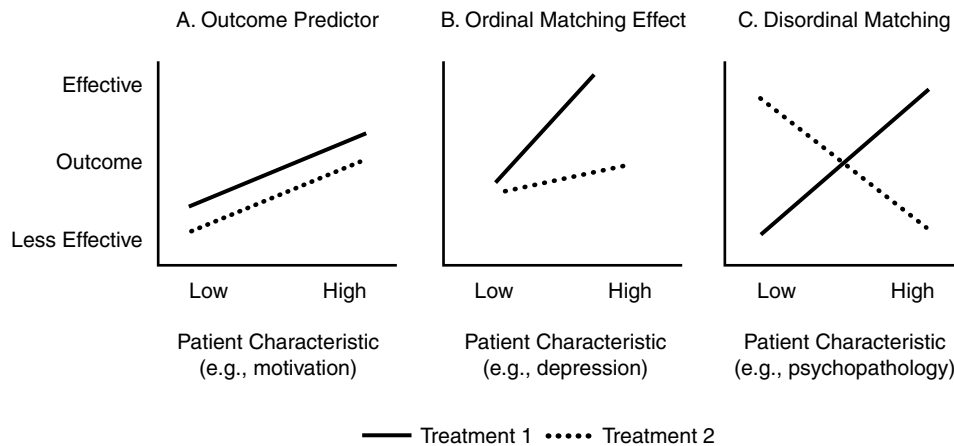

FIGURE 1 Three hypothetical examples of the relation of patient characteristics to treatment success are presented. The X axis (horizontal line) of each graph reflects the degree to which a patient has a certain characteristic. It may be a continuous variable (i.e., a patient may lie anywhere along a spectrum of characteristic levels varying from low to high), such as the degree of a patient's motivation, or a dichotomous variable, such as the presence or absence of a family history of alcoholism (not shown). The Y axis (vertical line) is a measure of treatment outcome (e.g., the percentage of days in a given period that the patient consumed alcohol). The relationship between the two lines that represent the two treatments being compared reveals information about the effects of varying levels of patient characteristics on outcome. (A) The relationship between an outcome predictor and two treatment types is shown. For example, how does a client's motivation affect the outcome of two different treatments? The outcome of treatment with both therapies is related to the patient's characteristic (i.e., the higher the motivation, the better the outcome for both treatments, although Treatment 1 appears a bit more beneficial than Treatment 2). The fact that the lines are parallel indicates that the effect of the patient's motivation is similar for both treatments. Therefore, the characteristic factor is an outcome predictor that does not affect the treatments differentially. (B) An ordinal matching effect is shown. Patients with low levels of the characteristic of interest, such as depression, appear to have about the same success regardless of the treatment they receive. For patients with higher levels of depression, the results diverge, and there is a definite advantage in choosing Treatment 1. (C) Disordinal matching is shown. Patients with low levels of a characteristic, such as psychopathology, have better success when receiving Treatment 2 than Treatment 1. For patients with high levels of psychopathology, the opposite occurs: Treatment 1 is more effective than Treatment 2.

be roughly divided into two eras. The first era consists of about 40 studies from the 1970s through the early to mid-1990s. These were mostly smaller scale, single-site studies. Some of the studies from the earlier portion of this period had methodological shortcomings, such as lack of a priori hypotheses; differing, less well documented therapies, and varying outcome measures that detracted from the studies and made comparisons across studies difficult. Nevertheless, the accumulating body of knowledge was viewed as promising not only for improving patient outcomes but also for making more effective use of ever-decreasing resources as reimbursement policies and other economic forces began to change the face of addiction treatment in this country.

During the 1980s and early 1990s, methodologic advances occurred in addiction clinical research and numerous more sophisticated matching studies were reported, further strengthening the hope for matching as a clinical tool. An important catalyst were two reports from the Institute of Medicine in 1989 and 1990

calling for additional definitive and systematic research on this question. The matching hypothesis had become part of the national research agenda.

B. Project MATCH

The second era of matching studies was marked by the 1989 launch of a multisite clinical trial, Project MATCH, by the National Institute of Alcohol Abuse and Alcoholism (NIAAA) the principal sponsor of research on alcohol disorders in the United States. It was conceived of as the largest, most statistically powerful and most methodologically rigorous psychotherapy trial ever undertaken. The stated objective was to subject the matching hypothesis to its most rigorous test to date. Its research questions were based largely on the previous body of published studies and the latest knowledge of treatments believed to be generally effective and suitable for delivery both in a multisite clinical trial and in actual clinical practice.

1. Project MATCH Design

The details of the rationale and design of Project MATCH are described in a publication of the Project MATCH Research Group in 1993 and by D. Donovan and M. E. Mattson in a 1994 monograph. The study tested promising patient-treatment combinations involving 21 patient characteristics and three treatments: twelve-step facilitation (TSF), motivational enhancement therapy (MET), and cognitive-behavioral therapy (CBT). After determination of eligibility and an extensive baseline assessment, 1,726 patients were randomly assigned to one of the three treatments. The treatments were administered during a 12-week period by trained therapists following standardized manuals. Therapist supervision continued during the trial to ensure fidelity to the treatment protocol across all sites. The treatments are described in three therapists manuals written by their developers and published by the National Institute of Alcohol Abuse and Alcoholism as part of the eight-volume Project MATCH Monograph Series.

Drinking outcomes and other indicators of function were assessed at the end of treatment (3 months) and thereafter at 6, 9, 12, and 15 months. A subset (outpatients only) were recontracted 39 months after treatment. The two primary drinking outcome measures were percentage days abstinent and drinks per drinking day.

2. Project MATCH Sample

Patients were treated at nine locations in the United States. Five sites functioned as outpatient clinics, and five sites delivered Project MATCH treatments as aftercare following an episode of inpatient treatment or intensive day hospital. (One site had both an outpatient and aftercare capacity.) Treatment-seeking clients at the 9 locations were recruited from a total of 27 treatment facilities. Individuals with concurrent drug dependence diagnoses (other than marijuana) were excluded from the trial. The participants were almost exclusively alcohol dependent (as opposed to alcohol abuse only) and had an average of six (out of a possible nine) *DSM-III-R* dependence symptoms, and drank on average 25 days per month, with an average of 15 drinks per drinking day. Over one half had a history of prior treatment for alcoholism, approximately 75% were male, and almost all showed chronic effects of alcohol consumption on various areas of life functioning.

3. Project MATCH Hypotheses

Based upon previous research, a series of client characteristics were identified and tested as potential treatment-matching variables. The matching variables and the measures used to operationalize them are described

in several publications authored by the Project MATCH Research Group. The patient-matching characteristics were alcohol involvement (i.e., severity of alcohol problems), cognitive impairment, conceptual level (a measure of abstraction ability), gender, meaning seeking (i.e., desire to find greater purpose in life), motivation (i.e., readiness to change), psychiatric severity, sociopathy, social support for drinking, alcoholic subtype, severity of alcohol dependence, psychiatric diagnosis (Axis I disorder), antisocial personality, anger, self-efficacy, social functioning, prior engagement in Alcoholics Anonymous, religiosity, treatment readiness, autonomy, and problem recognition. Hypothesized interactions between each of these client characteristics and the Project MATCH treatments were specified at the beginning of the trial. The matching hypotheses were a priori, that is specified in advance, and were not revealed during the trial to therapists and research assistants to maintain objectivity in treatment and assessment.

4. Project MATCH Results

In the following section, we consider how results of Project MATCH answered two questions: (a) How did patients fare in the different treatment conditions? and (b) Were any treatments particularly effective in subgroups of patients defined by the characteristics listed above?

a. Results: Main Effects. Patients in all three treatment conditions demonstrated major improvements in drinking, as well as other areas of functioning such as depression, use of illicit drugs, and liver enzyme status. Overall, MATCH clients were abstaining over 85% of the days throughout the year following treatment, and alcohol consumption decreased fivefold. Even those not successful in maintaining abstinence who continued to drink experienced a substantial reduction in alcohol consumption. In general, effects for the three treatments were similar, with the exception that 10% more of the outpatients receiving TSF attained complete abstinence over the 1-year follow-up period compared to the other two treatments. In addition, more aftercare patients were able to sustain complete abstinence throughout the year after treatment than the outpatients, despite the fact that the aftercare patients entered the study with more alcohol dependence symptoms.

b. Results: Matching Interactions. The findings of Project MATCH surprised many and challenged the belief that patient-treatment matching was critical in the treatment of alcoholism. Contrary to the expectations

generated by the supporting literature, large and uniform effects for matches between single-patient characteristics did not emerge. Many hypothesized matches were not supported, and those found were, for the most part, of rather modest magnitude and often varied over time, between arms of the trial, and for the two primary outcome measures.

Of the 21 patient variables studied, the four with matching effects deemed more plausible were those involving, in the outpatient arm: psychiatric severity, client anger, and social network support for drinking, and, in the aftercare arm, alcohol dependence. These are briefly described.

Patients in the outpatient arm with low psychiatric severity treated with TSF had more abstinent days as compared to those treated with CBT, a differential as high as 10% for several months during the follow-up period. The largest difference occurred 6 months after the end of treatment, when clients without concomitant psychopathology had 87% days abstinent in TSF versus 73% in CBT.

Motivational enhancement therapy was postulated to be more effective for clients with higher anger scores presumably because of its non-confrontive nature. MET clients in the outpatient study who were high in anger were abstinent more often than clients receiving the other treatments (a differential of 9%, i.e., 85% vs. 76%) and drank less intensely when they did drink. Clients with low anger fared better in CBT and in TSF as compared to MET. The effect persisted throughout the 1 year after treatment and was also present at the 39 months follow-up. This finding was the most consistent matching result across time.

As predicted, clients having a social network supportive of drinking did better in TSF than in MET. This difference was not apparent in the first year after treatment, emerging among the outpatients at the 3-year follow-up. TSF patients reported abstinence on 83% of days versus 66% for the MET patients. This difference of 17 percentage points was largest size effect observed in Project MATCH. The effects appear due to a steady decline among clients with high drinking support in the MET group after the end of treatment, whereas the TSF group maintained their gains. An influential factor may be differences in levels of AA attendance, with attendance levels higher in the TSF group than in the MET group.

It had been hypothesized that clients high in alcohol dependence would do better in TSF whereas those lower in that trait would benefit more from CBT. Because TSF is a treatment that puts greater emphasis on total abstinence, it was postulated to be more effective with highly dependent clients than either CBT (which

taught skills to deal with “slips”) or MET (which focused on clients’ own decision making to motivate them to become abstinent). Aftercare clients low in alcohol dependence had better outcomes when treated with CBT than TSF (i.e., abstinence on 96% of post-treatment days vs. 89%). However, at higher levels of dependence, the better treatment choice was TSF (i.e., 94 vs. 84% days abstinent). The effect was consistent for the posttreatment period of 15 months.

c. Results: Clinical Implications. The clinical implications of Project MATCH were described by the investigators in a 1998 publication as follows:

In summary, the results of testing the *a priori* matching hypotheses showed several matches of modest-to-moderate magnitude, often with variability over time, outcome measures and arm of the study. These results suggest that matching clients on several of the attributes tested in Project MATCH to one of the three treatments appears to enhance outcomes to a modest degree, with the most robust of the confirmed effects constituting a moderate difference of 17 percentage points in abstinent days.

The Project MATCH Research group concluded that viewpoints differ on how clinically important these single characteristic effects are, although, overall, the findings do not suggest that major changes in triaging procedures are warranted. R. Longabaugh and P. Wirtz have extensively analyzed the mechanisms and “active ingredients” involved in the matching hypotheses and have discussed possible reasons for the failure to find a greater number of matches.

C. Medications as Matching Targets

The literature on pharmacological agents in the treatment of alcoholism have been reviewed extensively and point to the increasing potential of pharmacologic agents as aids in treatment of alcoholism.

In the early 1990s interest in the opiate antagonist naltrexone as an adjunct in the treatment of alcohol dependence was illustrated by key studies from two groups in 1992, that of O'Malley and colleagues and Volpicelli and colleagues. Previously used as a treatment for opiate dependence, naltrexone was approved for treatment of alcoholism by the FDA in 1994. Previously, the only approved drug for this purpose was disulfiram (Antabuse). Disulfiram functions as a deterrent to drinking by producing an aversive effect if alcohol is consumed through inhibition of aldehyde dehydrogenase, an enzyme involved in the metabolism of alcohol.

Data from studies of the efficacy of naltrexone were subjected to subsequent post hoc analyses by A. J. Jaffe and associates in 1996. These results illustrate the possibility of matching subgroups of patients to drug/psychosocial combinations. The question examined was "Do patients with certain baseline characteristics respond more positively to the drug/psychosocial combinations than those without these characteristics?" The authors concluded that naltrexone appears more beneficial for alcoholics with high craving and poorer cognitive functioning.

Research by Mason and colleagues in 1996 suggested that the use of the antidepressant desipramine may reduce the risk of relapse in depressed alcoholics, but not in the nondepressed. In 1994, H. R. Kranzler and others found that buspirone appeared more helpful to anxious alcoholics although the same had not been observed in a previous 1992 study by Malcom and colleagues. In 2000, two studies on the agent ondansetron, a 5-HT₃ antagonist, suggested it differentially affected drinking in early versus later-onset alcoholics. Early-onset alcoholics were defined as those who showed drinking problems earlier in life, had antisocial characteristics, and a family history of the disorder in first-degree relatives. They found that ondansetron reduced drinking preferentially in the early-onset group. In a small pilot study also in 2000 the same investigators combined ondansetron with naltrexone and found that the combination reduced alcohol consumption in the early-onset group to a larger degree than either of the two medications alone.

Based on preliminary studies such as these, it is tempting to speculate that perhaps new and better matching algorithms may be found when matches are based on pairing of pharmacologic treatments with biologically based patient characteristics. Much additional research remains to determine if intriguing, but preliminary, results can be replicated and extended. Needed are future studies with larger samples in multiple sites and settings, and greater understanding of the neurochemical mechanisms underlying clinical observations. The future of matching patients to pharmacologic treatments remains open pending further investigation.

IV. SUMMARY

Although many alcoholics indeed benefit from treatment, no single treatment has been shown to be effective for all those diagnosed with the disorder. For many decades it was suggested that assigning alcoholic patients to treatments based on their particular needs and characteristics might improve treatment outcomes. In-

terest in matching accelerated during the 1970s and 1980s as supporting evidence accumulated in the literature. However, these studies were small scale, and replication was required before specific recommendations for clinical practice could be advanced. In late 1989 NIAAA launched a multisite clinical trial, Project MATCH, with the goal of learning whether different alcoholics respond selectively to particular treatments. The study tested a promising set of patient-treatment combinations in 1,726 patients randomly assigned to three well-defined psychosocial treatments.

Patients in all three treatment conditions demonstrated major improvements in drinking, as well as other areas of functioning such as depression, use of illicit drugs, and liver enzyme status. However, in terms of matching the findings of Project MATCH challenged the popular belief that matching patients to treatment was needed to significantly improve outcome. Of the 21 patient characteristics evaluated, only four statistically significant matches with potential clinical implications were identified. These matches involved psychiatric severity, anger, social support for drinking, and alcohol dependence.

Viewpoints differ on how clinically significant these single characteristic matches are, given their overall variability over time and the rather modest size of most of the effects. The Project MATCH investigators in 1998 concluded that

matching clients to particular treatment, at least based on the attributes and treatment studied in Project MATCH, is not the compelling requirement for treatment success as previously believed. The matches found, however, are reasonable considerations for clinicians to use as starting points in the treatment planning process.

It may be that other patient characteristics, or other treatments, or settings not studied in this large project may have matching potential. For example, continued future work involving matches of patient characteristics with pharmacological treatments that target the neurochemical pathways involved in addiction will assess the robustness of preliminary findings on this variant on the matching theme. Until such validation is forthcoming, no clinical guidelines can be made with reasonable certainty.

GLOSSARY

countertransference The therapist's partly unconscious or conscious emotional reactions to the patient.

psychodynamics The systematized knowledge and theory of human behavior and its motivation, the study of which depends largely on the functional significance of emotion. Psychodynamics recognizes the role of unconscious motivation in human behavior. The science of psychodynamics assumes that one's behavior is determined by past experience, genetic endowment, and current reality.

psychoeducation Information in which the content is psychological or psychiatric in nature.

somatization The unconscious manifestation of psychological conflicts, either fully or in part, as somatic or body symptoms.

transference The unconscious assignment to others of feelings and attitudes that were originally associated with important figures in one's early life.

In this article, we highlight the complex relationship between medical illness and emotional or psychological distress and present options for psychotherapy treat-

ment. This task is complex because of the variety of medical illnesses that individuals experience (e.g., from seasonal allergies to life-threatening forms of cancer), the unique psychological composition and reaction of each individual, and the many available treatment options that have been determined as efficacious.

Is there an association between medical illness and emotional distress? Among many patients, there appears to be. For example, 10 to 15% of individuals with medical illnesses suffer from depression, and among those with chronic illness, the prevalence of mood disorders increases up to 25 to 50%. It has been estimated that up to 25% of cancer patients suffer from depression, and that cancer treatment, itself, results in emotional distress for 40 to 60% of patients. Among patients with active medical illness, depression is one of the most common psychiatric complications in medical treatment and outcome. Surprisingly, not all patients with medical illness suffer from emotional distress, but no one knows exactly why this is.

Does emotional distress truly influence medical treatment and outcome? Among patients with similar types and severity of illness, those with depression remained in hospital for longer periods of time (up to 10 days). Depression among diabetic patients is associated with poor treatment compliance and an increased risk for vascular complications. Among cardiac rehabilitation patients, those who received treatment for depression had lower rehospitalization rates. Finally, following the hospitalization of one family member,

studies indicate that there is an increase in the health care utilization of the remaining family members during the subsequent 3 years. These examples underscore that psychological factors appear to have an effect on one's response to medical illness and treatment.

In examining that effect, it is clear that medical illness is associated with some form of loss. Whether the loss is functional (e.g., use of one's legs), economic (e.g., inability to sustain employment), relational (e.g., loss of significant other, friends, or family), and/or self-esteem, a variety of factors affect how illness will be experienced. For example, there may be factors that predate the medical illness, such as early developmental psychodynamics, major psychiatric disorders, and/or personality traits or disorders, that affect the subsequent experience of illness. In addition, the arrival of medical illness may precipitate major psychiatric disorders as well as psychodynamic issues related to the illness experience.

I. DESCRIPTION OF THE TREATMENT

A. Assessment

1. Patient Reactions to Psychological Referral

Patients may be self-referred or referred by the treating clinician or family for psychological treatment. The patient's perception of the referral for psychological intervention may affect the entry into the treatment process. For example, negative reactions may result in failed appointments and, thus, prolonged psychological distress.

Referrals for psychological assessment and treatment may precipitate a variety of patient concerns. These may include social stigmatization (e.g., "Others will think I'm crazy!") as well as damage to self-esteem (i.e., "I can't do this on my own?"). Psychological referrals may be confusing to the patient who does not understand the relationship between emotions and medical illness. In addition, the patient may resist psychological referral if the recommendation is misinterpreted as an abandonment by the physician.

2. Selection Criteria for Psychotherapy Treatment

The selection criteria for entry into psychotherapy treatment vary from therapist to therapist. In general, the patient must be sufficiently intact on a cognitive level to enable participation in treatment. Among pa-

tients with medical illness, common concerns are the cognitive effects of drug treatment as well as delirium. Patients must be able to verbally interact (e.g., exclusions include aphasic patients) and reasonably able to relate to others (e.g., exclusions include severe personality disorders such as schizoid or antisocial personalities).

The ideal patient has a healthy and mature relational capacity. H. Levenson and R. E. Hales note the importance of the patient's ability to view issues in psychological terms, respond to a therapeutic experience in a positive manner, and make adaptations through personal strengths. These authors indicate that psychological pain may actually function as a potent motivation for treatment and emotional growth.

3. Contributory Factors to Psychological Distress among the Medically Ill

In the psychological assessment of the patient with medical illness, the psychotherapist must consider various contributory factors that might account for emotional distress. These factors, which become focal points in the subsequent development of a treatment plan, are described later and noted in Figure 1.

a. Early Developmental Issues Early developmental issues can temper the present-day experience of medical illness. Areas that might be explored with the patient include: (1) the relationship with parents, particularly parental effectiveness as caretakers (i.e., based on past experience, can the patient reasonably trust others to take care of him/her?); (2) the family philosophy of and approach to illness (e.g., acceptability, response patterns

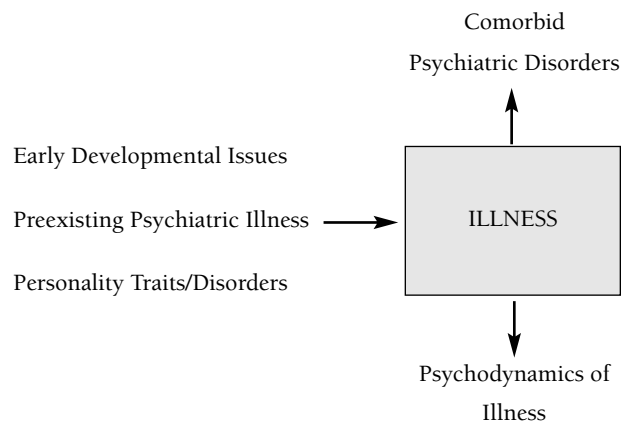

FIGURE 1 Contributory factors to emotional distress in patients with medical illness

to ill members, support and involvement; did parents effectively address, discredit, or dramatize illness in family members?); (3) prior personal experience with illness including illness among family members and friends; and (4) personal tolerability of dependency. It is also important to explore any cultural context or meaning of illness (e.g., the interpretation of hallucinations during delirium as a spiritual visitation from ancestors), and the expected response to illness within a specific culture, if applicable.

b. Preexisting Psychiatric Disorders Some of the current emotional distress may have actually predated the medical illness (i.e., the patient may have a preexisting psychiatric disorder). This possibility is based on the expected prevalence rates of major psychiatric disorders in the general population. For example, according to the National Comorbidity Survey, the lifetime prevalence of any depressive disorder is nearly 20%, anxiety disorder 25%, and substance abuse 27%. Therefore, it is worthwhile to explore for preexisting psychiatric disorders, particularly acute depression (major depression), chronic depression (dysthymic disorder), and substance abuse. These disorders may presently be comorbid, or co-exist, with the medical illness.

In addition to preexisting major psychiatric disorders, some adult patients also suffer from personality disorders. With their onsets in childhood, personality disorders result in long-standing and consistent deviations in cognition, behavior, and interpersonal relationships—all of which may influence the course and management of medical illness (e.g., medication compliance, appointment attendance, cooperation with treatment and medical personnel, reaction to illness, ability to elicit support from others). As an example of personality disturbance affecting illness, we have empirically determined that at least 7% of patients actively sabotage their medical care and that medically self-sabotaging behavior is typically associated with personality pathology, specifically borderline personality disorder.

Personality disorders can be difficult to diagnose during an initial evaluation, particularly if the patient is relatively high functioning and well educated. Oftentimes, diagnosis evolves with continuing or ongoing contact with the patient. However, health care personnel and family members may provide important historical information that suggests personality pathology, which is usually manifest in interpersonal functioning.

c. New-Onset Psychiatric Disorders After the onset of illness, patients may experience new-onset, or sec-

ondary, psychiatric disorders, most frequently either depression and/or anxiety. It appears that depression is particularly frequent among sufferers of neurological or cardiovascular disease. According to D. Spiegel and C. Classen, up to 50% of cancer patients experience clinical depression or anxiety, and the rate of depression in oncology patients is four times the prevalence found in the general population. Spiegel and Classen report that nearly 90% of these clinical syndromes are either manifestations of or reactions to illness or its treatment (i.e., secondary).

In addition to other factors, secondary mood disorders may be caused by a variety of medications administered to patients with medical illness. S. M. Valente and colleagues outline an extensive list of these medications (see “Further Reading”) that include specific anti-inflammatory drugs and analgesics (e.g., ibuprofen, baclofen, opiates), anticonvulsants, antihistamines, particular anticancer drugs, caffeine, and propranolol. As with preexisting psychiatric disorders, these secondary mood disorders have the same potential to interfere with treatment by reducing compliance, optimism, and cooperation.

d. Medical Illness Psychodynamics There are well-known psychodynamics that are outgrowths of medical illness (see Table 1). Many of these psychodynamics center on the patient’s experience of loss.

In addition to the themes relating to loss, D. Spiegel and C. Classen emphasize the importance of the patient’s reaction to the disease, itself. For example, with

TABLE 1
Psychodynamics That May Be
Associated with Medical Illness

- Greater helplessness and increased dependency on others
- Need for social support
- Loss and mourning (e.g., disability, disfigurement, employability)
- Significant changes in usual activities, routines, life patterns
- Increased responsibility for own care (e.g., medication regimens, follow-up visits)
- Need to reexamine life priorities
- Feelings of alienation from others
- Threat of premature death
- Unpredictable course of illness
- Symptom control
- Secondary gain (e.g., nurturance needs, deserved punishment)

regard to cancer, some patients attempt to overly control their feelings in an effort to literally control the cancer. Some patients believe that maintaining a positive attitude, even at the cost of dealing with and sorting through by-product issues, is a means of curing cancer. These beliefs may result in the patient's unrealistic needs to remain strong and in control. Patients may also struggle to maintain a self-perception of being "normal" which can cause unrealistic overextensions of self.

Following diagnosis, the psychological demands on patients continue. For example, D. Spiegel and C. Classen describe cancer as a series of stressors, from beginning treatment protocols to the changes in the social and physical environment to fears of death. The complex demands of illness, as well as the stigma of illness, may result in social isolation and breaches in social support. In our experience, it appears that genuine support can be maintained in most families for about a year, but gradually, family members may lose their stamina and resilience.

4. Use of Psychological Measures in Medically Ill Patients

a. Mood Assessment Mood and anxiety disorders, the most common psychiatric disorders among the medically ill, may be assessed in a variety of ways. However, sometimes the direct approach is the best approach. In support of this, a group of investigators reported that, among a group of patients with terminal illness, asking the direct question, "Are you depressed?" was more valid than three sophisticated psychological assessments for depression.

b. Psychological Measures of Illness Experience Psychological measures specific to the illness experience have not been broadly utilized in clinical settings. However, examples of general measures include the Millon Behavioral Health Inventory; the Psychological Adjustment to Illness scale; and the Illness Behavior Questionnaire. The latter measure contains seven scales including general hypochondriasis, disease conviction, psychological versus somatic concern, affective inhibition, affective disturbance or dysphoria, denial, and irritability. Examples of illness-specific psychological measures, which are uncommon, include the Mental Adjustment to Cancer scale.

c. Psychological Measures of Health-Related Quality of Life Of the measures available, the Medical Outcomes Study 36-Item Short Form, or SF-36, is probably the most commonly used measure of health-related

quality of life. This 36-item questionnaire, with known reliability and validity, contains eight subscales and measures health status, general functioning, and well-being. It has been used among broad samples of patients as a measure of outcome.

B. Treatment

Following assessment, the psychotherapist will hopefully have sufficient information to determine the initial foci of therapeutic work. These foci function as the basis for developing an eclectic and individualized treatment approach. Given the possible short duration of anticipated treatment, the therapist must, according to H. Levenson and R. E. Hales, select the symptoms, behaviors, or conflicts most amenable to treatment.

1. Timing of Psychotherapy Treatment

An important consideration for the therapist and patient is the timing of psychotherapy treatment. Coping strategies are ideally taught to the patient and family when motivation and physical stamina are relatively high (i.e., the early phases of illness), whereas treatment in the later phases of medical illness may limit efficacy.

2. Establishing the Therapeutic Relationship

a. The Paradox of Empathy Although most therapists have an understanding of what it feels like to be depressed or anxious, to suffer the loss of a relationship, or to mourn a death, far fewer have experienced the unique types of compromises precipitated by medical illness. This potential difference poses unique constraints with empathy in the therapeutic relationship because most of us do not understand what it is like to be burned beyond recognition or to deal with a disfiguring surgery. In this regard, we believe that it is important, when applicable, for therapists to actively acknowledge their lack of personal experience with a particular medical process, and the feelings associated with it, in an effort to promote a candid and sincere need to understand the patient. Likewise, therapists can explain their familiarity with a specific disease process and/or the illness experience from work with other patients.

b. Engagement with Emotional Boundaries Because of the potential devastation of medical illness and the resulting biological and psychological regression that occurs, the therapist needs to be sensitive to the extensive support needs of these patients. Spontaneity, genuineness, warmth, and the candid expression of support

are important qualities in the building of rapport. At the same time, realistic internal emotional boundaries need to be established within the therapist to avoid emotional overinvolvement.

c. Transference As the treatment relationship unfolds, various types of transferences may evolve. A transference is the patient's unconscious assignment to others of thoughts and feelings that were originally associated with important figures in one's early life (American Psychiatric Association's *Psychiatric Glossary*). As an example, the patient may have been abandoned by parents as a child and now unconsciously expects that the treatment team will also abandon him or her. Examples of more subtle transferences might be the patient's unconscious resentment about the health and well-being of the therapist. Differences in age, gender, professional backgrounds, and level of education may cause breaches in the therapeutic relationship based on early issues. Finally, the early relationship with caretakers may affect the patient's reaction to being helped and supported by the treatment team as well as accepting the natural and expected dependency that occurs in a treatment relationship.

d. Countertransference Countertransferences may also develop. Countertransference is the therapist's partly unconscious or conscious emotional reactions to the patient (American Psychiatric Association's *Psychiatric Glossary*). As examples, the therapist may not feel comfortable working with patients who are going to die, due to earlier unresolved experiences with death as well as our cultural discomfort with death. The therapist may also be concerned about the patient's medical illness prohibiting an orderly exploration of issues. Likewise, the therapist's own prior experience of illness may affect his or her perception of the patient. As a final example, the therapist may feel uncomfortable with the medical overlay associated with the care of the patient (e.g., hospital setting, liaison with medical personnel, medical communication or jargon, uncertainty about the treatment process or outcome), which may be a reflection of an early sense of helplessness in undefined or overwhelming situations.

Beyond transference and countertransference issues, other relationship dynamics may emerge. For example, as therapy progresses, a mutual denial regarding the severity of illness may develop between the patient and the therapist. This dynamic may function to protect the continuity of the therapeutic relationship.

e. The Therapist with Medical Illness One final issue involving the therapeutic relationship needs to be considered—that of the therapist who suffers from medical illness. In these circumstances, the therapist may experience prominent defenses against his or her own illness including denial, omnipotence, and reaction formation (i.e., the latter being an unconscious defense mechanism in which the individual adopts thoughts and behaviors that are the opposite of what he or she is really experiencing). Reaction formation may be in response to dependency and debilitation. Medical illness may also result in empathic failure in the treatment relationship because of the therapist's emotional preoccupation and subsequent withdrawal from the patient. For therapists with medical illness, there is also the delicate issue of disclosure to patients about the illness, particularly its course and prognosis.

3. Psychotherapy Treatment Components

In the remainder of this section, we discuss psychotherapy treatment from a general perspective in an effort to accommodate the most generic patient with medical illness. We wish to emphasize that most effective therapies with patients with medical illness incorporate an eclectic and individualized approach. Several common components will be discussed (i.e., psychoeducation, acute problem solving, cognitive-behavioral techniques, psychodynamic psychotherapy, family intervention). The resulting treatment structure, including the various treatment components, is not limited to an individual-therapy format but may be incorporated into a group format as well. In addition, different treatment providers may captain the individual components.

a. Psychoeducation Psychoeducation is typically an ongoing process during treatment. Psychoeducation may occur while describing the process of psychotherapy, when inviting the mutual sharing of medical information (e.g., disease effects, prognosis, necessary medical intervention), and while validating key psychodynamic issues such as loss. In this regard, therapists who treat patients with medical illness need to understand the natural course and treatment of the illness, if such information is available.

b. Acute Problem Solving A variety of practical life issues may need to be addressed with the patient. These may include inexpensive resources for medical supplies, financial aid, child care, transportation, sexual functioning, and cosmetic concerns (e.g., hair loss with chemotherapy). The therapist plays an active role in

triaging problems to appropriate adjunctive health care personnel (e.g., social work) and community resources (e.g., wig salons) as well as addressing issues relevant to psychotherapy treatment (e.g., telling a spouse the prognosis).

Acute problem solving may also be addressed in brief psychotherapy treatment models. H. Levenson and R. E. Hales describe two examples of specific models of brief, dynamic psychotherapy for medically ill patients. One model is Time-Limited Dynamic Therapy that is an interpersonal therapy approach based on the premise that present relational difficulties were learned in childhood. The preceding investigators report that this model is particularly applicable to patients with medical illness because chronic illness may initiate a pattern of disturbed interpersonal relationships. A second example of a brief psychotherapy model is Short-Term Dynamic Therapy of Stress Response Syndromes, a 12-session treatment developed by M. Horowitz in 1976. This model focuses on the alleviation of an immediate stressor and is intrapsychic, rather than interpersonal, in format.

c. Cognitive-Behavioral Techniques Cognitive-behavioral interventions can be very helpful for patients with medical illness by modifying thoughts, emotions, and behaviors. Cognitive-behavioral treatment focuses on the elicitation and “correction” of unintentional thinking errors or cognitive distortions that precede the exacerbation of emotional discomfort. Illogical thoughts (e.g., “I’ll never feel better”) are systematically elicited and processed to determine their nature (are they, for example, a result of magnifying or minimizing situations?). These thoughts, which are actively linked with emotional discomfort (i.e., “notice that when you think this, you feel like this”), are ultimately reformed, relabeled, or replaced (“you don’t feel good now; you will feel better, later”).

d. Psychodynamic Psychotherapy Although not applicable to all patients, many have early developmental issues, particularly parents’ responses to caretaking and illness as well as the patient’s experience of dependency, which relate to and affect the current medical illness. In working with the patient, the therapist needs to maintain an active mental checklist of prominent current issues with the intent of threading these back into the developmental history to explore for any former issues that might be affecting the current medical experience. We are fairly candid with patients about the purpose of this historical information (e.g., “I need

to understand your childhood background to determine its possible influences on your illness.”). When present, an understanding of the association between past and present relationships may help resolve excessive fears and address defenses such as denial.

Psychodynamic psychotherapy can assist patients by alleviating the complex issues related to loss and changing social and family roles. As an example, the therapist needs to explore and clarify the meaning of illness to the patient in terms of possible role reversal (i.e., being cared for by one’s children). Other common psychodynamic themes are listed in Table 1.

Terminal illness is a particular challenge in the treatment process, in part because of the therapist’s task of ascertaining the meaning and value of defense mechanisms such as avoidance and denial. For example, dying patients may avoid the disclosure of the extent of their disease to loved ones. Patients may even avoid asking the treatment team about the prognosis so as not to confirm a negative one. Denial may limit the patient’s reality of being finite as well as sabotage personal closure needs. On the other hand, some of these defenses may be the psychological substance of immediate survival. Therefore, the therapist must delicately explore the function of these dynamics and determine their adaptability. Again, these defenses are not always pathological or problematic.

Another challenging issue in the treatment of patients with medical illness is the patient’s personal determinism with regard to his or her own death. Although beyond the scope of this article, the patient’s desire to end pain, suffering, family stress, and financial exhaustion may precipitate the contemplation of suicide. Unquestionably, there are a variety of complex social, spiritual, religious, moral, and legal dilemmas entailed in this issue. However, the immediate clinical dilemma is the intended meaning of the patient’s disclosure of suicidal thinking. Is the disclosure a “cry for help” or is it the need to explore a difficult decision with another human being? Is the therapist’s contemplation of intervention an overt need to rescue the patient or avoid legal prosecution for inaction, or the therapist’s intolerance of the patient’s decision? What are the legal risks of not intervening with such a disclosure, particularly if the family supports the patient’s decision to suicide? Finally, is the decision to suicide a rational one or a decision driven by fear or untreated depression, and does it matter? As a general guideline for therapists, at this juncture, it is particularly important to reassess and treat (or alter treatment of) mood disorders as such intervention may result in the resolution of suicidal ideation.

e. Family Intervention Although most therapists do not undertake intensive family therapy work in the treatment of patients with medical illness, it is usually helpful to meet with the family. The family may provide additional background information, require individual professional support (e.g., the spouse who is depressed and needs antidepressant medication), and/or require a liaison between the patient and/or hospital personnel. In addition, families may require education about specific psychological issues (e.g., the role of depression, emergence of delirium secondary to the treatment) as well as some reframing about their loved one's behavior (e.g., the patient's low frustration tolerance, fear, confusion, inability to make decisions).

f. Group Therapy As noted previously, all the preceding treatment components may be undertaken in group format. The psychological advantages of group treatment of patients with medical illness include the ability to emphasize the universality of experiences, deal with disability on a mutual level, engage in emotional sharing, sort out relationships with family, and acknowledge and attempt to resolve grief and loss.

In working with cancer patients, D. Spiegel and C. Classen describe the goals of group therapy, many of which apply to all group treatments. These investigators emphasize the goals of building social bonds, using the group experience as a working lab to practice and express emotions, processing feelings about death and dying, redefining life goals, increasing social support, comparing health information, improving one's relationship with the health care team, and improving coping skills. With regard to the latter, a group experience is an excellent way to discover how others have dealt with and resolved specific issues or problems (e.g., having sexual relations while wearing a colostomy bag).

Group treatment is determined by the patient's individual needs (e.g., social comfort with groups, level of debilitation, type of medical illness), the available resources, and the availability of sufficient fellow patients (usually 7–10) who meet the group's criteria for entry (e.g., HIV infection). Some groups are very structured including an explicit number of sessions, while others are open-ended and continue as long as the need persists. In addition to patient groups, some therapists provide group intervention to families.

Group treatment is potentially more cost effective than individual treatment. However, potential difficulties in initiating group treatment include establishing the proper working group size, defining entry criteria (e.g., type of illness, stage of illness, age, sex), sollicita-

tion of members (e.g., bulletin board advertisements, physician referral only), duration of the group both per session and total duration, and whether the group is open to new members or not. Other potential problems include reimbursement, establishing and maintaining confidentiality, and leadership. Unlike typical psychotherapy groups, members may have to be prepared for the inevitable death of some participants, depending on the composition of the group.

4. Treatment Strategies for Major Psychiatric Disorders

a. Preexisting and Current Mood Disorders As noted previously, patients commonly develop depression and anxiety disorders, either prior to the onset of illness or during it. Mood and anxiety disorders are usually treated in a traditional fashion with antidepressant or antianxiety medications as well as the consideration of psychotherapy. Certain types of antidepressants, the selective serotonin reuptake inhibitors (SSRIs), are favored because of their ability to treat both depression and anxiety, and their minimal side effects, particularly the lack of cognitive and cardiovascular effects. With one exception (citalopram), these drugs tend to be very safe in single-drug overdoses.

b. Somatoform Disorders Somatoform disorders consist of a collection of psychiatric disorders that include somatization disorder (i.e., the presence of multiple physical complaints involving multiple body areas or body systems); conversion disorder (the presence of a symptom complex that is under unintentional but voluntary control and whose onset relates temporally to stress or conflict); pain disorder (pain symptoms in which psychological factors contribute in an unintentional way); and hypochondriasis (nondelusional, but persistent preoccupation with one's body or symptoms with regard to disease). These disorders may be associated with other types of psychiatric disorders, particularly mood and anxiety disorders. Because of the patient's focus on physical symptoms and the oftentimes unintentional generation of symptoms, there may be little interest in mental health support. However, symptoms may be reduced in some patients with supportive psychotherapy geared to stressors and interpersonal conflicts, frequent appointments with the primary care physician, conservative medical intervention, and the treatment of comorbid conditions such as mood and anxiety disorders with antidepressants. With regard to the latter, those antidepressants which exert an antiobsessive effect (e.g., SSRIs) may be particularly

helpful in some patients. Among this group of patients, there is a great deal of heterogeneity and in some cases, more sophisticated types of psychotherapy may be utilized in particular patients as well as more complicated combinations of psychotropic medications. Some of these patients may even benefit from hypnosis (e.g., conversion disorder).

5. Treatment Strategies for Patients with Personality Disorders

We believe that the presence of a personality disorder is one of the most difficult issues in the treatment of patients with medical illness. Because of their long-standing nature, personality disorders tend to be tenacious and difficult to change. Most theorists believe that long-term treatment is required and the outcome or prognosis may be limited. In addition, there are few studies that clarify the efficacy of treatment for personality disorders. Indeed, some disorders, such as antisocial personality disorder, have questionable responses to treatment. The interplay of medical illness and personality disorder can be exasperating for the clinician as well as the family and health care team. For example, the management of diabetes may be extremely difficult among patients who sabotage their administration of insulin, resulting in repeated hospitalizations and medical complications.

It is important to emphasize that the presence of personality disorder is not always a meaningful issue in treatment. For example, in cancer victims with poor prognoses, personality disorder treatment is neither realistic nor appropriate. In these latter cases, the therapist may limit treatment to minimizing the impact and effects of the personality-disordered behavior on family, medical staff, and other patients.

II. THEORETICAL BASES

It is difficult, at times, to accurately measure and describe the psychotherapy process and why it works. Perhaps it is the psychological intimacy that provides immeasurable support. Perhaps it is the revelation of fear, anger, disappointment, and shame—all the feelings that incarcerate the spirit. It may also be establishing new conceptual paradigms to replace the previous ones that no longer work. Whatever the growth-promoting elements of psychotherapy treatment are, they certainly apply to the treatment of those with medical illness. The modifications in psychotherapy treatment of this population primarily center on the additional knowledge

base required in working with a medical illness, the biological stress of the illness, and the ever-prominent issue of death. Although suicide is always a concern in working with patients with nonmedical illness, it remains an issue with the patient with medical illness as well, in addition to the threat of death from illness.

III. EMPIRICAL STUDIES

In a 1994 review of the literature, H. R. Conte reported that there were few controlled empirical studies, and only occasional case reports, exploring the efficacy of supportive psychotherapy for patients with medical illness. Results indicated beneficial effects, in general. Although it is impossible to compare outcome studies because of differing patient populations, therapeutic interventions, treatment settings, and types of medical illness, we present some highlights from the literature.

A. Psychoeducation

Among patients with chronic illness, researchers found that classroom as well as home psychoeducation (e.g., instruction on mind–body relationships, relaxation training, and communication skills) resulted in improvements with pain, sleep disturbance, mood, and anxiety. Formalized psychoeducation has also been undertaken with cancer patients and found to enhance both cognitive and behavioral coping skills.

B. General Psychological Intervention

In a group of patients with atopic dermatitis, those who entered into a psychological treatment demonstrated a greater improvement in their skin condition than did those patients in standard medical treatment. In a review of outcomes among those with chronic heart failure, it has been reported that psychological and behavioral interventions have the potential to substantially enhance treatment outcomes. Among patients undergoing coronary artery bypass surgery, those who participated in daily supportive psychotherapy had fewer medical complications and shorter lengths of hospitalization, compared with controls. Through meta-analysis, the efficacy of psychological interventions among both children and adolescents with chronic medical illness has been explored; despite a host of limitations, results support the overall efficacy of psychological intervention.

C. Cognitive-Behavioral Interventions

Cognitive-behavioral intervention has been found to improve depression among patients with chronic illness. Multicomponent behavioral therapy among patients with irritable bowel syndrome resulted in greater symptom reduction compared with controls.

D. Group Therapy

In examining the sense of well-being as an outcome measure for patients with serious medical illness in time-limited (12 sessions) group therapy, researchers found that although somatic concern remained sustained, all patients noted an improvement in their sense of well-being. Likewise, among cancer patients receiving radiation therapy, there were significant decreases in both physical and emotional symptoms for those who participated in 10 group therapy sessions of 90 min each. Through multicenter evaluation, group therapy with breast cancer patients has been empirically assessed and resulted in improved mood, fewer maladaptive coping responses, and improved support. Finally, group therapy (six sessions) among patients with malignant melanoma resulted in decreased stress, greater use of coping skills, and effective changes in the lymphoid cell system.

E. Cost Effectiveness of Psychotherapy

Researchers have found that psychotherapy can be cost effective among certain medical patients with concomitant psychiatric illness. In addition, there is evidence that psychiatric consultation-liaison services for medical patients reduces the overall cost of care. Studies indicate that psychiatric illness, notably depression, usually prolongs hospital stays for medical patients and intervention reduces cost. In summary, it appears that reducing psychiatric morbidity among medical patients also has the potential to reduce their overall cost of medical care.

F. Caveats

Although many studies clearly support the efficacy of psychological intervention in patients with medical illness, there are studies that do not. For example, the provision of group therapy for the relatives of patients with chronic aphasia was appreciated but did not lead to measurable improvements in participants' perceptions of personal, social, or family burdens. Among patients with

testicular cancer, psychotherapy did not affect outcome when compared with controls. In examining the impact of treating depression among hospitalized veterans and the effect on participants' preferences for life-sustaining therapy, surprisingly, these preferences did not change, regardless of the improvement in depression.

IV. SUMMARY

The psychotherapy of patients with medical illness must be individualized to the needs of each patient. Treatment components may include psychoeducation, acute problem solving, cognitive-behavioral techniques, psychodynamic psychotherapy, family intervention, and group therapy. The unique aspects of medical illness temper the psychodynamics of the issues in the treatment process. The therapist must integrate both the knowledge of psychology and biological disease to effect an outcome. Although most studies underscore the effectiveness of psychological interventions in the medical patient, the documented limitations of psychological intervention in some populations underscores the importance of further investigation.

GLOSSARY

minimal therapist contact treatments (MCT) Rely heavily on out-of-clinic interventions. Often it is referred to as a “home-based” treatment.

cost-effectiveness Percentage improvement per minute of clinician contact.

Minimal therapist contact is a term used to describe psychological interventions that utilize alternative forms of instruction and treatment administration (e.g., written materials, computer programs, videotapes, audiotapes, and portable biofeedback equipment) to reduce professional contact time without compromising treatment intensity. Because minimal therapist contact treatment (MCT) relies heavily on out-of-clinic interventions, it is often referred to as a “home-based” treatment.

I. TREATMENT DESCRIPTION

For the purposes of definition, it is important to distinguish between other forms of intervention that utilize alternative delivery methods and MCT treatments. These other forms of intervention, including certain types of bibliotherapy and many self-help interventions, effectively reduce the amount of contact time, but they accomplish this by decreasing the intensity of the intervention. For example, efficiency may be improved solely by decreasing the number of sessions in the intervention, limiting the patient–therapist interaction to a one-time, informational exchange, or eliminating the patient–therapist relationship altogether (e.g., pure self-help). MCTs on the other hand, seek to deliver an intervention of equal intensity and duration to standard clinic-based treatments (SCT) while maintaining ongoing (although less frequent) patient–therapist contact.

MCTs offer many potential advantages over SCTs. First, at-home skill acquisition and practice eliminates the need for frequent, lengthy clinic visits, improving access to care for many patients. Specifically for patients living in rural areas who must travel significant distances for care, a decrease in clinic visits makes obtaining treatment more feasible due to a reduction in transportation costs and lost work time. A reduction in clinic visits, however, will likely improve access to care for all patients, not just those living in rural areas. For example, recent treatment utilization data suggest that 80% of patients attend fewer than six treatment sessions, suggesting the length of standard interventions may be a barrier to patient care in general.

* The views expressed in this article are those of the authors and do not reflect the official policy or position of the United States Air Force, Department of Defense, or the United States Government.

Second, MCTs reduce the total amount of therapist contact time that results in decreased provider cost per patient treated. Cost-effectiveness, defined as percentage improvement per minute of clinician contact, has been shown to be as high as five times greater in MCTs as compared to SCTs. This characteristic of MCTs fits in well with the prevailing method of health care funding and delivery: managed care. Health maintenance organizations (HMOs) are concerned with treatment cost, treatment quality, and patient access to care. As a method of cost containment, many HMOs limit the number of preapproved clinic visits. MCTs respond to this need to balance cost containment and patient care by decreasing cost without sacrificing treatment efficacy.

Compared to efficiency-enhancing methods that rely solely on reducing or eliminating therapist contact time, MCTs offer the potential benefit of greater patient involvement and skill acquisition without the loss of intervention and monitoring by a trained therapist. In addition, this utilization of alternative mediums of instruction and delivery allows the therapist to focus on tailoring interventions to specific patients and to respond to factors and circumstances that arise during treatment. MCTs are also flexible and can often incorporate the beneficial aspects of other efficiency-enhancing formats. For example, the first author has designed a group administered MCT protocol for the treatment of chronic headaches (HA). Finally, MCT's use of extensive at-home skill acquisition and practice theoretically may facilitate skill generalization and internal attributions for change. However, no studies have examined differences in generalization.

Some potential disadvantages may also exist for MCTs. The first author's experience with MCTs suggests they may require a higher level of motivation or cognitive ability than SCTs, although no studies have investigated such a requirement. In addition, the increased reliance on patient self-administration presents the potential for reduced adherence, although poor adherence has not been reported in the existing literature.

II. THEORETICAL BASES

The term "minimal contact" implies a form of treatment administration and delivery that is not limited to a particular theory. This represents a significant advantage for MCTs because they can potentially be applied to any type of intervention that is translatable into a standard protocol, regardless of clinical orientation. However, the MCTs described in the literature have, almost entirely, been developed from treatments based in cognitive-be-

havioral theory. This trend is not a random occurrence but is due primarily to the nature and developmental stage of cognitive-behavioral interventions that make them especially suitable for MCT methods.

First, cognitive-behavioral interventions rely heavily on education and exposure to new experiences for treatment efficacy. Both of these treatment components lend themselves to home-based interventions that utilize alternative mediums to communicate information. Second, treatment efficacies of many cognitive-behavioral interventions for a variety of disorders have received significant empirical support. Once an intervention has been established and its efficacy empirically supported, the amount of additional clinical improvement gained by modifying the content of the intervention will eventually plateau. Cognitive-behavioral interventions for chronic headaches reached such a plateau, leading researchers to look toward enhancements in treatment delivery for further improvement of the interventions. MCT methods provide one means by which the efficiency of established interventions can be enhanced while the treatment content, intensity and efficacy remain intact.

III. LITERATURE REVIEW

Research exists to support various forms of MCT for adult patients with both physical and psychological disorders, including migraine and tension HA, hypertension, and panic disorder. In addition, research supports the use of MCT for HA and enuresis in children.

The literature on MCT of HAs in adults consistently finds MCT to be equally as effective as the more intensive SCTs. Results of a recent meta-analysis of 20 controlled clinical outcome trials suggest MCTs, on average, are more cost-effective and require substantially less professional contact time, as well as, fewer clinic visits. In addition, MCTs produced similar or significantly better outcomes than SCTs requiring more professional contact.

More specifically, a 1996 review article including eight studies of MCTs for tension-type HA found MCTs to be equally as effective as SCTs for the reduction of HA activity. MCT for tension-type HA has also been compared to prophylactic, pharmacological intervention (Amitriptyline HCL). The results suggest MCTs are similarly efficacious in terms of decreasing HA frequency and intensity. However, compared to the medication group, additional benefits were realized in the MCT group, such as more internalized locus of control, fewer general somatic complaints, and fewer side effects. Although long-term fol-

low-up studies of these interventions have been somewhat lacking, existing data have consistently shown good maintenance of effects throughout follow-up periods ranging from 3 months to 2 years.

Similar results have been reported for migraine HA. Three investigations comparing the efficacy of MCT and SCT relaxation/thermal biofeedback interventions suggest MCT is equally as effective as SCT for the reduction of migraine HA. One study to date has investigated the efficacy of MCTs as compared to abortive medication (ergotamine tartrate) for the reduction of migraine HA. The results found MCT to be equally as effective as this abortive intervention, although patients treated with medication experienced improvements more rapidly than those treated with MCT.

No research to date has been conducted comparing MCT to treatment with prophylactic medication. However, one study compared MCT alone to MCT plus propranolol (the most commonly used prophylactic agent for migraine HA). The results indicate that, although both interventions were effective, the addition of the prophylactic agent yielded significant enhancements in HA reduction.

MCT methods have also been used in the treatment of essential hypertension with equivocal results. One study investigated the efficacy of a 5-session, thermal biofeedback MCT for adults with essential hypertension who required at least two drugs for hemodynamic control. This intervention was compared to a standard, 16-session, thermal biofeedback SCT. The results suggest that patients in the MCT did significantly poorer controlling their blood pressures without medication than those in the SCT. However, a previous investigation comparing a 9-session thermal biofeedback MCT to a 20-session SCT found equivalent reductions in blood pressure and antihypertensive medication use. Methodological limitations, such as small sample size, suggest that more research is needed in the area of MCTs for hypertension.

A recent study also supports the efficacy of MCT methods in the administration of cognitive-behavioral treatment of panic disorder. When compared to a standard, 10-session cognitive-behavioral intervention for panic disorder, a minimal contact approach involving 5 sessions and supported by self-help materials yielded similar improvements both immediately posttreatment and at 12-month follow-up. In addition to applying minimal contact methods, this particular intervention also reduced the total length of therapy while maintaining the efficacy of the longer, clinic-based intervention.

Data have also been reported that support MCTs in pediatric populations. A review article including three

school-based and four home-based MCT interventions concludes that MCT for pediatric and adolescent migraine, regardless of setting, is equally as effective as SCTs. The existing research on pediatric tension HA for both SCTs and MCTs are more modest, however, with the percentage of participants experiencing clinically significant improvement (defined as > 50% reduction in overall HA activity) being low, but similar, for both types of intervention. In terms of mixed-type HA, a recent treatment study of a home-based MCT for children (ages 10–12) found the MCT to be as efficacious as the SCT and over twice as cost-effective.

Similarly, data supporting the efficacy of MCTs for the treatment of nocturnal enuresis in children have also been reported. This treatment relied on the children's parents for the administration of the treatment. Although some limitations may exist for the application of MCTs with children, such as inability to read and the need for significant parental involvement in treatment, more research is needed on MCT in this population.

In general, research has fairly consistently shown MCTs to be as effective as more costly SCT for the treatment of a variety of disorders in both adult and child populations. The extensive body of research demonstrating the efficacy of MCTs for chronic HA suggest MCTs for HA are ready for widespread clinical application. However, additional research is needed to verify MCTs for the treatment of other disorders and to investigate the potential advantages and disadvantages of minimal contact methods beyond increased cost-effectiveness.

IV. TREATMENT ABSTRACT

Although MCT methodologies could result in many different therapy formats, a prototype based on a typical intervention is presented here as an example.

A prototypical MCT might take an 8-session, 8-week SCT and administer it utilizing three in-clinic sessions, two telephone contacts, and a series of audiotapes and manuals across the same 8 weeks. Table 1 compares a typical minimal therapist contact treatment (MCT) to a standard clinic-based treatment (SCT).

The first week of intervention looks almost identical in the two forms of treatment except for the use of training materials. During Week 2, the SCT therapist meets the patient for another 60-min session, while the MCT therapist speaks with the patient briefly on the telephone. During this telephone conversation, the MCT therapist will ask general questions regarding treatment progress, relaxation practice, and any behavior monitoring/recording that was assigned during Week 1. The

TABLE 1
Example Minimal Therapist Contact Treatment versus Standard Clinic-Based Treatment Protocols

Week	Session content	Type of contact		Time (min)		Training material
		MCT ^a	SCT ^b	MCT	SCT	MCT
1	Education, treatment rationale, relaxation demonstration	Clinic	Clinic	60	60	Manual, audiotape
2	Progressive muscle relaxation (PMR) exercises; discrimination training (16 muscle groups)	Phone	Clinic	10	60	Manual, audiotape
3	PMR exercises (8 muscle groups)	None	Clinic	0	60	Manual, audiotape
4	PMR exercises (4 muscle groups)	None	Clinic	0	60	Manual, audiotape
5	PMR exercises (4 muscle groups); relaxation by recall, autogenic phrases, positive imagery, problem solving	Clinic	Clinic	60	60	Manual, audiotape
6	Same as Week 5	Phone	Clinic	10	60	Manual
7	Same as Week 5	None	Clinic	0	60	Manual
8	Review all components	Clinic	Clinic	40	60	Manual
Total		3 visits 2 phone calls	8 visits	180	480	

^a MCT = Minimal Therapist Contact Treatment.

^b SCT = Standard Clinic-Based Treatment.

MCT therapist will also briefly discuss the treatment activities for the upcoming weeks and remind the patient of the date and time of the second treatment session that will take place during Week 5.

During Weeks 3 and 4, the MCT patients do not have any contact with the therapist. They follow the readings and instructions regarding further development of relaxation and stress management skills that are contained in the manual and use the audiotapes to guide their skill acquisition and practice.

Week 5 for the MCT patients involves a 60-min clinic visit during which the therapist reviews the materials and the homework assigned during Weeks 3 and 4. The therapist also discusses problem solving, previews the information for Week 6, and schedules the final clinic visit for Week 8.

At the end of Week 6, a 10-min telephone contact is conducted. During this contact, the MCT therapist will ask questions regarding treatment progress, skills practice, and problem-solving exercises, discuss briefly the material for Week 7, reinforce the patient's effort and progress, and confirm the appointment for Week 8.

No contact is made with the patients in MCT during Week 7, and the patient meets with the therapist for a final 40-min session at the end of Week 8. During this visit, the materials and practice of skills from Weeks 5 through 8 are reviewed, posttreatment plans and goals

are developed, and feedback is acquired regarding the treatment process.

Throughout the same 8-week period, SCT patients are exposed to the same information and skills, but they are delivered in weekly, 60-min, in-clinic sessions, with or without supplemental written and audiotape materials. It is important to recognize that many SCTs utilize supplemental materials such as manuals and audiotapes; however, in SCTs the intention of these materials is to review and reinforce the information and techniques presented by the therapist during in-clinic sessions. On the other hand, training materials used in MCTs are intended to be the primary delivery medium for the majority of the instruction.

I. COMPONENTS OF MODELING INTERVENTION

As an intervention technique, modeling is relatively simple and is designed to assist clients in learning new behavior patterns. The procedure involves two primary components. First, the client is provided with an opportunity to observe the correct or desired form of behavior. Thus, theoretically any behavior that can be replicated in a form that is observable to the client may be taught through modeling. Second, the client imitates the observed behavior, demonstrating learning. For modeling to be effective as an intervention, the client must be able to demonstrate an imitative response. In other words, the client must be able to observe (i.e., pay attention to) the model (i.e., the person demonstrating the desired response) and then implement the skill that was just demonstrated. Clients who have particular characteristics that may interfere with attending to the model (e.g., blindness) or demonstrating the imitative response (e.g., physical disability) may not be good candidates for the use of this intervention.

Modeling is said to produce observational learning on the part of the client. Observational learning can be further divided into two forms of learning: imitation and vicarious learning. Imitation involves simply matching the topography of the observed behavior. For example, if a client observes a therapist demonstrate how to effectively introduce oneself to individuals unknown to the client (a skill that may be lacking in the

GLOSSARY

imitation Re-creation of an observed response.

vicarious learning Change in the likelihood that a person will demonstrate an observed behavior based on whether the observed model experiences reward or punish for engaging in the behavior.

Modeling is a psychotherapy technique utilized to produce changes in a client's behavioral repertoire by providing a demonstration of the desired behavior patterns and then affording opportunities for imitation. In this article, the basic components of the modeling procedure are discussed. Then, the theoretical bases on which the techniques are founded is explored. A review of the applicability of the technique follows, after which a synthesis of relevant research assessing the effectiveness of the approach is provided. Finally, a case example is given as an illustration of the process of using modeling as an intervention.

client's behavioral repertoire), imitation involves the client simply repeating or matching the demonstrated introduction responses. Vicarious learning, on the other hand, involves a change in the likelihood of the targeted response being imitated as a function of observing the model being rewarded or punished for engaging in the targeted behavior. Using the earlier example, vicarious learning may result in the client being more likely to demonstrate the effective greeting response if the modeling situation involves the model being rewarded for implementing the skill (e.g., through a warm reception by "unknown" individuals).

Observational learning as a result of witnessing a model can produce three different effects. First, observing a model can result in the acquisition of previously unlearned behaviors. Thus, modeling can be used to increase a person's behavioral repertoire. In addition to establishing completely novel behavior patterns, modeling can facilitate chaining—the process of sequentially exhibiting various behaviors so that they form a complex pattern.

Second, modeling can result in a strengthening or weakening of inhibitory responses, referred to as inhibitory or disinhibitory effects, respectively. Regarding the former, modeling can strengthen inhibition to engage in a particular response via exposure to a model who is punished for engaging in the targeted behavior. Take, for example, a young child who tantrums. Assume that her parents are using time out as a punishment technique to decrease tantrums. If the time-out procedure is effective, it will inhibit the likelihood that the young girl will tantrum. Furthermore, if she observed (perhaps at school) another child being placed in time out after engaging in a tantrum, this could further decrease the likelihood that she will tantrum. Through observing the model (in this case, the other child) being punished for the target behavior, she is now even less likely to engage in the tantrum, above and beyond the decrease produced by experiencing the time out directly. Alternatively, modeling can weaken previous learning that has inhibited responding. As an illustration, consider a student who was previously punished for participating in class (e.g., other students laughing at his incorrect answers, the teacher sternly correcting the student when he is wrong). If this student observes a model experience rewarding consequences as a result of participating in class, this may weaken the previous inhibitory learning, thus increasing the likelihood that the student will participate.

Finally, modeling may evoke previously learned behavior patterns, referred to as the response facilitation effect. Although seemingly similar to the disinhibitory effect,

the response facilitation effect differs because of the previous learning that was involved. The disinhibitory effect occurs when behavior was previously punished. However, the response facilitation effect produces an increase in the likelihood of the occurrence of a response pattern that was not previously punished. In essence, then, the modeled behavior in this case simply serves as a cue to engage in behavior that has already been learned.

In 1977, Albert Bandura described the factors that influence the effectiveness of modeling as a behavior change technique. First, if modeling is being used to facilitate the demonstration of a particular behavior pattern by the observer, then the modeled behavior should result in successful (i.e., reinforcing) consequences for the model. Second, modeling is more likely to produce the desired impact if the model is similar to the observer(s), or has a high status. For example, if one is working with an adult African American client, modeling may be more effective if the model is also an adult African American individual. Thus, attention to factors such as age, gender, and ethnicity are important when selecting a model. Third, the complexity of the behavior modeled should be appropriate based on the abilities and developmental level of the observer. Fourth, the observer has to attend to the model for the exposure to have an effect. Fifth, the modeled behavior should occur within the proper context. For example, if a therapist is trying to teach the social skills necessary for successfully greeting a new person, the therapist should arrange a situation in which the client can observe one person demonstrate the necessary skills while interacting with a second person, perhaps in the waiting room or other similar situation. Sixth, the modeled behavior should be repeated as frequently as necessary for the learner to demonstrate correct imitation. To facilitate generalized learning, the desired behavior should be modeled in various situations and context. Finally, the observer should be given opportunities to imitate the modeled behavior as soon as possible after modeling has occurred, with corrective and positive feedback provided.

There are several variations in the format of presenting the modeling procedure to the client. The traditional form involves a live model demonstrating the desired responses. The client watches the model and then is provided with the opportunity to demonstrate the imitative response. Live, or *in vivo*, modeling is advantageous because of the ability to adapt and modify the model selected and the demonstration of the desired response to best meet the needs of a particular client. For example, specific appropriate models can be selected to match the

characteristics of the client. Furthermore, particular behaviors of concern that are idiosyncratic to the client can be selected and demonstrated. However, the advantages of *in vivo* modeling can also be disadvantages in that it may be difficult to select ideal models or create the necessary conditions for the demonstration of various forms of behavior.

To provide for frequent exposure to the model, symbolic modeling may be used. Symbolic modeling can be achieved via the use of several different modeling formats, such as use of video, film, slide presentation, and so on. With symbolic modeling, the model is somehow recorded while demonstrating the desired responses. Then, the client is exposed to the recorded version of the modeling demonstration. Although the initial investment may be larger in terms of equipment and time needs, symbolic modeling can result in more efficient demonstration of the desired responses because once the model is recorded, it can be used repeatedly with the same client, or with multiple clients. In fact, there are commercially available resources to teach a variety of skills via symbolic modeling.

Finally, covert modeling has been described in the literature. Covert modeling involves carrying out the intervention via the use of imagery. With this variation, the client is instructed to imagine the model demonstrating the desired response, rather than actually witnessing the scenario *in vivo*. For a person to participate in covert modeling, she or he must be able to create detailed cognitive/mental images. Thus, careful assessment of a client's abilities to create detailed images is necessary prior to using covert modeling. Like live modeling, covert modeling has as an advantage flexibility in that a client can image models and scenarios that are particularly relevant. Furthermore, like video or film modeling, covert modeling has as an advantage ease of implementation in that a client can be repeatedly and frequently exposed to the model with minimal effort.

In addition to the general formats of modeling, the variants of this procedure can be further defined by whether they involve simple modeling or participant modeling. The former involves exposure to the model presented in any of the formats described earlier, followed by the opportunity for imitative responding. Participant modeling, on the other hand, also involves some form of guide practice either during or just after exposure to the model. With this form of modeling, the clinician physically guides the client to engage in the desired response, thus ensuring correct or successful performance.

Regardless of the form of modeling used, there are several components to the use of the intervention that

should be considered, as described by Sherry Cormier and Bill Cormier in their 2000 text. First, the client should be provided with a rationale for the use of the modeling procedure. Essentially, the therapist should explain that by observing effective demonstration of skills/behaviors, the client should be better able to learn those desired responses. Second, Cormier and Cormier recommend addressing five components of the actual modeling scenario: (a) specifying and dividing desired goals into identifiable behavioral responses, (b) arranging the actual behaviors into a logical order of presentation, (c) selecting the appropriate model, (d) providing verbal instructions to the client prior to modeling, and (e) demonstrating the targeted behaviors repeatedly. Third, the client needs to be provided with an opportunity to demonstrate the modeled responses. At this stage of the intervention, the therapist should observe the client imitate the response, provide induction aids (e.g., verbal or gestural prompts), and offer positive and corrective feedback. Feedback and induction aids can be reduced and eliminated as the client demonstrates mastery of the responses. Finally, critical to the success of any modeling situation, the therapist should ensure that the imitated behavior produces desired, positive outcomes.

II. THEORETICAL BASES

Several authors have hypothesized about the theoretical reasons for why modeling produces observational learning. Those explanations have ranged from being firmly grounded within behavior analytic theory to being linked to cognitive and social learning theories. The cognitive-behavioral account provided by Albert Bandura, the researcher perhaps most strongly associated with modeling and observational learning due to his prolific research and writings about the topic, has received the greatest acceptance within the field of psychology.

Bandura proposed the contiguity theory (which eventually became part of his more expanded theory of social learning) as a means for understanding the impact of modeling. According to this theory, an observer acquires (i.e., learns) the modeled response through continuous associations between the observed behavior and sensory events, mental representations, and so on, that occur during the exposure to the model. These "cognitive" events then serve as cues for the occurrence of the behavior that was originally modeled.

According to Bandura, there are four main processes that influence the observational learning that occurs as a

result of modeling. First, attentional processes are important in that they affect how much of an impact the modeled event will have on the observer. Attentional processes are affected by variables related to both the modeling stimulus (e.g., salience, distinctiveness, complexity, prevalence) and the observer (e.g., sensory capabilities, emotional arousal, past reinforcement history). Second, retention processes are involved, including such factors as symbolic coding of the modeled behavior, cognitive organization of the observed information, and symbolic and motoric rehearsal (i.e., imitation). Third, motor production processes are important influences in observational learning. Physical capabilities of the observer/learner, previous learning of similar responses, self-observation of imitation, and feedback regarding the accuracy of the imitative response are all variables that affect whether observing a model will result in imitative responding. Finally, motivational processes such as external reinforcement, vicarious reward and punishment, and self-reward or -punishment all are relevant to determining whether observing a model will produce imitation.

III. APPLICATIONS AND EXCLUSIONS

Unlike some psychotherapeutic techniques that are applicable for use with a limited number of clinical problems, evidence suggests that modeling strategies are effective with a wide variety of psychological, behavioral, emotional, and social problems. In fact, research evaluating the applicability of this intervention is so large that a thorough discussion is beyond the scope of this article. Instead, a brief discussion is provided to familiarize the reader with relevant issues.

As mentioned earlier, for modeling to be effective as a psychotherapeutic intervention, it is necessary for the person to be able to both attend to the model and engage in the imitative response. Thus, as the research supports, use of this intervention is possible with clients who meet these prerequisite skills. The clinician needs to determine whether the modeling procedure is the technique most likely to produce the desired effect. Thus, the clinician should consider various factors when determining whether to use this intervention, such as the clinical issue at hand, the complexity of the desired outcome, the ability to create the appropriate modeling conditions, and client interest and motivation.

Extending the applicability of the intervention even further, evidence suggests that modeling actually can be

used with people who do not already demonstrate imitative responses. Through the use of prompting, shaping, and differential reinforcement, the generalized imitative response can be taught to clients who do not already exhibit such behavior. As a result, modeling may be used with people with severe or profound retardation, autism spectrum disorders, and clients with psychoses who do not already demonstrate the imitative response. In such situations, if use of modeling is desired, clinicians must first teach the imitative response to the clients. Once imitation is established, continued use of reinforcement for said responses will ensure that such clients will be able to benefit from modeling.

When considering the use of modeling strategies, one should also consider that particular formats of modeling have been shown to be more beneficial for use with certain clinical issues. For establishing new behavioral repertoires, evidence suggests that modeling (*in vivo* or symbolic) with guided performance may be effective. With this variant of modeling the client is first exposed to the model (with steps taken to ensure that the client is attending). Then, the client is guided to perform the desired behavior, after which reinforcement is provided for demonstrating the behavior. Use of the physical guidance is gradually decreased as the client demonstrates the imitative response with increasing independence.

Presentation of coping versus mastery models should also be considered. Coping models are those models who initially exhibit flawed or fearful performances, but then become increasingly competent in the desired behavior. This transition may occur during one or repeated modeling implementations. Mastery models, on the other hand, demonstrate the desired behavior perfectly from the beginning. Evidence suggests that coping models may produce more beneficial outcomes for clients, particularly when targeting fears, phobias, or other avoidance-based clinical problems. The opportunity to observe someone experience similar fear reactions, and then learn to overcome them, appears central to this finding.

Finally, evidence suggests that modeling techniques are useful with clients from diverse ethnic and cultural backgrounds. Studies have evaluated various modeling interventions with African Americans, Asian Americans, Hispanic Americans, gays, and lesbians. The use of ethnic and/or culturally similar models increases the salience and relevance of the model, thereby increasing the likelihood that clients will attend to the models. Although the general intervention format will not vary greatly across ethnic groups, Sherry Cormier and Bill

Cormier suggest in their 2000 text that clinicians consider three issues to ensure cultural sensitivity: (a) ensure that the live or symbolic model is culturally similar to the client, (b) ensure that the content to be demonstrated in the modeling scenario is culturally sensitive, and (c) be familiar with and account for differences in how people attend to, learn from, and use modeled information.

IV. EMPIRICAL STUDIES

Although the phenomena of learning via observing a model has been recognized for many years, methodologically sound research on the influence of models on observer's behaviors dates back to the 1950s and early 1960s. During this early research, experimenters designed investigations that documented the occurrence of observational learning. For example, researchers demonstrated that participants would engage in imitative responses of observed behaviors in the presence of the model who had demonstrated the behavior. This early research was important in that it demonstrated the phenomena of interest could be investigated under controlled, replicable conditions.

In 1961, Albert Bandura, Dorothea Ross, and Sheila A. Ross expanded on earlier non-clinical research by investigating whether the imitative response would occur in the absence of the model. To do so, they had 36 boys and 36 girls with a mean age of 59 months observe adult models engage in either aggressive or non-aggressive behavior with inanimate objects (i.e., toys). Following the observation period, the children were allowed to interact with the toys in the absence of the models while experimenters documented the presence or absence of aggressive imitative responses. Those children who observed the aggressive models were more likely to be aggressive with the toys than those children who had watched non-aggressive models. More important, Bandura, Ross, and Ross demonstrated that the influence of the model persisted in the absence of the actual model. Over the next 10 to 15 years, Bandura and his colleagues conducted numerous studies evaluating the effectiveness of modeling, the conditions necessary to produce observational learning, and the extent of learning produced via the process of modeling.

Applied research also has emerged and strengthened the position that modeling is an effective therapeutic tool. Since the initiation of this research, investigations have demonstrated the effectiveness of modeling with children, adolescents, and adults, and for various clinical

problems (e.g., aggression, poor social skills). Furthermore, the intervention has proven effective with clients from various ethnic and cultural backgrounds. What follows is a sample of research on modeling in these different areas.

A significant amount of research has demonstrated the usefulness of various forms of modeling with children and adolescents. For example, in 1942 Gertrude Chittenden utilized symbolic modeling to alter aggressive responses by children. In this investigation, the participants were exposed to several "plays" in which an adult and a child used dolls to enact non-aggressive alternative responses in reaction to a situation in which both dolls wanted to play with the same toy, a scenario shown to produce aggressive responses in the participants. Furthermore, the plays involved the dolls receiving positive rewards for demonstrating the prosocial alternative responses. During observations conducted after watching the models, Chittenden found that there was a significant decrease in displays of aggressive responses and increase in modeled prosocial behavior.

In 1986, Eva Feindler, Randolph Ecton, Deborah Kingsley, and Dennis Dubey utilized modeling as one of several interventions to address anger management problems displayed by adolescent males residing in a psychiatric hospital. These experimenters used a between-groups wait-list control design to evaluate the impact of an 8-week group therapy program targeting anger control. The intervention group was taught various anger control strategies via the use of symbolic and participant modeling, which also included opportunities for role playing and behavioral rehearsal. Results indicated that the experimental group displayed significantly lower rates of anger problems posttreatment as compared to the members of the wait-list control group.

Research on the use of modeling to treat anger control problems and aggression is not limited to children and adolescents. In 1990 Frank Vaccaro assessed the impact of instructions, *in vivo* modeling, role playing, and feedback on verbal aggression displayed by 6 institutionalized older adults. Using an ABAB single-subject design, Vaccaro found that the intervention resulted in decreased instances of verbal aggression for all 6 participants. Further, improved behavior generalized from the experimental situation (i.e., the group therapy sessions) to the milieu setting.

A significant amount of research has been conducted assessing the utility of different modeling approaches to treating fears and phobias exhibited by both children and adults. In 1996, Rutger W. Trijsburg, Marko Jelicic, Walter W. van den Broek, and Annelies E. M. Plekker

utilized participant modeling to treat phobic reactions to injections experienced by a 26-year-old female. According to the authors, this client demonstrated a “resistant-type” phobia in that she displayed strong, sometimes violent resistance to receiving a shot. Utilizing both scores on the State-Trait Anxiety Inventory and heart rate monitoring, the researchers found that the client’s phobic reactions decreased as a result of exposure to a model receiving shots.

Matthew R. Sanders and Lyndall Jones provided a demonstration of the effectiveness of participant modeling with an adolescent female in 1990. In this investigation, the participant was a 13-year-old female with multiple medical and dental phobias, with comorbid oppositional defiant disorder. At the time of the investigation, she was scheduled for major surgery in 6 months. The investigators utilized coping skills training, systematic desensitization, and *in vivo* desensitization with participant modeling to help her overcome her fears.

As a final example of research demonstrating the utility of modeling to treat fears and phobias, consider a study conducted by K. Gunnar Goetstam and Dagfinn Berntzen in 1997. In this investigation, three pairs of adults with animal phobias participated. One person in each pair had stated that he or she was unable to participate in exposure therapy. Therefore, this person observed the other participant in the pair receiving direct exposure of the feared animal, thus creating a scenario involving *in vivo* modeling. Results showed that after observing the first person participating in direct exposure, the second person’s phobic reactions reduced significantly. Furthermore, following modeling, the second person engaged in direct exposure to further reduce phobic responding. Results showed that treatment goals were achieved within 15 min for participants who had experienced modeling before desired outcome goals were met, as compared to within 1.5 to 2 h for the participants who experienced direct exposure only.

In addition to research demonstrating the usefulness of modeling to treat aggression and phobias, a significant amount of research has shown that these procedures can be used effectively with individuals with developmental disabilities and/or mental retardation. Research with this population has utilized participant modeling, as well as various forms of symbolic modeling.

The use of modeling procedures with children and adults with autism has received particular attention. In 1986, Adeline S. Tryon and Susan Phillips Keane utilized participant modeling to target imitative play in 3 boys with autistic-like features. In this investigation, participants were exposed to a peer demonstrating appropriate play. Peers were selected for their similarity in

age and gender to the participants and for their ability to engage in appropriate play with toys. Results showed that exposure to peer models resulted in increased appropriate play across a variety of toys, as well as a decrease in self-stimulatory behavior.

Researchers have also evaluated the effectiveness of video (symbolic) modeling with individuals with autism. Thomas G. Haring, Craig H. Kennedy, Mary J. Adams, and Valerie Pitts-Conway effectively used video modeling to teach 3 adults with autism skills used to purchase items from grocery and other stores in their research study published in 1987. Furthermore, Marjorie H. Charlop and Janice P. Milstein’s 1989 research article describes the use of video modeling to teach 3 autistic children conversational speech. Finally, Marjorie H. Charlop-Christy, Loc Le, and Kurt A. Freeman demonstrated in their study published in 2000 that video modeling was more effective than *in vivo* modeling in teaching a variety of skills to 5 autistic children.

In addition to the research just mentioned, others have demonstrated the usefulness of modeling specifically with individuals with developmental disabilities to address developmental problems such as delayed social skills, deficits in expressive language, underdeveloped discrimination abilities (e.g., colors, shapes, on/under), and poor walking performance. Furthermore, researchers have demonstrated the utility of various modeling strategies with individuals with mental retardation who are experienced other clinical problems such as substance abuse problems, phobias and fears, selective mutism, and so on.

As should be evident from the brief review provided, modeling procedures are widely applicable and effective. The research described earlier only provides an introduction to the use of modeling, however. Evidence suggests that modeling procedures can be effectively incorporated into treatments for many different psychological, social, and emotional problems. Other clinical and social issues that have been shown to respond positively to modeling include smokeless tobacco use, parenting, child safety, breast self-examination, self-defense skills, altruistic behavior, and gender stereotyping modification, to name just a few more. Thus, the research supports the general applicability and versatility of modeling interventions with a variety of psychological, social, and health-related issues.

V. CASE ILLUSTRATION

Consider Jeremy, a 13-year-old Caucasian male receiving services in a large-scale residential facility. In

addition to full participation in the milieu therapy provided to all residents, Jeremy was also referred for individual psychological services due to social skills problems, oppositionality, and ongoing severe conduct problems. His behavior problems significantly affected his social functioning in that he was severely rejected by his peers. Teacher, peer, and other staff report all indicated that Jeremy was actively avoided, taunted, and made fun of by the majority of his peers. For example, it was not uncommon for Jeremy's peers to say something such as "Don't talk to me!" in response to his attempts to initiate interactions.

Further assessment on initiation of psychological services revealed the presence of significant social skills deficits that likely contributed to his social rejection. First, he was awkward in his attempts to initiate or maintain conversations. Specifically, he would attempt to start conversations by yelling hello to peers or adults from across the room and generally speak with a voice that was louder than conversational level. Second, Jeremy would attempt to procure interactions with popular peers by using age-appropriate phrases or wearing "trendy" clothes. Rather than elevating his social status, these attempts appeared to further alienate him from his peers, as evidenced by laughter and jeers directed toward him. Third, Jeremy tended to use mannerisms and gestures that were exaggerated and excessive. Fourth, Jeremy demonstrated poor table manners, as evidenced by him talking with food in his mouth, eating rapidly and/or with his finger, and eating in a messy manner (resulting in food being on his face and/or clothes). This particular behavior pattern often set the stage for ridicule and rejection during the lunch recess hour. Finally, Jeremy typically presented with a facial expression characterized by a clownlike vacant grin.

Modeling procedures were used during individual therapy sessions to target his social skills deficits directly. First, *in vivo* modeling was used to target his poor table manners. To accomplish this, the therapist conducted 3 one-half-hour sessions weekly while he and Jeremy sat together at a dining table in the lunchroom at Jeremy's junior high school. Sessions occurred during Jeremy's regular lunch period while he and his peers ate lunch. After establishing the need to target table manners, and describing the rationale for participant modeling, the therapist described verbally and demonstrated physically proper table manners (e.g., use of a napkin, appropriate rate of eating, chewing with one's mouth closed). Then, collaboratively the therapist and Jeremy selected a specific skill for focus, rather than attempting to intervene with all relevant behaviors at once.

Once the target skill was selected, the therapist initiated each session by verbally and physically reviewing the proper target behavior and then drawing Jeremy's attention to peers who were demonstrating that behavior while they ate lunch. During the observation, the therapist would verbally describe the behavior being modeled by the peer, as well as point out the positive social benefits of engaging in such behavior. After a brief period of observation, Jeremy was then instructed to eat his lunch while attempting to demonstrate the appropriate response. Positive and corrective feedback was provided during this time. Periodic prompts to observe his peers were also provided until Jeremy demonstrated the skill successfully.

In conjunction with *in vivo* modeling to target table manners, symbolic modeling was used to address various other social skills problems (e.g., facial expressions, voice volume). Sessions involving symbolic modeling typically occurred every other week in a therapy session room. Again, the deficit skills were identified and reviewed prior to implementing the intervention. Furthermore, appropriate skills were also discussed and modeled by the therapist. Examples of targets identified included taking turns appropriately, offering praise to his peer, and displaying facial expressions appropriate to the context. After establishing the target behaviors, symbolic modeling was implemented. Symbolic modeling in this case took the form of videotaped interactions between Jeremy, the therapist, and another similar-aged male peer. The peer was selected because care providers had identified him as being quite socially skilled. Interactions occurred in the context of involvement in some sort of board game. Following 10–15 min of playing the game while being videotaped, Jeremy and the therapist would review the videotape so that Jeremy could observe the peer implement appropriate social skills. Further, Jeremy's behaviors were evaluated, and positive and corrective feedback was provided. Then, Jeremy was provided with another opportunity to interact with the peer and the therapist while playing a game, thus allowing for imitation of the desired responses.

Modeling procedures were effective in altering some of Jeremy's serious social skills deficits in the therapeutic contexts. He learned how to eat in a more socially acceptable manner while the therapist was present, how to talk in a more normal tone of voice while playing a game with a peer, and how to change his facial expressions to more closely match the situation (e.g., smile when there was a joke told, scowl when losing the game). The level of prompting that was needed to ensure the use of these skills decreased during the ther-

apy situation. Unfortunately, however, Jeremy was discharged from the residential program before specific measures could be taken to prompt generalization and maintenance of treatment gains, as these did not appear to be occurring naturally.

VI. SUMMARY

Modeling is a psychotherapy technique that is designed to create opportunities for the client to learn new behavior patterns or alter existing ones. Implementation of the intervention involves several relatively simple steps. First, the client is exposed to a model who demonstrates the desired response. The model can be presented live, symbolically, or cognitively. Second, the client is provided with an opportunity to imitate the desired response. Finally, corrective and positive feedback is provided to the client.

Modeling can produce two different forms of learning, imitation and vicarious learning. Imitation simply involves the observer matching the topography of the model's behavior. Vicarious learning, on the other hand, involves either an increase or decrease in the likelihood that the client will demonstrate the modeled behavior as a result of the model being rewarded or punished, respectively. As a result, the modeling situation should be created in a manner that capitalizes on the desired outcome. For example, if modeling is being used to decrease problem behavior, then the intervention should associate negative consequences with engaging in the behavior.

Research has demonstrated that modeling is an effective psychotherapeutic technique. Evidence suggests

its utility with clients from diverse backgrounds, as well as those with diverse intellectual or developmental functioning. Furthermore, the intervention has been shown to affect a variety of clinical and social problems—such as smoking, phobias and fears, deficits in parenting skills—as well as important health-related behaviors (e.g., self breast examination). Finally, evidence suggests that the intervention may be most effective as a component of a larger set of strategies to address clinical or social issues.

unpleasant sense of agitation or sadness rather than classically elevated mood.

GLOSSARY

- depression** An abnormal psychological state that is characterized by reduction of mood, interest, and vitality. It can be considered as the opposite state of mania. Depression differs from normal sadness in the severity of the symptoms and the lack of reactivity to otherwise pleasurable activities.
- dysphoria** An unpleasant emotional state that may be a mixture of sadness, low-grade anxiety, and negativity. Dysphoria is most likely a nonpathological alteration of mood state that represents a part of the normal spectrum of human experience.
- dysthymia** A chronic, persistent disturbance of mood that has some low-grade features of depression persisting over prolonged periods.
- hypomanic episodes** These share many features of manic episodes although they are considered to be not as severe as mania, or to cause as significant an amount of disruption to a sufferer's social or work abilities.
- mania** An abnormal psychological state that is characterized by overexcitement and elevation of mood. A "manic episode" is considered to be present if the symptoms create marked impairment for a person in his or her working and social interpersonal lives.
- mixed mood states** Characterized by the simultaneous presence of manic symptoms and depressive symptoms. Some clinicians refer to this condition as "dysphoric mania," which is characterized by the presence of irritability or an

I. INTRODUCTION

Disorders of mood or affect are among the most commonly recognized psychological disorders in both clinical and community settings. Individuals can develop a mood disorder at any time in their lives, although the nature, clinical presentation, and course of mood disorders vary greatly from individual to individual. This article will describe the features of mood disorders, their etiology, and their treatment.

The terms "mood" and "affect" are often used interchangeably; however, they refer to two different concepts. Mood is best defined as, "the prevalent emotional state described by an individual, consistently present over a prolonged period of day to weeks," as opposed to affect, which is best defined as, "the observable emotional state of an individual at a specific point in time, that may be changeable from moment to moment." Metaphorically speaking, mood refers to a person's climate whereas affect refers to the day's weather conditions.

The disorders of mood clinically recognized currently in the *Diagnostic and Statistical Manual of Mental Disorder, 4th edition (DSM-IV)* are:

1. Depression
2. Mania or hypomania
3. Dysthymia

4. Mixed mood states
5. Dysphoria

II. DEPRESSION

A. History of Depression

Depression is a heterogeneous condition that encompasses different types of illness. In ancient Greece the term “melancholia” (referring to “black bile”) described a temperament characterized by lethargy, sullenness, and brooding. The concept infiltrated Western and non-Western cultures over time and numerous philosophers and physicians have written of its effects on the human psyche.

Sigmund Freud in his 1963 text *Mourning and Melancholia* conceptualized depression as a process of “internalizing” lost loved ones and “turning anger inwards” so that negativity directed at the loss would dominate the psyche. In the latter half of the twentieth century, psychological and psychiatric disorders were seen in more complex biological, psychological, and social terms, leading to a broader conceptualization of depressive disorders as having primarily psychological or biological origins. Currently, depression that is of clinical significance is referred to as a “major depressive disorder” by the American Psychiatric Association. This is the core concept around which our current classification of mood disorders revolves.

B. Phenomenology of Depression

The features of a major depressive disorder are shown in Table I. More severe forms of depression can occasionally have a number of unusual psychotic features such as delusions (false unshakeable beliefs) or hallucinations (disturbances of perception without a stimulus, e.g., hearing voices).

There is considerable variation in the experience and presentation of depression across the life span. In children and adolescents, depression may manifest in non-emotional ways such as behavioral deterioration, withdrawal, irritability, weight loss, school refusal, or self-injury. In the elderly, depression may manifest as preoccupation with health, paranoia, memory loss, cognitive impairment, or irritability. There is also a significant overlap between depression and responses to grief.

C. Epidemiology of Depression

Estimates of the prevalence of major depressive disorder by age and gender have been derived from the

TABLE I
Features of Major Depression

-
1. Significantly depressed mood that is in excess of normal sadness
 2. A loss of interest in an individual's usual activities
 3. Marked loss of self-esteem, or self-reproach
 4. Impaired sleep
 5. Psychomotor agitation or retardation (a subjective sense of either psychological and physical perturbation or slowing)
 6. Reduced or increased appetite with weight loss or weight gain
 7. Feelings of hopelessness about the future
 8. Suicidal thinking
 9. Significant anxiety such as panic attacks or generalized worry or obsessional thinking
-

The Epidemiological Catchment Area (ECA) study of 18,000 community and institutionalized subjects over 18 years of age at five sites throughout the United States, according to Weissman and colleagues in 1991. The ECA found that the overall lifetime prevalence of mood disorders is 6%. This differs slightly from the 1994 DSM-IV data that suggest a lifetime prevalence of 10 to 25% risk of depression in women as opposed to a 5 to 12% lifetime risk for men. The ECA data indicate a much higher prevalence of all the mood disorders among persons under the age of 45. The ECA also reported a relatively higher prevalence of major depressive disorder in women than in men, which, although consistent across the ages, was more evident among the younger adult group than in the elderly or in childhood. The study also found alcohol abuse and dependence was more prevalent in men than in women, leading some to argue that depressive disorders and alcohol abuse and dependence may be different manifestations of the same biopsychosocial vulnerability.

Sex differences in depression begin in early adolescence and persist at least until midlife. However, women with a previous history of a depressive episode are no more likely to experience a new episode than men with a previous history of a depressive episode. This suggests that the higher risk in women results from women having a higher risk of experiencing major depressive disorder for the first time.

A number of studies performed prior to the ECA study suggested that the prevalence rates of depressive disorders may be changing. The findings seemed to indicate a progressively lowering of the age of onset of depressive disorders and a possible increase in childhood

mood disorders as well as an observed reduction in suicide in the elderly.

D. Etiology of Depression

As with most psychological disorders, the causes of depression are multiple and overlapping. It is customary to divide etiological theories of depression into biological, psychological, and social factors.

1. Biological Factors

a. Biogenic Amines The human brain communicates with itself biochemically. The biological chemicals that are involved in this process are referred to as neurotransmitters. There are likely to be numerous neurotransmitters involved in the complex processes of the human brain; however two chemicals from the amine family have been implicated in the disordered functioning of the brain in depression, according to Nemeroff in 1998. The first, serotonin or 5-hydroxy-tryptophan (5-HT), is the most active biological amine in the human brain. A second biogenic amine, noradrenaline (NA), has also been implicated. The biogenic amine theory of depression postulates that levels of 5-HT and NA are present in subnormal levels in the parts of the human brain that regulate mood. The mechanism of action of virtually all antidepressant compounds is to effectively increase the level of activity of these compounds.

b. Neuroendocrine Factors Research by Nemeroff in 1998 indicated that the state of depression is associated with alterations in the level and activity of various endocrine glands, particularly the adrenal gland and the thyroid gland. This research demonstrated that higher levels of corticosteroids such as cortisol are associated with depression, as are alterations in responsiveness of the adrenal gland to the suppressive effects of artificial corticosteroids such as dexamethasone. Other hormonal disturbances include alterations in thyroid gland function.

c. Genetic Factors There have been numerous family and molecular studies of depression; however, progress has been limited by the fundamental problem of phenotypic identification. The controversy regarding the precise definition of depression has limited the study of depression to specific groups of individuals with “undisputed” depression. These patients tend to have more severe depression and are more similar in presentation than many patients treated in clinical settings. This has likely distorted the findings regarding depression to some degree, as most of the patients studied have had this more severe and uniform type of illness.

In general, most family studies highlight that depression and manic depression tends to cluster in families, according to Tsuang in 1990. The risk of developing depression in an individual with a first-degree relative with either depression or manic depression varies from 7 to 15% for depression and manic depression. Moreover, studies of identical (monozygotic) and nonidentical (dizygotic) twins indicate that the concordance for depression is approximately 60% for monozygotic twins and 30% for dizygotic twins, as discussed by Taylor in 1993.

Studies examining linkage of depression to other genes and molecular markers have been promising but inconclusive. In essence, the balance of opinion regarding the genetic etiologic factors in depression is that they are polygenic and multifactorial.

2. Psychological Factors

a. Attachment Style In the 1950s, John Bowlby evolved the concept of “attachment,” which referred to the complex process by which animals and humans seek proximity to and interact with caregivers. Bowlby postulated that there was a biological and psychological drive to seek proximity to caregivers. Later studies, such as Ainsworth and colleagues’ 1985 observations of infants’ responses to separation from their caregivers, created the notion that human attachment could be either “secure” and flexible, or “insecure.” The notion that attachment styles remained fixed throughout the life span suggested that adults could also be securely or insecurely attached. It is common to observe patterns of disturbed attachment in individuals who develop depressive disorders; however, insecure attachment in itself does not condemn an individual to depression. It is likely that a “poorness of fit” between a person with an insecure attachment style and his or her social environment will predispose an individual to depression.

b. Cognitive Style In the late 1960s, Aaron Beck formulated the idea that certain styles of viewing the world could predispose an individual to depression. Beck saw that individuals evolved a pattern of perceiving and interpreting events described as a “schema.” A cognitive schema that was “depressogenic” was characterized by a triad of a negative view of self, present circumstance, and future circumstances. Further, depressed individuals have been found to have depressive attributional styles that are more global and stable than nondepressed individuals. Beck’s clinical approach thus advocates identifying and altering factors in these types of schema.

c. Personality and Temperament Personality refers to the relatively enduring and stable patterns of thinking,

behaving, and acting that are present consistently over time. The various recent psychiatric classification systems such as the American Psychiatric Association's 1994 *Diagnostic and Statistical Manual of Psychiatric Disorders 4th Edition (DSM-IV)* and the World Health Organization's *International Classification of Disease (ICD-10)* have highlighted the concept of "personality disorder" as a substantive clinical entity. This construct emphasizes the presence of persisting maladaptive patterns of interaction that produce clinically significant impairment in social, occupational, and interpersonal functioning. Certain types of personality, such as those with unstable emotions or relationships (borderline personality disorder) or excess perfectionism (obsessional personality disorder) may be at higher risk for depression.

Temperament refers to those biologically based dispositions that color personality. It was of interest in antiquity and has more recently enjoyed increased attention in a research and clinical context. Temperament is evident across the life span and relatively stable over time. Authors such as C. Robert Cloninger in 1987 have described temperament-based personality variables such as "novelty seeking," "harm avoidance," and "reward dependence" that may have their origin in neurophysiological states. These temperamental characteristics may have significance in the genesis of depression.

3. Social Factors

a. Early Environment Loss of a parent in early childhood has been long considered a risk factor for the later development of depression. More recently, loss of a parent either through death or family disintegration and the associated ecological disruptions have been associated with depression as well. Early childhood difficulties such as childhood anxiety disorders, behavioral problems, or illness may predispose an individual to later adult psychopathology.

b. Gender There has been an apparent higher incidence of depression in women as opposed to men. This has been debated, however, as some experts, including Jorm in 1987, have argued that the prevalence of mood disorders is roughly equal between the sexes, but that women are more likely to present for treatment or divulge depressive symptomatology.

c. Interpersonal Factors Specific studies including Brown's 1978 research, have isolated independent risk factors for depression in women including the lack of a

confiding relationship and having more than three children. Similarly, the lack of a social support network seems to be a risk factor for depression in both sexes. Unemployment and other social adversity as well as abrupt loss of status are also associated with depression.

E. Treatment of Depression

As depression is invariably the product of a complex interaction of biological, psychological, and social factors, interventions in the treatment of depression are also grounded in these three areas.

1. Biological Treatments for Depression

a. Antidepressant Medication The current understanding of the biochemical origins of depression has led to several generations of medications that putatively correct the underlying "biochemical imbalance." At present these agents all have the effect of altering the activity of biogenic amines in the human brain. The classes of agent and their putative mechanisms of action are listed in Table II and depicted in Figure 1.

Duration of drug treatment. The duration of treatment with antidepressant agents has been an area of recent controversy. Studies have indicated that in many cases depression is a relapsing and remitting condition that requires long-term treatment, according to the American Psychiatric Association in 1993. Several useful terms describing the stages of treatment of depression include:

TABLE II
Classes of Antidepressants and
Their Putative Mechanisms of Action

Selective serotonin reuptake inhibitors (SSRI)—Inhibit serotonin reuptake pump
Serotonin-noradrenaline reuptake inhibitors (SNRI)—Inhibit serotonin and noradrenaline reuptake pumps
Monoamine oxidase inhibitors (MAOI)—Inhibit the enzyme that catabolizes biogenic amines
Tricyclic agents—Inhibit serotonin and noradrenaline reuptake and alter postsynaptic receptor activity
Tetracyclic agents—Block alpha-2 noradrenaline receptor (stimulation of this inhibits release of biogenic amines)
Other agents—Varied degree of activity
mirtazapine—blocks alpha-2 noradrenergic receptors and type 2 and 3 serotonin receptors
nefazodone—inhibits serotonin transporter and type 2 serotonin receptors

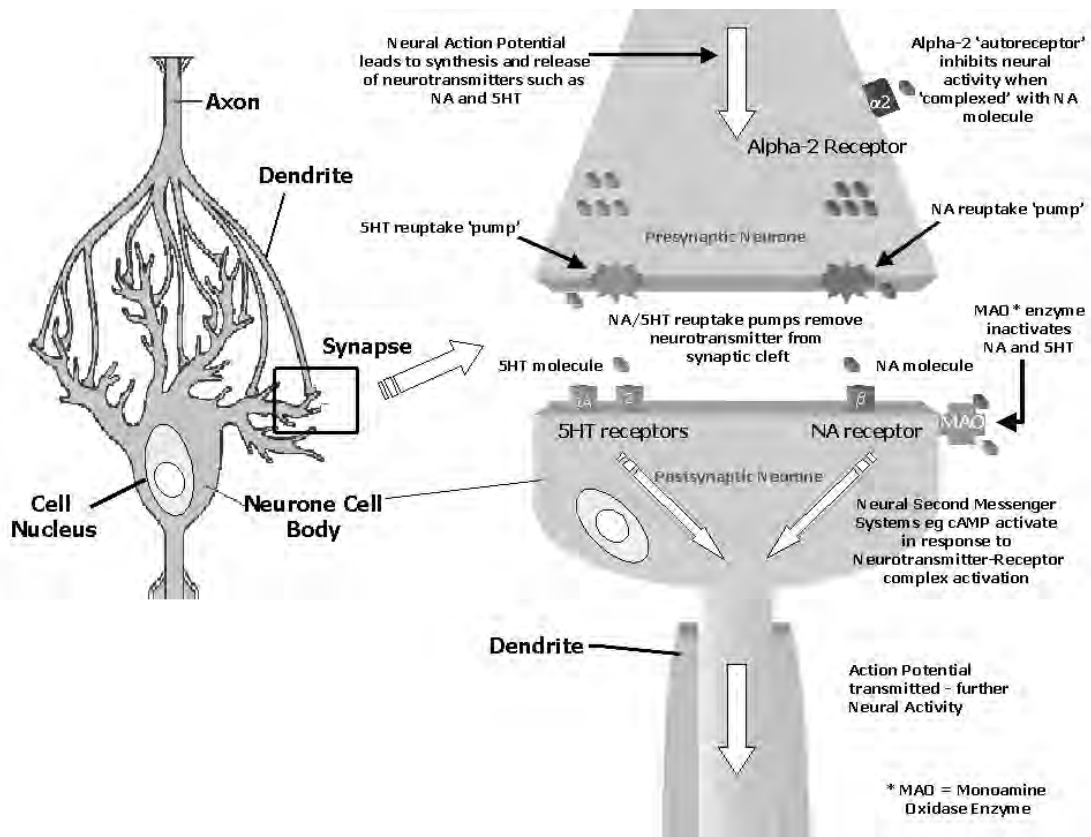

FIGURE 1 Putative mechanisms of action of antidepressant agents.

1. **Response:** the point at which depressive symptoms alter following treatment initiation. A 50% reduction in the level of symptoms is typically considered a response to treatment.
2. **Remission:** the point at which the diagnostic criteria for depression are no longer met. There may be residual symptoms at this point.
3. **Recovery:** the point of resolution of the depressive syndrome. This period requires 3 months of remission prior to being defined as remission.
4. **Relapse:** the reemergence of the depressive syndrome within the 3-month recovery phase.
5. **Recurrence:** the reemergence of symptoms during the remission phase.

The natural history of depressive disorders is for a 50% rate of recurrence after one episode of major depression and an 80 to 90% rate of recurrence after two episodes, according to the American Psychiatric Association in 1993. It states, therefore, that long-term treatment with antidepressant medication is necessary in cases where individuals are at high risk of recurrent depression.

b. Electroconvulsive Treatment Electroconvulsive treatment (ECT) is perhaps the most controversial area of psychiatric practice. In the late 1930s an Italian psychiatrist Ugo Cerletti experimented with convulsive treatments using electrical stimulation, as described by

Abrams in 1988. This was based on observations that people suffering comorbid epilepsy and depression experienced improvements in their mood after seizures. According to Abrams, as technology and neuroscience have advanced, ECT has become a safe and effective treatment for severe biological depression.

It is thought that the therapeutic effects of ECT result from changes in the brain's biochemistry. Over a course of treatment, ECT has anticonvulsant effects that raise seizure threshold and decrease seizure duration. The so-called seizure threshold at which seizures will occur increases during ECT and it is thought that this may be a part of its mechanism of action. Periods of increased electrical activity in the brain, including seizures, promote the release of the compound adenosine, which in turn acts on several neuroreceptors to produce alteration of their chemical activity. Additionally, ECT increases norepinephrine turnover and α_1 -adrenergic receptor sensitivity and decreases presynaptic α_2 -adrenergic receptors. ECT also appears to enhance the effects of the serotonergic system but differs from antidepressant medication treatment in producing increases in serotonin (5-HT₂) receptor binding in the cerebral cortex. These findings suggest that ECT may have important actions on monoaminergic transmission that contribute to its therapeutic effects.

c. Rapid Transcranial Magnetic Stimulation Rapid transcranial magnetic stimulation (rTMS) uses an exter-

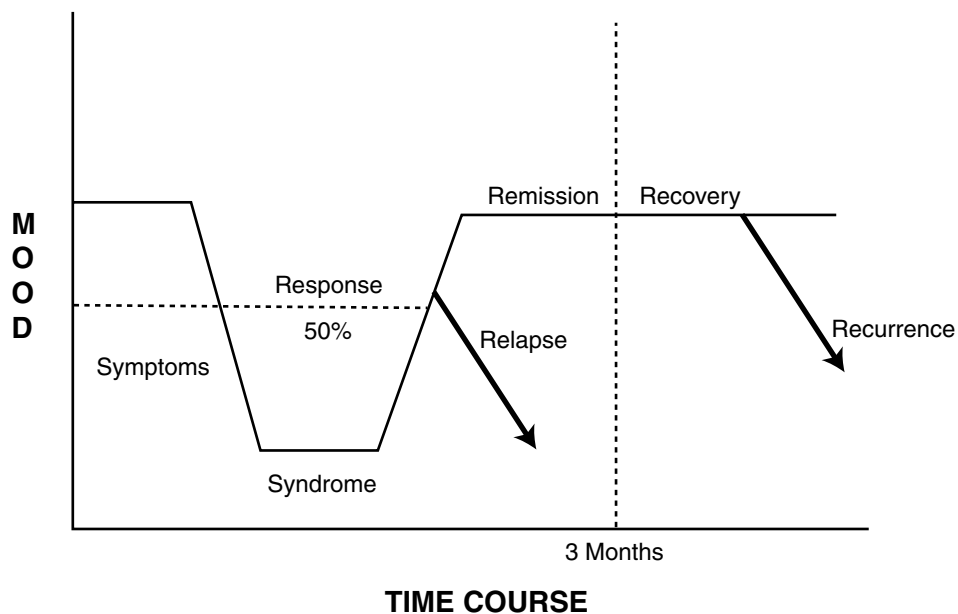

FIGURE 2 The stages of depression treatment.

nal magnetic field passed through a small coil applied to the scalp to allow focused electrical stimulation, which generates a focused magnetic field of 1.5 to 2 teslas. The magnetic field in turn depolarizes brain cells to a depth of 2 cm from the coil. Some evidence suggests that major depression may be characterized by hypoactive cortical areas. It was postulated by Post and colleagues in 1997 that rTMS stimulation of these frontal areas may help relieve symptoms.

Currently, the use of rTMS for the treatment of neurological and psychiatric disorders is still under investigation. Several open-label and controlled studies have suggested that rTMS may be at least temporarily effective in both animal models of depression and patients with major depression, according to Post and colleagues in 1997. A number of small, open-label studies have suggested that rTMS may be effective in some patients with treatment-resistant major depressive disorder as well as in those with milder major depressive disorder.

d. Phototherapy Phototherapy (light therapy) was first introduced in 1984 as a treatment for seasonal affective disorder (SAD; depression with seasonal pattern). In this disorder, according to Wehr and Rosenthal in 1989, patients typically experience depression as the sunlight period of the day decreases with advancing winter. Women represent at least 75% of all patients with seasonal depression, and the mean age of presentation is 40, as discussed by Blehar in 1989.

Phototherapy typically involves exposing the afflicted patient to bright light in the range of 1,500 to 10,000 lux or more with a light box that sits at face level for approximately 1 to 2 hours before dawn each day, according to Lam in 1994. As circadian rhythms are frequently disrupted in major depression, this is thought to be the basis of SAD and some of the features of depression. Exposure to light results in a phase advance that shifts the phase response curve earlier in the day. In addition, light suppresses the production of melatonin from the pineal gland at night. A number of controlled studies by Blehar in 1997 suggests that phototherapy is effective as monotherapy and as an adjunctive agent in the treatment of seasonal depressions.

2. Psychological Treatments for Depression

The specific details of this area are discussed elsewhere in this text. In brief, a number of studies have confirmed that the focal structured psychotherapies such as Beck's cognitive behavior therapy (CBT) and Klerman's interpersonal psychotherapy (IPT) are equivalent in antidepressant efficacy for depression of mild to moderate

severity, according to Elkin in 1989. There is also evidence that the combination of antidepressant medication and psychotherapy has greater efficacy than either alone. Evidence suggests that a short-term psychotherapy, while efficacious in acute depression, confers little protection against further episodes. There is now a shift to studying and providing psychological treatments in maintenance fashion as well as acute treatment for depression.

III. MANIA AND BIPOLAR DISORDER

A. History of Bipolar Disorder

Aretaeus of Cappadocia (ca. 150 AD) is likely to have initially nominated that mania and melancholy were associated entities stating, "It appears to me that melancholy is the commencement and a part of mania" (see Goodwin and Jamison's 1990 work). In the 19th century, French psychiatrists offered the description "folie à double forme." Later that century, the German psychiatrist Emile Kraepelin elaborated the ideas that the core of depression was lowered mood and slowed mentation, whereas mania was characterized by elation and accelerated mental activity. Unlike depression, which may have significant "neurotic" contributions, Kraepelin saw manic states as being hereditary and biologically determined.

B. Phenomenology of Bipolar Disorder

Bipolar disorder is diagnosed when a person suffers a manic episode at some point in his or her lifetime. People who suffer from bipolar disorder are prone to develop episodes of hypomania, mania, and depression. The features of a manic episode are listed in Table III.

A "manic episode" is considered to be present if the symptoms create marked impairment for a person in his or her work or social and interpersonal functioning. "Hypomanic" episodes share many features of manic episodes although they are considered to be not as severe or to cause as significant amount of disruption to a sufferer's social or work functioning.

Current classification systems describe a number of different types of bipolar disorder:

1. **Type I bipolar disorder:** Diagnosed if an individual suffers an episode of mania. Depressive episodes may or may not be present as well.

TABLE III
Features of a Manic Episode

-
1. Distinct periods of abnormal or persistently elevated or irritable moods
 2. Inflated self-esteem or grandiose behavior
 3. A decreased need for sleep
 4. Overtalkativeness
 5. Racing thoughts
 6. Being easily distracted
 7. Overactivity including increased productivity, increased sexual drive, or purposeless agitation
 8. Overspending
 9. Disinhibition in social activities
 10. Possible recklessness in behavior including gambling, sexual indiscretions, or exercising poor judgment
 11. Psychosis including hallucinations (abnormal sensory experiences), severe disorder of thinking, or delusions (fixed unshakeable ideas that are often false).
-

2. **Type II bipolar disorder:** Diagnosed if an individual suffers episodes of both depression and hypomania.
3. **Mixed mood states:** Characterized by the simultaneous presence of manic symptoms and depressive symptoms. Some clinicians often refer to a condition known as “dysphoric mania,” which is characterized by the presence of irritability or an unpleasant sense of agitation or sadness rather than classically elevated mood.

C. Epidemiology of Bipolar Disorder

The ECA data suggest that the lifetime risk for bipolar disorder is approximately 1.2% in the general population. It commonly affects young adults from 20 to 40 years of age. It tends to affect both men and women equally, and also appears to have a similar rate of occurrence across a variety of cultural and racial groups, according to Weissman and colleagues in 1991.

D. Etiology of Bipolar Disorder

1. Biological Factors

Unlike depression, mania is now regarded as primarily a biologically determined process. The general consensus is that during a manic episode the brain is usually overactive in terms of chemical activity, electrical activity, and generalized neurological processes. Most studies, according to Post in 1997, have consistently indicated

that there may be imbalances or overactivity of a number of neurotransmitters including serotonin, noradrenaline, dopamine, glutamate, and other excitatory compounds during acute mania as well as possible disturbances in thyroid hormone or cortisol and newly described neurochemicals such as neuropeptides.

More recently, researchers have uncovered some possible disturbances in complex chemical processes occurring within the neurons including alterations in the activity of so-called second messenger systems involving compounds such as cyclic adenosine monophosphate (cAMP) and phosphatidylcholine, as described by Post in 1997.

There has been some additional interest in a process referred to as “kindling” (in which a number of neurons are chronically hyperactive and have a tendency to summate with produced marked neural overactivity, rather like kindling in a fire combining to produce a large flame) in the temporal lobe of the cerebral cortex and more specifically the deep nuclei that comprise the limbic system including the hippocampus and amygdala, according to Post in 1997.

2. Genetic Factors

A first-degree relative (such as child or sibling) of someone suffering from bipolar disorder has approximately a 6% risk of developing bipolar disorder but a 15% risk of developing either depression or bipolar disorder, according to Tsuang in 1990. Tsuang notes that children of people suffering from bipolar disorder have approximately a 25% risk of developing a mood disorder if either parent suffers from bipolar disorder and a 75% risk of developing a mood disorder if both parents suffer bipolar disorder.

E. The Treatment of Bipolar Disorder

1. Medication

The treatment of mania and hypomania has two phases: an acute phase, in which the acute syndrome is quelled and social and occupational impairment is improved; and a maintenance phase, in which medications are administered long term to prevent the recurrences of the condition.

a. Mood Stabilizers

Lithium. In the 1940s Australian psychiatrist John Cade discovered the tranquilizing properties of lithium (see work by Goodwin and Jamison in 1990). Since

that time lithium has been the primary treatment for acute and prophylactic treatment of mania. In comparative studies with antipsychotic agents, it yields better overall improvement in most aspects of manic symptomatology, including psychomotor activity, grandiosity, manic thought disorder, insomnia, and irritability, according to Post in 2000. The type of patient most likely to respond to lithium carbonate is someone with a classic presentation and euphoric mania (rather than dysphoric mania) and a pattern of mania followed by a depression and then a well interval. The number of patients with this “classic” presentation is relatively small, hence lithium’s status as the “gold standard” treatment is under threat.

Valproic Acid. Studies by Bowden and colleagues in 1994 demonstrated that anticonvulsant medications such as valproic acid are efficacious in acute and maintenance treatment of bipolar disorder. This is possibly due to the effects on temporal lobe kindling and also its effects in acting on so-called inhibitory neurotransmitter systems that reduce neural activity. This research indicates that valproic acid seems to be the treatment of choice for dysphoric mania or mixed states as well as those patients with rapid-cycling types of bipolar disorder. Valproic acid also has the potential benefit of rapid oral loading in acute mania, which is usually well tolerated and associated with a rapid onset of response, according to Post in 2000.

Carbamazepine. Carbamazepine appears to have similar benefits as valproic acid, as described by Denikoff and colleagues in 1997; however, its side effect profile and potential for drug interactions tend to lessen its use.

Lamotrigine. Lamotrigine is a newly approved anticonvulsant for add-on therapy that has antidepressant and possibly mood-stabilizing properties, according to Calabrese and colleagues in 1999. Its place in the management of bipolar disorder is still being investigated; however, a significant risk of severe rash may limit its use.

Gabapentin. Gabapentin is a newly approved anticonvulsant for adjunctive therapy that may also have some mood-stabilizing effects in bipolar patients. The drug appears to have positive effects on sleep and anxiety.

Topiramate. Topiramate is a recently approved add-on agent for treatment of refractory epilepsy. Preliminary experience suggests that it may have mood-stabilizing properties in rapid-cycling patients, with better antimanic than antidepressant effects, according to Post in 2000.

b. AntiPsychotic Agents The use of major tranquilizers has historically been confined to the acute treat-

ment of mania, particularly if there are psychotic features present. In recent years, a new class of major tranquilizers that lack the troublesome side effects of older antipsychotic agents has helped to improve the acute management of mania. These agents include risperidone and olanzapine (both serotonin-dopamine antagonists), which are frequently coadministered with mood stabilizers to control acute mania. In some cases, these agents need to be used for maintenance treatment as well.

2. Psychological Management

Psychosocial factors may contribute 25 to 30% to the outcome variance of bipolar disorder and despite optimal pharmacotherapy, up to 50% of sufferers may encounter further episodes, according to Joyce in 1992. It is important to note, however, that all of the studies of psychological interventions in the treatment of bipolar disorder have been used during the recovery phase of treatment, and have been used only to prevent relapse—there is no evidence that any psychological intervention is of benefit in the acute treatment of mania.

a. Family Therapies Several studies support the efficacy of brief family-focused interventions in both inpatient and outpatient settings, with an emphasis on education, problem solving, and reduction of ambient stress within the family, as discussed by Miklowitz and colleagues in 1996.

b. Group Psychotherapies Several studies suggest the benefits of group therapies, although no actual controlled studies exist. There is limited evidence of benefits in the areas of compliance with medication, problem solving, and interpersonal functioning, according to Scott in 1995.

c. Cognitive Behavior Therapy Cognitive behavior therapy for bipolar disorder has focused on improving compliance and in recognition of early symptoms of relapse. The results of some trials suggest that this reduces relapse rates, and there are some observations of improvement in social functioning and employment stability, as discussed by Robertson in 2000.

I. THEORETICAL BASIS

Multicultural therapy (MCT) developed out of the recognition that current forms of psychotherapy were inadequate to meet the needs of ethnic minorities. In fact, some have suggested that ethnic minority clients have been harmed by psychotherapy as currently formulated and practiced. Barriers to effective cross-cultural counseling included the generic aspects of Eurocentric counseling: verbal and emotional expressiveness, individual centered, self-disclosure and intimacy, nuclear family orientation, and egalitarian relationships. These elements of counseling and therapy are often in opposition to the beliefs or values of ethnic minorities. Many ethnic groups value the family rather than the individual, have hierarchical family patterns, demonstrate different communication patterns and styles, and are more hesitant about revealing information of a personal nature. In addition, there has been little attention paid by humanistic, psychodynamic, and cognitive-behavior therapies to issues of racism, oppression, and acculturation conflicts. Because of the inadequacies of current counseling theories and techniques, there was a need to develop a multicultural therapy.

MCT has developed into two somewhat divergent camps, although both have stressed the importance of considering culture in counseling. Total immersion into the cultural group under study is a part of the emic approach (culture-specific model). It attempts to generate new theories of psychopathology and therapy from the study of different cultural groups. Current systems of

GLOSSARY

- acculturation conflict** Conflict between traditional ethnic values and the adoption of values of the host culture.
- barriers to cross-cultural psychotherapy** Values, expectations, and behavioral differences between the therapist and client that impede the therapeutic process.
- cultural encapsulation** Ethnocentric perspective that does not acknowledge cultural differences.
- culture-specific (emic) therapy** Therapies developed from the study of the helping processes found in specific cultural groups.
- co-construction** A process in which therapists work with and learn from clients in jointly developing appropriate intervention strategies.
- ethnic identity models** Models that indicate the “stages” that members of ethnic groups go through in attaining identity.
- generic characteristics of counseling** Traditional Euro-centered therapy that is based on the importance of openness of expression, individualism, action orientation, and a clear distinction between physical and emotional realms.
- universal (etic) multicultural therapy** Therapies based on hypothesized factors that transcend cultural differences and involve shared human experiences but holding that culture is universal.
- worldview** Frame of reference based on a particular set of values and beliefs.

the classification and treatment of mental disorders are considered to be “culturally encapsulated.” As Uchenna Nwachuku and Allen Ivey in 1991 pointed out, “In contrast with the conventional approach of adapting existing counseling theory to ‘fit’ a new culture, the culture-specific method seeks to generate a new theory and technologies of helping.” Only by adopting such a methodology can one prevent the imposition of an existing framework on other ethnic groups. New theories originating from the culture under study can be developed using anthropological methods and observations. Natural helping styles and means of problem solving for each cultural group are then identified. A culture-specific psychotherapy training model involving the African-Igbo, a tribe in Nigeria, was described by Nwachuku and Ivey. The steps involved:

1. Generating a culture-specific theory. Questions such as, “How do people in this culture view the helping relationship?” “What methods are used in solving problems?” “How similar or different are they from EuroAmerican approaches” were used to determine problem-solving approaches from the African-Igbo perspective. Study of the culture revealed a group, extended family, and community orientation. Childrearing was shared by the family and the entire community. The locus of decision making centered in the extended family and community, and problem solving involved participation by these units.

2. Generating training material based on the analysis of the culture. It was determined that effective helping approaches involved a multiperspective rather than individual frame of reference. The family and community values in decision making were stressed as well the need for harmony for cultural tradition. A more directive style was more in line with cultural expectations.

The emic or culture-specific orientation avoids the “imposed etic” or the presumed universality of theories developed in one culture and applied to another. Many EuroAmerican therapists apply psychodynamic, humanistic, or cognitive-behavioral techniques to members of different ethnic groups without questioning the validity of this practice. Donald Cheek was one of the first to point out the ethnocentric basis of traditional counseling approaches. He stated,

I am advocating treating one segment of our population quite differently from another. This is implicit in my statement that Blacks do not benefit from many therapeutic approaches to which Whites respond. And

I have referred to some of these approaches of counselors and therapists as “White techniques.”

Many of the recommendations regarding therapy with ethnic minorities contain aspects of the culture-specific approach. With American Indians, there has been suggestions to incorporate cultural healing elements such as the talking circle, sweat lodge, and community interventions such as network therapy. African American therapists often indicate the importance of the Afrocentric worldview. This perspective has its roots in both the African heritage and experiences from slavery. As opposed to the Eurocentric view, there is greater emphasis on interdependence, extended family orientation, spirituality, and holism. Treatment modalities are expected to include Afrocentric elements.

In 1993, Paul Pedersen and Allen Ivey developed a description of four synthetic cultures that are actually based on the extreme grouping of the values of different cultural groups found in the world: (a) The Alpha culture is described as high in power distance. Inequalities as accepted and expected. Children are taught to obey and authority is respected; (b) The Beta culture is characterized as strong uncertainty avoidance. To deal with uncertainty, rigid rules have developed, and deviant or different ideas are suppressed. Citizen protest is repressed and conservatism and emphasis on the law is popular; (c) The Gamma culture is associated with high individualism. Emphasis is on the individual or the nuclear family. People have the right to express their own opinion and freedom of the press is supported. Education is the process of learning how to learn and evaluate; (d) The Delta culture is highly masculine. Money and possessions are dominant values. Men are expected to be assertive and tough while women should be nurturing and tender. Performance, strength and accomplishments are admired. Culture-centered therapy skills involve identifying culturally learned values and expectations and developing techniques and goals that are consistent with the specific groups.

In general, the culture-specific models have identified the differences in values, orientation, and philosophy that need to be addressed in counseling and the new therapy skills that need to be learned in working with culturally different populations. However, not all multicultural clinicians share the culture-specific perspective in multicultural therapy. Suzette Speight, Linda Myers, Chikako Cox, and Pamela Highlen argued in 1991 that the culture-specific approach makes multicultural psychotherapy an “extra skill area” that is somehow different from “regular counseling.” They

contend that culture-specific methodology could have negative consequences, particularly if a “cookbook” method of therapy is employed with a checklist of the values of each cultural group and directions on how counseling should proceed. Such an approach would overemphasize cultural differences, ignore individual variations, and lead to possible stereotyping ethnically different clients.

The second trend in multicultural therapy involves an etic or modified universal perspective. Under this framework, all counseling is considered to involve cultural factors (defined broadly to include differences between the therapist and client in terms of diversity issues such as age, gender, social class, religious background, and ethnicity). A proponent of the universal perspective to multicultural therapy is Mary Fukuyama who argued that cultural factors are present in all psychotherapy and must be addressed. In working with all clients it is important to consider the context and social environment when conceptualizing the presenting problem. Such a focus would enable the therapist to gain an understanding of the worldview of the client. The modified universal approach would also reduce the danger of stereotyping, encourage the assessment and consideration of cultural values and beliefs, and understand how societal norms and values can affect processes such as acculturation. Criticisms of the universal multicultural perspective include the continued reliance on therapy approaches based on individualistic and Eurocentric models with culturally different groups. Others are concerned that defining culture to include sexual orientation, age, religiosity, and other diversity issues will dilute the emphasis on the plight of ethnic minorities.

Although the culture-specific and universal forms of multicultural therapy have been espoused, neither has not been fully developed as a theory. Not until 1996 was a multicultural therapy theory presented in a complete form. In a book titled, *A Theory of Multicultural Counseling and Therapy* by Derald Sue, Allen Ivey, and Paul Pedersen, multicultural counseling and psychotherapy (MCT) is described as a “metatheory” of counseling or a “theory or theories.” MCT incorporates elements of both the universal and cultural-specific perspectives. As currently constructed, the theory of multicultural counseling and psychotherapy is composed of six propositions:

1. MCT is considered a metatheory of counseling and psychotherapy that includes a culture-centered organizational framework in which to view different theories of

counseling. All theories of psychotherapy are identified as stemming from a particular cultural context. Mental health professionals need to identify the values, assumptions, and philosophical bases in their work. Not recognizing these can result in the imposition of their worldview onto their clients. MCT accepts aspects of the psychodynamic, humanistic, behavioral, and biogenic approaches as they relate to the worldview of the client. MCT co-constructs definitions of the problem and solutions with the client that reduces the chances of oppression. The approach attempts to help individuals, families, and organizations develop new ways of thinking, feeling, and acting both within and between differing worldviews. Failure in therapy can result from an overemphasis on either cultural differences or similarities. Successful therapy involves utilizing a combined perspective.

2. Multiple levels of experiences (individual, group, and universal) and contexts (individual, family, and cultural) affect both the counselor and the client. Although the salience and strength of these identities vary from individual to individual and over time, they must be considered part of the focus of treatment. Elements of the similarities and differences between the therapist and client can either assist or obstruct development of a working alliance. It is important for the therapist to identify and strategize in dealing with these factors. The person–environment interaction is central to MCT. Both the therapist and client are affected on multiple levels through these identities, and this interaction can influence the conduct and success of therapy.

3. Cultural identity of both the client and the therapist can affect problem definition and the identification of appropriate goals and treatment. These dynamics are also influenced by the dominant–subordinate relationship among different cultural groups in the United States. Most theories of helping have ignored issues of dominance and power. The stage of ethnic identity for both White and ethnically different clients can affect the relationship. For many ethnic minorities, the cultural identity can go through stages such as unawareness or unacceptance of the self as a cultural being, recognizing the impact of cultural variables, redefining the self as a cultural being, and the development of a multicultural perspective. Therapists who are not members of ethnic minorities are also hypothesized to go through a parallel process.

4. When the processes of helping and goals are consonant with the experiences and cultural values of the client, the outcome is likely to be enhanced. This can be accomplished by matching the counselor and client on relevant variables or to have the counselor develop a

larger repertoire of multicultural skills. MCT recognizes the two aspects of culturally-sensitive therapy, that of the cultural specific and the universal. The cultural-specific approach can help generate new helping skills and theories whereas the universal can help identify therapy processes transcending culture. Co-construction with the client can facilitate these processes.

5. MCT stresses the importance of developing additional helper roles such as that of an advisor, consultant, advocate, systems interventionist, and prevention specialist. Traditional psychotherapy has emphasized one-to-one interactions. The new roles help focus attention on the family, community, and government policies that may also affect the mental health of a particular client.

6. Instead of self-actualization, insight, or behavior change, the basic goal of MCT is the "liberation of consciousness." It involves the expansion of consciousness as it applies to the individual, family, group, and context for behavior. The underlying cultural dimensions of specific problems are identified with the specific client. MCT therapists are able to draw on both Eurocentric and other cultural forms of helping. The psychoeducational component of MCT is emphasized in helping the client gain awareness of the cultural aspects related to the presenting problem.

II. DESCRIPTION OF TREATMENT

Cross-cultural psychotherapy is still in the evolving phase and has not developed a specific course of treatment. Instead it advocates incorporating a "culture-centered" perspective when employing the different therapeutic approaches and techniques. As mentioned earlier, there are two major models for MCT, the culture specific and the universal. Although the techniques for each are discussed separately, many are shared between the two approaches.

A. Culture-Specific Treatments

1. Assess and explore the indigenous cultural belief systems of the culturally different client. Study and understand culture-bound syndromes and the explanatory basis of disorders. For example, "sustos" is the folk belief among some Latinos and people from Mexico and other Latin American countries, that the soul has left the body because of a frightening event resulting in illness. Healing results in the return of the soul to the body. In "rootwork," a belief found in certain African- and EuroAmerican populations, generalized anxiety

and somatic problems are thought to be the result of witchcraft or sorcery. Cure is effected by utilizing a "root" healer who can remove the spell. *DSM-IV* lists a number of culture-bound syndromes that reveal the belief system underlying the cause and treatment for disorders found in different cultural groups.

2. Become knowledgeable about indigenous healing practices. As opposed to Western beliefs and practices, indigenous practices often involve the support of the disturbed individual through the use of communal and family networks, efforts to problem solve or develop treatment through a group context, reliance on spiritual healing, and the use of shamans or a respected elder from the community. Although we may not subscribe to these particular beliefs or practices, the psychotherapist can assist as a facilitator of indigenous support.

3. Consult with and seek the services of traditional healers within a specific culture. A liaison with indigenous healers can help deliver treatment more effectively. When the problem is clearly defined as primarily rooted in cultural traditions, referral to traditional healers becomes necessary. Advice regarding specific intervention strategies and how they can be reinterpreted to fit the specific culture can lead to more effective outcome.

4. Developing indigenous helping skills entails working in the community, making home visits, and expanding roles to include activism, prevention, outreach and social change. The culture-specific approach can be helpful to therapists in exposing them to multiple cultural perspectives, becoming aware of different philosophical and spiritual realities, and developing a more holistic outlook on treatment.

Techniques based on the universal perspective on psychotherapy are discussed in the context of the multicultural counseling and therapy theory. MCT provides a culture-centered element in traditional forms of intervention. Indeed, the different Eurocentric approaches to psychotherapy can be effectively employed when modified to be appropriate with multicultural populations. Following are some suggested steps in multicultural psychotherapy:

1. Role preparation and establishing rapport. To establish a working alliance, a therapist must be able to establish rapport with a client. The client must feel understood and respected. Some ethnic group members are responsive to emotional aspects of the interview process; for others "credibility" can be demonstrated through the identification of appropriate issues. For many ethnic minorities, therapy is a foreign process. To

enhance the working relationship, it is helpful to explain what happens in therapy, the roles of the both the client and the therapist, and confidentiality. Determining the expectations of the clients, their understanding of the treatment process, their degree of psychological mindedness and difficulties they might have with the therapy is an important aspect of role preparation. The concept of “co-construction”—that solutions will be developed only with the input and help of the client is introduced. Explain that problems are often complex and can be influenced by family, social, and cultural factors, and that you work together to determine if these are areas that need to be addressed.

2. Assessment—incorporating contextual and environmental factors. A culture-centered assessment would begin with an exploration of issues that may be faced by members of ethnic minorities such as immigration or refugee experiences, difficulties at work or in school, language and housing problem, possible issues with discrimination or prejudice, and acculturation conflicts (Recent immigrants or even individuals from first and second generations often show a pattern in which the children acculturate more quickly than the parents, and this difference often leads to conflict within the family). Social and community supports should also be identified. The assessment allows one to determine the possible impact of environmental, cultural, and social issues on the presenting problem. If the therapist determines the problem is external in nature, the therapist must help the client not to internalize the problem. Instead, the therapist might assist the client with developing strategies to cope with the external issues.

a. Ethnic or cultural identity. The cultural identity of both the therapist and client can affect both the problem definition and goals. Different identity development models have been developed for specific ethnic groups, but they all describe the process in which an individual moves from the host culture frame of reference to an acceptance of one's own cultural group. Determining the degree of ethnic identity of a particular client can help prevent stereotyping. Some clients will show little adherence to ethnicity and consider it unimportant whereas others may have a very strong ethnic identity that may influence how they perceive the presenting problem. Intervention strategies will depend on the stage of ethnic identity of the client. Those with a strong desire for assimilation into White society may reject attempts to explore ethnic variables. If the clinician determines that the presenting problem does not involve a rejection of the client's own ethnic identity, then mainstream psychotherapy

approaches can be useful. At another stage of ethnic identity, the individual may become angry over issues of racism and oppression and respond with suspicion to the therapist. They may feel that therapy attempts to have them adjust to a “sick” society. Ethnic identity issues have to be identified to determine if this should be a focus of therapy.

b. Although controversial, a number of ethnic researchers and clinicians posited models of White Racial Identity Development that apply to EuroAmerican therapists. Hypothesized stages are: (a) conformity or the obliviousness and lack of awareness of racism. Success in life is seen to be dependent on effort and not race. Ethnic minorities are evaluated according to EuroAmerican standards. The therapist professes to be “color blind” and does not question the relevance of applying therapy approaches to ethnic groups; (b) disintegration or the conflict produced by the beginning recognition of discrimination and prejudice against ethnic minorities. An individual at this stage may avoid contact with people of color; (c) Reintegration that involves resolving conflict by returning to beliefs of minority inferiority; (d) Pseudoindependence or the acknowledgement of societal biases and the recognition of White privilege. However, the individual may perpetuate racism by attempting to have minorities adjust to White standards; (e) immersion/emersion that is marked by a personal focus on one's own biases and to directly combat racism and oppression; and (f) autonomy in which the individual accepts one's whiteness and is comfortable acknowledging and accepting ethnic differences.

(1) Intake forms. Background information, history, description of the problem, mental status exam, and other means of gathering data should include a section determining whether the characteristics or behaviors are considered normative for the particular cultural group. If the clinician determines the problem may have cultural aspects, a determination has to be made if it applies to a particular individual. This would reduce the chances of stereotyping. When using *DSM-IV-TR*, it is especially important to do a thorough assessment of Axis IV (psychosocial and environmental problems) to eliminate the possibility that the presenting problems may actually be “other conditions that may be a focus of clinical attention” rather than a mental disorder. It is essential that the therapist remain aware of validity issues with different types of assessment and clinical judgments involving specific ethnic minorities. *DSM-IV-TR* warns that there may be a tendency to

overdiagnose schizophrenia in certain ethnic groups. Behaviors considered normative in a specific ethnic group may be seen as pathological from another group's perspective. Asian Americans tend to score low on assertiveness and high on social anxiety. Rather than being considered negative attributes, these may represent the Asian values of modesty and group orientation. African Americans may show a "healthy paranoia" or suspiciousness resulting from experiences associated with oppression and racism.

(2) Problem definition. Consider the clients' perspective on problems. How did they arise and how are they affecting functioning? Are specific cultural factors involved? In interviewing an individual make certain information about family, friends, and possible cultural/environmental factors is also obtained. When working with a family, these areas are also explored along with the possibility of acculturation conflicts between the parents and children.

(3) Goal definition. First, identify the different theoretical therapeutic techniques or processes used to attain goals. What assumptions underlie the techniques, and are they acceptable to members of other cultural groups? What kinds of modifications may have to be made or new techniques adopted? Second, the therapist should acquire knowledge of the experiences of ethnic minorities in the United States and issues involving oppression and discrimination. Many are still affected by their minority status and face conflicts over acculturation issues. There must be a willingness to acknowledge and address cultural and value differences with clients. Third, therapists should seek continuing education and consultation when working with ethnic minority populations and be willing to take on different roles such as advisor, advocate, and consultant.

B. Culture-Centered Interventions

Although psychoanalytic, humanistic, and behavioral models have differences in theory and techniques, they still share similarities in their "generic" approaches to psychotherapy and the conceptualization of the "healthy" client. There has been some movement in each of these approaches to make them more compatible for the different cultural groups. One such suggestion involves coconstruction. In *DSM-IV-TR*, it is noted that is important to identify possible "cultural explanations of the individual's illness." These explanations are how the particular individual views the problem and are part of the co-construction process.

In general, the research on therapy for ethnic minorities has revealed that they prefer techniques that are di-

rective, action oriented, and concrete. Some have suggested that cognitive-behavioral approaches show promise. However, as with all therapies, the cultural elements have to be identified. For example, what constitutes an "irrational belief" for particular cultural groups would have to be determined. Also, as with all Eurocentric psychotherapies, the focus has to change from the individual to include family, community, and societal factors. An individual's current mental complaints might stem from oppression and discrimination.

Currently, there are no specific guidelines in modifying traditional forms of psychotherapy to make them more appropriate for the problems of ethnic minorities. Regardless of psychotherapeutic orientation, the suggestions for multicultural assessment and co-construction can be helpful. All Eurocentric schools of psychotherapy face similar problems. They tend to have an individual focus and only work with the client rather than to attempt to address social and cultural concerns. Psychodynamic approaches could perhaps include exploration of a family or cultural unconscious to determine how these influenced individual development. Questions related to how these affected the identity of the individual could be explored. Humanistic therapists might use Abraham Maslow's hierarchy of needs to help identify the satisfaction of needs and the consideration of environmental concerns. Again, there could be a developed focus on cultural and family dimensions.

Empathy and other helping skills could not only be directed to the individual but to interpersonal relationships, the family, and the environment. The notion of co-construction fits well in the humanistic framework. With both the psychodynamic and the humanistic therapies, action and concrete suggestions need to be included as part of the therapy. Cognitive-behavior therapies are direct and action oriented and fit well into the expectations of many ethnic minority clients. However, they are also focused on the individual and need to be modified in use with other cultural groups. Cognitions considered to be "irrational" may not be perceived that way by ethnic minorities. The challenge is to understand what thoughts might be considered irrational by members of different cultural groups. In addition, the "unit" of treatment may not be the individual but the family, community, or even society. Group therapy with ethnic minorities also has to involve alterations. Techniques such as "ice breakers" are often used to facilitate interaction among the participants. Again, many of the activities reflect a cultural basis, and as therapists, we must analyze it as such. Some members of ethnic minorities may be uncomfortable participating because of the seeming lack of structure and ambiguity of these activities. Pairing individuals up with

other group members or providing structured tasks may generate more responsiveness. The focus of groups often is in personal development, and being a member of a family or particular ethnic groups is ignored. It may be valuable to focus on social identity and the increased understanding and responses to differences between groups.

Family therapy is also based on Eurocentric models and should not be imposed on families from different cultural groups. The family structure needs to be identified and relationships assessed. Therapy should be co-constructed with the help of family members. Systems theories should be expanded to include societal issues such as discrimination, poverty, and conflicting value systems. Reframe the concept of the "identified patient" as conflicts between different value systems. Again, the emphasis is to help the family develop better ways of handling problems within and between cultural constraints. It will be a challenge for individuals with training in Eurocentric therapies to develop more culture-centered treatment strategies.

III. EMPIRICAL STUDIES

There has been a number of studies examining some of the factors that affect cross-cultural therapy. However, most of these are not theoretically based, and few have addressed either the culture-specific or modified universal multicultural therapy models. For the culture-specific approach presented earlier by Uchenna Nwachuku and Allen Ivey on the African-Igbo culture, U.S. graduate students in a counseling program responded to problems presented by videotaped African-Igbo clients. The counselors displayed listening skills, allowed the client to determine direction, and focused clearly on the individual. The counselors were then trained in a workshop with information gained from the analysis of African-Igbo culture and were again rated on their performance with videotapes of African-Igbo clients. Improvement was noted in the use of more culturally aware responses but difficulty was still displayed in focusing on family and community values rather than the individual and the use of influencing skills such as giving advice. The study indicated that culture-specific information and training can improve sensitivity to different cultural styles, but that aspects of Eurocentric therapy remain difficult to alter.

There has been no direct research on either the modified universal model or the six propositions of multicultural counseling and psychotherapy. Indeed it can be argued that past research on culturally different populations is culture bound and difficult to interpret from

a culture-centered perspective. However, although the theories have not been directly examined, some of the research can apply to the propositions in multicultural counseling and psychotherapy. It must be noted that many of the cross-cultural studies involve college populations, and the findings may not be valid with ethnic clients living in the community. The following are hypotheses and research support in the area of multicultural counseling and psychotherapy that could be predicted from MCT. These are from the chapter "Research and Research Hypotheses in Intercultural Counseling" by David Sue and Norman Sundberg.

1. Conceptualization of mental disorders and psychotherapy will influence access. In general, Southeast Asians are less likely to enter psychotherapy because they associate mental illness with stigma and shame and are not acquainted with the notion of psychotherapy. Asian American groups tend to believe that mental illness is due to a lack of willpower and believe that they should deal with the problem themselves. Hispanic American families are more likely to utilize family, relatives, or community resources for emotional problems. Both groups underutilize mental health resources. African American and American Indians may show cultural mistrust of psychotherapy feeling that the therapy symbolizes oppression. African Americans tend to overutilize mental health services but also tend to terminate more quickly and show little positive gain. There is also some evidence that they use the therapy session to deal with external problems such as problems with agencies and the law rather than personal issues.

2. The degree of similarity in the expectation between client and therapist toward the process and goals of counseling affects effectiveness. In a number of research studies, ethnic minorities are more likely to be responsive to approaches that are more directive and action oriented and rate therapists using these approaches as more "credible." Pretherapy explanations of the process of therapy and the responsibilities of the client and therapist lead to greater satisfaction of services.

3. Ethnic similarity between client and therapist will enhance the probability of a positive therapeutic outcome. Reviews of ethnic matching have produced mixed results. Some support has been found in some studies and not in others. There is some support that African Americans prefer an ethnically similar therapist and that stage of racial identity development is related to this preference. Among Hispanic Americans, a slight preference for an ethnically similar therapist was found, especially among those low in acculturation. In one study of clients in the Los Angeles area, ethnic

matching was a significant predictor of outcome for Hispanic Americans and approached significance for Asian Americans, especially among recent immigrants. For all groups, including EuroAmericans, ethnic match was related to length of treatment except for African Americans. In many of the studies, other similarities between the therapist and client involving attitudes, values, or style was as, if not more, important than ethnic matching.

4. Among ethnic minorities, degree of acculturation or stage of ethnic identity affects receptivity to counseling. In general, low-accultured ethnic minority individuals appear to prefer an ethnically similar therapist. This has been found with Asian American, Hispanic American, and American Indian participants. For African American clients, there is some support for the view that those with a cultural distrust were more likely to terminate earlier with a White than a African American therapist. There is limited support for the view that the stage of ethnic identity is related to the types of problems presented and reaction to the counselor.

5. Exploring cultural and environmental variables can increase the "credibility" of the therapist. Cultural sensitivity as defined by the acknowledgment of culture, acculturation conflicts, and other issues faced by ethnic minorities demonstrated by therapists increased their ratings of credibility. The acknowledgement of ethnic differences between the client and therapist has also found to be related to positive outcome. Demonstrating a culturally sensitive approach by exploring cultural issues increased the therapeutic alliance, regardless of ethnic differences between the client and therapist. Cultural sensitivity displayed by the therapist has been found to be related to greater client self-disclosure and satisfaction.

6. The stage of identity for a EuroAmerican therapists can affect their reaction to ethnic minority clients. The concept of "White identity" is controversial in that EuroAmericans also go through a stage of racial identity. Certainly it would seem that if therapists denied the possibility of prejudice and discrimination faced by ethnic minority group members, they would not be able to understand the worldview of many culturally different clients and not be able to provide appropriate interventions. There has been limited support for the impact of the specific stage of White identity development and self-reported multicultural competencies.

7. Ethnic minorities prefer directive, concrete, and action-oriented psychotherapy techniques. Most of the studies indicate that ethnic minorities show a preference for a directive when compared to a client-centered approach. This appears to be more true for recent im-

migrants or those with low acculturation. Ethnic minority females show somewhat greater acceptance of a client-centered approach than males. However, what ethnic clients may want is more structure and guidance in therapy and advice or suggestions for different courses of action.

Thus, it would seem that some of the predictions made by multicultural therapy has received some support. However, what is needed are more explicit testable hypotheses to measure outcome in a varied of ways (symptom reduction, termination, and satisfaction) and to involve the use of actual patient populations.

IV. SUMMARY

Consideration of cultural factors in psychotherapy is being addressed by the different mental health organizations. It is receiving greater recognition in *DSM-IV-TR* where it is discussed both in the Appendix and as a subheading under the different disorders. The mental health field has responded primarily by drawing attention to possible cultural factors but not questioning the universality of psychotherapies developed according to Eurocentric models. Multicultural therapy approaches attempt to have practitioners understand the culture-specific nature of Western therapies and to identify assumptions and values under their system of psychotherapy. All therapies develop under some type of cultural framework. To deal with the inadequacies of current counseling theories and techniques in working with different ethnic groups, there is an increased attention to the impact of cultural factors.

Multicultural therapy has developed into somewhat different theoretical models. The culture-specific model or emic approach attempts to determine how a cultural group defines problem behaviors and problem-solving techniques. Anthropological observations and interviews are used to gather information. The concept of "healer" within the culture is identified to understand the philosophical nature of "therapy." From this, new theories of psychopathology and psychotherapy may develop. Criticism of the culture-specific model includes the possibility of overemphasizing culture, ignoring individual differences, and the necessity of developing a different approach for the cultural groups.

The modified version of multicultural therapy attempts to identify universals and considers all therapy to have cultural components that need to be identified. Some criticize the universal approach as just adding

culture to Eurocentric psychotherapies. A multicultural therapy that lies in between the culture-specific and universal perspectives was recently developed. It emphasizes the cultural aspects of all forms of counseling, emphasizing that practitioners need to identify the value system underlying their therapeutic approaches, and the importance of considering behaviors in context and multiple levels of experience (individual, group, universal). This theory is considered to be a theory of theories and has formulated a number of testable propositions and corollaries.

Intervention strategies based on culture-specific models are developed specifically for the population under study. With the African-Igbo, U.S. counseling students learned the methods of therapy derived through interviews with indigenous "experts" and observation and workshop material. The universal and multicultural therapy models develop intervention based on a culture-centered approach. Cultural factors are identified and assessments modified. The culture-specific nature of psychodynamic, humanistic, and cognitive-behavioral theories are identified and modified to incorporate family, groups, and environmental considerations. To reduce stereotyping, the ethnic identity of the client is assessed along with the identity of the therapist. Co-construction or the understanding of the problem, solutions, and appropriate interventions are made with the help of the client. Individual, family, and group therapies need to go through the process of identifying the assumptions underlying the models and altering the techniques to fit the worldview and expectation of ethnic minorities.

Research on cultural factors in psychotherapy has been relatively limited and without a theoretical basis. Most studies involve college populations and deal with specific aspects of cross-cultural counseling such as the rating of credibility, preference, and expertise. Although the findings are mixed, there is some support for ethnic matching of the therapist and client, espe-

cially for African Americans and less acculturated Hispanic and Asian Americans. It also appears that ethnic minorities feel more comfortable with action-oriented and concrete approaches of helping. Therapists are also rated higher when they demonstrate cultural sensitivity when dealing with an ethnic minority client. These findings are only tentative and need to include more actual clients and therapists.

GLOSSARY

- BASIC I.D.** An acronym of Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal relationships, and Drugs/Biological processes.
- bridging** A procedure in which the therapist deliberately tunes into issues that the client wants to discuss, then gently guides the discussion into more productive areas.
- second-order BASIC I.D.** Focusing on a specific problem in the BASIC I.D. to flesh out more information; useful for breaking impasses in therapy.
- social learning theory** A system that combines classical and operant conditioning with cognitive mediational factors (e.g., observational learning and symbolic activity) to explain the development, maintenance, and modification of behavior.
- structural profile inventory** A 35-item questionnaire that assesses the extent to which one is apt to be active or inactive; emotional or impassive; aware of or indifferent to sensory stimuli; reliant on mental imagery; inclined to think, plan, and cogitate; gravitate toward people and social events or avoid them; and engage in healthful habits and activities.
- technical eclectic** The use of techniques drawn from diverse sources without also adhering to the disciplines or theories that spawned them.

tracking the firing order A careful scrutiny of the firing order of the BASIC I.D. modalities to facilitate more effective sequencing of treatment procedures.

I. DESCRIPTION OF TREATMENT

Multimodal behavior therapy (also called Multimodal therapy) rests on the observation that at base, we are biological organisms (neurophysiological/biochemical entities) who *behave* (act and react), *emote* (experience affective responses), *sense* (respond to tactile, olfactory, gustatory, visual, and auditory stimuli), *imagine* (conjure up sights, sounds, and other events in our mind's eye), *think* (entertain beliefs, opinions, values, and attitudes), and *interact* with one another (enjoy, tolerate, or suffer various interpersonal relationships). By referring to these seven discrete but interactive dimensions or modalities as Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal, Drugs/Biologicals, the convenient acronym BASIC I.D. emerges from the first letter of each one.

Many psychotherapeutic approaches are trimodal, addressing affect, behavior, and cognition—ABC. The outcomes of several follow-up inquiries pointed to the importance of *breadth* if treatment gains were to be maintained. The multimodal approach provides clinicians with a comprehensive template. By separating sensations from emotions, distinguishing between images and cognitions, emphasizing both intraindividual and interpersonal behaviors, and underscoring the bio-

logical substrate, the multimodal orientation is most far-reaching. By assessing a client's BASIC I.D. one endeavors to "leave no stone unturned."

The elements of a thorough assessment involve the following range of questions:

B: What is this individual doing that is getting in the way of his or her happiness or personal fulfillment (self-defeating actions, maladaptive behaviors)? What does the client need to increase and decrease? What should he or she stop doing and start doing?

A: What emotions (affective reactions) are predominant? Are we dealing with anger, anxiety, depression, or combinations thereof, and to what extent (e.g., irritation versus rage; sadness versus profound melancholy)? What appears to generate these negative affects—certain cognitions, images, interpersonal conflicts? And how does the person respond (behave) when feeling a certain way? It is important to look for interactive processes—what impact do various behaviors have on the person's affect and vice versa? How does this influence each of the other modalities?

S: Are there specific sensory complaints (e.g., tension, chronic pain, tremors)? What feelings, thoughts, and behaviors are connected to these negative sensations? What positive sensations (e.g., visual, auditory, tactile, olfactory, and gustatory delights) does the person report? This includes the individual as a sensual and sexual being. When called for, the enhancement or cultivation of erotic pleasure is a viable therapeutic goal.

I: What fantasies and images are predominant? What is the person's "self-image?" Are there specific success or failure images? Are there negative or intrusive images (e.g., flashbacks to unhappy or traumatic experiences)? And how are these images connected to ongoing cognitions, behaviors, affective reactions, and so forth?

C: Can we determine the individual's main attitudes, values, beliefs, and opinions? What are this person's predominant shoulds, oughts, and musts? Are there any definite dysfunctional beliefs or irrational ideas? Can we detect any untoward automatic thoughts that undermine his or her functioning?

I: Interpersonally, who are the significant others in this individual's life? What does he or she want, desire, expect, and receive from them, and what does he or she, in turn, give to and do for them? What relationships give him or her particular pleasures and pains?

D: Is this person biologically healthy and health conscious? Does he or she have any medical complaints or concerns? What relevant details pertain to diet, weight, sleep, exercise, and alcohol and drug use?

The foregoing dimensions or modalities are some of the main issues that multimodal clinicians traverse while assessing the client's BASIC I.D. A more comprehensive problem identification sequence is derived from asking most clients to complete the Multimodal Life History Inventory. This 15-page questionnaire facilitates treatment when conscientiously filled in by clients as a homework assignment, usually after the initial session. Seriously disturbed (e.g., deluded, deeply depressed, highly agitated) clients will not be expected to comply, but most psychiatric outpatients who are reasonably literate will find the exercise useful for speeding up routine history taking and readily provide the therapist with a BASIC I.D. analysis.

A. Placing the BASIC I.D. in Perspective

The treatment process in multimodal behavior therapy rests on the BASIC I.D., which serves as a template to remind us to examine each of the seven modalities and their interactive effects. It implies that we are social beings that move, feel, sense, imagine, and think, and that at base we are biochemical–neurophysiological entities. Students and colleagues frequently inquire whether any particular areas are more significant, more heavily weighted, than the others are. For thoroughness, all seven require careful attention, but perhaps the biological and interpersonal modalities are especially significant.

The biological modality wields a profound influence on all the other modalities. Unpleasant sensory reactions can signal a host of medical illnesses; excessive emotional reactions (anxiety, depression, and rage) may all have biological determinants; faulty thinking, and images of gloom, doom, and terror may derive entirely from chemical imbalances; and untoward personal and interpersonal behaviors may stem from many somatic reactions ranging from toxins (e.g., drugs or alcohol) to intracranial lesions. Hence, when any doubts arise about the probable involvement of biological factors, it is imperative to have them fully investigated. A person who has no untoward medical/physical problems and enjoys warm, meaningful, and loving relationships, is apt to find life personally and interpersonally fulfilling. Hence the biological modality serves as the base and the interpersonal modality is perhaps the apex. The seven modalities are by no means static or linear but exist in a state of reciprocal transaction.

A patient requesting therapy may point to any of the seven modalities as his or her entry point. *Affect:* "I suffer

from anxiety and depression.” *Behavior*: “It’s my compulsive habits that are getting to me.” *Interpersonal*: “My wife and are not getting along.” *Sensory*: “I have these tension headaches and pains in my jaw.” *Imagery*: “I can’t get the picture of my grandmother’s funeral out of my mind, and I often have disturbing dreams.” *Cognitive*: “I know I set unrealistic goals for myself and expect too much from others, but I can’t seem to help it.” *Biological*: “I’m fine as long as I take lithium, but I need someone to monitor my blood levels.”

It is more usual, however, for people to enter therapy with explicit problems in two or more modalities—“I have all sorts of aches and pains that my doctor tells me are due to tension. I also worry too much, and I feel frustrated a lot of the time. And I’m very angry with my father.” Initially, it is usually advisable to engage the patient by focusing on the issues, modalities, or areas of concern that he or she presents. To deflect the emphasis too soon onto other matters that may seem more important is only likely to make the patient feel discounted. Once rapport has been established, however, it is usually easy to shift to more significant problems.

Any good clinician will first address and investigate the presenting issues. “Please tell me more about the aches and pains you are experiencing.” “Do you feel tense in any specific areas of your body?” “You mentioned worries and feelings of frustration. Can you please elaborate on them for me?” “What are some of the specific clash points between you and your father?” The therapist will then flesh out the details. However, a multimodal therapist goes farther. She or he will carefully note the specific modalities across the BASIC I.D. that are being discussed, and which ones are omitted or glossed over. The latter (i.e., the areas that are overlooked or neglected) often yield important clinical information.

In this description of the overview of treatment processes, it is important to explain several procedures that are employed by multimodal behavior therapists.

1. Second-Order BASIC I.D. Assessments

The initial Modality Profile (BASIC I.D. Chart) translates vague, general, or diffuse problems (e.g., depression, and unhappiness, and anxiety) into specific, discrete, and interactive difficulties. Techniques—preferably those with empirical backing—are selected to counter the various problems. Nevertheless, treatment impasses arise, and when this occurs, a more detailed inquiry into associated behaviors, affective responses, sensory reactions, images, cognitions, interpersonal factors, and possible biological considerations may shed light on the situation. This recursive applica-

tion of the BASIC I.D. to itself adds depth and detail to the macroscopic overview afforded by the initial Modality Profile. Thus, a second-order assessment with a client who was not responding to antidepressants and a combination of cognitive-behavioral procedures revealed a central cognitive schema—“I am not entitled to be happy”—that had eluded all other avenues of inquiry. Therapy was then aimed directly at addressing this maladaptive cognition.

2. Bridging

A strategy that is probably employed by most effective therapists can readily be taught to novices via the BASIC I.D. format. We refer to it as bridging. Suppose a therapist is interested in a client’s emotional responses to an event. “How did you feel when your father yelled at you in front of your friends?” Instead of discussing his feelings, the client responds with defensive and irrelevant intellectualizations. “My dad had strange priorities and even as a kid I used to question his judgment.” Additional probes into his feelings only yield similar abstractions. It is often counterproductive to confront the client and point out that he is evading the question and seems reluctant to face his true feelings. In situations of this kind, bridging is usually effective. First, the therapist deliberately tunes into the client’s preferred modality—in this case, the cognitive domain. Thus, the therapist explores the cognitive content. “So you see it as a consequence involving judgments and priorities. Please tell me more.” In this way, after perhaps a 5 to 10 minute discourse, the therapist endeavors to branch off into other directions that seem more productive. “Tell me, while we have been discussing these matters, have you noticed any sensations anywhere in your body?” This sudden switch from cognition to sensation may begin to elicit more pertinent information (given the assumption that in this instance, sensory inputs are probably less threatening than affective material). The client may refer to some sensations of tension or bodily discomfort at which point the therapist may ask him to focus on them, often with a hypnotic overlay. “Will you please close your eyes, and now feel that neck tension. (Pause). Now relax deeply for a few moments, breathe easily and gently, in and out, in and out, just letting yourself feel calm and peaceful.” The feelings of tension, and their associated images and cognitions may then be examined. One may then venture to bridge into affect. “Beneath the sensations, can you find any strong feelings or emotions? Perhaps they are lurking in the background.” At this juncture it is not unusual for clients to give voice

to their feelings. “I am in touch with anger and with sadness.” By starting where the client is and then bridging into a different modality, most clients then seem willing to traverse the more emotionally charged areas they had been avoiding.

3. Tracking the Firing Order

A fairly reliable pattern may be discerned of the way that many people generate negative affect. Some dwell first on unpleasant sensations (palpitations, shortness of breath, tremors), followed by aversive images (pictures of disastrous events), to which they attach negative cognitions (ideas about catastrophic illness), leading to maladaptive behavior (withdrawal and avoidance). This S-I-C-B firing order (sensation, imagery, cognition, behavior) may require a different treatment strategy from that employed with a C-I-S-B sequence, a I-C-B-S, or yet a different firing order. Clinical findings suggest that it is often best to apply treatment techniques in accordance with a client’s specific chain reaction. A rapid way of determining someone’s firing order is to have him or her in an altered state of consciousness—deeply relaxed with eyes closed—contemplating untoward events and then describing his or her reactions.

One of my clients was perplexed at the fact that she frequently felt extremely anxious “out of the blue.” Here is part of an actual clinical dialogue:

Therapist: Now please think back to those feelings of anxiety that took you by surprise. Take your time, and tell me what you remember.

Client: We had just finished having dinner and I was clearing the table. (Pause) I remember now. I had some indigestion.

Therapist: Can you describe the sensations?

Client: Sort of like heartburn and a kind of a cramp over here (points to upper abdomen).

Therapist: Can you focus on the memory of those sensations?

Client: Yes. I remember them well. (Pause) Then I started remembering things.

Therapist: Such as?

Client: Such as the time I had dinner at Tom’s and had such a migraine that I threw up.

Therapist: Let me see if I am following you. You started having some digestive discomfort and then you had an image, a picture of the time you were at Tom’s and got sick.

Client: Yeah. That’s when I stopped what I was doing and went to lie down.

This brief excerpt reveals a sensation-imagery-behavioral sequence. In the actual case, a most significant

treatment goal was to show the client that she attached extremely negative attributions to negative sensations, which then served as a trigger for anxiety-generating images. Consequently, she was asked to draw up a list of unpleasant sensations, to dwell on them one by one, and to prevent the eruption of catastrophic images with a mantra—“this too shall pass.”

II. THEORETICAL BASES

Multimodal behavior therapy is behavioral in that is based on the principles and procedures of experimental psychology, especially social learning theory. According to this theory, all behaviors—normal and abnormal—are maintained and modified by environmental events. The initial behavioral theories rested on animal analogues and were decidedly mechanistic. They put forth rather simplistic analyses of stimulus-response contingencies. The advent of what is now termed cognitive-behavior therapy rests on a much more sophisticated foundation. Emphasis is now placed on the finding that cognitive processes, which in turn are affected by the social and environmental consequences of behavior, determine the influence of external events. The main focus is on the constant reciprocity between personal actions and environmental consequences.

Social learning theory recognizes that association plays a key role in all learning processes. Events that occur simultaneously or in quick succession are likely to be connected. An association may be said to exist when responses evoked by one set of stimuli are similar to those elicited by other stimuli. The basic social learning triad is made up of classical (respondent) conditioning, operant (instrumental) conditioning, and modeling and vicarious processes. Added to the foregoing is the personalistic use of language, expectancies, selective attention, goals, and performance standards, as well as the impact of numerous values, attitudes, and beliefs. A person’s thoughts will determine which stimuli are noticed, how much they are valued, and how long they are remembered. In the brief space allocated, it is not possible to do justice to the nuances of social learning theory, but I hope that its level of sophistication and experimentally based outlook can be appreciated.

A pivotal concept in multimodal behavior therapy is that of technical eclecticism. As more therapists have become aware that no one school can possibly provide all the answers, a willingness to incorporate different methods into their own purview and to combine different

procedures has become fairly prominent. There are several different ways in which methods may be combined. The first is to utilize several techniques within a given approach (e.g., exposure, response prevention, and participant modeling from a behavioral perspective). One may also combine techniques from different disciplines, especially when confronted by a seemingly intractable patient or problem. Yet another way of combining treatments is to use medication in conjunction with psychosocial therapies. In addition, one may treat certain clients with a combination of individual, family, and group therapy, or look to other disciplines (e.g., social work in the case of vocational rehabilitation).

There are three principal routes to rapprochement or integration: technical eclecticism, theoretical integration, and common factors. Those who attempt to meld different or even disparate theories (theoretical integrationists), differ significantly from those who remain theoretically consistent but use diverse techniques (technical eclectics). And those who dwell on the common ingredients shared by different therapies (e.g., self-efficacy, enhanced morale, or corrective emotional experiences), are apt to ignore crucial differences while emphasizing essential similarities. Unfortunately, there are still many school adherents who refuse to look beyond the boundaries of their own theories for ideas and methods that may enhance their clinical acumen.

In essence, there appear to be no data to support the notion that a blend of different theories has resulted in a more robust therapeutic technique or has led to synergistic practice effects. It cannot be overstated that the effectiveness of specific techniques may have no bearing on the theories that spawned them. Techniques may, in fact, prove effective for reasons that do not remotely relate to the theoretical ideas that gave birth to them. This is not meant to imply that techniques operate or function in a vacuum. The therapeutic relationship is the soil that enables techniques to take root. Theories are needed to explain or account for various phenomena and to try to make objective sense out of bewildering observations and assertions. And it is precisely because social learning and cognitive theories are experimentally grounded that multimodal behavior therapy embraces them rather than any of the other theories in the marketplace. It makes sense to select seemingly effective techniques from any discipline without necessarily subscribing to the theories that begot them.

In multimodal behavior therapy, the selection and development of specific techniques are not at all capricious. The basic position can be summarized as fol-

lows: Eclecticism is warranted only when well-documented treatments of choice do not exist for a particular disorder, or when well-established methods are not achieving the desired results. Nevertheless, when these procedures, despite proper implementation, fail to prove helpful, one may resort to less authenticated procedures or endeavor to develop new strategies. Clinical effectiveness is probably in direct proportion to the range of effective tactics, strategies, and methods that a practitioner has at his or her disposal. Nevertheless, the rag-tag importation of techniques from anywhere or everywhere without a sound rationale can only result in syncretistic confusion. A systematic, prescriptive, technically eclectic orientation is the opposite of a smorgasbord conception of eclecticism in which one selects procedures according to unstated and unreplicable processes. It needs to be emphasized again that arbitrary blends of different techniques are to be decried.

The cognitive-behavioral literature has documented various treatments of choice for a wide range of afflictions including maladaptive habits, fears and phobias, stress-related difficulties, sexual dysfunctions, depression, eating disorders, obsessive-compulsive disorders, and posttraumatic stress disorders. We can also include dementia, psychoactive substance abuse, somatization disorder, multiple personality disorder and various other personality disorders, psychophysiological disorders, pain management, and diverse forms of violence. There are relatively few empirically validated treatments outside the area of cognitive-behavior therapy.

III. APPLICATIONS AND EXCLUSIONS

Multimodal behavior therapy is not a unitary or closed system. It is basically a clinical approach that rests on a social and cognitive learning theory, and uses technically eclectic and empirically supported procedures in an individualistic manner. The overriding question is mainly "Who and what is best for this client?" Obviously no one therapist can be well versed in the entire gamut of methods and procedures that exist. Some clinicians are excellent with children whereas others have a talent for working with geriatric populations. Some practitioners have specialized in specific disorders (e.g., eating disorders, sexual dysfunctions, PTSD, panic, depression, substance abuse, or schizophrenia). Those who employ multimodal behavior therapy will bring their talents to bear on their areas of special proficiency and employ the BASIC I.D.

as per the foregoing discussions, and, by so doing, possibly enhance their clinical impact. If a problem or a specific client falls outside their sphere of expertise, they will endeavor to effect a referral to an appropriate resource. For example, if a client who speaks only Spanish is to be treated by multimodal behavior therapy, obviously a therapist who is fluent in Spanish will be chosen. Thus, there are no problems or populations per se that are excluded. The only exclusionary criteria are those that pertain to the limitations of individual therapists.

IV. EMPIRICAL STUDIES

A crucial question is whether or not there is evidence that a multimodal approach is superior to more narrow or targeted treatments. During the 1970s and 1980s issues pertaining to focused versus combined treatment modalities were addressed in several quarters. Interestingly, for some disorders, specialized or highly focused interventions appeared superior to broad-spectrum approaches. For example, in weight-loss programs a specialized stimulus-control procedure was often favored over multidimensional treatments. Similarly, several other problem areas may respond better to specialized procedures: some phobias, compulsive disorders, sexual problems, eating disorders, some cases of insomnia, tension headaches, and the management of oppositional children.

On the other hand, a strong argument for combined treatments can be made for the treatment of alcoholism. Studies have shown that those treated only by aversion therapy were more likely to relapse than their counterparts who had also received relaxation training. And more recently, several studies have indicated that a combination of imipramine and exposure is more effective in treating panic disorder with agoraphobia than either exposure treatment or drug treatment alone.

In a carefully controlled outcome study conducted by Tom Williams in Scotland, multimodal assessment and treatment were compared with less integrative approaches in helping children with learning disabilities. Clear data emerged in support of the multimodal procedures. In Holland, M.G.T. Kwee and his associates conducted a multimodal treatment outcome study on 84 hospitalized patients suffering from obsessive-compulsive disorders or phobias, 90% of whom had received prior treatment without success, and 70% of whom had suffered from their disorders for more than 4 years. Implementing multimodal treatment regimens

resulted in substantial recoveries and durable 9-month follow-ups.

The main criticism of multimodal behavior therapy is that it is so broad-based, so flexible, so personalistic and adaptable that tightly controlled outcome research is virtually impossible. Thus, it depends too much on the artistry of the individual therapist. This reproach is only partly true. Multimodal behavior therapy endeavors first and foremost to apply empirically validated methods whenever feasible. Beyond the cognitive-behavioral parameters, there is suggestive evidence, rather than hard data, to confirm the clinical impression that covering the BASIC I.D. enhances outcomes and follow-ups. Similarly, although there is considerable clinical evidence that the multimodal approach keeps treatment on target and often brings to light issues that remain hidden from therapists of other orientations, there are no hard data to confirm these impressions.

Aside from outcome measures, there is research bearing out certain multimodal tenets and procedures. For example, multimodal clinicians often use a 35-item Structural Profile Inventory (SPI) that provides a quantitative rating of the extent to which clients favor specific BASIC I.D. areas. Factor analytic studies gave rise to several versions of the SPI until one with good factorial stability was obtained. The instrument measures the extent to which people are action-oriented (behavior), their degree of emotionality (affect), the value they attach to various sensory experiences (sensation), how much time they occupy with fantasy and day dreaming and "thinking in pictures" (imagery), how analytical they tend to be (cognition), how important other people are to them (interpersonal) and the extent to which they are healthy and health-conscious (drugs/biology). The reliability and validity of this instrument has been borne out by research conducted by Steven Herman. One of the most important findings is that when clients and therapists have wide differences on the SPI, therapeutic outcomes tend to be adversely affected.

V. CASE ILLUSTRATION

A case illustration should amplify and clarify all of the foregoing elements and details.

Ken, a 46-year-old accountant employed by a large corporation, suffered from bouts of depression, had problems maintaining an intimate relationship (he was twice divorced), expressed concerns about his relation-

ship with his son and daughter from his first marriage, and was unhappy at work. Previously, he had been in couples therapy, had seen various individual counselors and clinicians from time to time, but felt that he had derived minimal benefits from counseling and psychotherapy.

During the initial interview it was soon apparent that Ken tended to denigrate himself and seemed to have unrealistically high expectations for himself. These issues were broached and Ken agreed to read selected chapters of two books I handed him, one by Albert Ellis and the other coauthored by my son and myself. At the end of the initial interview, as is customary with literate clients who are not excessively depressed or otherwise too disturbed or distracted to focus on filling out questionnaires, Ken was handed the Multimodal Life History Inventory (LHI). This is a 15-page survey that covers the BASIC I.D. He was requested to complete it in his own time, but not to attempt to finish it in one sitting, and asked to bring the completed inventory with him to the next meeting. A depression inventory had also been administered and revealed that Ken's degree of melancholia fell within normal limits.

The therapist usually studies the LHI after session number 2, so by the time the client returns for the third session, the impressions gleaned from the inventory are discussed and treatment priorities are established. However, before perusing the entire document, it is my custom to turn to the bottom of page 4, which inquires about the client's "Expectations Regarding Therapy." Ken had written: "I want my therapist to remember the things I discuss with him. I also appreciate someone who will disclose pertinent things about himself. I am looking for someone to advise me, and point me in the right direction." Contrast this with another client's expectations. She had written: "A good therapist is an active listener who says little but hears all." It would be naive to assume that clients always know what they want and what is best for them. But without slavishly following their clients' scripts, if therapists had more respect for the notion that their clients often sense how they can best be served, fewer blunders might result.

In Ken's case, the therapeutic trajectory was clearly enhanced by my willingness to self-disclose. (I revealed strategies that I found helpful in my own marriage and with my own children, and I discussed problems that I had encountered in various work situations and tactics that had proved useful for me.) He took very kindly to the fact that I transcended the usual clinical boundaries by meeting him for lunch on a couple of occasions. He also appreciated the fact that I was quite forthright in

offering advice ("I don't see a down side to your asking for two things. (1) More challenging work. And (2) a raise.")

Several interconnected problems were brought to light. His behaviors were characterized by too much passivity; affectively, he was apt to depress himself needlessly; at the sensory level, generalized muscular tensions seemed widespread; his mental imagery was replete with pictures of his past failures; his cognitions were fraught with statements of self-denigration, perfectionism, and categorical imperatives; and his interpersonal relationships were characterized by unassertive and avoidant patterns.

Initially standard cognitive-behavior therapy strategies were employed: relaxation training, positive imagery exercises, cognitive restructuring (especially antiperfectionistic teachings), and assertiveness training. Ken made good progress across several dimensions but there seemed to be three sticking points: (1) Tensions between Ken and his woman friend were escalating; (2) he was feeling more resentful at work because his boss was so remote and unsympathetic; (3) his unsatisfactory relationship with his children remained a source of pain.

A Second-Order BASIC I.D. assessment was attempted by asking Ken to picture himself attaining some of his immediate goals—achieving harmony at home with his woman friend, coming to terms with his boss, mending fences with his son and daughter. These situations were addressed one at a time, and Ken was asked to discuss the repercussions in each modality.

It became clear that a few sessions with Ken and his significant other might prove beneficial and he agreed to ask Norma, his lady friend, to accompany him to our next session. Subsequently, during three meetings with Ken and Norma they were each able to express their specific complaints and learned how to derive more satisfaction from their relationship by avoiding traps into which they tended to fall. For example, Norma was inclined to dredge up negative events from the past, Ken was apt to say "No" too often even to simple requests, and they both rarely complimented one another. More intensive role-playing procedures were used to enable Ken to take the risk of approaching his boss and expressing his dissatisfactions. At his own initiative, Ken started actively pursuing a new job search.

With regard to his children, given they both lived too far for them to consider some family therapy sessions, Ken agreed to call them, express his love for them and his desire for a better relationship, and to continue a dialogue via letters and e-mail. These active methods

primed Ken to approach all problems now and in the future by deliberately cultivating a forthright, assertive, outgoing, and nonavoidant *modus vivendi*.

A. Outcome

Multimodal behavior therapists have no ironclad adherence to weekly sessions, especially when clients need time to practice homework assignments. Thus, Ken had 16 sessions over a period of 8 months. His gains were clearly evident. He no longer described himself as depressed, and as the result of his newfound nonavoidant behaviors he reported having greater levels of interpersonal satisfaction and closeness. At a follow-up interview 6 months later he mentioned that he had obtained a new job at a higher salary.

It is noteworthy that although Ken was not a resistant, or especially difficult, combative, or seriously disturbed individual, he could easily have continued to suffer needlessly for the rest of his life. Many strategies and tactics were covered in the 16 sessions (e.g., relaxation training, mental imagery methods, cognitive disputation, and assertiveness training), but significant psychosocial gains accrued only after he started taking interpersonal risks. Because the therapist–client relationship is the soil that enables the techniques to take root, it must be remembered that the therapeutic alliance was deliberately tailor-made to fit Ken's needs and expectancies.

VI. SUMMARY

Multimodal behavior therapy draws on the same principles of experimental and social psychology, as do other cognitive–behavioral therapies. It emphasizes that for therapy to be comprehensive and thorough it must encompass even discrete but interactive modalities—behavior, affect, sensation, imagery, cognition, interpersonal relationships, and drugs/biological considerations. The first letters of the foregoing dimensions yield the con-

venient acronym BASIC I.D. This results in broad-based assessment and treatment foci.

Whenever feasible, multimodal behavior therapy practitioners use empirically supported treatment methods. The therapeutic relationship is pivotal. Rapport and compatibility between client and therapist is the soil that enables the techniques to take root. It is also considered essential to fit the requisite treatment to the specific client.

Multimodal behavior therapy is technically but not theoretically eclectic. As has been emphasized by Lazarus and Beutler, one need not draw on any theoretical underpinnings that gave rise to a specific technique when borrowing that procedure and applying it in a different context. The multimodal approach makes effective use of methods from diverse sources without relinquishing its social learning and cognitive theoretical underpinnings.

GLOSSARY

affective variable A feeling or emotional response that follows a behavior or event.

habit Any learned way of living or fixed way of responding.

ideational variable Thought or belief regarding a behavior or event.

negative practice A technique in which a problem behavior is deliberately repeated or practiced by a patient to decrease the response in the long term.

paradoxical intention Therapeutic technique in which a patient suffering from a certain problem is encouraged to focus upon it and try to induce it rather than ignore it or avoid it.

reactive inhibition Principle which states that after any behavior there is an immediate increase in motivation not to perform the behavior.

I. DESCRIPTION OF TREATMENT

Negative practice is a technique in which a problem behavior is deliberately repeated, or practiced, by a patient to decrease the response in the long term. Nega-

tive practice has been used as a response reduction procedure primarily for habits, such as tics or nail biting; or in the treatment of specific types of anxiety. To treat nail biting, for example, clinicians prescribe scheduled practice sessions in which patients deliberately bite their nails until they learn to control the habit. Less often, negative practice has been used as a response reduction procedure for the modification of maladaptive behavior in persons with developmental disabilities.

II. THEORETICAL BASES

The origin of negative practice is associated with the work of Knight Dunlap, Ph.D. (1875–1949), Professor of Experimental Psychology at Johns Hopkins University. Dunlap published several critiques of imagery, consciousness, and instinct; however, his interests in neuropsychology and the impact of cognition on learning were closer to what is currently labeled as cognitive-behaviorism.

In 1928, Dunlap published a brief paper in *Science* in which he hypothesized that errors could best be corrected by repeatedly practicing those errors while acknowledging their incorrectness. He applied this technique to the correction of common typing errors (e.g., “hte” instead of “the”) and found that negative practice remediated the error more rapidly than positive practice. Dunlap then wrote a monograph entitled *Habits, Their Making and Unmaking* in 1932 that out-

lined both his views on the formation of habits and his method to decrease these behaviors. He defined a "habit" as any learned way of living or fixed way of responding. His innovative suggestion for treatment was to repeat deliberately the response to unlearn it, that is, to implement negative practice.

Dunlap discussed several classes of habits, including stuttering (inadequate speech habit) and tics (obsessive motor habits). Although previous methods prescribed simply stopping the habit, for Dunlap this was the end goal, not the means to an end. In Dunlap's conceptualization of negative practice, the patient must understand the inappropriateness of the habit and the benefits of breaking the habit, have the desire to break the habit, and commit to the effort required to break it. In short, both motivation and effort are essential treatment components. Although contemporary psychologists may see this approach as similar to the cognitive-behavioral orientation, at the time Dunlap labeled his methods atheoretical.

In his monograph, Dunlap further explained his methodology using the example of stuttering. He took what a person who stuttered could consistently do (stutter) and used it as the basis of the treatment by which the behavior could be modified. Dunlap felt that if the patient could voluntarily practice stuttering under the conditions of wanting to eliminate the habit, then the habit could be modified. Voluntarily stuttering was the initial part of the process of eliminating the habit. However, Dunlap said that it was the desire to eliminate the habit that was the foundation of the curative process. The patient was not to avoid stuttering but should voluntarily practice stuttering for at least 30 minutes daily. After three or four weeks of practice, most people could then attempt to practice normal speech. If stuttering resumed, negative practice should be reinitiated. Dunlap noted that after three months of treatment, many adolescents responded with no trace of stuttering.

Dunlap wrote that treatment of tics generally paralleled the treatment of stuttering. The treatment of tics may be more rapid, but relapses are more likely. After approximately a dozen deliberate movements, the tic itself may disappear for an hour or two. Sometimes a tic may be completely eliminated, but another may take its place (this should be treated concurrently). Initially, daily practice should be performed with a subsequent schedule to be determined by the psychologist. Dunlap also successfully treated other habits similar to tics, namely, thumbsucking in children and nail biting in college students. Dunlap proposed extending negative practice to a range of personal habits, such as eating noisily or laugh-

ing while telling a story. He believed that the key to negative practice was not to yield to the impulse but to initiate the practice voluntarily in the absence of the impulse. Negative practice was the beginning of the learning process of not performing the habit.

Knight Dunlap's use of negative practice was intended to bring an involuntary behavior under voluntary control. In his perspective, this shift occurred due to both affective and ideational variables. When patients practice the behavior, they do so with a different purpose (ideational variable) and experience the behavior with a different feeling (affective variable). Dunlap believed these variables were essential in achieving voluntary control over the behavior. In fact, the subjective state of the patient was seen as more important than the behavior of the clinician.

Negative practice has been compared to other techniques such as paradoxical intention and therapeutic paradox, both of which have their origins in analytic psychotherapy. Although the techniques vary by theoretical orientation, in each case patients are encouraged to continue their problematic behavior on a schedule established by the clinician. A major distinction between negative practice and these methods involves the role of the clinician: for paradoxical intention and therapeutic paradox, the patient-clinician relationship is seen as paramount; in negative practice, patient variables are considered essential to therapeutic success.

Whereas Knight Dunlap considered negative practice devoid of a theoretical basis, in 1959, Aubrey Yates suggested a formulation of negative practice based on Hullian learning principles of reactive inhibition. According to the principle of reactive inhibition, after any response there is an immediate increase in motivation not to perform the response. The repeated rehearsal of the target response would lead to reactive inhibition. The reduction of the aversive state of reactive inhibition achieved by not performing the tic would lead to conditioned inhibition of the tic.

In 1982, Richard Foxx offered a more parsimonious explanation of negative practice. Based on an applied behavior analytic perspective, he suggested that the high response effort of repeating the behavior served as a punisher for the behavior.

III. EMPIRICAL STUDIES

Although Knight Dunlap provided extensive descriptions of his procedure in his 1932 monograph, the first empirical evidence to support the effectiveness of

negative practice did not come until 1935. Winthrop Kellogg and colleagues compared the rate of maze learning across three conditions: in the first, participants were given no instructions regarding errors; in the second, participants repeated their errors (negative practice); and in the third, participants retraced a distance along the correct pathway that corresponded to the length of their error (positive practice). The negative practice group made significantly fewer errors than the original group and had a slight advantage over the positive practice group.

Since this time, negative practice has been researched periodically. Although initial studies showed successful results for repetitive behaviors and habits, positive outcomes tended to wane following the introduction of newer treatment approaches. This trend can be seen across research for the following behaviors.

A. Tics

Negative practice has been researched as a treatment for tics, although most studies used only one to two subjects. These studies were at least moderately successful in reducing tics such as eyebrow raising, eye blinking, mouth grimacing, head jerking, and multiple tics.

Frank Nicassio, Robert Liberman, Roger Patterson, and Eleanor Ramirez in 1972 used negative practice to treat successfully a single tic in one participant but had no success with a second participant who displayed multiple tics. In the case of the single tic, it subsided after 33 days of negative practice (approximately 16 hours total) and remained absent at 18-month followup. The second participant had multiple vocal and motor tics; three were targeted for intervention in a multiple baseline design. No reduction was observed in any of the tics, and rates remained at high at three-month followup. The authors suspected that this failure resulted from a lack of understanding of the complete behavioral complex (functions) of the multiple tics.

In 1974, Kenneth Knepler and Susan Sewall demonstrated rapid (80-minute) reduction of an eye-blink tic that maintained over a six-month period when smelling salts were paired with negative practice. The authors hypothesized that the use of smelling salts would accelerate the development of an aversive internal state. Negative practice was done as described by Aubrey Yates in 1958: five one-minute trials of practice interspersed with one-minute rest periods during clinic sessions.

Nathan Azrin, R. Gregory Nunn, and S. E. Frantz in 1980 compared negative practice to a newer procedure known as habit reversal. They found that habit reversal reduced tics by 92% by the fourth week, whereas nega-

tive practice only reduced tics by about one-third. Negative practice consisted of 30 seconds of practice every hour. With habit reversal, participants were taught to engage in a motor response incompatible with the tic.

Nathan Azrin and Alan Peterson (1988) reviewed the research to that date that had occurred with negative practice in the treatment of Tourette's Syndrome. Negative practice had a therapeutic effect in 10 out of 18 studies. For five studies with available data to analyze, there was an average of a 58% decrease in tics. Other studies showed an increase or recurrence in tics following treatment, and followup data indicated that the effect may not persist over time.

B. Nail Biting

Negative practice was used as an early treatment for nail biting by M. Smith, who eliminated the habit or markedly reduced it in about half of his sample of college students in 1957. During a two-hour session, the participants simulated nail biting in front of each other while telling themselves how ridiculous they looked. They were supervised by a therapist who explained the rationale, answered questions, and monitored practice. The participants were given instruction to practice nail biting for 30 seconds every hour until nail biting had been eliminated for four consecutive days. At that point, participants were to fade their practice schedule over a two-week period.

In 1976, however, John Vargas and Vincent Adesso found equal effectiveness between negative practice, self-imposed shock, and use of bitter taste. The effects for each of the three treatments were greater than those seen for self-monitoring (e.g., increased attention to the behavior) alone.

Nathan Azrin, R. Gregory Nunn, and S. Frantz in 1980 again compared habit reversal with negative practice in a study of treatments for nail biting. They found that habit reversal reduced nail biting by about 99%, whereas negative practice reduced it by only 60%, although both treatments had components of awareness, motivation to change, and repeated practice of a response. Negative practice within this study consisted of the identical method used by M. Smith in 1957. Azrin and colleagues then continued to pursue research on habit reversal, and subsequent studies of negative practice diminished in the research of treatments for this behavior.

C. Smoking

Negative practice has been used as a form of in vivo aversive conditioning to treat smoking. This procedure

was used by J. H. Resnick in 1968 and again by James Delahunt and James Curran in 1976. However, Delahunt and Curran compared four groups: (1) negative practice alone, (2) self-control alone, (3) a combined treatment package, and (4) a control group of nonspecific therapy. They found that each component separately did not differ from the control group, while the combined group had a significant reduction of 70% from baseline rates. The authors hypothesized that this effect was due to a combination of operant and respondent factors that were in effect in the combined treatments group; both factors appeared necessary to reduce smoking according to the body of research on the reduction of this behavior. The specific method of negative practice in Delahunt and Curran's study involved having subjects smoke 1.5 times more than their usual average for one day, a day of abstinence, smoking 2 times their baseline rate for one day, and then quitting.

Although early studies reported the success of negative practice in the modification of smoking behavior, subsequent studies demonstrated that the effect did not last in followup data and that this therapeutic technique led to relapse, as did most treatments for smoking at the time. In 1968, Edward Lichtenstein and Carolyn Keutzer conducted a followup study of 148 participants who were involved in a treatment study that compared breath holding, negative practice, and covert control (use of high-probability behaviors to reinforce covert thoughts). Although initial treatment gains were seen across all treatment groups at the end of treatment, by a six-month followup, the differences between treated and untreated groups were barely distinguishable. Richard O'Brien and Alyce Dickinson in 1977 compared negative practice, satiation, and control groups following one week of treatment. Initially, each treatment group had a significant decline in daily cigarette consumption. However, this effect was lost at three-month followup. This effect occurred despite manipulation of variables such as cigarette consumption within the negative practice and the baseline frequency of cigarette smoking.

D. Anxiety

In 1976, Richard M. O'Brien demonstrated that negative practice in the form of repeated exaggerations of anxious behaviors could decrease test anxiety and improve course grades in college students. A comparison group of students treated with group desensitization (graduated exposure to test-related stimuli paired with

relaxation training) reduced their anxiety but did not improve their grades. The students practiced for 10 minutes each hour on the first day, 10 minutes each 2 hours the next day, and 10 minutes three times per day for the remainder of a week. However, when Richard Levine and Richard O'Brien attempted to replicate these results with a control group and another test group of systematic desensitization in 1980, they saw no significant treatment effects for any condition. They hypothesized that since this group of participants had lower scores on a test anxiety measure, the negative practice schedule was not intense enough to produce the desired treatment effect.

Richard Wolff in 1977 employed negative practice to treat the compulsive checking rituals of a woman who feared the possibility of intruders in her home after enduring a rape attempt. The participant was a 20-year-old woman who had a 13-step checking ritual that she performed following each return to her apartment. The woman was instructed to repeat the ritual five times contingent on each incident of checking for two weeks. The ritual was eliminated and remained absent at 6- and 12-month followup.

E. Bruxism and Oral Habits

The use of negative practice to treat bruxism (teeth grinding) was first reported by William Ayer, who did his research in 1969, 1973, and 1976. In the 1976 study, he reported successfully treating a group of adults with bruxism by having them schedule negative practice sessions six times a day for a total of 30 to 45 minutes of practice during a two-week period. All participants reported a decrease in bruxism, and 75% remained free of the behavior at one-year followup.

Although Ayer reported successful treatment in the above studies, these data were limited to patient or spousal report of occurrence. In 1988 Ross Vasa and Holly Wortman conducted a single-case study with a 22-year-old woman in which they restricted the massed practice time intervals to the period before bed time. Practice sessions were faded to alternating nights once a treatment effect was observed. A 90% reduction was observed in 10 weeks' time.

Nathan Azrin, R. Gregory Nunn, and S. E. Frantz-Renshaw extended their previous work with negative practice and habit reversal to oral habits such as biting, chewing, licking, or pushing of cheeks, lips, teeth, or palate in 1982. Again, a single-session treatment with followup across 22 months resulted in significantly

greater reduction in the group treated by habit reversal (99%) as compared to that treated by negative practice (65%). The treatment method was identical to that used in their earlier studies treating tics. That is, a two-hour practice period was followed by 30 seconds of practice every hour until the behavior was eliminated. As previously mentioned, Azrin and colleagues proceeded to investigate habit reversal further and discontinued their work in negative practice.

F. Applications for Individuals with Mental Retardation

In all reported applications, negative practice has been used as a contingent procedure for persons with mental retardation. That is, following an occurrence of an inappropriate behavior, the procedure is implemented with the anticipation that it will serve as a punisher and thereby decrease the chance of recurrence. For example, following an instance of clothes ripping, an individual may be guided to repeatedly tear a rag for a specified period of time. When used in this context, negative practice typically is considered a moderately aversive procedure.

Richard Foxx described the use of negative practice with persons with mental retardation and autism. He cautioned that the applicability of this procedure with this population was limited for several reasons. First, negative practice as described in the general research literature requires a certain degree of motivation by the patient to eliminate a problem behavior, something that may not be present to the same level in persons with mental retardation. As a result, the use of negative practice would require physical guidance by a caregiver, which may lead to the patient becoming combative. Next, the treatment acceptability of this procedure may be low among caregivers. Both research and clinical observations have long held that if staff do not find a treatment acceptable, they will be less likely to implement it, resulting in less behavior change in the client. Finally, this procedure is limited to a subgroup of the wide range of problem behaviors that are typically exhibited by this population. It would not be appropriate, for example, to implement negative practice with aggressive behavior, self-injury, or destructive behavior that significantly disrupts a person's environment. The majority of these studies have shown effectiveness, especially when the problem behavior appeared not to be maintained by environmental consequences.

Lombana Durana and Anthony Cuvo in 1980 used negative practice in conjunction with differential reinforcement of other behavior (DRO) and restitution to

eliminate public disrobing in a woman with profound mental retardation. This treatment proved effective even though DRO plus restitution plus positive practice (repeatedly putting on clothes) failed to significantly reduce the behavior.

Pieter Duker and Monique Nielen in 1993 decided to use a response-contingent negative practice procedure to reduce the pica (ingestion of inedible items) of a 33-year-old woman with mental retardation. Pica is a behavior that is often resistant to intervention and is therefore rarely researched. Negative practice in this case consisted of a caregiver approaching the participant when she engaged in pica attempts and pressing the object she was attempting to chew to her lips for a two-minute period. Pica was significantly reduced, and the authors concluded that the contingent negative practice served as a punisher for pica behavior. The authors hypothesized that the continuous repetition of the behavior may have become aversive to the participant.

G. Unique Applications

Several isolated studies exist that describe the application of negative practice to unique topographies of behaviors. For example, in 1974, Howard Wooden described the case of a 26-year-old married man who reportedly displayed nocturnal headbanging for 25 years. After four nights of negative practice (carried out before bed until the patient subjectively experienced physical fatigue), the behavior dissipated and recurred only twice in six months on followup data.

The effectiveness of negative practice for improving spelling ability has been researched with mixed results. Constance Meyn and others in 1963 compared negative practice and positive practice as correction techniques when fourth grade students misspelled words in a research study. There was no difference in outcome between positive and negative practice techniques. Other studies reported both increased errors and improvement in correct spelling with negative practice.

Negative practice has been used in conjunction with other elements of a treatment package for treatment of fire-setting. Typically, the practice component would involve having the child set a fire (or as many fires as possible within a time period) while supervised by an adult who verbally reviewed fire safety procedures. The child would set the fire in a designated area and then be responsible for cleanup. The outcome of this study is difficult to discern because treatment was evaluated as a package and not by the individual components.

In summary, negative practice initially seemed promising as a treatment for many repetitive behaviors. As research progressed, however, most findings tended to show a lack of sustained effect in followup data or more beneficial effects from newer treatment approaches.

IV. SUMMARY

Negative practice is a therapeutic technique in which the patient deliberately repeats a problem behavior until the behavior is reduced or eliminated. Originally, it was hypothesized that negative practice functioned through the principle of reciprocal inhibition, a concept in Hullian learning theory. Due to a lack of supporting data, more recent hypotheses suggest that guided repetition of a behavior may lead to fatigue or another aversive state, thereby defining the technique as a punisher. Negative practice has been used to treat a limited number of symptoms with some success, although many of these symptoms (e.g., tics, smoking, anxiety) can be successfully treated with newer and

more comprehensive approaches. In some cases, it can be successfully applied to certain problem behaviors exhibited by persons with mental retardation.

GLOSSARY

aversive A nontechnical term often used to refer to punishment and negative reinforcement procedures.

behavior Any action of a living creature. Behavior can be overt or covert.

consequence An event that follows and is produced by a behavior.

environment The natural world in its entirety, including all events that occur inside and outside living creatures.

functional assessment Procedures that are used to identify the variables responsible for a problem behavior.

negative punishers Punishers that involve removing or preventing the delivery of a stimulus.

negative punishment A procedure (or process) in which the removal or prevention of the delivery of a stimulus as a consequence of behavior weakens (e.g., reduces the likelihood of) that behavior in the future.

operant conditioning A form of learning in which behavior is controlled primarily by its consequences.

positive punishers Punishers that involve adding something to an individual's environment.

positive punishment A procedure (or process) in which the presentation of a stimulus after a behavior weakens that behavior in the future.

punishers Consequences that weaken behavior.

response cost A negative punishment procedure that involves removing something of value from an individual after an inappropriate behavior occurs.

rules Overt or covert statements of relations among stimuli and responses. Rules describing the consequences of behavior can evoke behavior similar to that associated with direct exposure to those consequences.

stimulus A physical event.

time out A negative punishment procedure that involves the temporary removal of an individual from an environment in which positive reinforcers are available.

token economy A therapeutic system based on providing appropriate consequences for important behaviors.

Most human behaviors considered by psychologists as important are operant behaviors. That is, these behaviors operate on the environment to produce particular changes, called consequences. Consequences are reinforcers if they strengthen the behavior that produced them and punishers if they weaken it. Punishment occurs when a behavior is weakened by its consequences. In 1953, B.F. Skinner noted that punishment was the most common form of behavior control. He strongly opposed its use in clinical applications and in society in general, and many other prominent people have done likewise. Nonetheless, punishment continues to be ubiquitous in everyday life. It is also used systematically to improve behavior in therapeutic applications, although ethical, practical,

and legal considerations limit where, how, and with whom punishment can be utilized.

I. DESCRIPTION OF TREATMENT

Psychologists commonly distinguish between negative and positive punishment. Positive punishment occurs when the presentation of a stimulus, termed a positive punisher, weakens the behavior that caused this consequence to occur. In contrast, negative punishment occurs when the removal or prevention of delivery of a stimulus, termed a negative punisher, weakens the behavior that produced this consequence. As an everyday example of negative punishment, envision two friends who are sitting together having a friendly conversation when one makes a highly critical comment about a presidential candidate. The other person likes the candidate and is angered by the comment and abruptly gets up and walks away upon hearing it. If this results in fewer negative comments about the politician in the future, then negative punishment has occurred. In this hypothetical example, and in most cases, the response-weakening effect of punishment involves a decrease in the frequency of responding, although other changes in behavior (e.g., increased latency to respond or decreased intensity of responding) may be indicative of a punishment effect.

For negative punishment to be effective, the stimulus that is removed or avoided must have positive hedonic value. In general, such stimuli serve as positive reinforcers, which are stimuli that strengthen behaviors that produce them. Many writers describe negative punishment as a procedure that weakens a particular kind of behavior because that behavior removes a currently available positive reinforcer or prevents the delivery of an otherwise forthcoming positive reinforcer. Although this conception of negative reinforcement makes intuitive sense, stimuli that serve as negative punishers for a particular individual's behavior may never have served as positive reinforcers for that individual's behavior. For instance, a child who has been given CDs by family members may value them, and taking them away following an undesired behavior, perhaps cursing, might function as negative punishment. Thus, the CDs are negative punishers. But they were given to the child independent of her behavior, and no behavior was strengthened by their delivery. Thus, they have not functioned as positive reinforcers for any behavior of the individual in question. Whether they have the capacity to serve this function is not a

fixed characteristic of the CDs but depends on the context in which their presentation follows behavior.

Basic and applied studies demonstrate conclusively that the behavioral function of a given stimulus is not fixed but rather depends on historical and current circumstances. Although stimuli that serve as negative punishers often also serve as positive reinforcers, this is not always, nor necessarily, the case. Moreover, thinking of the stimuli that are removed or avoided as positive reinforcers may cause confusion about the behavioral effects of negative punishment. Reinforcement always strengthens behavior, and punishment always weakens it; this principle holds regardless of whether either procedure is "positive" or "negative." In addition, these terms refer only to whether the procedure involves adding something to an individual's environment or taking something away. They do not refer to the kinds of behavior that are affected or to the "goodness" of the consequences that are arranged.

Although the behavioral functions of stimuli are not fixed, they are not capricious, and it is usually possible for psychologists and others to predict with some accuracy whether an event will function as a negative punisher in a given context. Personal experience, scientific reports, and theoretical deductions are all useful in predicting that a specific event will punish behavior, although the ultimate test is to arrange the event as a consequence for the behavior that is to be reduced. Operations that fail to weaken behavior do not constitute punishment, even if the persons who designed and implemented them intended them to reduce responding.

When used therapeutically, negative punishment is used to weaken inappropriate target behaviors. The two most commonly used procedures that involve negative punishment are time out (also spelled timeout or time-out) and response cost. As discussed later, these procedures have been effective in reducing a variety of target behaviors in various settings with diverse client populations.

Time out generally involves temporarily removing an individual from an environment in which positive reinforcers are available whenever the behavior that is to be reduced occurs. That is, when the client performs the undesired behavior, she or he loses the opportunity to earn positive reinforcers. The two broad classes of time out are exclusionary and nonexclusionary. In exclusionary time out, the client is moved from a setting that provides many positive reinforcers to a setting that provides few, if any, positive reinforcers. For example, a child who misbehaves in a classroom may be moved from the classroom to an empty room for a two-minute

period as a form of exclusionary time out. If successful, this procedure would reduce the subsequent rate of occurrence of the undesired behavior.

Time out has been used most extensively in educational settings. In such settings (and some others as well), exclusionary time out commonly is implemented in one of three ways. In one, the client is required to spend the duration of the time out in a secluded time-out room whenever the behavior targeted for reduction (e.g., swearing) occurs. Time-out rooms should be well ventilated, well lit, and reasonably comfortable but should not contain obvious sources of positive reinforcement (e.g., toys, chairs that rock). If necessary, such rooms should be padded to protect clients from injuring themselves. Provision should be made for observing clients during time outs (e.g., through one-way mirrors) and intervening rapidly to terminate dangerous activities. Clients should not spend more than a few minutes in the time-out room. Long periods of time out do not necessarily reduce behavior more effectively than do short periods, and the former may be abusive to the client.

A second exclusionary time-out method uses a partitioning wall that separates the time-out area from the normal setting (e.g., a classroom). This method is similar to the use of a time-out room in that it involves a move from a more to a less reinforcing environment, but the client is moved to a place behind the partition instead of being moved to a separate room. One problem associated with the partition method is that disruptive clients can continue to disrupt normal activities from behind the partition. Furthermore, other individuals can still reinforce problem behaviors by laughing, making comments, or otherwise responding to the misbehavior.

A third, and perhaps the most popular, method of arranging exclusionary time out, involves taking the client to the hallway outside of the room where the problem behavior occurred. Although this method may be the only practical option for some situations, hallway time outs should generally be avoided because hallways typically contain many sources of positive reinforcement, such as other students, drinking fountains, windows into other rooms, bulletin boards, and posters.

To ensure the safety of students and to prevent them from running away, arrangements must be made for monitoring students placed behind partitions or in hallways during time out. These forms of time out, like all others, should be as brief as possible.

Exclusionary time out is likely to be effective in reducing behavior if four criteria are met. First, the time

out must involve a move from an environment that provides a relatively high frequency of positive reinforcers to an environment that provides a relatively low frequency of positive reinforcers. If the frequency and quality of reinforcers in the time-out environment are equal to or greater than those in the regular environment, then time-outs will not punish, and may even reinforce, the undesired behavior.

Second, time outs must occur immediately after the problem behavior occurs. Delays in implementing time outs are apt to reduce their effectiveness substantially. Third, time outs should be ended only when the individual is engaging in appropriate behaviors. If time outs end while the individual is behaving unacceptably, or immediately thereafter, termination of the time out and return to the normal environment could reinforce the undesired behavior.

Finally, time-out procedures should be clearly explained to the client. This allows for rules about the consequences of behavior, as well as direct exposure to those consequences, to affect the target response. Rules specify relations among stimuli and responses and can engender behaviors similar to those produced by actual exposure to those relations. Helping clients to formulate and follow appropriate rules is apt to increase the effectiveness of any intervention and should be part of almost all treatments. This includes response-cost procedures.

Sometimes it is not possible or desirable to remove a misbehaving client from the situation in which the misbehavior occurs. In such cases, nonexclusionary time out is often used. In nonexclusionary time out, the individual remains in the setting where the problem behavior occurred but loses the opportunity to earn positive reinforcers. For example, a teacher may briefly ignore a student who behaves inappropriately. Ignoring, in this case, prevents the student from earning social reinforcers from the teacher.

Psychologists have developed four general methods of nonexclusionary time out: time-out ribbon, planned ignoring, contingent observation, and prevention of preferred activities. The time-out ribbon provides an excellent example of nonexclusionary time out. This method requires that all clients receive a ribbon when they enter the treatment setting. Possession of the ribbon indicates that the individual is allowed to participate in the reinforcement system (usually a token economy, which will be described later). Whenever a client performs a behavior targeted for reduction, the ribbon is taken from the client, indicating that the client can no longer obtain reinforcers from staff for

some predetermined time. Unfortunately, this intervention is unsuited for reducing behaviors not maintained by staff-delivered reinforcers, or behaviors (e.g., self-injurious responding) maintained by staff attention that cannot be withheld for ethical or practical reasons.

As the name implies, planned ignoring involves having caregivers ignore predetermined problem behaviors. For example, in a therapy group designed to reduce interpersonal aggressive behaviors, the therapist (and others) may briefly ignore a client every time the client makes an aggressive remark (e.g., "I'm gonna kill you"). Planned ignoring tends to be most effective when the individual's social environment is highly reinforcing and when the therapist consistently implements the intervention. One problem with this intervention is that some behaviors are difficult or dangerous to ignore. Using the therapy group example, if a client actually engaged in an aggressive act against another person, it would be unethical simply to ignore this behavior. Another problem with planned ignoring is that this intervention is effective only if the client's behavior is maintained by social reinforcers that caregivers control.

Contingent observation is usually implemented in a group setting, such as a classroom. In contingent observation, a misbehaving client is asked to sit outside of a group of individuals and observe the group for a brief period of time (e.g., two minutes). During this time, the client cannot participate in group activities and, hence, cannot receive social reinforcers. In addition, the client observes others behaving appropriately and receiving reinforcers. Thus, this intervention uses negative punishment and modeling to achieve its effects. As with other time-out procedures, contingent observation requires that reinforcers are not available for the misbehaving client during observation periods and that the intervention be applied consistently and immediately after the problem behavior occurs.

A final nonexclusionary time-out procedure consists of preventing the client from engaging in a preferred activity, such as playing cards, whenever the target behavior occurs. For example, one study demonstrated that children's thumbsucking could be reduced by turning off the television the children were watching immediately following each incident of thumbsucking. In some cases, it may be appropriate and possible to reduce problem behaviors without clients' knowledge using this time-out technique. This may be important in situations where other behavior-weakening techniques have produced disruptive or aggressive behavior in clients.

There are obvious benefits and drawbacks to both exclusionary and nonexclusionary time out. Nonexclusionary time out is thought to be more beneficial to the client because he or she is allowed to remain in the educational (or therapeutic) environment. In addition, if the client does not have to be removed from the environment, there is less chance that he or she will become aggressive or hostile. As previously mentioned, however, nonexclusionary time out allows highly disruptive individuals to remain in the setting, providing them with the opportunity to disrupt further the ongoing activities. Exclusionary time out, on the other hand, has the virtue of removing disruptive individuals from the setting, allowing other clients to benefit from ongoing activities. Unfortunately, exclusionary time out removes from the instructional situation the very individuals who may need instruction the most. There is no obvious solution to these problems, and therapists must find a way to weaken inappropriate behavior while ensuring that clients receive the educational opportunities they require.

Whereas time out involves removing the opportunity for an individual to gain access to positive reinforcers, response cost involves taking valued stimuli away from an individual when misbehavior occurs. That is, response-cost interventions make problem behaviors "costly" in that the individual who emits these behaviors loses something of value. Put simply, the client has to pay for engaging in inappropriate behavior. Examples of response-cost procedures often appear in our daily lives in the form of fines and points lost in classroom settings. Implementing a response-cost procedure in no way guarantees that negative punishment will occur. In order for response cost to weaken behavior, the individual must lose something of greater value than whatever the individual gains by misbehaving.

Response-cost procedures are commonly implemented in four ways. First, response cost can be combined in a package intervention with procedures, such as differential-reinforcement-of-incompatible-behavior (DRI) schedules, that increase appropriate behaviors. Here, reinforcers earned under the DRI schedule for appropriate behavior would be lost if the undesired behavior occurred.

Second, response cost involving fines of specific amounts through loss of points, money, tokens, or quantifiable amounts of other valued stimuli already in the individual's possession can be used alone. Third, "bonus" or "free" reinforcers can be delivered at the start of the response-cost period and then removed if inappropriate behaviors occur. Finally, response cost

can be implemented for a group of clients such that inappropriate behavior on the part of one group member will result in the loss of valued items for the entire group. In this case, the response-cost procedure results in group members exerting “peer pressure” on other members to remain well behaved. Although such peer pressure can maintain appropriate behavior, it may be too stressful for some clients. Thus, group procedures should be monitored carefully.

Psychologists often implement time out and response-cost procedures in settings where token economies operate. Token economies are behavior management systems that provide tokens, such as poker chips or points, for appropriate behaviors. The tokens can then be traded for a variety of backup reinforcers, such as tangible items like candy, soda, and toys, or for privileges like going to the park or checking out a book at the library. As a result of being exchanged for a variety of backup reinforcers, the tokens eventually come to function as generalized conditioned reinforcers and effectively maintain appropriate behaviors. In this way, tokens allow the psychologist to deliver consequences immediately following the performance of target behaviors, thereby maximizing the likelihood of the desired behavioral effect.

In the context of a token economy, time out involves the restriction of a client’s ability to participate in the token system for a short period of time (e.g., two minutes) whenever the individual engages in an inappropriate behavior. Response cost in a token economy is relatively straightforward and involves the removal of a specified number of tokens whenever an individual engages in inappropriate behavior.

The implementation of a token economy requires: (a) specification of observable, easily measured behaviors to be reinforced or punished; (b) delivery or removal of tokens when the behaviors specified in (a) occur; (c) identification of effective backup reinforcers for which tokens can be exchanged; and (d) specification of rules by which the economy runs, including rules concerning exchange rates, magnitude of reinforcers and punishers, schedule of consequence delivery, and frequency of exchanges. In theory, token economies can be of any size if sufficient resources to manage the system are available.

Token economies must be flexible enough to support each client’s personalized treatment goals and to provide consequences that may differ widely across individuals. As systems become more individualized, however, they become more complex, which can result in staff performance problems. No token system will

function perfectly all of the time, so they should include mechanisms that allow treatment providers to monitor how well the system is performing and to correct any problems that arise. One way to increase the possibility that the token system will function smoothly is to obtain client’s cooperation and input when designing the system. Including clients in the system development process increases their involvement in the system and gives them a greater degree of control over their lives.

Regardless of whether or not response cost is implemented as part of a token economy, the procedure is not likely to be successful unless the undesired behavior leads rapidly and consistently to the loss of enough of a valued item to be of significance to the client. A potential problem with the procedure is that, if response cost is implemented repeatedly, there may be no more of the specified valued item to take away. This difficulty sometimes can be averted by arranging a number of “different costs” for a target behavior. For example, tokens might be taken away until none are left; then loss of a specified series of privileges could occur.

What might be termed intermittent response cost is regularly used in educational settings. Here, something of value is lost after the target behavior occurs a specified number of times. For example, a teacher might make a check mark on the board each time a student talks out in class. When the third check mark appears, the child loses access to the playground during the next recess period. Although this procedure is often effective, some students might “figure out the system” and misbehave twice before behaving appropriately. This outcome might or might not be acceptable to the teacher, depending on the nature of the undesired behavior.

The procedure described in the preceding example was presented as a response-cost manipulation; this is legitimate because the student lost something of value—access to recess—because of misbehaving. But the procedure could also be construed as time out because the child lost access to reinforcers associated with the playground dependent on misbehaving. Although it is of heuristic value to distinguish between time out and response cost, the distinction often blurs in everyday applications.

II. THEORETICAL BASES

Punishment has generated a great deal of theoretical interest, although positive and negative punishments characteristically are not distinguished in these discussions. From the earliest days of psychology as a formal

discipline, it has been widely acknowledged that consequences can weaken as well as strengthen behavior. For instance, Edward Thorndike pointed this out early in the 1900s in his famous Law of Effect. The version that appeared in his 1905 book, *The Elements of Psychology*, reads:

Any act which in a given situation produces satisfaction becomes associated with that situation, so that when the situation recurs the act is more likely than before to recur also [this is reinforcement]. Conversely, any act which in a given situation produces discomfort becomes disassociated from the situation, so that when the situation recurs the act is less likely than before to recur [this is punishment].

Over time, however, Thorndike became convinced that punishment did not produce enduring effects. This view was based on limited studies of positive punishment that he conducted. The preeminent behavioral psychologist B. F. Skinner supported this view in his 1953 book, *Science and Human Behavior*, and elsewhere. Skinner contended that not only does punishment typically fail to produce lasting response suppression, but it also characteristically engenders negative reactions, including aggression, escape, and attempts at countercontrol. Consequently, punishment (and negative reinforcement, claimed to have similar adverse effects) should be avoided in clinical applications and in society at large. Skinner described a society without aversive control in his utopian novel, *Walden Two*, published in 1948.

Despite arguing forcefully against the use of punishment, Skinner recognized that operant behavior was sensitive to both negative and positive punishment. In fact, throughout Skinner's long life, both were included as principles of behavior in his analysis of operant conditioning. Skinner did not argue that behavior could not be reduced by negative punishment. Rather, he argued on practical and ethical grounds that behavior should not be reduced in this way because there are better alternatives (e.g., positive reinforcement).

Arguments against the use of punishment similar to those first advanced by Skinner half a century ago have been repeated and extended in the ensuing years. Over this same period, laboratory studies with nonhumans and humans and clinical studies with various client populations have provided clear evidence that both negative and positive punishment can produce strong and enduring reductions in operant behavior. Insofar as theory in psychology should be based on data, there is substantial theoretical support for the effectiveness of procedures based on negative punishment.

Whether such procedures are appropriate for therapeutic use in general, or in specific cases, is another issue altogether. Some theoreticians argue for and against therapeutic techniques based on the principles of behavior that underlie their effects. They claim, for instance, that positive reinforcement is good and negative punishment (along with positive punishment and negative reinforcement) is bad. But in the everyday world of the clinic and classroom, and in courts of law, the acceptability of procedures is usually based on their details (who does what to whom, for what reason, and with what real or anticipated result?), not on their mechanism of action. In the following section, we discuss general restrictions on the use of negative punishment and discuss appropriate safeguards for the use of procedures that involve negative punishment. Although such procedures should always be used with care, mild and generally accepted interventions (e.g., teachers' use of nonexclusionary time out for classroom management) typically are not subjected to the same scrutiny as more unusual and potentially intrusive interventions (e.g., time out in a secluded room to reduce severe self-injury in a person with severe mental retardation).

III. APPLICATIONS AND EXCLUSIONS

Even though negative and positive punishment can be distinguished procedurally and arguments against punishment have focused on the latter, procedures involving both forms of punishment (and negative reinforcement) are commonly considered as "aversive" and relatively restrictive (harmful) interventions. Therefore, the use of negative punishment is limited by both ethical and legal considerations, although the extent of these restrictions depends on the specific procedure, client, problem behavior, and setting under consideration. Like all "aversive" interventions, procedures involving negative punishment may generate negative affective behavior (e.g., crying), aggression, and escape responding. Moreover, negative punishment procedures are easily misused by ill-informed or ill-intentioned caregivers, as when clients are placed in a time-out room for long periods for staff convenience.

In view of the foregoing considerations, negative punishment should not be used until less restrictive interventions have proven ineffective. As with positive punishment, a clear decision-making process regarding the use of negative punishment should be in place. Specific guidelines must be established regarding the

exact nature of the proposed punishment procedure, including who is to implement it and the specific standards of accountability. Unambiguous rules regarding the behavioral data that will support continuation, modification, and termination of punishment must be established and followed by a vigilant, expert, and caring treatment team before punishment is implemented. Input from clients, client's advocates, behavior-change experts, and the individuals responsible for implementing procedures is invaluable in formulating guidelines for the use of negative punishment in schools and other settings.

Before a negative punishment procedure is implemented, the treatment team, as Ray Miltenberger suggests in his excellent 1997 text *Behavior Modification*, should

1. Conduct a functional analysis to ascertain the consequences and other variables that are maintaining the problem behavior. This information is invaluable for planning effective interventions.
2. Determine whether the proposed intervention (e.g., time out or response cost) is practical in the present situation.
3. Determine whether the proposed intervention is safe.
4. Determine whether the client can readily escape from or avoid the proposed intervention.
5. Determine whether the intervention can be implemented consistently.
6. Determine whether all parties with a legitimate interest in the intervention find it acceptable.

Adhering to these guidelines often requires substantial time and effort. But doing so is essential to ensuring the well-being of clients.

In general, with the proviso that clients with special needs require special protections, issues of client diversity do not strongly enter into whether or not procedures based on negative punishment are appropriate. Interestingly, such procedures are frequently used with children and with adults with mental illness or mental retardation, and these are the very people most in need of special protections.

IV. EMPIRICAL STUDIES

The clinical literature relevant to negative punishment is sizable; numerous studies have shown that time out and response cost, if properly arranged, can effec-

tively reduce a wide range of target behaviors in numerous settings with a variety of client populations. Time out is the negative punishment procedure most often examined in published studies, and it has a long history of success in the treatment literature. Published studies have demonstrated time out to be effective in reducing cursing, off-task behaviors, stereotypic behaviors, thumbsucking, pica, self-injury, disruptive meal-time behaviors, tantrums, self-stimulation, perseverative speech, noncompliant behaviors, physical aggression, verbal abuse, hoarding, and rule violations. Settings in which time-out procedures have been successfully implemented include psychiatric hospitals, elementary and high schools, juvenile facilities, and day-treatment schools. Among the clients with whom time-out procedures have been effective are children with autism, people with mental retardation and other developmental disabilities, people with mental illness, and children, adolescents, and adults without disabilities.

Response-cost interventions have been shown to be effective in decreasing smoking, cocaine use, opiate use, rule violation, off-task behavior, hyperactivity, aggressiveness, psychotic speech, stuttering, overeating, tardiness, perseverative speech, anxious and depressive behavior, and self-injurious behavior. Furthermore, response-cost interventions have been effective in improving academic performance and vocational training activities.

The effectiveness of response-cost procedures has been demonstrated in a wide range of settings. The literature shows these procedures to be effective in settings such as preschools, middle schools, high schools, and vocational education schools, as well as in prisons, psychiatric hospitals, day-treatment facilities, and home settings. This intervention has been used successfully with many client populations, including children with autism, people with mental retardation and other developmental disabilities, people with mental illness, prison inmates, predelinquent boys, and people without diagnostic labels. Furthermore, therapists often use behavioral contracts with response-cost components to benefit married couples, families, teachers, and individual clients. Behavioral contracts are agreements among committed parties regarding the consequences of specified behaviors.

V. CASE ILLUSTRATION

The director of a residential treatment facility wished to reduce the relative frequency of episodes of

nonsensical speech in Ronald, a 15-year-old male diagnosed with schizophrenia. Ronald had engaged in nonsensical speech frequently over the past two years, and his statements usually centered around conversations with Ashtar, described by Ronald as the captain of an omnipotent space fleet. Because of his frequent episodes of nonsensical speech, other residents avoided Ronald. Indeed, nonsensical speech prevented Ronald from engaging in conversations with most people. In addition, the director realized that Ronald's bizarre speech interfered with the staff's ability to gather useful information about Ronald's needs. For example, when Ronald became ill, a reasonable description of symptoms might well facilitate his treatment, whereas statements concerning spacecraft and the beings who pilot them would be of no benefit whatsoever.

The director observed Ronald for five minutes at 30-minute intervals over a five-day period. During these baseline observations, the director recorded the percentage of intervals in which nonsensical speech occurred. In the process of collecting baseline observations, the director noticed that a few of the staff members spent time talking with Ronald about his conversations with Ashtar. From this, the director hypothesized that social reinforcers might help maintain Ronald's nonsensical speech.

The data indicated that Ronald engaged in nonsensical speech in 91% of the intervals. After collecting these data, the director met with Ronald's treatment team to discuss the results of the baseline observation. It was decided that a treatment package in which sensible speech was strengthened through positive reinforcement and nonsensical speech was weakened through a negative punishment component would be implemented. The positive reinforcement component consisted of a DRI schedule. The incompatible behavior that was reinforced was sensible speech (i.e., speech that did not contain references to Ashtar or the space fleet). Specifically, if Ronald spoke sensibly when a staff member came to observe him, then the staff member spent two minutes in conversation with Ronald and provided social reinforcers, such as smiles, eye contact, and questions about Ronald's interests. The negative punishment component consisted of a planned ignoring procedure in which the staff member turned and walked away when Ronald made a nonsensical remark.

After 10 weeks of treatment, the percentage of intervals in which Ronald made a nonsensical remark decreased from the baseline level of 91% to less than 25%. Unfortunately, in the eleventh week of treatment, volunteers from the local university visited the facility and

spent much time speaking with the residents. After the volunteers' visit, the relative frequency of Ronald's nonsensical speech increased to nearly 50% and remained at that level for three weeks but declined to around 20% after another month.

At this point, a decision was made to add token reinforcers to Ronald's treatment package. These tokens (poker chips) were delivered when Ronald spoke sensibly. When he spoke nonsensically, one token was taken away. Social reinforcers continued to be provided when Ronald spoke meaningfully, and staff interacted only minimally when taking the tokens, then walked away. This altered intervention reduced intervals with nonsensical speech to approximately 5%. At that point, the frequency of reinforcement was gradually reduced, although the response-cost component stayed in effect. Ronald continued to talk appropriately most of the time, and there was general agreement that the problem was solved.

VI. SUMMARY

Negative punishment refers to a procedure (or process) in which the removal or avoidance of a stimulus as a consequence of behavior weakens such behavior. Response cost and time out are two common clinical interventions based on negative punishment. Published studies have shown these interventions to be effective in reducing a wide variety of inappropriate behaviors in several client populations in a variety of settings. Nonetheless, procedures based on negative punishment are widely construed as aversive and restrictive, and both ethical and legal considerations limit their range of utility.

GLOSSARY

aversive A nontechnical term often used to refer to punishment and negative reinforcement procedures.

avoidance conditioning A procedure in which behavior postpones or prevents the delivery of an otherwise forthcoming negative reinforcer and is therefore strengthened.

behavior Any action of a living creature. Behavior can be overt or covert.

conditioned negative reinforcer An event that acquires its capacity to serve as a reinforcer through learning.

consequence An event that follows and is produced by a behavior.

environment The natural world in its entirety, including all events that occur inside and outside living creatures.

establishing operation An event that alters the reinforcing or punishing value of a consequence.

escape conditioning A procedure in which behavior terminates or reduces the intensity of an ongoing stimulus and is therefore strengthened.

extinction A procedure (or process) that reduces behavior by failing to reinforce a previously reinforced response.

functional assessment Procedures that are used to identify the variables that maintain a problem behavior.

negative reinforcement A procedure (or process) in which the removal or postponement of a stimulus after a behavior strengthens (e.g., increases the likelihood of) that behavior in the future.

operant A behavior that “operates” on the environment and is controlled by its consequences.

reinforcer A consequence that strengthens operant behavior.

respondent conditioning A procedure in which a previously neutral stimulus comes to control behavior by virtue of reliably preceding a stimulus that controls behavior at the onset of and throughout stimulus–stimulus pairings.

response A defined unit of behavior.

rules Overt or covert verbal descriptions of relations among stimuli and responses. Rules describing consequences can engender behavior similar to that produced by actual exposure to the consequences.

stimulus A physical event.

unconditioned negative reinforcer An event that does not require learning to serve as a reinforcer.

The term negative reinforcement refers to one of the basic principles of operant conditioning rather than to a specific therapeutic technique. Operant conditioning is a form of learning in which behavior is controlled primarily by its consequences, that is, by changes in an individual's environment that are produced by the behavior. When the consequences of behavior increase the future probability of that kind of responding occurring under similar circumstances, or otherwise strengthen behavior, the consequences are termed reinforcers and the process

(and procedure) through which responding is strengthened is called reinforcement. Although a number of prominent psychologists have argued against the practice, theoreticians and practitioners commonly distinguish between positive and negative reinforcement. The definitions and examples provided here illustrate the similarities and differences between them.

I. DESCRIPTION OF TREATMENT

When a stimulus (physical event) strengthens behavior by virtue of being presented (or increased in intensity) following the occurrence of such behavior, the stimulus is called a positive reinforcer and the procedure is termed positive reinforcement. For example, the behavior "bringing home flowers" is strengthened when a pleasantly surprised spouse says, "Thank you, sweetheart. You are really thoughtful." The positive reinforcer is the appreciative statement, and bringing home flowers is strengthened because the behavior resulted in its occurrence.

When behavior is strengthened because it terminates (or reduces the intensity of) a stimulus, or prevents or postpones the delivery of an otherwise forthcoming stimulus, the procedure is termed negative reinforcement and the stimulus is called a negative reinforcer. For example, a teenager who picks up his room thereby prevents or postpones his mother's angry lecture about responsibility and cleanliness. Picking up the room is strengthened because it results in a negative reinforcer. The negative reinforcer (i.e., the angry lecture) is also commonly called an aversive stimulus.

The designation aversive stimulus is also applied to stimuli that serve as positive punishers. Perhaps for this reason, many people confuse negative reinforcement with positive punishment. The two procedures can be distinguished on one primary basis. While negative reinforcers strengthen behavior, positive punishers weaken (decrease the rate or intensity) behavior when delivered as consequences. For example, a child reaches toward a sharp knife (behavior) and a watchful parent exclaims sharply, "no" (positive punisher). The surprised child draws the hand back and does not reach for sharp knives again (weakened behavior). Stimuli that function as a negative reinforcer in one context frequently serve as a positive punisher in similar contexts. Nonetheless, negative reinforcement and positive punishment are independent processes that produce opposite effects on behavior, and the terms should never be used interchangeably.

Two variants of negative reinforcement can be distinguished: escape conditioning and avoidance conditioning. When behavior terminates or reduces the intensity of an ongoing stimulus and is therefore strengthened, the procedure is called escape conditioning and the behavior is termed an escape response. The reader should note that with escape conditioning the aversive stimulus is ongoing and thus is always present when the escape response occurs. For example, a person who is listening to the radio when a program that she dislikes comes on may turn a knob on the radio labeled "OFF-ON" to the left, terminating the aversive sound. If turning the knob to the left terminates the sound and knob-turning is strengthened, escape conditioning is evident. Here, the response-strengthening effects of negative reinforcement would most likely be evident not as a progressive increase in the rate of turning off the radio over time, but rather as reliably doing so each time a disliked program was aired. Reinforcement increases the rate of responding initially and subsequently maintains established rates and patterns of behavior.

When behavior postpones or prevents the delivery of an otherwise forthcoming aversive stimulus and is therefore strengthened, the procedure is called avoidance conditioning and the behavior is termed an avoidance response. Because the avoidance response prevents or postpones the occurrence of the aversive stimulus, the aversive stimulus is not present when the avoidance response occurs. A child who regularly says "please" when making requests because failing to do so historically has led to parental reprimands provides a good example of avoidance conditioning. Here, if "please" is not included as part of a request, then a reprimand is forthcoming. If, however, the child says "please," there is no reprimand. These consequences cause the child to say "please" consistently, as an avoidance response when no aversive stimulus is present.

Some stimuli, termed unconditioned (or primary) negative reinforcers, "automatically" strengthen behavior as consequences. That is, no conditioning history is required for them to serve this behavioral function. High-intensity sensory stimulation in any modality (e.g., loud sounds, bright lights, forceful pressure on the skin, extreme heat or cold) characteristically serves as a primary negative reinforcer.

As their name implies, conditioned (or secondary) negative reinforcers require a particular conditioning (learning) history to strengthen behavior as consequences. Respondent conditioning, in which a previously neutral stimulus reliably and immediately

precedes presentations of an unconditioned negative reinforcer, can serve to establish the neutral stimulus as a conditioned negative reinforcer. So, too, can verbal mediation, as when a friend tells a person holding illegal drugs “that the guy in the brown sweater is a cop,” and the drug-holder subsequently avoids the officer.

II. THEORETICAL BASES

A large number of studies have examined escape and avoidance conditioning in laboratory animals and in humans under laboratory settings. These studies provide clear evidence of the effectiveness of negative reinforcement in initially increasing the rate of, and then maintaining, operant behavior. They also have revealed much about the variables that influence the effectiveness of negative reinforcement in strengthening behavior, and therapeutic applications of negative reinforcement are built on a solid experimental foundation.

Since B. F. Skinner's early writings, most behavioral psychologists have favored explanations of operant behavior based on its more-or-less immediate consequences. Such explanations, which are termed molecular, work well with respect to escape conditioning. The usual theoretical explanation of escape conditioning is that responses immediately terminate an aversive stimulus, and this change in the environment is responsible for the strengthening of behavior. This analysis is straightforward and poses no conceptual difficulties. Explanations of avoidance conditioning are conceptually more difficult and have occasioned some debate.

Two variants of avoidance conditioning, signaled and unsignaled, are commonly distinguished. In signaled (or discriminated) avoidance, presentations of a forthcoming aversive stimulus are preceded (signaled) by a warning stimulus. A response during the warning stimulus terminates the warning and prevents the occurrence of the aversive stimulus. In unsignaled (also termed free-operant or nondiscriminated) avoidance, no specific stimulus precedes delivery of the aversive stimulus.

Signaled avoidance is easy to explain theoretically in terms of a two-factor theory initially proposed by Mowrer in the late 1940s. The essence of this widely accepted account is that the warning stimulus, which is highly predictive of the aversive event, comes through respondent conditioning to elicit what is commonly termed “fear.” Fear is unpleasant. It ends when the warning stimulus ends, and this happens as soon as the avoidance response occurs. Therefore, the avoidance response does have an immediate consequence—it ter-

minates the aversive warning stimulus and the accompanying “fear.”

This account must be substantially modified to explain unsignaled avoidance, where there is no apparent warning stimulus. The general approach taken by molecular theorists is to posit that the passage of time since the last occurrence of the aversive stimulus, or of the avoidance response, serves as a warning stimulus that elicits fear. Occurrence of the avoidance response, which is never immediately followed by the aversive stimulus, terminates the fear, and it is this immediate outcome that strengthens responding. Although the results of some studies support this view, the results of others do not. Particularly troublesome for two-factor theories of avoidance are that (1) studies often fail to find unequivocal evidence of “fear” in subjects responding under avoidance procedures, and (2) studies regularly find that avoidance responding persists for long periods even though subjects never contact the aversive stimulus. This latter effect is evident when, for example, extinction is arranged for avoidance responding.

Unsignaled avoidance responding is notoriously slow to extinguish, in part because an individual who is efficient at avoidance responding never contacts the aversive stimulus either prior to or during extinction. Therefore, it is impossible to discriminate between the negative reinforcement and extinction conditions. This difficulty can be overcome by presenting the aversive stimulus regardless of whether or not the behavior that previously was an effective avoidance response occurs.

Because of the difficulties that molecular explanations of avoidance conditioning pose, molar, or one-factor, alternatives have been offered. The essence of these theories is that behaviors need not have immediate consequences to be strengthened by negative reinforcement, but need only produce a detectable reduction in the overall frequency of exposure to the aversive stimulus. Therefore, hypothesized fear produced through respondent conditioning is not necessary for unsignaled avoidance conditioning to occur.

Although the relative merits of various one- and two-factor explanations of avoidance responding have been debated for decades, and alternatives to both approaches have been offered, there is no general agreement as to which theory of avoidance conditioning is best. With respect to clinical applications, the matter is not of crucial importance, and the primary virtue of the debate has been in fostering a wealth of laboratory studies of avoidance conditioning.

III. APPLICATIONS AND EXCLUSIONS

Negative reinforcement is important clinically in two regards. First, procedures that involve negative reinforcement may be systematically arranged to strengthen desired behaviors of clients. Second, negative reinforcement may play a role in the genesis and maintenance of undesired behaviors. Therapeutic procedures that involve the direct (contrived) arrangement of negative reinforcement have not been used as often as procedures involving positive reinforcement because of the ethical considerations involved in presenting unpleasant stimuli to clients, just so those clients can learn appropriate behaviors that allow them to escape or avoid these stimuli.

More often than they arrange contrived negative reinforcement, therapists help clients to understand the role of negative reinforcement in controlling their own troublesome actions in naturally occurring aversive situations and assist such clients in developing appropriate escape and avoidance responses. For instance, many teenagers engage in risky behaviors (e.g., drinking and driving) in part to avoid criticism and ridicule from peers. A therapist may help the teenager by pointing out less dangerous response options (e.g., staying away from situations where risky behavior is encouraged and peers who encourage it) that also are effective avoidance responses.

Interestingly, as Brain Iwata points out in an excellent 1987 review, negative reinforcement appears to play a generally unrecognized role in a number of procedures generally construed as "positive." For example, an educator may arrange consequences such that (a) a student's incorrect responses to problems result in statements of disapproval or remedial trials and (b) correct responses lead to praise. The educator assumes that improvements in the student's performance occur because praise is a positive reinforcer. Although positive reinforcement may contribute to the improvements, correct responses may also be strengthened because they allow the student to avoid aversive statements (of disapproval) and repetitions of an unpleasant task. That is, negative reinforcement may play an important but unrecognized role in producing the treatment gains.

Similarly, a therapist may think that positive reinforcement stemming from social interaction is responsible for a married couple's self-reported completion of an instruction to spend a half-hour of quiet time alone each evening. Instead, negative reinforcement in the form of avoiding the therapist's disapproval may be responsible for the couple's inaccurate report that they

spent time together. In truth, unintended negative reinforcement is very common in therapeutic settings, as in everyday life.

Even though negative reinforcement is common, clinicians should be cautious about its use because of the potential for engendering negative emotional responding, aggressive behavior, and escape from or avoidance of the situation in which negative reinforcement occurs. In these regards, negative reinforcement is similar to punishment, and the two often are considered together as aversive and relatively restrictive (harmful) strategies for changing behavior. For example, throughout his long life the eminent behavioral psychologist B. F. Skinner argued against the use of both punishment and negative reinforcement in clinical settings and in general society, although he recognized their ubiquity. Similarly, Murray Sidman (1999) considers procedures based on negative reinforcement as well as punishment "coercive" and advocates nonaversive alternatives to them wherever possible. These views are shared by many therapists as well as theoreticians.

Issues of client diversity bear on the use of negative reinforcement primarily when clients who are unable to make informed choices regarding their own treatment are concerned. For example, children and people with substantial intellectual impairment require special protections with respect to aversive interventions, including punishment and contrived negative reinforcement. In brief, a clear decision-making process regarding the use of negative reinforcement should be in place. This process should recognize that negative reinforcement is a restrictive (harmful) intervention and adhere to the doctrine of the least restrictive alternative intervention, which states that other, less restrictive interventions must be evaluated and found ineffective before negative reinforcement is considered.

Clear guidelines must be established regarding the exact nature of the negative reinforcement procedure, including who is to implement it and the specific standards of accountability. Input from clients and client's advocates, as well as behavior-change experts, should play a crucial role in determining treatment details, including who is to arrange negative reinforcement and how its effects are to be monitored. Unambiguous rules regarding the behavioral data that will support continuation, modification, and termination of the negative reinforcement procedure must be established by a vigilant, expert, and caring treatment team before treatment is implemented. These rules must be followed unless the good of the client dictates otherwise in the

opinion of the team. When possible, negative reinforcement should be avoided entirely.

IV. EMPIRICAL STUDIES

Relatively few clinical studies have evaluated interventions that involved intentionally arranging aversive stimuli that clients could escape or avoid by emitting appropriate behaviors. Most of the studies that have appeared involve clients with mental retardation, although other client populations (e.g., people with schizophrenia, children and adults with no diagnostic label) have been studied. Several different target behaviors (e.g., slouching, naming pictures, recognizing objects, approaching adults, speaking appropriately, solving math problems, stretching burned joints, sitting quietly during dental procedures) have been increased through escape and/or avoidance conditioning. A variety of aversive stimuli have been used, including electric shock, unpleasant noises, dental procedures, and required work or exercise. Clearly, procedures that involve systematically arranging aversive stimuli that clients can escape or avoid can be effective in generating appropriate behavior. Unless, however, those stimuli are only mildly aversive and generally accepted as part of the client's everyday world (e.g., requiring a student to work on math during a study session, unless the assignment was completed during math class), the use of such procedures is widely restricted. Moreover, too little work has been done with specific procedures to allow for general statements regarding the costs and benefits of specific interventions based on negative reinforcement relative to alternative interventions.

In recent years, behavioral psychologists have emphasized that an important early step in the treatment of many troublesome operant behaviors is isolating the reinforcers that maintain those behaviors, as well as any events that reliably precede them. The term functional assessment refers to a variety of procedures used to identify important environmental variables that maintain behavior. Functional assessment provides a basis for developing rational interventions that directly address the causes of the troublesome behavior. As noted previously, naturally occurring negative reinforcement can be responsible for a variety of behavioral problems. Once this is recognized, it may be possible to plan effective interventions. Many different interventions have been used to treat troublesome behaviors maintained by negative reinforcement; we will make no

attempt to review this extensive literature. Instead, we will describe a single intervention strategy for dealing with inappropriate escape/avoidance responses.

This strategy involves teaching clients an appropriate alternative to inappropriate behaviors. It is exemplified by functional communication training, an intervention developed by Edward Carr and Mark Durand. This procedure has proven effective in reducing a variety of inappropriate behaviors acquired because they historically produced reinforcement. As a case in point: a student with a developmental disability may have learned to scream and strike out during demanding academic tasks because doing so terminated the tasks. Functional communication training involves arranging conditions so that the inappropriate behavior no longer produces reinforcement (i.e., extinction is arranged) and teaching the person an appropriate communication response that allows the individual to escape the aversive situation. For instance, the student in our example might be taught to raise a hand to "request help" with aversive schoolwork rather than to engage in disruptive behavior. The value of functional communication training and similar interventions has been demonstrated in a number of published studies.

Strategies that involve reducing the aversiveness of the situation that a client historically has escaped or avoided by emitting an undesired response also can be effective in reducing troublesome behavior. For example, a 1999 study by Jennifer Asmus and her colleagues determined through functional assessment the variables that influenced the problem behavior of children during academic tasks. The results were idiosyncratic for each child, but relevant variables included the novelty of the task, the person administering the task, and the setting in which the task was conducted. In a similar vein, Richard Smith and his colleagues reported in 1999 that task variables such as rate of presentation of demands, task novelty, and duration of task affected the rate of problem behavior. Any of these task variables could be altered to decrease the aversiveness of the instructional situation without diminishing educational opportunities. Typical interventions might involve interspersing easier tasks with more difficult tasks, altering the task to match the student's current performance level, decreasing initial task requirements, and allowing additional time to complete difficult tasks. Such interventions should serve as establishing operations, reducing the effectiveness of escape or avoidance of academic tasks as a negative reinforcer and reducing the probability of occurrence of responses that historically have produced this outcome.

The clinical literature regarding negative reinforcement is neither extensive nor focused. Brian Iwata contends that further research in the area is warranted, and he suggests three interesting directions for it to take:

First, negative reinforcement may provide an alternative means for establishing behavior when attempts to use positive reinforcement fail... If so, we will want to know the behaviors for which specific contingencies are useful and the conditions under which they should be applied. Second, it appears that the acquisition of adaptive behavior in our training programs is at least partially a function of negative reinforcement. Further research must evaluate the roles of escape and avoidance within the training context so that (a) we will have a proper estimate of the effectiveness of commonly used positive reinforcers (the results of this estimate may indicate that more potent reinforcers are needed), (b) we can determine whether procedures such as remedial trials, physical assistance, and so on, serve any useful function and if that function is one of negative reinforcement, and (c) we can base future training successes on the planned rather than the accidental use of negative reinforcement. A third promising application involves further elaboration of behavioral replacement strategies. If we are willing to entertain the assumption that it is impossible to eliminate all sources of aversive stimulation, the use of such stimulation to alter the topography of escape and avoidance behavior, from an undesirable one to a tolerable one, makes eminent sense from a clinical standpoint.... As with punishment, we should conduct research on negative reinforcement with great care and under the appropriate conditions to determine how it might be used effectively and humanely, its limitations, and its proper role within the larger realm of currently available treatment. (1987, p. 78)

Negative reinforcement may well be coercive and unappealing, but it is also ubiquitous. Better understanding of its role in the genesis and maintenance of behavior disorders, and of its current and ideal role in treating those disorders, can only benefit psychologists and their clients.

V. CASE ILLUSTRATION

A study published by Nathan Azrin and his colleagues in 1968 provides a clear example of the logic of negative reinforcement. They treated postural slouching in 25 adults through the use of an automated device that detected slouching and, when it occurred, produced an audible click followed three seconds later by

a loud tone. The click and tone could be avoided by standing upright (not slouching), and escape from the tone could be effected by standing upright after the tone had started. This procedure reduced slouching in all clients exposed to it. The aversive stimulation that they received was mild, and they agreed to its appropriateness. These factors helped to make negative reinforcement an acceptable intervention.

A study published in 1986 by Hegel, Ayllon, Vanderplate, and Spiro-Hawkins provides an excellent example of the therapeutic use of negative reinforcement in another kind of situation, one in which a necessary medical procedure caused pain. The clients treated were three men who were recuperating from extensive burn wounds in a hospital. As part of their rehabilitation, they were required to stretch burned joints to increase and maintain flexibility. The stretching, which was initially arranged as part of mandatory staff-directed physical therapy sessions held each day, was quite painful. None of the patients showed increased range of motion in the burned joint during the period of staff-directed physical therapy. Range of motion increased substantially in all of them in a subsequent condition, where staff-directed physical therapy sessions could be avoided by engaging in sufficient self-directed exercise to meet daily goals. If the client failed to meet a daily goal, he was required to participate in staff-directed exercise. Thus, self-directed exercise was maintained by negative reinforcement in the form of avoidance of staff-directed physical therapy. Although the exercise undoubtedly was painful, no alternative would produce the same long-term benefits for the client. Unfortunately, aversive situations and activities are sometimes an intrinsic part of the human situation.

VI. SUMMARY

Negative reinforcement, one of the basic principles of operant conditioning, is evident when behavior is strengthened because its occurrence results in the termination or avoidance of aversive stimuli. The technique is important clinically in two general ways. First, negative reinforcement can be responsible for the development and maintenance of both healthy and pathological behaviors. Knowing this can help therapists understand and, more importantly, develop effective interventions for their client's troublesome behaviors. Second, procedures that involve negative reinforcement can be systematically implemented to strengthen

the desired behaviors of clients. Ethical and practical considerations place substantial limits on the range of situations where it is appropriate to use negative reinforcement as part of therapy, and whenever it is used due caution and appropriate safeguards are necessary.

GLOSSARY

amygdala A limbic system structure adjacent to the hippocampus that is responsible in part for regulation and valence of emotions (especially fear) and their related somatic expression.

brain-derived neurotrophic factor (BDNF) A molecule that is released by the targets of neurons and that promotes chemical alterations in the neuron responsible for its growth and maintenance.

explicit (or declarative) memory Learned factual knowledge and autobiographical information that requires conscious awareness and intact hippocampus.

glutamate An important excitatory neurotransmitter.

hippocampus The limbic system structure (extremely sensitive to high levels of stress hormones) responsible for significant aspects of both learning and memory.

hypothalamic-pituitary-adrenal (HPA) axis A feedback circuit between the hypothalamus, pituitary, and adrenal gland that regulates the release of glucocorticoids or stress hormones such as cortisol.

implicit (or nondeclarative) memory Nonconscious simple learning that although out of a patient's awareness, often has significant impact on behavior and perception.

neuronal plasticity The capacity of the central nervous system to strengthen and create neural connections (neurogenesis).

positron emission tomography (PET) A functional neuroimaging technique employing radioactive tracers that can demonstrate activation of brain regions through measurement of blood flow.

selective serotonin reuptake inhibitor (SSRI) A group of antidepressants that increase levels of the neurotransmitter serotonin in the synaptic cleft by impeding its degradation.

working memory A type of short-term memory, often referred to as the "blackboard of the mind," most often anatomically associated with the prefrontal cortex, that facilitates moment to moment perception, information processing, and explicit memory retrieval.

I. INTRODUCTION

Mental disorders and their treatments have long been viewed within a flawed intellectual framework, namely, that mental diseases are either biologically or psychologically based, and that treatment is best conducted with biological or psychotherapeutic tools, respectively. Many mental health professionals have adopted this view, as has an insurance industry that has often enforced criteria whereby treatment for "biological" illnesses (such as schizophrenia or bipolar disorder) is reimbursed while the treatment of "psychological" maladies (dysthymia or personality disorders, for instance) are less well supported. The very nature of professional

practice has been affected, with a dramatic reduction in the number of hours that psychiatrists or hospital-based (and sometimes community-based) nonpsychiatric clinicians spend in the performance of psychotherapy. Combined treatment with psychotherapy and medication, although a common practice, founders within this theoretical quagmire, often leaving practitioners without a logically consistent theoretical framework in which to skillfully and rationally deliver treatment.

This conceptual dichotomy is indeed ironic and unfortunate, for a careful review of the remarkable contributions from the neurosciences and cognitive psychology describe a very different intellectual framework, one in which psychology and biology are indistinguishable, and in which mental disturbances may be understood simultaneously on both levels in a heuristically harmonious manner. As Nobel laureate Eric Kandel asserted, “all mental processes, even the most complex psychological processes, derive from operations of the brain.” However, elucidating the neurobiological correlates of mental processes should not preclude the patient’s need for the psychotherapist to appreciate their unique meaning.

In this article, we will attempt to explain the relation of biology to psychotherapy. Current knowledge about certain critical brain functions, particularly learning and memory, which form the basis for our understanding of the biology and cognitive psychology of all psychotherapies, will be reviewed. We will discuss the remarkable capacity of the brain to adapt to environmental changes, expressed in the construct of neural plasticity and findings related to new cell growth in the adult brain, followed by a brief review of the effects of stress on the brain. Finally, we will conclude by offering evidence that psychotherapy does indeed exert measurable biological effects in the brain, findings that may ultimately guide therapeutic decision making.

II. LEARNING, MEMORY, AND NEURAL PLASTICITY

A. Phenomenology of Memory

Memory is not a unitary function of the brain. Indeed, memory can be categorized into at least two major functional and neurobiological categories, namely, explicit (or declarative) memory and implicit (or nondeclarative) memory. Explicit memory refers to factual knowledge such as place, people, things, and autobiographical information. Working memory is one variety of explicit memory that is distinct from long-

term explicit memory. Working memory refers to the short-term memory that facilitates active, conscious perceptual attention and initial processing of information, and later permits the purposeful retrieval of stored explicit memories. Implicit memory refers to the non-conscious effects of past behavior, and involves a heterogeneous set of abilities and knowledge, such as (1) associative learning (classical and operant conditioning); (2) procedural memory (learned skills and habits); (3) sensitization and habituation (exaggeration or attenuation, respectively, of behavioral responses to specific environmental stimuli); and (4) priming (enhanced recall aided by prior exposure to related stimuli, such as words or objects). In other words, and perhaps more germane to our understanding of psychotherapy, implicit memory refers to those past experiences that influence our current behavior even though we do not consciously remember them. Implicit memories form the rules that govern the interpretation of later life experiences. Because implicit knowledge is not readily available for conscious reflection, these rules self-perpetuate, even in the face of new life experiences that might demand a different (and more adaptive) perceptual bias.

As we might expect, there is an interaction between explicit and implicit memories that is utilized in psychotherapy. Implicit biases are examined and made explicit, creating an opportunity for conscious processing, reflection, and new experiences, hopefully leading to an adaptive change in the implicit memory system. To be more specific, the phenomenon of transference is understandable, for example, in light of the repetition of specific behaviors and beliefs that are governed by early experiences encoded in both implicit and explicit memories. In psychoanalytic psychotherapy, distortions that characterize transference within the doctor–patient dyad as well as throughout all sectors of a patient’s interpersonal world can be examined and interpreted within a safe, nonjudgmental, and empathic new relationship.

It is worth pointing out that this discussion of memory, particularly as it applies to our understanding of psychotherapy, is by necessity simplistic. Most notably it neglects the phenomenon of consciousness, the neurobiology of which would justify an entire article. (For such a treatise, please see the reference to Regina Pally’s work in the Further Reading section.) Consciousness, most often defined simply as awareness, probably represents a complex interaction between multiple brain functions and regions in the cortex and brain stem (at a minimum). Although a full elaboration of these systems and

relationships is beyond the scope of this article, several points of relevance to psychotherapy are worth mentioning. If conscious perception is the product of the shaping influences of our conscious belief systems on environmental reality, then we may resist not only unconscious material, but the conscious as well if it conflicts with our belief systems. Yet the essential function of consciousness is, according to Pally, to “provide ... a means by which we notice changes and can flexibly choose the most adaptive response to that change.” This is true of changes in the environment, as well as changes in our responses to those environmental events. Therefore, we simply cannot appreciate the processes of learning, growth, and therapeutic change without accounting for the role of conscious self-reflection.

Similarly, this article cannot address the broad field of human development as it relates to learning and memory. Questions about the relative stability versus alteration in these mechanisms at different stages in the individual's life cycle clearly have implications for clinical intervention as well as general understanding of learning and memory. This is a critically important area for further study.

B. Functional Neuroanatomy of Memory

An abundance of experimental data (human and animal, lesion and brain imaging studies) indicate that explicit and implicit memory depends on different brain structures and systems. Explicit memory relies on intact medial (i.e., inner surface) temporal structures, including the hippocampus, parahippocampal gyrus, and the entorhinal and perirhinal cortices, as well as association areas in the neocortex. New facts and event information are first processed in the association areas of the frontal, temporal, parietal, and occipital lobes. Working memory in particular relies on regions of left frontal lobes such as the prefrontal cortex. From the association cortices, information is conveyed to the parahippocampal and perirhinal cortices, and then to the entorhinal cortex, hippocampus, and adjacent structures (Fig. 1). Taken together, these steps represent the encoding and consolidation steps of memory formation. The specific functional tasks of each area remain unclear, and current investigations are under way to clarify the distinct roles. For example, the parahippocampal gyrus may support the encoding of information about the occurrence of an item, whereas the hippocampus may support the encoding of relationships between the item and its context.

The newly formed explicit memories return through the aforementioned systems back to the association cortices where long-term storage occurs. The fact that storage occurs in the association cortices explains why people and experimental animals that have bilateral lesions of the medial temporal lobes that damage the hippocampus are relatively unable to form new explicit memories but can recall previously stored (prelesion) knowledge. There is no single cortical storage area. Knowledge is distributed throughout the neocortex and is “reconstructed” into a single data set during the retrieval process.

The functional neuroanatomy of implicit memory, taken as a whole, is somewhat less well defined than that for explicit memory, in part because of the heterogeneity of cognitive phenomena collectively grouped as implicit memory, but also due to methodological problems involved in the study of implicit memory (preventing the “contamination” of implicit memory processing with conscious or explicit memory activation). However, it is fairly clear that the striatum, a component of the basal ganglia (a system of several nuclei, or functionally related collections of neurons, located deep within the cerebral hemispheres) is involved. The striatum actually includes several discrete nuclei: the caudate, putamen, and ventral striatum. The striatum plays a role in a variety of brain functions, including cognitive functioning, mood regulation, and motor and nonmotor behaviors. As with explicit memory, various areas of the neocortex are also involved with implicit memory.

Another brain structure of paramount importance to memory function, especially as it relates to our understanding of trauma and psychotherapy, is the amygdala. The amygdala sits in the anterior temporal lobe, just in front of the hippocampus. It plays a central role in the regulation of emotions, including the mediation of conscious emotional feelings (such as fear) with related somatic expressions (autonomic and motoric expressions). Electrical stimulation of the amygdala in humans results in feelings of fear and apprehension. Rare bilateral lesions of the amygdala disrupt the ability of the individual to apprehend fearful facial expressions and discern other fear cues in the environment.

The amygdala is involved in the encoding and consolidation of emotion-laden explicit and implicit memories. Emotional arousal activates the amygdala, resulting in the modulation of other memory regions influenced by the amygdala, thus regulating the strength and persistence of affectively charged memories. Larry Cahill, James McGaugh, and colleagues at the University of California, Irvine, have performed a

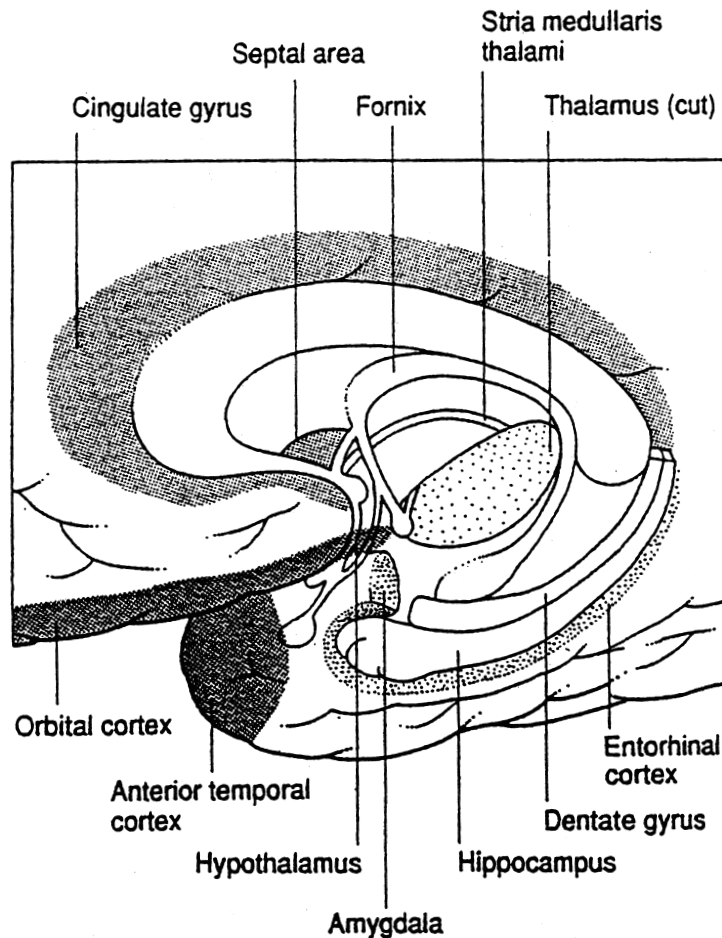

FIGURE 1 Medial view of cortical and subcortical limbic areas. From Fitzgerald (1992). "Neuroanatomy: Basic and Clinical," 2nd ed., W.B. Saunders Co.

number of experiments that demonstrate this phenomenon. For example, they showed emotionally neutral and emotionally arousing film clips to healthy volunteers who then underwent a functional brain imaging study (fluorodeoxyglucose positron emission tomography, or FDG PET) designed to demonstrate relative activation of various brain regions. The amygdala activated during viewing of the arousing films, but not the emotionally neutral clips. Later, the subjects were better able to recall the arousing clips, with the degree of amygdala activation correlating with the degree of recall.

The amygdala's memory role is therefore a selective one, with little involvement in the absence of emotional arousal. Furthermore, the amygdala is involved

only in memory encoding and consolidation (prestorage activities), not retrieval.

C. Cellular Mechanisms of Learning and Memory: Neural Plasticity

We have reviewed known elements of how the brain, as a collection of macroscopic brain regions, obtains and retains new knowledge. But how do the actual individual functional units of the brain, that is, the nerve cells (or neurons), facilitate these changes?

Neurons communicate with one another through a process of chemical signaling known as neurotransmission. An impulse (action potential) traveling down the outbound fiber (axon) of a neuron reaches its terminus

at the juncture between the signaling neuron and another nerve cell. This juncture is known as the synapse. The synapse may impinge on the body of the target neuron, or on one of its projections (an axon, or an inbound fiber, or dendrite). At the synapse, the “upstream,” or presynaptic neuron releases chemicals (neurotransmitters) into the synaptic space. The neurotransmitter diffuses across the space and comes into contact with special proteins (receptors) imbedded in the outer membrane of the “downstream” (postsynaptic) neuron. When the neurotransmitter interacts with the receptor in a chemical “lock-and-key” fashion, an excitatory or inhibitory effect is exerted on the postsynaptic neuron. The intended action of the signaling neuron is thus accomplished.

We now know that the brain possesses a remarkable capacity for structural change throughout the life cycle. This idea was first articulated in 1911 by the neuroanatomist Santiago Ramon Y Cajal, who postulated that repeated behavior must cause the neuron’s dendrites and axons to undergo structural changes, revising the preexisting pattern of neuronal interconnections. In other words, learning is the product of new or enhanced connections between nerve cells. The neurophysiologist Donald Hebb experimentally demonstrated this phenomenon in 1949, resulting in what has become known as “Hebb’s Rule.” Hebb wrote: “When an axon of cell A ... excites cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A’s efficiency as one of the cells firing B is increased.” Hebb asserted that this change is the result of a strengthening of the connections between neurons. This phenomenon is known as neural (or neuronal) plasticity, and represents the process whereby learning experiences are physically encoded.

Eric Kandel was awarded the 2000 Nobel Prize in Physiology or Medicine for demonstrating the molecular mechanisms of this process in the marine sea slug (*Aplysia californica*), an invertebrate with a relatively simple nervous system consisting of about 20,000 nerve cells. The structural simplicity of *Aplysia*’s nervous system facilitated Kandel’s demonstration of the mechanisms of implicit learning. A mild touch of the animal’s siphon (a structure used to expel waste and seawater) normally elicits a reflexive withdrawal of its gill and siphon. This reflex is known as the gill-withdrawal reflex. Repeated stimulation of the reflex leads to habituation, or attenuation, of the reflex. On the other hand, the administration of a noxious stimulus to its tail produces a sensitization, or exaggeration, of the

reflex. Briefly repeated trials of either kind of stimulus lead to a change in the reflex that is relatively short-lived (i.e., lasting minutes). However, the administration of four or five series of stimulations administered periodically over hours results in a change that lasts from days to weeks. Therefore, habituation and sensitization have short- and long-term forms. Kandel discovered that short-term habituation and sensitization result from a decrease or increase, respectively, in the amount of neurotransmitter released into the synapse (in the case of *Aplysia*, the connection between the sensory neuron bringing information about the stimulus and the motor neuron that mediates the withdrawal reflex). Importantly, although the exact mechanism of this alteration is unclear, changes in protein synthesis do not appear to be necessary.

Long-term alterations in the reflex were observed after repeated stimulus applications. It is noteworthy, although of little surprise to many behavioral scientists, that spaced training (small amounts of training spaced over many minutes or hours) produced substantially greater behavioral alterations than did massed training (a lot of training all at once). Long-term alterations were facilitated by changes in gene expression and the protein-manufacturing apparatus of the cell. This cascade of molecular events described by Kandel and subsequent investigators can be simplified as follows.

During repeated stimulation, a neurotransmitter known as glutamate accumulates in synapse. Activation of a subtype of the glutamate receptor, the so-called NMDA (*N*-methyl-D-aspartate) receptor, opens membrane channels that permit the entry of calcium into the neuron. In the interior of the cell, calcium triggers a series of enzymes (adenylate cyclase and protein kinases) to initiate gene expression in the nucleus of the cell. The activated genes encode proteins important for the regulation, growth, or elimination (pruning) of synaptic connections. When the cell’s protein synthesis apparatus is turned on, and regulatory or structural proteins are manufactured, new receptors or synaptic sites are created, or existing ones functionally or physically eliminated. The ultimate result is a long-term change in synaptic excitability, effectively altering the way in which the brain’s circuitry responds to later stimulation.

Evidence for anatomical changes in the brains of stimulated individuals is found in the work of Anita Sirevaag and William Greenough, who during the 1980s showed that different rearing conditions affect brain structure. Rats raised in a complex toy-rich environment showed indications of enhanced brain development compared to rats raised in isolated, uninteresting

conditions. Specifically, the stimulated rats' brains had a greater density of synaptic nerve endings (boutons), higher volume of dendrites per neuron (more complex branching, implying more neuron-to-neuron communication), and more support structures, indicating more active neuronal activity (more blood vessels, for instance).

The individual genetic traits of an individual modulate the robustness of the plastic cellular adaptations. For instance, Joe Tsien and colleagues at Princeton University bred a genetic strain of mouse (dubbed "doogie the supermouse") in which the postsynaptic NMDA receptor density was intentionally increased (overexpressed). Compared to unaltered control mice, the mutant mice showed superior abilities in learning and memory in various behavioral tasks, as would be predicted by the neural plasticity model.

D. Neurogenesis

In addition to the above scenario, another mechanism may explain the remodeling of the nervous system in response to life experiences. Until the 1960s, neuroscientists had long believed that the adult brain was incapable of generating new neurons. In 1965, Joseph Altman at MIT described the production of new neurons in the brains of adult rats. Inexplicably, little work was done to further the study of the remarkable phenomenon of neurogenesis until the past decade or so, when several investigators resumed work on this critically important area of neuroscientific study. Elizabeth Gould of Princeton University has studied factors that appear to regulate neurogenesis in various animals, including primates. One of the most important findings was that neurogenesis is stimulated by environmental complexity and learning. Experimental training activities resulted in increased formation of adult-generated nerve cells (granule cells) in the black-capped chickadee. Training conditions also enhanced the survival of those cells. Conversely, conditions of deprivation reduced the generation and survival of new cells. Another important finding was that adrenal hormones, normally released in greater quantity during times of stress, suppresses the formation of precursor cells. We will discuss other effects of stress on the brain later in this article.

Even after neurogenesis was demonstrated in a wide variety of animals, the scientific community was resistant to accept that neurogenesis occurs in humans. That changed when Fred Gage and his colleagues at the Salk Institute for Biological Studies in La Jolla, California,

studied the postmortem brains of cancer victims who had received a dosage of a diagnostic drug called bromodeoxyuridine (BrdU) before they died. BrdU is incorporated into the DNA of dividing cells and can be used as a marker for dividing and newly formed cells in the body. Gage found BrdU-containing cells in the studied brains, conclusively establishing that adult humans grow new neurons. Of great significance to our topic, the new cells were found in the hippocampus, already shown to be essential to learning and memory.

Last, although the exact mechanisms that regulate neurogenesis are still undetermined, existing work gives us every reason to believe that neurogenesis, like neural plasticity, results from interactions between experience and genes. Indeed studies by Liu and colleagues support that early life experiences can profoundly determine both brain structure and function. For example, high levels of maternal rat behavior promote hippocampal synaptogenesis, enhance memory and learning in adult offspring, and increase both NMDA receptors as well as brain neurotrophic factors that play a central role in the growth and maintenance of neurons. Conversely, rats experiencing maternal separation early in their postnatal development have decreased brain neurotrophic factors (BDNF) and in the presence of elevated levels of stress hormones that accompany acute stress, are unable to modulate BDNF as are sibs who are not separated from their mothers.

E. Implications

The implications of these findings about the biology of learning and memory are indeed broad. We now have an elegant scientific framework with which to understand the interaction between genes and environment. These models give us an idea why different individuals, with diverse genetic "blueprints," may respond to nearly identical environmental circumstances in strikingly different ways, including why some trauma victims may develop posttraumatic stress disorder (PTSD) whereas others survive with little detriment to their mental health. It also helps us to understand why identical (monozygotic) twins (with identical genetic content, but different life experiences) may have such divergent personal features. For example, we know that a monozygotic twin of an individual with schizophrenia—a mental disorder considered to be highly "genetic"—has no more than a 50% chance of developing the disease. Life experiences, through the previously described (and related) mechanisms, determine whether genetic predispositions and vulnerabilities are

realized, or whether they remain latent throughout our lives.

In the case of depression, Kenneth Kendler studied more than 2100 female twins over 17 months. The probability for those twins at lowest risk for major depression increased from 0.5% to 6.2% and those at highest risk from 1.1% to 14.6% if a twin had experienced stressors such as a recent death, assault, marital problems, and divorce or separation. David Reiss' work with more than 700 multiconfigured families has demonstrated that when a parent differentially and persistently relates to one adolescent in a conflictual or negative manner, nearly two thirds of the variance in the teenager's antisocial behavior and one third in his depressive symptomatology can be accounted for by the conflicted parent-child relationship. Life experiences through the previously described (and related) mechanisms determine whether genetic predisposition and vulnerabilities are realized, or whether they remain latent throughout our lives. Moreover, recent research appears to support the possibility that psychotherapy and medication may share salutary effects through moderating the genetic effects of those with vulnerable phenotypes.

III. THE BIOLOGICAL EFFECTS OF STRESS

Most people who seek psychotherapy, or any mental health treatment for that matter, do so during times of increased subjective life stress or following a highly stressful, even traumatic, life experience. Psychosocial stress has long been recognized as a major contributor to the onset of mental disorders and to the recurrences or exacerbations of those maladies. For that reason, any attempt to understand the neurobiology of psychotherapy requires some understanding of the biological effects of stress.

Biologists have long been fascinated by the natural phenomenon of animal population crashes. Typically, environmental conditions favoring the exponential growth of a particular species' population results in intra- and interspecies competition for food and mates, and territory. When the population exceeds the carrying capacity of the environmental niche, vast numbers of the affected community die, sometimes losing 90% or more of its members within a very short period of time. Examinations of population crash victims typically reveal multiple organ abnormalities, including enlarged adrenal glands—the small hormone-producing organs that sit on top of each kidney and secrete adren-

alin (also known as epinephrine) and corticosteroids. These substances are known collectively as the body's stress hormones.

Using less dramatic experimental and naturalistic research designs, many investigators have explored the consequences of stress in animal and human nervous systems. These investigations demonstrate that stress is associated with disruption or alteration of various mechanisms involved in learning and memory, and presumably, adaptation. We will illustrate this point with a description of selected findings.

A. Studies of Care-Related Stress

Stephen Suomi performed a series of experiments with rhesus monkeys that shed light on the interaction between genetic vulnerability, stress, and potentially corrective experiences. He first observed that infant monkeys separated from their mothers developed social anxiety-like behavioral responses. They were later reared by peers raised by the subject monkey's own mothers. The peer interaction resulted in some amelioration of the behavioral disturbance, but the subject monkeys remained prone to a return of the behavioral disturbance when placed in novel or stressful circumstances, accompanied by high levels of stress hormones (see later discussion). Suomi then observed that a minority of monkeys that were raised by their own mothers showed exaggerated separation disturbances that were similar to those shown by the original subject monkeys. This latter group of disturbed monkeys was placed in the care of highly nurturant foster monkeys. The change in rearing resulted in the relief of behavioral problems. But more surprisingly, the offspring that were "adopted" by the "supermothers" went on to rise to the top of the colony hierarchy, implying that the constitutional sensitivity of these monkeys was preserved in a way that conferred an attunement to the needs and cues of the colony, allowing them to respond in a socially adaptive and successful manner.

A more dramatic example of the deleterious effects of separation (without subsequent surrogate caregiver nurturance) can be found in René Spitz's historic study of infants of unwed mothers placed in foundling homes in the 1940s. In order to reduce infection risk to the infants, handling was kept to a minimum, and the infant's view of caregivers' faces was blocked by masks and sheets. Despite receiving sufficient nutrition and an attractive physical environment, almost all of the infants died or developed mental retardation within 1 to 2 years. Spitz contrasted this to the healthy,

normal outcomes of children raised by their mothers in a squalid prison environment. He concluded that nurturant human contact was as essential for growth and survival as was food and sanitary conditions.

Rosenblum and Andrews studied infant monkeys raised by either normal mothers or by mothers made anxious by an unpredictable feeding schedule. The monkeys with anxious mothers demonstrated social impairment and biochemical abnormalities (serotonin and norepinephrine abnormalities). Interestingly, the changes did not appear until adolescence, lending credence to clinical observations that early environmental disturbances may have long-ranging effects that do not manifest until later in life.

B. Role of Stress Hormones

The stress hormones have been an important focus of stress response studies. For the purposes of this discussion we will focus on the most important of the stress hormones—the category of corticosteroids known as the glucocorticoids—exemplified by cortisol. The glucocorticoids are involved in immune function and a number of other physiological processes as well as the stress response. Glucocorticoid release is regulated by a homeostatic feedback mechanism involving the hypothalamus, pituitary gland, and the adrenal glands (the hypothalamic-pituitary-adrenal, or HPA, axis). Many studies have examined the role of the HPA axis during stress, showing that glucocorticoid concentrations (and the levels of other brain chemicals that stimulate glucocorticoid production and release, such as adrenal corticotropin hormone [ACTH] and corticotropin releasing hormone [CRH]) go up during times of brief or prolonged stress. Elevated glucocorticoid levels are found in laboratory animals separated from their mothers or social groups, or otherwise placed in stressful conditions. Stress-related human cortisol elevations were demonstrated as long ago as the Korean War, when urinary cortisol levels of soldiers under random artillery bombardment were higher than during periods away from the battle zone.

The hippocampus, equipped with a high density of glucocorticoid receptors, is the principal target location in the brain for the glucocorticoids. The hippocampus is also an important inhibitory regulator of the HPA. Under conditions of modest stress, a resultant facilitation of hippocampal plasticity appears to enhance cognition. This is consistent with the observation that people tend to perform better when mildly or moderately challenged. However, major or prolonged stress

produces sustained high levels of glucocorticoids that seem to have deleterious effects in the brain, including cell loss. The mechanisms of glucocorticoid-mediated harmful effects are unclear, but may involve inhibition of the chemicals inside the neuron that turn on gene transcription and protein synthesis. The consequences may include inhibition of neural plasticity (with reduced dendritic branching and alterations in synaptic structure) and/or neurogenesis, a decreased rate of new neuronal survival, and actual neurotoxicity with permanent cell loss (i.e., a direct lethal effect on hippocampal neurons, possibly through mechanisms involving the neurotransmitter glutamate, resulting in activation of programmed cell death processes known as apoptosis). Animal studies and human brain imaging studies have demonstrated atrophy (shrinkage) of the hippocampus (and to a lesser extent, other brain regions) during prolonged periods of stress. As well, enduring hormonal changes throughout the life of an animal subjected to early maternal separation have been demonstrated. More will be said about the role of the HPA axis in depression and PTSD later in this article.

IV. EVIDENCE FOR THE BIOLOGY OF PSYCHOTHERAPY

In this section we will review present evidence that psychotherapy is a powerful tool that exerts its effects by changing the structure and function of the brain. Before presenting that evidence we will briefly describe background material regarding brain imaging methods, findings related to the biology of human emotions, and comments regarding the biology of personality.

A. Brain Imaging

It is beyond the scope of this chapter to attempt even a modest brain imaging primer. However, these tools have permitted the study of cognition and emotion, in normal and pathological states, to an extent that was previously impossible. A very brief description of imaging methods may therefore assist the reader as we subsequently present imaging data that inform the primary subject at hand.

Neuroimaging methods may be separated into structural and functional imaging techniques. Structural imaging methods provide information about the anatomy of the brain but say nothing about its present physiology. Many readers will be quite familiar with the two major structural imaging methods: computed tomography

(CT) and magnetic resonance imaging (MRI). Although CT has many valuable clinical applications, its resolution is inadequate to quantify the structural changes reflective of the processes described in this article. Therefore, research questions about brain structure are generally answered using MRI.

Functional imaging methods are less familiar to most clinicians as they have only recently found a limited role in clinical medicine. For now, their major role is still limited to research. These methods share a common theme: They provide information about the present physiology of the brain. Depending on the method chosen information about the metabolism or blood flow in a specific brain region (reflective of regional brain activity), and receptor and/or neurotransmitter levels, can be acquired. Brain activation studies may be performed under a variety of conditions, including a resting state, or when the subject is engaged in a specific sensory, cognitive, or emotional task. The most common functional imaging tools used to study emotional and cognitive function are positron emission tomography (PET), single photon emission computed tomography (SPECT), both of which involve introduction of a radioactive tracer into the subject's body, and functional magnetic resonance imaging (fMRI).

B. Functional Neuroanatomy of Human Emotions

Functional imaging tools can show us "real-time" information about brain activation during various emotional states and tasks. Eric Reiman performed a series of experiments with normal subjects and sufferers of panic or phobic disorders to characterize the biology emotions using functional brain imaging methods (PET), each constructed around a distinct mental task. His findings indicate that human emotional functioning is highly complex, involving multiple brain regions. To illustrate this point, we will present a selection of his findings.

A group of normal subjects underwent PET imaging while watching a series of silent film clips, some that were emotionally neutral and others that were emotionally arousing. He later performed a similar study using cognitive rather than visual stimuli. Subjects were instructed to recall (rather than view) happy and grievous events. A wide variety of regions again activated during the performance of both emotional tasks. However, when comparing the results of the studies, Reiman was able to make the following generalizations. Limbic areas (the hippocampal formation and amy-

dala) and paralimbic areas (anterior temporal cortex and parahippocampal gyrus) long thought to participate in emotion, while activated in both sets of subjects, were preferentially involved in the response to externally presented (film clips) emotional stimuli. In contrast, a region in the vicinity of the anterior insular cortex was preferentially involved in the response to distressing cognitive stimuli (recalled experiences).

Reiman concluded that the anterior insular region might serve as an internal alarm system, investing potentially distressing thoughts and bodily sensations with negative emotional significance. On the other hand, the anterior temporal region might serve as an external alarm system. Several structures activated in a way that indicated that they serve a general role in emotional response, irrespective of the quality or valence of the emotion. These areas included the thalamus and medial prefrontal cortex, the latter seeming to facilitate conscious experience of emotion, inhibition of excessive emotion, and monitoring of one's emotions in order to make personally relevant decisions.

Louis Gottschalk and Monte Buchsbaum also used PET to study the emotional phenomena of hope and hopelessness. Twelve healthy male volunteers were imaged during a state of silent, wakeful mentation. The thoughts that they experienced during the study were later rated using the "Gottschalk Hope Scale." As with Reiman's subjects, many regions activated during the mental task. The interesting conclusion made by the authors was that the metabolic changes associated with hope and hopelessness had some different regional locations and characteristics, indicating that from a neurobiological standpoint, hope and hopelessness are not simply opposite manifestations of a single emotional phenomenon.

It is too early to attempt a broad neurobiologically based explanation for mood and mood regulation. As can be surmised from the above discussion as well as earlier sections of this article (such as the role of the amygdala), the answer is likely to involve a complex interplay between numerous brain areas. In addition to those already mentioned, the anterior cingulate almost certainly plays a key role. John Allman at the California Institute of Technology has asserted that the anterior cingulate appears to be an area in which functions central to intelligent behavior, such as emotional self-control, focused problem solving, error recognition, and adaptive response to changing conditions, are juxtaposed with the emotions.

Whether mood disorders reflect a primary disturbance of the brain systems that control emotion, or involve dysregulation in other brain systems with secondary

“downstream” disruption of mood regulation, remains to be seen. For additional reading beyond this discussion or that found in Section D later, see the reference to Dennis Charney’s text in the Further Reading section.

C. Personality

If implicit learning is the result of experiential and genetic interactions, we are left to wonder about the biology of personality development. To what extent is personality already genetically directed at birth, versus a series of implicitly learned rules, perceptions, and emotional and behavioral responses? Anyone who has spent much time with infants has certainly observed the striking differences in behavioral responsiveness from one infant to another, yet we still traditionally think of personality as an acquired constellation of personal characteristics.

Robert Cloninger of Washington University has attempted to explain this conundrum with a psychobiological model of personality development. He suggests that personality consists of two independent multidimensional domains that he terms “temperament” and “character.” Temperament consists of four independent dimensions, including novelty seeking, harm avoidance, reward dependence, and persistence. Temperament involves automatic, preconceptual, or unconscious responses to perceptual stimuli, reflective of biases in information processing by perceptual memory systems. Temperamental factors are independently heritable, manifest early in life, and are highly stable over time. The factors may be observed in childhood and predict adolescent and adult behavior.

The dimensions of character are self-directedness, cooperativeness, and self-transcendence, or, respectively, identification as an autonomous individual, integral part of human society, and integral part of the universe. In contrast to temperamental factors, character factors are concept-based and less stable (i.e., more malleable) over time, although genetics may still play a role in character development. Someone low in the first two character traits is, according to the author, likely to suffer a personality disorder. Although the importance of self-transcendence is of questionable value to the person early in life, it takes on great importance during times of death, illness, and misfortune.

This model has implications for the treatment of personality disorders. For instance, it is possible that temperamental factors may be attenuated using certain medications (some of which have already found an effective adjunctive role in the treatment of certain per-

sonality disorder traits). On the other hand, the factors of character may be more productive targets for psychotherapeutic interventions. Clearly more work must be done to test the validity of this construct, particularly as it translates to clinical settings with disturbed individuals.

D. Depression

1. *Psychotherapy versus Antidepressant Medication: Imaging Findings*

Psychotherapy of depression in its various forms is among the most well-validated of all psychological treatments. Yet fundamental questions about which form of psychotherapy to apply, when, to which patient, and whether a depressed person should receive psychotherapy, medication, or both, remain largely unanswered. Information from the neurosciences may soon inform these issues, and is already offering exciting clues.

Two investigators performed functional neuroimaging with depressed people treated with psychotherapy or antidepressant medicine. In the first study, Arthur Brody and Lewis Baxter used pre- and posttreatment PET imaging to examine regional brain metabolism changes in 24 people suffering from major depression treated with 12 weeks of either paroxetine or interpersonal therapy (IPT). The posttreatment changes in brain activation were very similar, with both groups showing a normalization of excessive pretreatment activation in a variety of brain regions (the right dorsolateral prefrontal cortex, left ventrolateral prefrontal cortex, right dorsal caudate, and bilateral thalamus). Only the medicated group showed a significant reduction in the right ventrolateral prefrontal cortex, possibly reflecting the fact that the medicated subjects were less symptomatic pretreatment and experienced a proportionately more robust response to treatment.

In a study performed in the United Kingdom, Stephen Martin used SPECT to measure changes in regional cerebral blood flow (rCBF) in 28 depressed people who were treated for 6 weeks with either venlafaxine or IPT. The two groups had a similar degree of pretreatment symptoms, and again, the drug group showed a more robust improvement, although 6 weeks of treatment is minimally adequate for an antidepressant trial, but probably not for IPT. The imaging studies showed that both groups showed increased rCBF in the right basal ganglia. Only the IPT group showed increased rCBF in the right posterior cingulate, an ambiguous finding due to potential confounding effects.

A preliminary study by Viinamaki and colleagues in Scandinavia suggests that psychodynamic psychotherapy, as is the case with CBT and IPT, may change brain function. A patient with both depression and borderline personality disorder was treated for 1 year with psychoanalytic psychotherapy and compared to another patient with the same conditions who received no treatment, as well as with 10 normal controls. Pre- and posttreatment SPECT scans demonstrated normalization of serotonin uptake in the prefrontal cortex and thalamus of the treated patient but not in the untreated subject.

Although not an imaging study, it is worth mentioning work done by Russell Joffe in which he treated 30 mildly depressed people with 20 weeks of cognitive therapy (CT), 17 of whom responded to treatment. Blood was drawn from the subjects before and after treatment, and assayed for concentrations of thyroid hormone. Prior studies have shown that thyroid hormone, a general regulator of the body's metabolic activity, is elevated in many people with depression, and tends to normalize after effective treatment with antidepressant medicines. Joffe found that thyroid hormone levels came down in CT treatment responders, but not in nonresponders. Although the implications of abnormal thyroid function is unclear as it relates to depression and its treatment, this study provides another piece of evidence that psychotherapy resembles medication treatment in terms of biological changes that follow effective treatment.

From these very preliminary studies we may conclude that there is little neurobiological evidence of differential antidepressant medicine–psychotherapy treatment effects, suggesting that a unitary pathway for relieving depressive symptoms might exist, shared by antidepressant medicines and psychotherapy. Yet even if there is, on some level, a common biological antidepressant mechanism, that possibility does not help us to decide which treatment might best help a given patient. Biological markers that predict response to one treatment or another could help the patient and clinician rationally choose the most promising treatment. Better understanding of the involved pathways may also provide a biological basis for synergistic antidepressant–psychotherapy combinations, analogous to the strategy commonly used in anticancer chemotherapy in which drugs are combined that attack a common biochemical pathway at different steps in the sequence.

2. Sleep Studies

Sleep studies have been used to identify just such a marker. Michael Thase and others at the University of

Pittsburgh performed three studies of almost 300 depressed people treated with either antidepressant medication or psychotherapy (CBT in the first study; IPT in the subsequent studies). Prior to treatment, subjects underwent a sleep electroencephalogram (sleep EEG, or polysomnography). This test uses measurements of the brain's electrical activity to characterize a subject's sleep, in terms of the amount of actual sleep and the relative normalcy of the pattern of sleep stages. The investigators found that people with abnormal sleep profiles responded less well to CBT, and had a higher recurrence rate. Interestingly, the sleep EEG did not predict response to medication.

3. A Cellular Mechanism of Antidepressant Treatment

Hypotheses concerning the cellular mechanisms of effective psychotherapy are entirely conjectural at this time. However, the mechanisms of antidepressant medication action are being elucidated, and may offer us testable hypotheses about the mechanisms of action for psychotherapy.

Ronald Duman and colleagues at Yale University have studied the biology of mood disorders as well as possible cellular mechanisms of antidepressant treatments. Chronic administration of four different classes of antidepressant drugs and electroconvulsive shock increased levels of brain-derived neurotrophic factor (BDNF)—a chemical inside of the nerve cell that indirectly turns on gene transcription, and inhibits cell death pathways—in the hippocampus of unstressed rats. Furthermore, the antidepressant treatment blocked the expected downregulation of that chemical in response to stress. They concluded that antidepressant treatments might work by enhancing neural plasticity and supporting neurogenesis and neuronal survival. Although this offers a hypothetical cellular mechanism of action for antidepressant treatments, it also raises the intriguing prospect, albeit conjectural at this time, that psychotherapy may act in a similar fashion. Duman hypothesized that depression (and possibly other psychiatric conditions) may result from a failure of neural plasticity in various brain regions, particularly the hippocampus and prefrontal cortex. Might effective antidepressant therapies, somatic or psychotherapeutic, act by restoring normal neural plasticity?

E. Posttraumatic Stress Disorder

Human history quickly dispels any notion that tragedy and trauma can ever become infrequent occurrences. Despite the best of societal intentions, wars

rage, terror menaces, and trusted caregivers violate. Trauma survivors persevere in states ranging from health to mental debilitation. PTSD is a potential consequence of trauma that renders its victim chronically anxious and phobic, prone to awful reexperiencing episodes, avoidance behavior, and a range of behavioral, cognitive, and affective symptoms.

Our earlier discussion of the biology of stress is highly relevant to the study of PTSD. Douglas Bremner at Yale University has studied the biology of PTSD in combat veterans and victims of domestic violence. He and others have concluded that PTSD is associated with hippocampal defects that may result from the deleterious effects of stress-induced glucocorticoid exposure. Bremner showed that combat veterans had hippocampal volumes 8% smaller than control subjects. He also found that memory deficits correlated with hippocampal volume reduction. Later studies with abuse victims showed hippocampal volume reductions of 12 to 16% in people with abuse-related PTSD compared to abuse victims who did not develop PTSD. The age of traumatization (stage of development) may influence the nature of the memory deficits and hippocampal atrophy. For example, imaging studies of children who were maltreated demonstrate smaller hippocampal volumes than children who were not abused. Because of its central involvement in multiple memory- and stress-related functions, the hippocampus may also provide an anatomical explanation for the fragmented or delayed recall of highly stressful or traumatic memories.

Lisa Shin and Scott Rauch at Harvard University examined 14 Vietnam combat veterans, 7 with PTSD and 7 without, using PET. The subjects viewed pictures with various themes (emotionally neutral Vietnam-unrelated themes; emotionally negative Vietnam-unrelated themes; and emotionally negative Vietnam-combat-related themes). The PTSD subjects showed increased blood flow in the anterior cingulate gyrus and right amygdala when they were exposed to combat-related stimuli. They also had decreased blood flow in an important language area of the brain (Broca's area), which the authors conjectured "may be consistent with diminished linguistic processing while subjects with PTSD viewed and evaluated combat pictures." The subjects without PTSD did not show these changes.

Chris Brewin at the University College London has posited a novel "dual representation" theory of memory that he extends to understand PTSD and its behavioral treatment. He postulates the presence of two memory systems, which he terms verbally accessible memory (VAM) and strategically accessible memory (SAM).

VAM relates to ordinary autobiographical information. Memories stored in the VAM system can interact with the rest of autobiographical memory base, and deliberate retrieval is straightforward. On the other hand, SAM is characterized by the processing of information from "lower level perceptual processing of the traumatic scene and of bodily response to it." Perceptions stored as SAM memory undergo less initial conscious processing, and such memories (that may take the form of "flashbacks") are more detailed and affect-laden.

Brewin extends this construct to psychotherapy, asserting that "therapy assists in the construction over time of detailed, consciously accessible memories in the VAM system which are then able to exert inhibitory control over amygdala activation." The therapy process creates new representations of critical retrieval cues stored in the VAM system. The new, verbally processed, trauma-related cues are identified as belonging to a specific past event that does not now constitute an ongoing threat ("that was then, this is now"). Initially, memories in the SAM and VAM systems compete when the patient is confronted with trauma reminder. VAM may be given a retrieval advantage if treatment strategies are used to "make the new representation highly distinctive," which may lead to encoding effects that improve memory retrieval. Brewin hypothesizes that EMDR may do just that: the EMDR cue (therapist's finger, for instance) encodes a very distinctive attribute to the new VAM representation. "Imaginal reconstructions" (i.e., deliberate fantasies about acting differently in the trauma) may also lend a distinctive cue to the new representations. His hypothesis, while intriguing, awaits experimental validation.

F. Obsessive–Compulsive Disorder

Perhaps no mental disorder has so represented each of the conceptual poles of the psychological–biological dichotomy as obsessive–compulsive disorder (OCD). Only a few years ago OCD was considered the classic psychological disorder, requiring the rigorous application of psychoanalytic psychotherapy. In recent years it has been conceptually transformed into the prototype of a "biological" malady that can only be truly relieved with serotonin-elevating drugs, with or without the aid of adjunctive behavioral or cognitive psychotherapy. However, as we learn more about OCD, and pay heed to the robust therapeutic potency of psychotherapy or pharmacotherapy monotherapy (as well as combinations), both models are revealed to be simplistic distortions of a complex environment–genetic interactive

phenomenon (as we believe to be the case with the great majority of mental disturbances). Much research has been accomplished regarding the biology of OCD. We will concentrate on evidence for biologic change in response to psychotherapy.

Lewis Baxter and Jeffrey Schwartz at UCLA have published results from several experiments involving PET imaging of people treated for OCD. In their first study, they treated nine OCD sufferers with behavior therapy (BT) and nine with an SSRI antidepressant, fluoxetine (Prozac^R). Similar proportions from each group responded to treatment (6 of 9 BT, 7 of 9 fluoxetine). The responders' pre- and posttreatment PET images showed the same change, specifically a reduction in the metabolic activity of a part of the striatum called the caudate nucleus. They later treated nine more OCD patients with structured exposure and response-prevention behavioral and cognitive treatment. Again, PET scans showed a reduction in the metabolic activity in the caudate of responders, but not nonresponders. The shared ability of BT and SSRIs to reduce OCD symptoms may be partially explained by studies on classical conditioning in dogs. Injecting serotonin into the anterior limbic cortex of low-serotonin dogs decreases the effects of classical conditioning. Furthermore, high levels of conditioned and unconditioned reflexes in dogs are accompanied by low levels of serotonin in the blood. During exposure treatment, one tries to extinguish pathological, classically conditioned responses.

Baxter, Schwartz, and Arthur Brody conducted another study to attempt to identify a PET marker that might differentially predict response to BT or fluoxetine. They treated 27 OCD sufferers, 18 with BT and 9 with fluoxetine. Remarkably, the degree of pretreatment activity in a part of the left frontal lobe called the orbitofrontal cortex (LOFC) appeared to differentially predict response to the two treatments. Higher pretreatment activity in the LOFC was associated with a better response to BT, whereas lower LOFC activity was associated with response to fluoxetine. The investigators postulated that this effect can be explained by considering two of the (many) functions of LOFC. Specifically, the LOFC appears to (1) mediate behavioral responses to situations in which the affective value of a stimulus changes, and (2) mediate extinction. The authors pointed out that successful behavior therapy leads to a change in the affective value assigned to stimuli that had previously brought on compulsions. Subjects with higher pretreatment LOFC activity may possess a greater capacity to "change the assignment of affective value to stimuli and be better able to extinguish habitual, compulsive responses. These abili-

ties may lead to a better response to BT." This represented the first study in which a single biological marker provided an explicit guide to differential treatment planning.

G. Psychotherapy and Cancer

The study of the biology (and effectiveness) of psychotherapy need not be limited to psychiatric diseases. Fawzy I. Fawzy examined the outcomes of 80 people with malignant melanoma, an aggressive skin cancer with high mortality rate, who were treated at the John Wayne Cancer Clinic at UCLA. Some of the patients were enrolled in a 6-week supportive therapy group that provided education, stress management, enhancement of coping skills, and psychological support from group members and staff. The investigators compared the 6-year survival of the group-treated subjects and subjects who did not participate in the group. A significantly greater proportion of the group-treated patients were alive after 5 years than those who did not receive group therapy. Group-treated subjects also showed a trend toward lower recurrence rates.

David Spiegel studied 86 women with metastatic breast cancer. Fifty of the women participated in 1 year of weekly supportive group therapy, while 36 women did not. Because of the advanced stages of breast cancer in all subjects, most women (83 of 86) died within 10 years of participation. However, the mean survival time in the women who had group therapy was 36.6 months, whereas the control group lived for an average of 18.9 months.

Clearly, psychosocial factors influence the outcome of many (if not all) general medical illnesses. The mechanisms of this interaction deserve the attention of neuroscientists and psychotherapists alike.

V. CONCLUSIONS

We have sufficient evidence, some of which has been presented in this article, to reach certain neurobiological conclusions related to psychotherapy:

1. Psychotherapy is a powerful tool that produces functional and/or structural changes in our patients' brains.
2. These changes tend to reflect a relative normalization of the biological anomalies characteristically associated with the underlying illness.
3. Psychotherapy-induced changes occur in a variety of brain regions, including those involved in learning and memory.

4. Psychotherapy may exert its effects through the cellular mechanisms related to learning and memory, namely neural plasticity and possibly neurogenesis.
5. Psychotherapy may promote neural plasticity by inhibiting the cellular effects of stress.
6. Genetic diversity among individuals almost certainly contributes to the remarkable range of individual responses to stress, traumatic and nontraumatic life events, and to treatment.

Present knowledge and research tools (most notably brain imaging techniques) enable us to propose myriad testable hypotheses pertaining to psychotherapy and related topics. For instance, how is the interaction between implicit and explicit memory processes influenced or utilized by psychotherapy? Details about this interaction might guide the design of specific psychotherapeutic interventions.

Studies of stress and trauma raise many critically important issues. It is quite foreseeable that psychotherapy might be used to protect the brain from the deleterious effects of stress. Identification of the environmental conditions that are most likely to produce “toxic stress” (traumatic and subtraumatic) can facilitate that eventuality. As we clarify the interactions between genes and the environment, we may be able to identify genetically at-risk individuals to whom we could target our preventive approaches. Used in that manner, psychotherapy might reduce the likelihood of symptomatic mental illness (new onset or recurrence) during or following times of stress. It is worth noting that recent evidence indicates that critical incident stress debriefing (CISD) may not be as effective as we had thought in reducing the incidence of posttraumatic psychopathology in people who have recently experienced traumatic events. Thus, effective prophylactic psychotherapies must be as carefully tailored, delivered, and validated as therapies for existing mental disturbances.

Another important consideration involves the refinement of psychotherapies to best address specific mental diagnoses or symptoms. The scientific basis for selecting one psychotherapy over another is still weak, relying, at best, on empirical evidence that a particular type of therapy did or did not work in a particular sample population. A time may come when we will be able to rationally design optimal psychotherapy based on the neurobiology of the mental disease and the proposed treatment. On a related note, we hope that Cloninger’s theories of personality development (or similar work) will be refined in a way that might also guide specific psychotherapeutic strategies.

Research described earlier in this article involving sleep EEG (in depression) and PET (in OCD) provides

a tantalizing glimpse at the potential of diagnostic tools to identify predictors of treatment response. Brain imaging methods, HPA axis parameters, and other biological markers may someday offer accurate and practical ways to monitor progress in psychotherapy.

Substantial advancement in the effectiveness of combined psychotherapy and pharmacotherapy will certainly require additional research. Important questions concerning strategies for optimizing combined treatment abound. Ideally, combined therapies would offer synergistic, rather than redundant or even antagonistic mechanisms of action.

Do different psychotherapies act on different parts of the brain? Some have suggested that psychoanalytically oriented psychotherapy may have greater influence on the lateral hemispheres since this type of treatment focuses on internal representation and expectations of others. In contrast, behavioral therapy often focuses on simpler forms of learning and memory that may involve more directly the amygdala, hippocampus, and basal ganglia.

The healing professions have long paid insincere homage to the biopsychosocial model of human cognition, emotion, health, illness, and behavior. A true integration of biology and psychology into a coherent conceptual framework, subscribed to by medical and nonmedical clinicians and researchers, is essential if we hope to take full advantage of the remarkable healing power of psychotherapy and move from a reductionistic mind–brain dichotomy in understanding our patients in health and illness.

GLOSSARY

- dominant hemisphere** The hemisphere of the brain dominant for language functioning.
- frontal/prefrontal lobe:** The area of the brain anterior (in front of) the precentral gyrus.
- intelligence** Measures of overall capacity to process external and internal stimuli.
- neuroimaging tools** Nuclear medicine tools used to picture the functional and structural components of the brain in a systematic manner.
- neuropsychological assessment (NPA)** Systematic evaluation of the brain-behavior relationships in an individual.
- neuropsychologist** Clinician with specialized training in neuropsychology and involved in neuropsychological assessment.
- normative sample** Sample from population of interest with no known neurological impairments.
- pathognomonic approach** Use of a variety of measures that are designed to identify symptoms associated with characteristics of a particular disease.
- premorbid ability** Abilities prior to the neurologic event resulting in brain injury.

referral question The question for which the client was referred for the evaluation.

I. DESCRIPTION OF ASSESSMENT

Neuropsychological assessment (NPA) is the systematic evaluation of the brain-behavior relationships in an individual. The purpose of an NPA is to define the client's specific cognitive strengths and weaknesses and to identify the relationships between the neuropsychological findings and the client's medical and psychiatric condition. Tools used to complete the NPA are measures of cognition and intelligence that have been standardized on a neurologically normal sample. By administering the measures in the identical, systematic manner, as described in the instruction manual for the testing instrument, the evaluator can compare the individual's performance on the measure to the performance of a normative sample. It is optimal if the normative sample is subdivided by gender, age, and years of education. In that way a very specific comparison can be made. Neuropsychological test performance has been generally shown to vary according to gender, age, and years of education in control samples.

Localization of brain injury was the intent of neuropsychological testing in the 1970s but with current functional and structural neuroimaging tools, there is a reduction in the need to "localize" the brain injury. The purpose of neuropsychological evaluation is currently

multifaceted and often is dependent on the referral question. A complete NPA helps the client, clinician, and referral source gain an understanding of the client's cognitive processes such as memory, language, and perception. In addition it can assist in diagnosis and identification of difficulties in cognition that might be related to psychiatric conditions and motivation. Finally, a thorough NPA can help to determine rehabilitation potential by identifying pathways for compensation and extent of cognitive involvement.

II. CASE ILLUSTRATION

The NPA report and raw data shown below provide an example of a case referred by a neurologist. This 55-year-old man was referred because, during a standard mental status evaluation, visual perceptual problems were observed.

A. Neuropsychological Testing Report

1. *Relevant Past History*

Dr. C is a right-handed, 55-year-old, Caucasian male, previously employed as an optometrist. Dr. C reported that he first noticed changes in his cognition while on an out-of-town visit. He became disoriented and he reported that he got lost for many hours while driving to a known location. He reported that he is happily married and has two children who have been very successful in their own vocations. Both his mother and father are deceased. His father died recently from a series of illnesses, including a bowel obstruction and pneumonia. His mother died in 1985 of Alzheimer's disease. Dr. C reported a recent fall from a horse while on a vacation, but he denied receiving a head injury from it, only reporting minor bruises. He also reported that last summer he was camping and his dog was exposed to ticks. He is concerned that the current problems that he is having may be related to Lyme disease. Dr. C denied other significant stressors in his life and continues to remain active, playing tennis regularly. He is on no medications.

2. *Behavior During Evaluation*

Dr. C arrived late for the interview because he was unable to find the location of the room. He was very guarded during the initial interview and overtly frustrated during some of the more difficult portions of the evaluation. Mood was observed to be slightly depressed

but toward the end the session Dr. C was able to talk more freely and seemed to become more relaxed. His attention and effort were adequate and the current evaluation is thought to be an accurate measure of his current abilities.

3. *Tests Administered*

Tests administered included the Wechsler Adult Intelligence Test-R, Wechsler Memory Scale-R, Wide Range Achievement Test (Reading subtest), Stroop, Trails A & B, and the Adaptive Category Test.

4. *Results of the Evaluation*

Dr. C's full-scale intelligence was estimated to be within the very high average range but a significant discrepancy was noted between his verbal abilities and his visual-perceptual skills (Full-Scale IQ 124, Verbal IQ 130, Performance IQ 110). Dr. C demonstrated an exceptional vocabulary and understanding of the world around him. His speech was fluent and detailed, and no signs of expressive speech limitations were observed. When presented with visual stimuli Dr. C had difficulty identifying missing essential details within a visual percept. Dr. C also had great difficulty reproducing visual spatial designs. He was unable to segment accurately the design and work on parts to complete the whole design. Graphic motor speed was high average and he was able to copy simple figures accurately and rapidly. It is expected that, given his educational background and his vocation's emphasis on visual perception, his current visual perceptual skills represent a significant decline for him.

Speed of processing was found to be average and high average given simple material. Verbal short-term attention was average for his age. Dr. C was able to maintain seven digits in his head and present them forward. When asked to recall the numbers in reverse order, he was only able to recall four digits. Simple reading speed was average. In addition, Dr. C was able to keep a strategy in mind while he quickly read given words. When asked to scan for specific numbers and letters Dr. C demonstrated greater difficulty and he was unable to accurately alternate between number and letters. His performance on a difficult task requiring sustained attention and visual scanning with interference was significantly impaired.

Memory abilities were also variable and his pattern of performance is reflective of his memory complaints. Verbal memory skills are within the high average to superior range given his age. He was able to recall lengthy stories (98th percentile and 92nd percentile) immediately after

presentation and again report the stories 20 minutes later accurately. He was also able to rapidly learn pairs of words. Dr. C had more difficulty recalling visual material presented. He was unable to encode essential details of the visual stimuli and his recall of the given visual designs was between the 25th percentile and 33rd percentile. Once he had learned the material, Dr. C was able to accurately reproduce the visual information even given a significant delay. His visual memory impairments are most likely related to his recent difficulty getting lost when not using a map. In addition, his memory is hampered by his difficulty identifying essential details and visual-spatial relationships in abstract visual percepts.

The complex visual problem-solving task administered on the computer was also difficult for Dr. C. He was inefficient in his ability to develop effective problem-solving strategies to apply to the sets of figures presented. He demonstrated difficulty planning and tended to act impulsively in response to the presented stimuli. This task was frustrating for him and his performance was severely impaired. Dr. C demonstrated excellent verbal abstraction abilities when he was given uncommon proverbs as part of the intelligence test.

Dr. C was administered the Symptom Checklist 90-R and denied all types of psychiatric symptoms. On this survey form, he did not acknowledge difficulty in thinking or a change in his appetite even though he had recently gained 65 pounds. His response pattern on the checklist and during the interview indicates that Dr. C is unable to fully acknowledge the significance of his cognitive changes. When his difficulties were pointed out, Dr. C had a tendency to use his excellent verbal skills to externalize the existing problem.

5. Summary

Dr. C has experienced significant neuropsychological changes that involve moderate visual-perceptual and visual-spatial impairments, moderate visual memory limitations, and moderate impairments in problem solving. In contrast, Dr. C continued to demonstrate exceptional verbal skills and verbal memory. Dr. C denied problems with mood or the recent occurrence of psychiatric symptoms.

Because of the importance of memory and visual-perceptual abilities in his work, it is not recommended that Dr. C return to his current job. It is recommended that Dr. C consider cognitive rehabilitation therapy to help him learn to compensate for his current limitations. In rehabilitation there will be an attempt to help him learn to use his verbal skills to compensate for his

visual memory limitations. Because Dr. C displayed limited insight regarding his difficulties, his family will need to be involved in helping him learn to use compensation strategies. Supportive psychotherapy for himself and family members is also recommended.

Dr. C meets the criteria of dementia because of a decline in visual memory and problem solving. It is suspected that Dr. C is experiencing degeneration in both the right temporal and frontal lobes. This may be associated with frontal-temporal dementia. Repeated testing in 6 months will determine if the condition is progressive.

TABLE I
Neuropsychological Testing Scores

<i>Wechsler Adult Intelligence Test-R</i>			
Verbal Tests		Performance Tests	
Information	15	Picture Completion	8
Digit Span	10	Picture Arrangement	9
Vocabulary	16	Block Design	7
Arithmetic	14	Object Assembly	9
Comprehension	15	Digit Symbol	13

Wechsler Memory Scale-R

Logical Memory I	98th percentile
Logical Memory II	92nd percentile
Visual Reproduction I	25%
Visual Reproduction II	33%

Symptom Checklist 90-R
All 90 questions responded with "0" score.

Adaptive Category Test
Total Adaptive Error Score = 122

III. THEORETICAL BASES

Russia was one of the first countries in the world to begin NPA. In the early 1900s, A.R. Luria used a flexible, clinical evaluation approach in his work with patients who had brain injury. His model of brain functioning, published in English in 1970, outlined

“three principal functional units of the brain ... a unit for regulating tone or waking, a unit for obtaining, processing and storing information ..., a unit for programming, regulating and verifying mental activity.” Luria defines the purpose of NPA as being twofold: “to pinpoint brain lesions responsible for specific behavior disorders ... provide us with a factor analysis that will lead to better understanding of components of complex psychological functions” (p. 66).

In the United States in 1986 Donald T. Stuss and Frank Benson provided a behavioral anatomical theory of brain functioning to guide NPA. They stressed the global influence of the frontal/prefrontal lobe on mental activity. In their theory, executive functioning attributed to the frontal/prefrontal lobes of the brain provides conscious direction and efficient processing of internal and external stimuli. The second unit of the brain is associated with the posterior region of the brain and involves attention, visual-spatial processing, language, sensory perception, memory, motor, and emotional status. In their theory they create a hierarchy of brain functioning and they identify *self-awareness* as the highest cognitive attribute of the frontal lobes. Although many individual mental functions, assessed by neuropsychological tests, can be maintained without prefrontal and frontal participation, the responses are automatic and insight and planning are lacking. Adequate frontal/prefrontal functioning is essential for control of intelligence, consciousness of self, and independent thinking.

It has not been possible for neuropsychologists to develop specific measures that are 100% diagnostic of any type of brain injury. Instead most neuropsychologists now use a pathognomonic approach. This approach involves the use of a variety of measures that are designed to identify symptoms associated with characteristics of a particular disease. In the United States most neuropsychologists use a flexible battery approach. Instead of using standardized test battery in its entirety, a selection of tests from a variety of batteries and separate, individual tests are utilized. Standardized batteries that have been developed over the years are the Luria-Nebraska Neuropsychological Battery and the Halstead-Reitan Neuropsychological Battery. A flexible battery approach allows the clinician to match the referral question and the examinee's pattern of abilities to the test battery. It is the aim of the neuropsychologist to understand the reason for the evaluation, the questions being presented by the individual being evaluated, and the functional implications of the symptoms in making decisions concerning

the assessment tools to be used in the evaluation. Although NPA batteries may differ, generally, a core set of assessment tools are used in each case. This core is included because the psychologist is most familiar with these assessment tools, understands the cognitive component skills that are part of the measure, and has appropriate normative data available. Flexibility in the NPA derives from the needs of the individual being evaluated. Clinical neuropsychologists regularly address a large range of referral questions, clinical behaviors, and patients with very disparate capacities. So although there is an overall structure to the NPA, there is significant diversity in the details of each NPA.

Generally a measure of intelligence is administered as part of the NPA battery. By administering a measure of overall general abilities such as an intelligence test, the clinician can compare overall level of functioning to specific cognitive skills such as memory, attention, and problem solving. Examination of the subtests may also provide clues to premorbid functioning. Most NPA batteries also include measures of expressive and receptive language, visual perception, visual scanning, and visual-spatial processing. A variety of measures of attention and memory are commonly included. Finally tests of executive processing such as problem solving are administered. Also included in an NPA will be at least a basic measure of emotional or psychiatric status. Because depression and anxiety can influence cognitive abilities, a measure of psychiatric symptoms needs to be administered to determine if there is an emotional component to the client's current cognitive status.

The battery of tests will generally be preceded by a clinical interview. Background information concerning the client's social history, present life circumstances, medical history and current medical complaints, and reasons for referral are obtained.

Information regarding social and medical history, psychiatric history, drug and alcohol abuse history, neurotoxin exposure, history of head injury, a list of current medications, family psychiatric and dementia history, and client's social, employment, and educational history should be obtained because these factors can influence test interpretation. The NPA will include an observation of the client's general appearance, ambulation, sensory limitations, and behavior. In an NPA the examiner needs to observe attention, distractibility, and motivation on all tests administered.

The entire test battery may require anywhere from a few hours to a day or two to complete, depending on the client's attention and stamina.

IV. APPLICATIONS AND EXCLUSIONS

NPA is most often not attempted in children younger than the age of 4 years. Normative data are available for the geriatric population on a select number of neuropsychological tests. Therefore, NPA is possible in individuals between the ages of 5 to 95 years.

Currently relatively few NPA tools used in the United States have been translated to languages other than English. The Wechsler Intelligence tests for children and adults are available in Spanish. Since the intelligence tests are some of few tests translated and normed for Spanish-speaking individuals, full NPA often takes place using informally translated NPA tools. It is very important to consider ethnic variations in administering NPA tools to individuals outside the normative sample on which standardization took place. Fortunately, many countries have developed NPA tools within their own culture.

NPAs vary extensively in length. Length of the testing will vary depending on the referral question, finances of the individual being evaluated, and complexity of the presenting symptoms or neurological condition. Therefore, testing is limited to individuals able to tolerate the interpersonal and lengthy testing situation. NPA is managed by a clinical psychologist trained in NPA but in many environments a student in clinical psychology or a testing technician may give some of the assessment tools. Because the assessment tools used in NPA are standardized in their administration, students and technicians can be trained to administer many of the tests. Close supervision is essential because the clinical neuropsychologist needs to be available if problems arise and to ensure that the tests are administered in the standardized manner.

As can be surmised, a psychologist involved in NPA needs to have extensive expertise. Generally specific neuroscience training while in a school of clinical psychology is required. Classes concerning normal child and adult brain functioning and neuropathology (neuroanatomy and neurophysiology principles) should be part of the student's experience. The clinician completing the NPA needs to have a broad understanding of brain function and its neuroanatomical correlates. Clinical experience in assessment of both neurologically normal and impaired individuals needs to be extensive. Given the complexity of each examinee's cognition and emotional status at the time of the evaluation, every NPA completed offers new learning experiences to the student in training. Currently graduating

clinical psychologists are asked to continue their supervised experience for 2 years after completing an internship specializing in neuropsychology. This further training is called postdoctoral training in neuropsychology. The division of neuropsychology within the American Psychological Association offers these specialized training opportunities.

V. EMPIRICAL STUDIES

In 1981 Heaton and Pendleton completed one of the earliest studies of the predictive abilities of neuropsychological testing on everyday function. They reviewed the relationship between neuropsychological testing results and various aspects of everyday life: self-care, independent living skills, and academic and vocational achievement. They found that intelligence tests scores relate to the clients' ability to care for themselves and their understanding of everyday routine situations. The Category Test from the Halstead-Reitan battery was related to judgment and decision making in routine daily activities. Memory measures were related to learning capacity and forgetfulness in everyday functioning.

There is a continuing need for neuropsychologists to effectively address functional questions after the neurologic diagnosis has been established. Central to the success of NPA is its ability to present useful and valid information regarding issues for everyday living. Neuropsychologists, using the NPA, need to be able to identify the client's individual cognitive strengths and deficits. It is especially important for the NPA to identify residual strengths that can be used to improve everyday functioning within work and home situations. NPA should address the client's ability to function safely and efficiently within an existing or new work environment, assess ability to perform adequately in school, and determine whether the client is able to remain at home without supervision. These are just a few of the many questions needing to be addressed in a thorough NPA.

VI. SUMMARY

NPA is an applied science involving systematic measurement of brain-behavior relationships. It involves the complete and detailed assessment of behavioral expression of brain dysfunction. It is generally a lengthy process involving a clinical interview, a flexible battery of standardized cognitive measures, and measures of

psychological functioning. The time and effort required of the client is compensated by the clinical neuropsychologist's careful consideration of questions concerning cognitive strengths and weaknesses, rehabilitation strategies, work and educational potential, and safety within home and outside environment.

GLOSSARY

classical conditioning Learning that occurs when a response is elicited by a particular stimulus. This process occurs when a previously neutral stimulus (e.g., a tone) occurs in conjunction with another (unconditioned) stimulus (e.g., food presentation) that results in a unconditioned response (e.g., salivation). Over repeated pairings, the neutral stimulus obtains the properties of the unconditioned stimulus and elicits the same response. The neutral stimulus is then referred to as the conditioned stimulus and the response is referred to as the conditioned response. Also known as Pavlovian conditioning.

dry bed training An intensive treatment for nocturnal enuresis that involves a combination of procedures, including urine alarm, retention training, and practice of correct toilet skills.

negative reinforcement Form of operant conditioning that occurs when a behavior is immediately followed by the removal of a stimulus that results in an increase in the future likelihood of the behavior.

nocturnal enuresis Repeated voiding of urine in one's bed or clothing at night that is inappropriate at a given age (5 years). Can be classified as primary (child has never been

continent) or secondary (child previously has been continent). Also referred to as bedwetting.

operant conditioning Learning that occurs based on the consequences that follow a response. This process occurs when a behavior is emitted and the resulting consequences either increases or decreases the likelihood of the behavior occurring in the future.

positive reinforcement Form of operant conditioning that occurs when a behavior is immediately followed by the presentation of a stimulus that results in an increase in the future likelihood of the behavior.

punishment Form of operant conditioning that occurs when a behavior is immediately followed by a consequence such that there is a decrease in the future likelihood of the behavior.

retention training Treatment involving a gradual increase in bladder capacity by delaying urination for successively longer periods of time.

urine alarm Common treatment for nocturnal enuresis involving a pad placed on the child's bed and an alarm that is activated when the child urinates. Also known as the "bell-and-pad" treatment.

I. INTRODUCTION

Enuresis, the repeated voiding of urine into one's bed or clothing, is a fairly common childhood behavior problem. Based on the criteria described in the *Diagnostic and Statistical Manual, Fourth Edition*, a diagnosis of enuresis is appropriate if incontinent voiding has occurred for a minimum period of 3 months, and the

child must be at an age where appropriate continence is expected (i.e., 5 years). The diagnosis of enuresis is divided into three types: diurnal, nocturnal, and combined, with the most frequently diagnosed type being nocturnal enuresis. Because of the frequency of the diagnosis, the majority of this article focuses on nocturnal enuresis.

As implied by the name, nocturnal enuresis refers to incontinent urination at nighttime. More commonly, the behavior is referred to as "bedwetting." Nocturnal enuresis can be classified as either primary or secondary, depending on the child's history of continence. If the child has never been continent, primary enuresis is diagnosed; conversely, secondary enuresis is diagnosed if the child previously has experienced a period of continence.

Nocturnal enuresis is a relatively common childhood problem. Prevalence estimates for the disorder vary widely; however, the occurrence of the behavior tends to decrease with age such that approximately 20% of 5-year-olds display the behavior compared to 10% of 10-year-olds. In addition to the variation with age, the prevalence of nocturnal enuresis varies with gender with an approximate 3:2 male to female ratio. Enuretic children often have an immediate family member who also displayed bedwetting. As noted by Shaffer this relationship is poorly understood. That is, it is unknown if this relationship is genetic in origin or if the families of enuretic children are more permissive in their views of the behavior (i.e., parents who displayed enuresis are more accepting of its occurrence).

Several hypotheses have been reviewed regarding the development of enuresis. A psychodynamic hypothesis posits that enuresis is related to the presence of an unresolved internal conflict. Psychological stressors (e.g., parental separation, poor academic performance) might also be related to the occurrence of enuresis. Some researchers have hypothesized that enuretic children have smaller bladder capacities than their nonenuretic peers. Finally, in some cases, it appears that enuretic children simply have not learned correct bladder control. The latter opinion is perhaps the most tenable hypothesis given that the teaching of correct skills has been shown to lead to a decrease in enuresis and other toileting accidents.

II. DESCRIPTION OF TREATMENT

As with all childhood behavior problems, the treatment of enuresis should begin with a comprehensive medical and psychological examination. Friman and

Jones described several factors to consider in the assessment of enuresis. Examples of these factors include parental beliefs about the severity of the problem, parent and child motivation to implement treatment, and the child's concerns over the bedwetting. Knowledge of these factors may predict treatment efficacy in some cases. For example, Butler, Brewin, and Forsythe found that children who are not concerned with their enuresis are more likely to demonstrate treatment relapse than children who are concerned. Finally, it is recommended that the assessment of nocturnal enuresis include data collection prior to the onset of treatment. Such baseline data will assist in identifying the frequency of the behavior as well as other dimensions of the behavior (e.g., the time at which wetting occurs). In some cases, additional assessment procedures such as direct observation may be used to develop treatment alternatives.

Following assessment, treatment development should occur in accordance with the desires and needs of the child and the caregivers. That is, treatments of enuresis may vary in terms of caregiver vigilance in implementation or the occurrence of behavioral side effects. In addition, caregivers may find certain therapies unacceptable and may be less likely to implement the procedures. Regardless of the type of intervention employed, treatment application and its effectiveness should be monitored by either the prescribing physician or psychologist.

In general, treatment of nocturnal enuresis consists of medication or behavioral intervention. Among medications, the most frequently prescribed for the treatment of enuresis are the antidepressants, particularly imipramine. Imipramine has been shown to produce an immediate reduction in enuresis in many cases; however, withdrawal of the medication may produce a relapse in treatment in over 60% of cases as well as behavioral side effects (e.g., nausea, drowsiness). In addition, the use of imipramine and other medications does not teach the child appropriate toileting skills.

Behavioral interventions have been the focus of many empirical investigations and have been demonstrated to be effective in reducing nocturnal enuresis. Thus, the remainder of this article summarizes the procedures and empirical support for the use of behavioral interventions in the treatment of nocturnal enuresis.

III. THEORETICAL BASES

Some research suggests that the occurrence of enuresis may be due to the improper learning of bladder retention

and toileting skills. Thus, interventions that teach new skills (i.e., behavioral interventions) generally are more effective than pharmacological interventions. Various behavioral interventions have been described in the extant literature, with the most commonly employed procedures consisting of the urine alarm, bladder retention training, and dry bed training.

In general, the effectiveness of the various behavioral interventions has been attributed to both classical and operant conditioning. For example, it was initially hypothesized that classical conditioning was responsible for behavior change when using a urine alarm. That is, the alarm was conceptualized as the unconditioned stimulus, passing of urine was the condition stimulus, and waking was the conditioned response. More recently, an operant hypothesis has been used to interpret the learning mechanism that occurs with the urine alarm. Specifically, the alarm is an aversive stimulus and a full bladder or urine release is a stimulus associated with the activation of the alarm. The child awakens when the bladder is full and urinates in the toilet to avoid the activation of the alarm. Successful avoidance of the alarm increases the future likelihood that the child will urinate when internal cues (i.e., a full bladder) are present.

Successful retention training and dry bed training have been attributed to a combination of operant mechanisms. For example, the use of extrinsic reinforcers (contingent on bladder control) functions as positive reinforcement for bladder retention in both retention training and dry bed training. Waking and urinating in the toilet at night may function as negative reinforcement through the elimination of a full bladder and the avoidance of wet clothing and bedding. Finally, repeated practice of correct toilet skills and the changing of clothing and bed linens as a component of dry bed training may alter behavior through punishment.

IV. EMPIRICAL STUDIES

A. Urine Alarm

The urine alarm, also known as the bell-and-pad procedure, is one of the most well known and commonly used treatments for enuresis. Although there are variations of the treatment, the basic procedure is similar to that originally described by Mowrer and Mowrer. The child sleeps on a specially constructed pad covered by two foil outer shells. The top layer of the pad has holes, which are separated by an absorbent paper connected to a buzzer. The presence of urine on the absorbent paper

activates an electric circuit that produces an alarm (e.g., a buzzer). Presumably, the alarm quickly awakens the child and teaches the child to associate a full bladder with awakening. The alarm may also inhibit additional urination as the bladder contracts. The child then progresses to the toilet and finishes urinating.

To produce maximum treatment effects, several manipulations should occur prior to the child's going to bed and following activation of the alarm. Before going to bed, the child should drink extra amounts of fluid. The buildup of fluid in the child's bladder throughout the night increases the probability that he or she will contact the "wetness equals alarm" contingency during the initial stages of treatment. In addition, the child should be put to bed with minimal clothing to ensure that only a small amount of urine is necessary to activate the alarm. That is, as less urine activates the alarm, the child awakens with more fluid in the bladder thus enhancing the training by teaching the child to associate a relatively full bladder with awakening. Other training procedures should be implemented following activation of the alarm. For example, if a child is clothed, he or she may be required to clean the soiled clothing or change into clean clothing. In addition, the child should be required to change the bed linens and wash the pad before going back to sleep. Finally, in an attempt to decrease the probability of relapse, an intermittent schedule of alarm activation has been effective in some cases (e.g., alarm activation on 50% of trials).

It is essential that parents become actively involved in the implementation of the treatment. For example, parents should be responsible for collecting data following each accident. Data may be collected on the frequency of accidents per night or week, the time of the accident, or the diameter of the wet spot. Such data are useful in determining minute treatment gains following repeated exposure to the alarm. In addition to data collection, parents should be responsible for reinforcing the absence of bedwetting and the occurrence of correct elimination in the toilet. For example, in our clinical practice, we often suggest that parents provide access to a highly preferred item or activity following no incontinence for a period of time (e.g., one or two nights, or one week). Toward this end, it is recommended that the supervising therapist conduct an assessment with the child and parents to identify potential reinforcing stimuli.

Training with a urine alarm is relatively brief and the results are relatively durable. In addition, the procedures implemented in urine alarm training are also easily modified for training skills in other settings. For example, one common modification involves the attachment of an

alarm to a child's underwear. The alarm is connected to a pad that, when wet, sounds the alarm. Using a similar method, Edgar, Kohler, and Hardman successfully reduced the occurrence of urinary incontinence in 8 of 10 participants with profound mental retardation. More recently, Friman and Vollmer used a modified urine alarm to treat one girl's diurnal enuresis. Results showed that the use of the alarm produced an immediate reduction in enuresis; however, Friman and Vollmer noted that the participant experienced some social embarrassment on activation of the alarm.

B. Retention Control Training

It has been hypothesized that enuretic children have a smaller bladder capacity than nonenuretic children. Retention control training involves gradually increasing the bladder capacity of the child. As reviewed by Friman and Siegel and Smith, retention training involves a child drinking an amount of fluid (e.g., 8 oz.) and delaying urination for a set amount of time (e.g., 3 min) or for as long as possible after the initial urge to void. On subsequent days, the child is encouraged to refrain from urination for a longer period of time (e.g., progressing from 3 to 5 min). Successful bladder control should be reinforced through the use of extrinsic reinforcers. During the training, parents should collect data on the latency to urination after drinking and on the amount of urine emitted. Across successive days, the child holds the urine for longer periods of time, thereby increasing bladder capacity. Increasing bladder capacity within the course of a day indirectly may reduce the enuresis at night.

Retention control training does not yield as high of a success rate as does the urine alarm. However, this procedure may be preferred to the urine alarm because it does not require nighttime awakenings, and new bladder control skills are mastered.

C. Dry Bed Training

Dry bed training consists of a combination of the urine alarm and retention control training procedures. Due to the combination of these two practices, in addition to the incorporation of several other procedures, dry bed training is the most labor-intensive treatment for nocturnal enuresis. Dry bed training consists of a therapist coming into the child's home during at least the first night of treatment. In addition to the basic retention training and urine alarm procedures, Azrin and colleagues also suggested presleep practice of correct toileting skills, practice

of changing clothes, and practice of changing the bed linens. That is, prior to going to bed, the child is exposed to the events that will take place should he or she wet the bed. Scheduled nighttime awakenings (e.g., once each hour) combined with prompts to go to the bathroom, checks for wetness, and additional fluids are incorporated into the treatment as well. At each waking, the child is reminded what will occur if the bed is wet. If the child appropriately urinates in the toilet when awakened, parents provide effusive praise. By contrast, if the bed is wet, the child is responsible for repeatedly practicing appropriate urination and is made responsible for cleaning all bedding and clothing. For each night without an accident, a reinforcement-based component is included such that the child receives access to a highly preferred reinforcer and praise contingent on appropriate bladder control. Using these procedures, Azrin and colleagues reported a 100% success rate in training 24 children within 7 days. It should be noted that almost 30% of the children relapsed following treatment; however, once the treatment was reimplemented, accidents decreased again. Finally, Azrin and colleagues found that the multicomponent dry bed procedure was more effective than the more commonly used urine alarm.

V. SUMMARY

In this article, several potential treatments for nocturnal enuresis were reviewed. One consistent finding in the literature is that behavioral treatments (i.e., urine alarm, retention control training, dry bed training) are generally as effective as pharmacological treatments. For these reasons, behavioral treatments represent the best practice for the treatment of nocturnal enuresis.

Initial implementation of behavioral treatments varies across children, with most children requiring several weeks of exposure before significant treatment gains are noted. Thus, the length of treatment exposure, combined with the treatment procedures that must be implemented by the parent and child, make behavioral interventions relatively labor intensive relative to medication. However, the relapse rate of children treated with behavioral interventions generally has been lower than relapse associated with medication. Finally, the focus of a medication-based treatment is the amelioration of enuresis, whereas the focus of behavioral treatment is the amelioration of enuresis plus the acquisition of appropriate replacement skills

Follow-up data suggest that behavioral treatments produce very durable effects. For example, Gustafson exposed 50 children to urine alarm treatment as described by Mowrer and Mowrer. All children were referred for the treatment of primary nocturnal enuresis, and each participant had displayed the behavior for at least 6 years. Results showed that 90% of the participants were trained successfully following one to three exposures to the treatment procedures. Furthermore, only five of the trained participants (11%) were reported to show relapse (defined as one or two wet nights) in the year following treatment. These results suggest that the use of the urine alarm is an effective and long-lasting method for treating nocturnal enuresis.

Regardless of the type of intervention used, practitioners should be aware of their patients' goals and their willingness to engage in various treatments. If caregivers find it unacceptable to awaken multiple times per night, or if they feel that certain procedures are unfair to the child, treatment with medication may be indicated. By contrast, if the child and caregivers are interested in teaching new skills with the lower probability of relapse, behavioral treatments should be prescribed.

One final consideration in treatment development should be the willingness of the caregivers or child to collect objective data on the occurrence of enuresis. Observational data can be graphed to yield a pattern of behavior that can be visually reviewed to determine the child's progress toward continence. In addition, data collection may facilitate child and caregiver implementation of a rather strenuous treatment (e.g., dry bed training) such that a visual representation of improvement may directly reinforce these behaviors.

GLOSSARY

borderline syndrome A severe form of character pathology characterized by a high degree of instability, low frustration tolerance, impulsivity, demandingness, and little regard for others.

ego The part of the psyche charged with the responsibility of mastering competing pressures while maintaining the functional capacity of the organism.

narcissism An early state of infancy, often carried into adulthood in pathological states, in which the child is organized around the self and self-pleasures with little awareness of the desires of others.

object relation A relationship to an other seen from the viewpoint of the experiencing participant; includes both the way of relating to the other and the experience of the other in fantasy.

psychoanalytic therapy Any of a variety of psychotherapeutic approaches that seeks to uncover unconscious material and, thereby, achieve a depth understanding of the psyche.

resistance The tendency of psychotherapy patients to defend against the therapeutic process to protect against the uncovering of painful, unconscious material.

transference The unconscious tendency of psychotherapy patients to perceive the therapist in ways similar to important figures of the past, such as parents.

Object-relations psychotherapy is a growing and commonly used branch of psychoanalytic therapy. Beginning with the roots of this form of psychoanalytic therapy and its deviation from the classical model, this article shows the fundamental developmental principles on which this form of therapy is based and then demonstrates the basic concepts that define this therapeutic approach. Finally, the contributions of object-relations therapy to psychoanalytic treatment will be reviewed.

I. THE ORIGINS OF OBJECT-RELATIONS THEORY

When Sigmund Freud developed psychoanalytic theory and therapy, he did so on the basis of his view that repressed childhood memories were the source of neurotic symptoms, especially hysteria, the most prevalent form of psychopathology of his day. When he changed his view of pathogenesis from actual memories to fantasies, or wishes, he shifted psychoanalytic theory to a drive model. That is, Freud believed that the child's sexual wishes for the parent were the repressed material, rather than events. Freud's belief in the ubiquity of childhood sexual longings for the parent of the opposite sex led him to a drive-based view of human motivation. The eventual addition of the aggressive drive did not alter his view that our adult behavior manifests either repression or sublimation of our endogenous drives. These drives are biological in origin, seek satisfaction via tension relief, and have a fixed quantity of energy. The object of the drive is

the means for its satisfaction. The child becomes attached to figures who provide this tension relief. Interpersonal relationships, for Freud, are motivated by tension relief. The child is born under the sway of the pleasure principle, the need for tension relief, and gradually, through the necessary frustrations of life, becomes adapted to the reality principle, the recognition that the world will not provide the gratification of drive pressures whenever and wherever the need is felt. Out of this frustration, the ego, the adaptive capacity of the organism, is born, and in the healthy personality, the ego is primarily in charge of the individual's relationship to both drives and the world.

W. D. R. Fairbairn was the first psychoanalyst to question the drive basis of human motivation and propose an alternative based on object relationships. Fairbairn contended that the baby is not pleasure seeking as Freud thought, but "object seeking." Fairbairn believed that Freud's theory ignored the role of the self's relationship to the object. That is, the ego can grow only through satisfactory object relationships. If the parental figures do not provide good care, the ego cannot develop, and pathology results. Consequently, according to Fairbairn, the child seeks relationships before pleasure. Indeed, he pointed out that one sees pure pleasure seeking only in states of severe pathology in which the ego is "fractionated." Fairbairn pointed out that children, and even adults, prefer painful relationships to none at all. This would not be the case were the child governed by the pleasure principle, as Freud thought. Part of Fairbairn's evidence was the behavior of abused children. According to the pleasure principle, children should not attach to their abusers. However, in fact, as Fairbairn and others have found in their work with such children, they actually attach more stubbornly to their abusers than other children do to their caretakers. Fairbairn took this as evidence of the primacy of object attachments over pleasure in human motivation. On this basis, Fairbairn developed a theory of the personality as formed from attachments to early figures. These object relationships, not reducible to drive gratification or any other motive, are, according to Fairbairn, taken in, or "internalized" in the form of objects. That is, the child makes a part of the psyche the images of the caretakers, and these images become the blueprint for all later relationships.

The idea of internalization was not new with Fairbairn or object-relations theory. Psychoanalytic theory since Freud had seen the ego as formed from the legacy of early relationships. The decisive difference between Freud and object-relations theory is that the latter does not see the motivation to internalize early relationships as reducible to any other motive, whereas for Freud the child internalized the image of the parent in an effort to

master the frustration of childhood desires. That is, according to Freud, when the child finally realizes that longings will not be fulfilled, the child abandons the desire for the parent and internalizes the object to manage the loss. By contrast, object-relations theory sees internalization as motivated by the needs for self-development and a guide to navigate the interpersonal world.

II. DEVELOPMENTAL AND ETHOLOGICAL EVIDENCE

Fairbairn's intuitive insight that the infant seeks objects rather than tension reduction has now been substantiated by controlled empirical investigations. As early as 1960, Harry Harlow reported his famous experiment that baby monkeys attach to a cloth monkey that provides no nourishment rather than a wire monkey that gives them milk. At about that time John Bowlby began reporting ethological studies showing that subhuman primates will attach to whatever figure is available, even a different species, irrespective of whether the figure has a role in tension reduction. Bowlby also concluded that the available evidence indicated that human children also will attach to figures who have no role in the meeting of biological needs. Since this early pioneering work, a great deal of carefully controlled empirical investigations by a variety of researchers such as Daniel Stern and Beatrice Beebe has shown that the human child is "prewired" for a relationship with the caretaker. Distinguishing mother's voice and face from others in the early days of life, the child seeks interaction with others and shows pleasure when it is attained. This desire takes place irrespective of the meeting of drive reduction needs. The infant will learn tasks for the sole purpose of interacting with others. Furthermore, child and mother tend to form a relationship based on an interactional pattern from the inception of life. Independent of the meeting of tension reduction needs, the child not only seeks and helps to form and sustain this rule-based interactional system but also expects it. If the established patterns are not followed, the child becomes distressed. This evidence is but a small sampling of the data substantiating Fairbairn's claim that object relationships are autonomously motivated.

III. CLINICAL AND THEORETICAL BASIS

Since Fairbairn's pioneering work, a large group of psychoanalytic clinicians have adopted a clinical stance

based on the primacy of object relationships. These psychotherapists follow a psychoanalytic model in that they believe in the importance of unconscious motivation, the patient's defenses against awareness of unconscious motivation, and the uncovering of underlying meaning. However, they are decisively different from classical psychoanalysts in that they do not adhere to the drive model. Rather, they see the human organism as autonomously motivated to form object relationships and personality formation as a product of the object relationships internalized in the developmental process. This theoretical shift, based on clinical findings and an abundance of experimental results, has led to the development of a variety of clinical approaches built on the importance of object relationships. Each theory within the object-relations model has a somewhat different emphasis, but each is built on the principle that object relationships are the primary building blocks of the psyche.

Object relationships are interpersonal relationships seen from the point of view of the experiencing participant. They differ from interpersonal relationships in that they are not the relationship viewed in terms of its external behavior as seen from the viewpoint of a third person. For example, a third party might describe two people as having a "good" or "friendly" relationship, or a "bad" or "hostile" relationship, but an object relationship is the experience of one party to the relationship. So, while an observer might say two people have a "bad" relationship, one person might experience the self as trying to please an implacable other whom this person regards as possessing exceptional qualities. That is the object relationship. As can be seen from this example, an object relationship always includes a self-state, an "object," who is the target of the experience, and an affective link between the two. The object relationship tends to be complex, including unconscious motives and affects and complex interplays between participant and object. As long as the relationship is viewed from the viewpoint of the experiencing participant, it is an object relationship.

Because of the overriding importance of the attachment to the caretaker, the child will do whatever is necessary to secure this attachment. If the relationship requires the suppression of aspects of the self, those potential components of the self are arrested, thus crippling self-development. For example, if the caretaker will not tolerate aggressive feelings and requires that the child avoid all angry or aggressive expression, the child will learn not to feel or act in an aggressive manner. The aggressive component of the personality will be arrested, thus crippling all areas that rely on aggression,

such as self-assertion, ambition, and competitiveness. In this way, the object-relations viewpoint replaces the Freudian theory of symptom formation as rooted in internal defenses against drives with the conflict between the need for the object and the development of the self. What appears to be the repression of a drive is the child's burial of those potential aspects of experience that the child fears will be threatening to early caretakers. To some degree, such adaptations are an expectable part of life, as all caretakers require some adaptation from the child that does not allow for full self-development. However, when such accommodations interfere with the development of crucial components of the self, such as excitement, interest, enjoyment, aggression, and sexuality, the self will be fundamentally split in a way that arrests the development of essential components of the self. Winnicott called this division the split between the "true self" and the "false self." Those buried aspects of the self continue to seek expression and will gain it only through symptom formation. To continue with our example, the aggressive component of the self may seek veiled expression as a somatic pain or become part of a sadomasochistic sexual fantasy life.

From the object-relations viewpoint, all psychogenic pathology is a function of self-arrest induced by anxiety-driven object attachments. Pathological differences being due to the phase, degree, and type of arrestation, object-relations theory does not make decisive distinctions among causes and types of pathology. This view puts all psychopathology on a spectrum and makes distinctions among types of pathology a matter of degree.

All object-relations theories are built on the principle that development and psychopathology are a product of the object relationships internalized in the developmental process. However, theorists from various schools differ in emphasis and in details. For example, followers of Melanie Klein, known as Kleinians, tend to see drives as important to the formation of object relationships even if they see object relationships as the building blocks of all development beginning in early life. Kleinians view problems with the aggressive drive as fundamental to pathological states, although they acknowledge that all drives are seen only within object relationships. Fairbairn, as mentioned earlier, sees no role for drives in development or pathology. In contrast to the Kleinians, Fairbairn saw the child's most fundamental motive to be the need to love and have that love accepted by the caretaker. Donald Winnicott, a primary English object-relations theorist, saw the child's dependence on the mother and the phases of its relinquishment to be the most important variable in development and psychopathology. According to Winnicott, each infant is born with potential that cannot be

changed, but can be either facilitated or interfered with by caretakers. Impingement by the caretaker interferes with the maturational process, and this arrest in the development of the true self is the source of psychopathology, including the most severe forms. Many followers of Winnicott, such as Mhasud Khan, Margaret Little, and Andre Green, have used his work to apply object-relations concepts to the treatment of severe character and even psychotic disorders, thus broadening the scope of psychoanalytic therapy beyond the neurotic patients who tend to be the target of classical technique to the treatment of more severe emotional disorders.

Christopher Bollas, a contemporary Winnicottian, has shown how the mother's ministrations to the infant are taken in or "internalized" by the growing child. Bollas has pointed out that the original mother-child relationship becomes embedded in the psyche of the child in a way that results in a unique personal idiom the growing child and adult is unaware of, but always knows is there. Bollas calls this personal idiom the "unthought known."

Heinz Kohut developed a school of psychoanalysis that has come to be known as self psychology. In Kohut's view, the child is born with a nascent self that comes to fruition as a function of the interplay between the child's "nuclear program of the self" and the caretaker's ministrations. The child's experience of a caretaker is called a self-selfobject relationship. A selfobject is an other experienced as a provider of functions for the self. The degree to which the selfobject provides necessary functions abets the development of the nuclear program via a process of "transmuting internalization," a microscopic "taking in" of the selfobject until the internalizations replace the archaic forms of narcissism characteristic of infancy and early childhood. Disruptions in the self-selfobject relationship cause vulnerabilities in the emerging self and the need to protect this vulnerability by splitting off the original narcissistic state that, being unresolved, continues its influence on the personality. Although self psychologists prefer to regard their theory as wholly unique in psychoanalytic thought, the fact is that their view of self-development as a function of the relationship to early objects and the internalization process fits this school into the object-relations rubric. It is true that self psychology differs from other object-relations theories in its emphasis on the importance of self-esteem in normal development and vulnerabilities to self-esteem in psychopathology. However, this uniqueness exists within the object-relations paradigm that views self-development as a product of the relationship between self and object and the internalization of the latter by the former. Each form

of object-relations theory has a unique emphasis; that is why there are different viewpoints within the object-relations model.

Whatever the particular differences in detail and emphasis, each object-relations theorist sees the child's absorption of the early relationships with caretakers to be fundamental to the growing personality of the adult. These internalizations are the legacy of the early object relationship and are often referred to as "internalized object relationships." From an object-relations viewpoint, who we are is fundamentally a product of our internalized object relationships. It is important, however, to emphasize that these internalizations are not regarded as copies, as though the mind is composed of the wholesale absorption of the childhood view of the early figures. What the child takes in from the parental figures is a complex creation based on the child's experience with the figures. If this were not the case, people would be photostatic copies of their caretakers. The child's internalized images of the parents are based on the child's experience with the caretaker, but the child creates meaning from this experience that cannot be reduced to the parental behavior. Again, this view of internalization is substantiated by developmental research. Virginia Demos, who researches affective development, has found that the child does not take in the parents' behavior, but makes meaning out of it, and this meaning is the legacy of the parent-child interaction. The lasting impact of the relationship on the child has been referred to by Christopher Bollas as "the shadow of the object." These "shadows" form the template of the child and growing adult's pattern of interpersonal behavior.

When the early caretakers do not meet the child's needs well, the child will experience the caretaking figure as traumatizing. To master the trauma while maintaining attachment to the traumatizing figure, the child will internalize the figure as a "bad object." These internalized bad objects become the source of psychic distress, self-abuse, and many forms of psychopathology. For example, the child may internalize the caretaker's attacks. Treating himself as he was treated, the child has an internalized bad object that may be relentless in flagellation of the self for every mistake or peccadillo. Such a patient will complain of being "hard on myself," or being a "perfectionist." Or, to take another example, the bad object may be projected onto others resulting in a paranoid stance to the world. These are just two of many possible outcomes. Whatever the result of the bad object experience, it will result in some form of pathological expression. All of this has far-reaching clinical implications.

IV. THE OBJECT-RELATIONS MODEL OF PSYCHOTHERAPY

This object-relations theory of development and pathology has direct implications for the conduct of psychoanalytic therapy. Due to its emphasis on the importance of attachments and the legacy of the child's interactions with caretakers, the focus of an object-relations clinical approach is the object-relations structure that gives rise to the symptoms or inhibitions. Consequently, the goal of any object-relations approach is to uncover the object relations internalized in childhood and early life and help the patient relinquish them and create a new object-relations structure that fosters self-development. Thus, in the object-relations model the traditional emphasis on discrete affects is replaced by a focus on the structure of the self.

Object-relations therapy looks at each symptom as an outgrowth of an anxiety-driven object relationship. For example, in the case discussed earlier of the patient who had to disavow any aggressive expression to secure the tie to the early caretaker, the emphasis in object-relations therapy would not be as much on "repressed aggression" as on the object relationships that required the disavowal of aggressive experience. In this case, the caretaker was threatened by aggressive expression, a threat that led to an internalized object relationship in which aggression threatens relationships. The developmental origins of the child's relationship with the caretaker who could not permit aggression would be a first critical step in the understanding of the patient's fear of her aggressive feelings. The internalized object relationship in which aggression is a threat to the object would then be the source of the aggressive inhibition. The consequence of this inhibition is an arrest of the patient's self-development that interferes with all aspects of life that require aggression, such as self-assertion, ambition, and competitiveness.

A. Resistance

One of the most vexing problems in any form of psychotherapy is the strength and resilience with which patients tend to cling to their painful and dysfunctional patterns. From the object-relations viewpoint, the patient's relational patterns reflect an underlying object-relational structure. Therefore, to relinquish the current patterns, no matter how painful or dysfunctional they may be, is tantamount to separating from the objects of the past. If the patient gives up the internalized bad mother, she has yielded the only tie to the mother of her

childhood. This is an intense, painful loss for the patient. One might wonder why the loss is so painful and so strenuously avoided given that the object is "bad," painful. This is one of the great ironies of object relationships and the human condition: As mentioned in the first section of this article, the more painful the early relationships, the stronger is the clinging to the object. As Fairbairn pointed out a long time ago, the painful early relationships create anxiety and the need to attach ever stronger to the abusive object. The abused child is more attached to the abusive parent than is the healthy child to his parent. Similarly, the adult subjected to abuse and pain by an early caretaker holds on tenaciously to the internalized bad parent, whereas the child raised in a healthy environment tends to more easily separate from the internalized parental figures. Patients who suffered from abusive, painful parental relationships are filled with anxiety that leads them to cling desperately to bad internalized objects. This is why such patients are so difficult to treat.

Furthermore, this object-relations structure forms the fabric of the self. To give up the object is in a very real sense to give up the self. As Fairbairn pointed out many years ago, every internalized object is a piece of self-structure, so that to yield the object is to relinquish a part of the self, a loss that evokes annihilation anxiety, the dread of nonexistence. In this way, the object-relations approach makes a unique contribution to understanding the patient's attachment to painful and dysfunctional patterns.

It follows that a critical step in the resolution of pathological patterns lies in the understanding of the origin of the patient's unconscious object-relationship structure. The therapeutic task in each case is to identify and help the patient relinquish the object-relations structure that underlies the symptom or inhibition. For example, many depressed and masochistic patients will berate themselves mercilessly for seemingly trivial mistakes, and some will unconsciously seek out punishment for peccadilloes. They know that their behavior toward themselves creates pain, but they are unable to break free from their patterns. Even after the patient is well aware of the origins and meaning of her self-abuse, she is unable to control it. The object-relations model understands the patient's self-flagellation as an internalized bad object; the unconscious need to be punished is a product of a feeling of badness that originates in such an object. To change her self-abusive behavior is to separate from the abusive figure of the past. This example is prototypical of the object-relations interpretive emphasis on anxiety-driven early attachments and the resulting object-relations

structure that strangulates self-development, in contrast to the classical emphasis on defenses against endogenous drives or discrete affects.

However, awareness of the object-relational structure in itself tends to have limited mutative effect. Here the object-relations model makes a contribution to the time-honored problem of “resistance.” Clinicians from Freud to the present day have found that even after patients seem to have a good understanding of the underlying motivations and developmental origins of their problems, they tend to remain frozen in their patterns. They know what they are doing, but continue to do it anyway, and seem unable to control their repetitive patterns. Freud and generations of subsequent analysts have identified the problem of the persistence of pathological patterns despite insight, a problem classical analysts call “resistance.” From this perspective, resistance is motivated by the patient’s fear of knowing specific information regarding his wishes or past experiences. Here again the object-relations viewpoint has a unique contribution to make. The object-relations perspective sees the patient’s attachment to these patterns as a reflection of an underlying object-relations structure woven into the fabric of the self. As we have seen, the patient is clinging to old objects and the sense of self. Awareness, no matter how meaningful, can have little mutative impact on the structure of the self. Therefore, from an object-relations viewpoint, the recalcitrance of patterns even after awareness is a product of a clinical strategy that: (a) focuses on understanding affects and “impulses” without appreciating the underlying self structure and (b) relies exclusively on interpretation. Because interpretation cannot alter the object-relations structure, pathological patterns will remain stubborn until the therapeutic relationship provides an alternative to the old, familiar patterns. The therapist is often opposed, or even disliked or hated, because she represents the effort to loosen the patient’s bond to the object and thereby threaten the self. The patient’s adherence to the bad object is not treated as resistance, but an anxiety-driven attachment that the therapist will understand and interpret. So, “resistance” from this viewpoint is not resistance at all, but clinging to a desperately needed object.

B. The Patient–Therapist Relationship

Although interpretation is important for making the patient aware of her object-relations structure, awareness by itself does not create new structure. Consequently, in most object-relations approaches to psychotherapy, mak-

ing conscious the patient’s early experience is considered necessary but not sufficient to effect lasting therapeutic change. It is here that the relationship between patient and therapist becomes crucial. The therapeutic relationship must create the conditions in which the patient can create new, more adaptive, authentic, and meaningful object relationships to form the basis for new psychic structure. Object-relations theorists vary in the emphasis they put on the therapeutic value of the patient–therapist relationship, but all, including Kleinians who have traditionally emphasized interpretation, see a critical role for the therapeutic relationship in the patient’s ability to create a new object and healthier psychological structure.

Winnicott viewed the psychotherapeutic relationship as a “transitional space” akin to the child’s use of a transitional object, such as a blanket or teddy bear. Winnicott pointed out these attachments are transitional between the world of omnipotent fantasy life of early infancy in which the child has the delusion that she meets her needs by their very existence and the later appreciation for the world of objective reality in which the child recognizes that people and material objects exist apart from her, outside of her control. There is a third world, according to Winnicott, between fantasy and objective reality, that must be traversed before the child can accept objective reality. In this transitional world, the child knows objects exist outside of her control but treats them as though they are part of her. Transitional experience is the basis for play, creativity, and aesthetic experience. To play one must know what objects are but treat them according to illusions of one’s own creation. The clay is molded into a shape the child calls a “fish.” The child knows the clay is not a fish but puts it in the water to swim. It is equally important that the child adapt to the materials at hand. The child must mold the clay for the play to work. The limitations of the materials differentiate play as a transitional experience from fantasy. If she tries to mold wood, or water, she will not see a “fish.”

Winnicott viewed the psychotherapeutic relationship as a transitional space in which the therapist provides the conditions the patient can use to create new ways of being and relating. The patient has to operate within the objective constraints of the setting, analogous to play materials, but within that boundary creates the relationship she needs. What is created between therapist and patient is unique to the pair. The success of the therapeutic enterprise is a function of the degree to which the created relationship facilitates the development of the true self. Thus, it is not interpretation that is ultimately mutative for Winnicott, but what

the patient creates in the transitional space of the therapeutic relationship. In object-relations therapy, the patient's use of the therapist is decisive for therapeutic outcome rather than the therapist's understanding. The therapist's role is not so much to offer information about the patient as to create the kind of relationship the patient can use to create something the patient has never had before. The therapist's role, then, is to adapt to the patient's needs, rather than find the correct understanding of the patient's unconscious. This adaptation is different for each patient, but it always includes the provision of a space that the patient can use to create something new. This conception of the therapeutic process is decisively different from the classical model in which the assumption is made that understanding is sufficient to produce the desired changes.

The therapeutic action, then, is the patient's use of the analytic space to create a new object relationship with the therapist that facilitates the articulation of arrested aspects of the self. Endemic to the therapeutic process is the creation of new ways of being and relating. This point requires emphasis because it is regarded by object-relations theorists as a major advantage over the classical psychoanalytic model in which the analyst is limited to interpreting the unconscious, and the patient's role is confined to receiving the analyst's understanding or "taking in" the analyst in the form of internalization. What the patient passively receives from the therapist may or may not be meaningful or authentic, but what the patient creates is the articulation of buried aspects of the self that are deeply authentic and meaningful because the patient created them.

In this model the concept of transference is broadened beyond the patient's projection of a past image onto the therapist. Just as in any other relationship, the patient forms the relationship she needs based on a variety of factors, one of which is past object relationships. Because this relationship is based on the patient's hopes and desires, adaptation to the current situation, defenses against the anxiety it causes, as well as the patient's history, this creation is rarely a simple copy of early relationships. This relationship will be a complex amalgam that shifts as the relationship evolves. Most object-relations theorists have a concept of transference broader than the traditional notion that includes the patient's creation of something new with the therapist, so that the transference is regarded as a complex blend of past images and present adaptations. That is to say, transference is not reduced to the repetition of past patterns; it includes the patient's contributions, often developed for the first time in the therapeutic process. For

example, an inhibited patient may eventually explode with rage at the therapist, not because she is repeating an early relationship, but because she feels safe enough with the therapist to risk including an aggressive component in the relationship, an element that may be wholly new in the patient's experience. Or, sometimes the patient who feels cheated by having a weak father will idealize the therapist to create a relationship that he desires but never had. This type of object relationship has its own problems, but its very existence indicates that the transference is not the clear repetition depicted by classical psychoanalysis.

C. The Creation of a New Object Relationship

Like the classical psychoanalytic therapist, the object-relations therapist interprets the transference, but she is not prone to reduce every aspect of the therapeutic relationship to the patient's past experience. The object-relations therapist tends to search not only for the roots of the relationship in the patient's past, but also the adaptive function of the relationship in the present. Perhaps the patient idealizes the analyst because such an idealizing object relationship provides the protection lacking in the early caretaker relationship. The therapist interprets not only the lack of protection in the past, but also the safety afforded by the creation of an idealized therapeutic relationship. However, the object-relations therapist is never satisfied with interpretation alone. The therapist interprets the idealizing transference as a means toward helping the patient relinquish it so that a new type of object relationship may be formed. She then provides the opportunity for the patient to form a relationship that does not repeat the patterns of the past. In our example of the idealizing transference, the therapist attempts to facilitate the formation of a safe, protective relationship so that the patient may be able eventually to have this relationship without the unrealistic idealizing perception of the therapist. To use another example: The therapist helps the inhibited patient include aggression in his therapeutic relationship without feeling threatened that the aggressive expression will damage the relationship.

The therapist will include with interpretation the facilitation of a new relationship with the patient to replace the internalized bad object. Fairbairn referred to this new therapeutic relationship as the "beneficent parental figure." Some Winnicottians refer to the "good enough mother/therapist," and self-psychologists emphasize the provision of "selfobject functions."

Whichever nomenclature is used, all these terms signify the therapist as offering a new, different kind of relationship. The purpose of this relationship is to adapt to the patient so that the patient has the opportunity to create a more positive, benevolent object than the bad object it replaces. This active provision of a new, different relationship is one of the decisive differences between the object-relations model of psychotherapy and the classical psychoanalytic viewpoint. From the latter perspective, the therapist should never become a different object but rather interpret the patient's desire for her to become such an object. From this viewpoint, the object-relations strategy is a gratification of the patient's wishes and, therefore, is a technical error. By contrast, the object-relations model sees the fabric of the personality as consisting of internalized objects and the health or pathology of the individual as a direct product of the nature of these objects. Therefore, from this viewpoint, anything the therapist can do to facilitate the relinquishing of old, negative objects and their replacement with new, good objects is beneficial to the therapeutic process and the goals of the therapy. Having said that, it needs to be emphasized that the object-relations model does not believe that simply "being different" will effect the desired therapeutic effect. The old object-relations structure forms the very fabric of the self and will not be easily given up. This is why a new relationship in the patient's life will rarely affect lasting psychological change. In fact, often patients enter psychotherapy because they are in danger of damaging a potentially positive relationship by operating in accordance with their long-standing patterns. If psychotherapy is necessary, that is because a new relationship is insufficient to produce change and may even be threatened by the patient's old pathological patterns. As mentioned earlier, the object-relations structure formed in early childhood tends to be resilient because the patient is attached to not only her internalized objects but also her sense of self derived from them. The patient's object-relations patterns must be interpreted so that she can see their origins and damaging consequences before the therapist's influence as a new object can be experienced. The former allies the object-relations model with the classical psychoanalytic perspective, and the latter decisively separates it from the traditional viewpoint.

D. The Widening Scope of Psychoanalytic Therapy

A major advantage of this model is that it applies to a wide variety of patients, including many who were believed to be inaccessible to in-depth psychotherapy from the classical perspective. According to the latter view-

point, the crux of psychoanalytic therapy is the resolution of intrapsychic conflicts caused by the repression of forbidden wishes. Consequently, patients for whom the very structure of the psyche is malformed were considered unsuitable for in-depth psychotherapy. The object-relations model blurs this either/or distinction between intrapsychic conflict and character pathology. If a conflict requires treatment, then the conflict has not been mastered by the structure, resulting in a symptomatic outbreak. Even the mildest case of neurosis must have some defect in the structure of the personality for the conflict to have erupted in a symptom. The distinction between intrapsychic conflict and character disorder is a matter of degree, as every patient has each to some extent. Consequently, the psychic structure must be addressed in every case. In terms of clinical strategy the implication is that both types of problem are resolved with a combination of interpretation and the provision of a new relationship. By including the importance of the therapeutic relationship in the therapeutic action, the object-relations model has found a way to address character issues, even primitive characterological expressions, with a psychoanalytic framework.

This widening scope of psychoanalytic therapy is one of the most profound implications of the object-relations approach to treatment. By addressing the object-relations structure of the personality via interpretation and the inclusion of the provision of a new relationship, psychoanalytic therapy becomes accessible to severe psychopathology. In the case of the most severe form of non-psychotic character pathology, the borderline syndrome, object-relations therapists have devised strategies designed to address the primitive needs and demands of those patients. Again, Winnicott was a primary leader in this movement. Following an object-relations model that sees the borderline patient as an arrest in the early development of the self, Winnicott responded to the expressed desires of such patients, rather than "setting limits" on them. His reasoning was that the patients' needs were not responded to in childhood, leading to a defensive protective response on the patient's part. This defensive shell buries the early needs and leads to the demandingness so typical of borderline patients. The hostility and oppositionalism of the borderline patient is seen as part of the protective posture. In fact, the patient defends against all needs and desires for others because the intensity of those needs is painful, frightening, and shameful. However, precisely because the needs are so intense, the patient is hungry and demanding. What makes these patients so difficult and perplexing to the clinician is the combination of the intensity of their longing and avoidance of all contact.

Winnicott's clinical strategy was to take seriously the patient's longings and respond to them any way he could. He regarded the therapist's responsiveness to the patient's needs to be far more important than interpretation in the treatment of such patients. He let the patient take the lead in where the treatment would go. If the patient needed to rage at him, he would allow that and "hold" the rage. If the patient needed to regress to infantile needs, he would allow the patient to curl up, hold a blanket, wander around the room, sleep, or do whatever the patient felt she needed. Any such patient behavior, if spontaneous and authentic, he regarded as an expression of a developmentally arrested state that must be met by the therapist's active responsiveness. He allowed the patient to determine what happened because in this way the development of the patient's arrested true self was facilitated. He conceptualized the therapist's role as the facilitation of the resumption of arrested growth. As can be seen, this is not a conflict model, but a model based on developmental arrest. Winnicott believed that such arrests required the meeting of the early needs in some way to stimulate arrested growth. Interpretation alone could never accomplish this type of renewal.

From this example of Winnicott's treatment of the borderline patient, one can see that the object-relations model is based on responsiveness to needs, rather than always interpreting them, a limitation of the classical viewpoint. According to object-relations theory, such gratification of the patient is not only called for but is a necessary ingredient of the treatment. Whereas for a neurotic patient, this meeting of "regressed needs" may be unnecessary or at most play only a small role in the process, with the borderline patient it is the essence of therapeutic action. Although this meeting of early needs can never replace what is missing from the past, it gains a responsiveness in the patient that allows for a new beginning, a beginning in which the patient can begin to live in accordance with her authentically experienced self. This meeting of regressive needs and the willingness of the therapist to allow the patient to stay in the regressed state as long as necessary is the crux of therapeutic action with severely disturbed patients, according to Winnicott. Harry Guntrip, a foremost object-relations therapist, called this process "meeting the needs of the regressed ego." Even contemporary Kleinians, such as Herbert Rosenfeld, see the relationship and the needs it meets for the patient as the most crucial factor in the therapeutic action with patients who are severely disturbed. The key for Winnicott as for most object-relations therapists is that the patient determines the depth and length of regression, and therapist's role is to be responsive to the patient. The elucidation of this treatment approach to

character pathology, including substance abusers, food disorders, narcissistic personalities, and depression, among others is one of the seminal contributions of object-relations psychotherapy to psychoanalytic therapy and psychotherapy in general. There are many cases reported in the literature of successful psychotherapy conducted by object-relations therapists with borderline and other patients with character disorders.

SUMMARY

Object relations psychotherapy is built on the principle that the child's relationships with early figures are autonomously motivated. The child meets the parental ministrations with innate affective dispositions to form a unique personal idiom. This parental relationship is internalized by the child as internalized object relationships that form the character structure. The degree to which the child's innate direction is facilitated by the environment is the extent to which the personality becomes healthy. Impingements that interfere with the maturational process force the child's maturational process away from this inborn direction to a self protective stance that arrests the articulation of the personal idiom. If significant aspects of the self are blocked, this buried self will seek veiled expression as a symptom. Consequently, object relations therapy is directed both to understanding the defensive constellation and facilitating the articulation of buried affective dispositions that lie beneath it. Emphasis is placed on insight into the transference and the patient's creation of a new object relationship with the therapist. Thus, both interpretation and the therapeutic relationship are mutative factors in this type of psychotherapy. Insight helps to understand the patient's defenses and current character patterns, and the therapeutic relationship fosters the development of alternatives based on authentic affective experience. Consequently, the therapeutic relationship is given considerable weight in the therapeutic action of object relations psychotherapy. This model widens the scope of psychoanalytic treatment beyond neurotic conditions to characterological disturbances.

GLOSSARY

Butcher Treatment Planning Inventory (BTPI) An objectively derived, self-report, structured personality inventory that endeavors to obtain and organize relevant personality and symptomatic information into a cohesive picture to be used for treatment.

Minnesota Multiphasic Personality Inventory-2 (MMPI-2) A comprehensive, objective, self-report, personality inventory that provides the tester or practitioner with a general picture of the client's symptoms, beliefs, and attitudes.

multimodal therapy An approach to planning and delivering psychotherapy that takes into consideration a variety of different domains of functioning, including behavior, affective processes, sensation, images, cognitions, interpersonal relationships, and biological issues. These functions also relate to therapeutic techniques.

I. INTRODUCTION

Mental health professionals conducting psychotherapy are initially faced with the question of how to de-

sign a treatment regimen that suits the unique needs of the client. Clinicians must identify the patient's problem areas that need to be addressed and evaluate the client's personal qualities and strengths needed to solve the present problems. Regardless of the mode of psychological intervention, whether it is psychodynamically oriented psychotherapy or behavior therapy, the mental health practitioner must appraise the client's problems, motivations, strengths, and limitations if the intervention is to proceed toward a successful outcome. In an effort to understand these pertinent "patient variables" many therapists rely on personality and symptom information from psychological evaluations to accomplish this important task.

The assessment process typically involves using objective psychological tests that provide the practitioner with clues to the psychological and environmental characteristics involved in the problems and identify factors that might contribute to a positive outcome. Effective psychological assessment in pretreatment planning can add considerably to the likely success of psychotherapy by providing the therapist with an objective appraisal of the client's problems, psychological resources, and potential treatment failures due to resistance. Moreover, psychological test results can also be effectively incorporated into the treatment process as a medium for facilitating change in therapy.

There are several reasons why psychological assessment should be incorporated into the early stages of psychological treatment planning:

1. It is important in the early stages of therapy to assess the severity of the patient's mental disorder to ensure that the treatment focus is appropriate and effective for the client;

2. Obtaining an objective personality evaluation can also help the therapist uncover personality factors that could lead to treatment resistance. For example, some clients rely on psychological defense mechanisms such as projection and avoidance of blame to deal with conflict;

3. In the early stages of therapy it is also important to appraise the client's strengths that can be drawn on in crisis situations or circumstances that require change; and information on the client's personality characteristics in the early stages of therapy can be employed to facilitate the treatment process through providing personality feedback to the client.

II. TREATMENT PLANNING

Three assessment strategies used in pretreatment assessment are described briefly to illustrate the information that can be obtained in the assessment process. The assessment strategies described in this article are not tied to a particular treatment orientation or limited to a specific psychotherapeutic approach but address the important task of assessing the client's symptoms, motivations for treatment, and likely patterns of treatment resistance.

A. Multimodal Therapy

Although its initial focus and orientation was strictly behavioral in nature multimodal therapy has developed into a model in which all treatment orientations can be included. Lazarus noted in 1981 that its goal is not to fit clients to the "treatment," but rather to illustrate precisely how to fit the therapy to the requirements of the client. This approach by Lazarus employs a model of human personality that is composed of the following component behaviors, affective processes, sensations, images, cognitions, interpersonal relationships, and drugs (more accurately termed "biological functions"). Each of these areas of functioning must be understood before effective treatment can be initiated. The practitioner pays clear attention to excesses and deficits in each assessment area. The practitioner uses several approaches to assess these attributes, for example, interviews, observations, and questionnaires. Multimodal therapy begins with assessment, which traditionally has

been considered to be the most important step in the process.

In terms of assessing behaviors in pretreatment planning, the therapist and client must consider what the client is doing or not doing that is interfering with his or her life. The therapist and client need to come to terms with what behaviors should be increased and decreased in frequency for therapy to be successful. For the assessment of the second area for multimodal therapy, affect, the therapist needs to determine what situations or events elicit different emotional responses in the client. What negative feelings, such as depression or anxiety, is the client experiencing. The third area to assess, sensation-related concerns, involve the clients' preferences for what they hear, see, smell, taste, and touch. Are they experiencing any particularly negative sensations, such as tension, dizziness, pain, or tremors? Next comes the assessment of images that require an evaluation of the effects particular images have on the clients' behaviors, affect, and sensations. The focus of the next assessment domain, cognitions, include opinions, values, beliefs, and attitudes. Do the patients hold any irrational beliefs or ideas that interfere with their functioning? An extremely important area to assess in pretreatment planning is the quality of the patient's interpersonal relationships. The final step in the assessment involves an assessment of the client's physical health including substance use or abuse. This task involves appraisal of the client's current use of alcohol, illicit drugs, and prescription medications.

Once the therapist has acquired the necessary relevant information, the next step in the process is to develop a modality profile, which provides a "blueprint" for establishing the goals of treatment and allowing both the patient and therapist input into what treatment will entail. In addition to being used to formulate treatment goals, the profile may also enable the client to aid the therapist in selecting the most appropriate psychotherapy strategies. Lazarus advocates the use of a wide variety of principal techniques representing a broad range of theoretical orientations, with particular emphasis given to behavioral therapy, rational-emotive therapy, and cognitive therapy.

B. Minnesota Multiphasic Personality Inventory (MMPI-2)

The most widely used personality measure used in pretreatment evaluation is the Minnesota Multiphasic Personality Inventory (MMPI). This inventory was developed in the 1940s as a means of evaluating mental

health problems in psychiatric and medical settings. The original test developers considered it crucial in evaluating patients' problems to ask them about what they felt and thought. The MMPI is a self-report personality scale that includes a very broad range of problems and was developed according to rigorous empirical research methods. The MMPI was revised and updated in 1989 and provides a broader range of clinical information than the original test.

The MMPI-2 is a comprehensive objective self-report personality inventory that provides the practitioner with a general picture of the client's symptoms, beliefs, and attitudes. The MMPI-2 contains 567 true-false questions addressing mental health symptoms, beliefs, and attitudes that are grouped into scales (clusters of items) that address specific clinical problems such as depression or anxiety. An MMPI scale allows the clinician to compare the responses of the client with those of thousands of other people. To gain a perspective on what the patient's test results mean, the MMPI-2 scores are compared to the normative sample, a large representative sample of people from across the United States. This comparison allows the interpreter to determine if the person's responses are different from people who do not have mental health problems. If the patient obtains scores in the extreme ranges, for example on the Depression scale (compared with the normative sample) then they are likely to be experiencing problems comparable to the clinical samples of depressed clients that have been studied. The MMPI-2 results provide the practitioner with a clearer understanding of the patient's symptoms and personality features and help to identify possible areas to explore in therapy.

C. Butcher Treatment Planning Inventory (BTPI)

The BTPI was created for the purpose of incorporating objectively derived, self-report information into the treatment process when a tactical therapeutic approach is being formulated and time is crucial. The BTPI assists the therapist by obtaining and organizing relevant personality and symptomatic information into a cohesive picture early in the treatment process.

The BTPI is a structured personality inventory that takes about 30 min. to administer. It contains several empirically validated scales that were developed to provide treatment-relevant information about clients. Three types of scales are included: validity or response attitude measures, treatment-related attitudes, and major symptom areas. The first cluster of scales assesses the client's cooperativeness with the personality evalua-

tion. Four scales address different test-taking strategies presenting an overly positive self-view, symptom exaggeration, inconsistent symptom presentation, and non-compliant treatment attitudes. The second BTPI cluster consists of five scales that assess specific treatment-related issues: problems in relationship formation, somatization of conflict, low expectation of benefit, self-oriented narcissism, and lack of perceived environmental support. The third symptom cluster addresses the following symptom areas: anxiety, depression, anger-in, anger-out, and psychotic thinking.

The practitioner obtains a summary of the client's likely cooperativeness in engaging into the therapy process, clues with respect to several areas of treatment resistance, and an indication of the extent to which anxiety, depression, anger, or unusual thought processes are likely to be encountered in the treatment process.

III. PROVIDING TEST FEEDBACK TO CLIENTS IN PSYCHOTHERAPY

Clients who are provided test results in the early stages of psychotherapy tend to improve as a result of the test feedback process. This strategy, referred to as "assessment therapy," is a procedure in which the therapist uses a feedback model to review psychological test information with the client and thereby promote the process of behavioral change. Several studies have shown that providing psychological test results to clients early in therapy can have powerful effects in terms of lowering symptomatic status and increasing self-esteem in patients. Research on assessment therapy has shown that providing psychological test feedback is an effective means of engaging the client in the treatment process early in the therapy and produces positive treatment effects by informing the client of likely problems, personality characteristics, and strengths.

In summary, psychological assessment in the early stages of psychotherapy can provide the clinician with a great deal of valuable, objective information concerning the clients problems and strengths. Moreover, the judicious incorporation of the test results into the therapy by using test feedback can facilitate the treatment by engaging the client in the process early in therapy.

GLOSSARY

castration complex A universal unconscious fantasy that women are castrated and inferior because they do not possess a penis. Castration refers to real or fantasied loss or injury to the genitals of either gender in general psychoanalytic usage.

compromise formation Any mental phenomenon that is the product of internal conflict and that expresses all components of the conflict.

conflict Opposition between mental forces. These forces can be instinctual or Freud's structures of the mind (id, ego, superego).

defense The methods used by the ego to master and control id impulses or superego injunctions.

ego The hypothetical construct defined in Freud's structural model to enable the mind to organize its various components and to adapt to the external world.

ego ideal A set of functions within the superego. These include ideal representations of the self and idealized representations of the love object.

fixation Persistent, infantile modes of gratification, object relations, and defenses are thought to be fixed in the mind and available to be regressed to at later moments of stress.

identification The process by which a person borrows his or her identity from someone else through internalizing aspects of the other person into the self-representation. Identifi-

cation is often seen as the most mature level of internalization by modern psychoanalysts.

infantile neurosis A confusing psychoanalytic concept that, at times, is used to refer to the childhood neurosis that is assumed to antedate all adult neuroses and, at other times, to the intrapsychic conflict that occurs during the Oedipus Complex.

libidinal wishes Wishes infused with affectionate or sexual urges thought to be ubiquitous in human functioning.

libido The hypothetical psychic energy attached to the sexual instincts.

narcissistic injury Experiences of having one's self-esteem lowered that are accompanied by painful affects of sadness, embarrassment, or humiliation.

neurosis Refers to psychological symptoms that develop from mental conflict that is primarily unconscious and derived from experiences in childhood.

object relations Refers to relationships to other people. In psychoanalysis, it is the internal representations of self and others that are important in motivating and mediating interpersonal interactions. A developmental distinction is often made between dyadic and triadic object relations. The former refers to relationships modeled on pre-Oedipal experiences where the major goals of the child revolve around need satisfaction by the mother. Triadic relations are seen as more mature, implying Oedipal engagement and the increasing mental complexity implicit in being aware of needs and wishes toward one parent vis-a-vis the other parent.

psychosexual Based on Freud's early finding that all aspects of mental functioning are affected by infantile sexual development and the wishes that derive from these experiences. The term is usually used as an adjective to imply

that some mental or behavioral action is influenced by oral, anal, phallic, or genital urges.

regression A key psychoanalytic concept that thoughts, emotions, or behaviors can involve a return to developmentally immature levels. It also refers to a defense mechanism. Regression can occur along any developmental line.

signal anxiety Freud's second theory of anxiety stated that mental maturity brings with it the ego's ability to anticipate the danger of unconscious mental content becoming conscious so that appropriate defenses can be mobilized. Signal anxiety refers to the affective sense of danger that stimulates defense.

structural model Freud's final model of the mind introduced in 1923 in *The Ego and the Id*. The mind was conceived of having three structures (the id, ego, and superego). Interaction between these three structures is thought to account for all mentally mediated behavior.

sublimation This concept refers to mental contents or processes being separated from the drives that might have influenced their origins. As socially more acceptable motives affect these contents and processes, defenses are no longer needed against them.

superego The mental structure that creates and maintains ideals, values, prohibitions, and commands. It observes and evaluates the self's compliance with these ideals and generates affects to encourage compliance.

transference The process by which the patient displaces onto the therapist or analyst feelings, impulses, attitudes, or defenses derived from important interactions in the past.

"The Oedipus Complex" is a concept in which psychoanalytic history, theory, and clinical work converge. Freud described the Oedipus complex as a universal aspect of human psychological development. He found that in the life of every child, there comes a juncture at which the child strives for sexual union with the parent of the opposite sex, wishes for the death of the same-sex parent, and consequently fears retaliation. In short, Freud believed each of us has once been "a budding Oedipus" with fantasies of incest and murder. Since Freud, the Oedipus complex has been reexamined, reconceptualized, and integrated into different developmental theories of psychoanalysis. Though much of Freud's assertions have been reformulated, especially with respect to the development of the female, many psychoanalysts maintain that the Oedipus complex is a cornerstone in development, the "shibboleth" of psychoanalysis, the watershed of individuation, and one of the most influential and fundamental psychic organizers of mental life.

Currently, the Oedipus complex can be defined as a configuration in which the child's attachments to par-

ents become infused with sexual feelings leading the child to compete with each parent for the attention of the other. With these emerging sexual strivings and their connection to the parents, fantasies form and shift, identifications deepen, interpersonal conflict becomes internalized, intrapsychic conflict results, and internal compromise formations become possible. This psychic organizer occurs between the 3rd and 6th years of life, at the height of "the infantile genital" or "phallic" phase: a phase that follows the oral and anal phases and that overlaps with the pre-Oedipal and Oedipal phases of development. Intense love and hate, envy and rivalry, fears of loss of love and bodily injury, a growing capacity to differentiate between fantasy and reality, and a new awareness of morality characterize a child in the midst of the Oedipus complex. Developmentally, the Oedipus complex is thought to signal a pivotal maturation, not only in the instinctual drives, but also in the ego and object relations. One cannot think about the Oedipus complex today without exploring the concepts of superego formulation, Oedipal and pre-Oedipal object relations, infantile neurosis, and differences in male and female development.

I. HISTORICAL CONTEXT

How Freud came to discover the Oedipus complex requires tracing his thoughts back before his conceptualizations of libido, dual-drives, and structural concepts to his famous 1887 note to Fliess. In that note Freud explained how his self-analysis led him to a radical revision of his seduction-trauma hypothesis. Exploring his own internal world brought the startling realization that the sexual experiences and seductions reported by some of his patients were really fantasies containing wishes, not actual memories. This turning point in his theory resulted from a discovery in himself of the fantasy he saw depicted in Sophocles' *Oedipus Rex*. In the play, the gods place a plague on Thebes for the murder of King Laius. "Oedipus" had been abandoned at birth by Laius and Jocasta for being defective. Oedipus means "clubbed foot." Now married to the widowed queen Jocasta after having solved the riddle of the Sphinx, Oedipus searches for the murderer only to find that he, himself, is not only the murderer but the murderer of his own father and the lover of his mother. In fact, in *The Interpretation of Dreams* (1900), in which Freud first published his formulation of what later he would call the Oedipus complex, he referred to the Greek myth of Oedipus as confirmation of the

profound and universal power of the incest–parricide fantasy. Though it was not until his “Contribution to the Psychology of Love” in 1910 that Freud first used the term, “Oedipus complex,” and not until a 1920 footnote added to *Three Essays on the Theory of Sexuality* in 1905 that he gave his first synopsis of the complex, from 1897 onward the discovered fantasy was already destined to be linked to the tragedy bearing the name of “Oedipus.”

Though it percolated through his thoughts from 1887 onward, nowhere did Freud give a systematic account of the Oedipus complex. For Freud, the Oedipus complex was inseparable from sexuality, and, in his writings from 1905 to 1940, Freud integrated the Oedipal fantasy with his discovery of infantile sexuality and his understanding of psychosexuality. While Freud continued to develop, reassess, and revise his theories and models, the basis idea of the Oedipal fantasy remained a constant. However, the specifics of the Oedipus complex in relation to intrapsychic development were transformed as Freud’s thinking and theories evolved. Prior to the formation of the structural model in 1923, Freud’s understanding of development was influenced by his conviction that sexual and aggressive urges, otherwise referred to as “instinctual drives,” provided most of the motivation for psychic function. These drives were mental representations or a “psychical representative of an endosomatic continuously flowing source of stimulation” and not simply somatic entities. In *Three Essays on the Theory of Sexuality*, Freud linked instinctual drives to erogenous body zones and proposed that a sequential progression occurred as the child matured. At birth the libidinal drives seek gratification through oral means. Later the anal arena becomes the focus of pleasurable sensations. Finally, in the infantile genital or phallic phase, the source of drives resides in the genitals, and, at this juncture, children show evidence of the Oedipus complex. While introducing a wealth of data on infantile sexuality that related to the Oedipus complex, Freud did not explain the complex as a whole until the addition of the earlier mentioned 1920 footnote that referred to the Oedipus complex as “the nuclear complex of the neurosis” representing “the peak of infantile sexuality” and the “shibboleth that distinguishes the adherents of psycho-analysis from its opponents.”

Freud elaborated his understanding of infantile sexuality and development following his analysis of Little Hans in *On the Sexual Theories of Children* and *Analysis of a Phobia in a Five-year-old Boy*. He introduced the role of “castration threat” and “the castration complex”

as well as fantasies of fertilization through the mouth, of birth through the anus, and of the woman having a penis in these writings. In *Totem and Taboo*, Freud linked the Oedipus complex to the cultural institution of totemism. He viewed the primitives’ ban on killing the totem animal as an external representation of an intrapsychic prohibition against killing the father. In this way Freud elevated the Oedipus complex to a primary role in the origin and evolution of human psychic development. Freud further elaborated on the connection between castration and the Oedipus complex in his *Introductory Lectures*. Unfortunately these ideas were contaminated by his incorrect assumption that there was little difference in the early sexual development between boys and girls.

In *The Ego and the Id*, Freud broadened his theory by putting more emphasis on the environment and external experience as organizers of psychological development. Freud proposed that three hypothetical psychic structures—id, ego and superego—organized experience. The instinctual drives were subsumed into the metapsychological structure of the id. The ego was the psychological structure that synthesized and organized the personality by mediating between internal and external experience. The superego, referred to interchangeably in the 1923 paper as the ego ideal, was the structure that contained internalized real and fantasied approvals, criticism, threats, moral standards, and ideals of parents. Freud now expanded the idea of shifting developmental progression of erogenous zones to include the shifting progression of related wishes and fantasies with the structural model. And, perhaps most important, the structural model brought two new concepts to Freud’s understanding of the mind: (a) the idea that these wishes and fantasies were connected not only to drives but also to objects and the child’s shifting relationships to those objects, and (b) that these relational configurations were internalized. The Oedipus complex was further refined and highlighted in a new way within the structural model.

In 1923, Freud used the concept of identification in the context of the Oedipus complex to explain how the ego, like the rider on the horse, is able to rein in the drives of the id. First Freud wrote of the side-by-side existence of the “positive Oedipus complex” and the “inverted negative Oedipus complex.” The former included the child’s libidinal wishes for the opposite sex-parent and rivalrous feelings toward the same-sex parent. The latter referred to libidinal wishes towards the same-sex parent and rivalrous feelings toward the opposite-sex parent. Freud explained that the complete

Oedipus complex was “twofold, positive and negative ... due to the bisexuality originally present in children.” He described a precipitate forming in the ego resulting in a special modification when mother and father identifications unite. This newly formed identification-based aspect of the ego was called the ego ideal or superego. Because this higher order structure was the means by which the child relinquished infantile sexual wishes, Freud declared the superego to be the “heir” to the Oedipus complex. Infantile sexuality would be left behind, and infantile omnipotence would now be denied by a new sense of reality that included inner reality and Oedipal identifications with the development of the new “heir.” The Oedipus complex became a developmental landmark signaling a further and fundamental structuralization of the mind that resulted in the child’s initiation into a moral order and an individuation founded on the basis of intrapsychic conflict.

Freud extended his theory on how the child resolved an Oedipal conflict 1 year later in *The Dissolution of the Oedipus Complex*. He emphasized the relinquishment of libidinal attachment to Oedipal objects and their substitution by identifications with parental authority. Freud spoke of the desexualization and sublimation of these Oedipal striving, and he stressed the importance of the ego’s defense against castration anxiety. For the first time, Freud delineated different paths for the Oedipus complex in boys and girls. He emphasized that boys were driven to resolve their Oedipal longings after seeing the female genitals. With the sight of the female “castrated” genitals “the loss of his own penis became imaginable and the threat of castration takes its deferred effect.” Fear of castration and guilt motivated the boy to identify with and internalize the father’s moral rules and standards. In contrast, the girl’s dissolution of the Oedipus complex requires the acceptance of her castrated state as an accomplished fact, something that occurred prior to the formation of the Oedipus complex. Freud had already elaborated on the weaker state of the female superego and, in 1924, he asserted that the dissolution of the Oedipus complex in the girl is never fully accomplished.

Freud’s struggle to explain female development continued in *Some Psychological Consequences of the Anatomical Distinction Between the Sexes* in 1925 wherein he posited a developmental sequence for female Oedipal development. The core of this scheme centered on the vicissitudes of the questionable “penis-envy” phenomenon that Freud had first mentioned in *The Sexual Theories of Children* in 1908. The sequence was described as follows: (a) the girl discovered her lack of penis; (b) the

discovery of her castrated state gave rise to feelings of inferiority, penis envy, and anger at her mother for not providing a penis; (c) consequently there is a loosening of the libidinal ties toward mother and a turning to father; and (d) the father is then looked to as a provider of a penis and a baby to compensate. Freud added a caveat at the end of the paper that his opinions could be wrong because they were based on a handful of cases, and that further observation was needed to validate his findings. Unfortunately, despite his own caveat and others’ questions, these ideas became enshrined as the classical position on female sexuality for several decades.

Freud collaborated with Ruth Mack Brunswick prior to his death to write *The Preoedipal Phase of the Libido Development* that was published posthumously in 1940. In his final work, Freud wrestled with the importance and impact of pre-Oedipal attachment to the mother and clarified the fantasy of the “phallic mother.” He had considered the girl’s pre-Oedipal attachment to her mother earlier in *Female Sexuality* in 1931. In the 1940 paper, Freud rebutted those authors (Klein, Horney) who challenged his view of the female Oedipus complex. After discovering the Oedipus fantasy in himself, after dedicating years to understanding how the complex formed, how it evolved differently in boys and girls, how it may or may not resolve, and how it intensified to yield the superego, in the end Freud turned back developmentally. Although still holding to his shibboleth of psychoanalysis, Freud moved back toward that “dark continent” with which he was far less familiar to seek what nodal fantasies might be hidden beneath the Oedipal wish.

II. CURRENT CLINICAL RELEVANCE

Despite Freud holding his discovery of the Oedipus complex to be the “nucleus of neurosis”, contemporary psychoanalysts continue to question its relevance to contemporary theory and practice. For a patient to have a successful analysis must today’s analyst continue to whisper the Freudian shibboleth of “Oedipal fantasies” or “Oedipal conflicts?” Research on early childhood development in the decades following Freud has yielded findings that not only have resulted clearly in the redefinition of the Oedipus complex but have also led to a shift in the centrality of the Oedipus complex. Infant and child observational studies have provided new information about gender identity formation, female psychology, and sexuality. Freud’s assumptions about the timing of several phenomena crucial to his

theory that the Oedipus complex is the nucleus of psychological development have been challenged. For example, Freud was wrong when he stated that the discovery of the anatomical differences between the sexes occurred during the phallic phase. We now know that this discovery is made between 16 to 24 months, during the 2nd year of life. Freud was also inaccurate when he assumed that boys' and girls' development were the same up until the phallic years. We now know that gender identity (one's sense of whether one is a boy or a girl) is determined by the time the child reaches age 2 to 3. Such research has allowed analysts to rethink the concepts of penis envy, the negative Oedipal complex, and superego formation, and how they apply to both the boy's and the girl's psychological growth.

Penis envy was a concept which originated with Freud and became pivotal in his understanding of female psychology. This clinical concept of penis envy is manifested in an unpleasant feeling of inadequacy associated with and triggered by a covetous wish for the phallus. Freud asserted several ideas about penis envy: (a) the child discovered that the boy has a penis and the girl has no penis in the phallic phase; (b) the discovery led to castration anxiety and superego formation in the boy; and (c) in the girl, this discovery led to narcissistic injury with hostility toward the mother and subsequent turning to the father for a baby to replace the missing penis. The idea of penis envy in girls has been reconsidered and questioned as being a masculine or "phallogocentric" perspective as psychoanalytic researchers have gained a greater understanding of female development. At the same time, clinicians have become more sophisticated in their attempts to understand clinical material about the penis and a wish for it in female patients. It is common these days for analysts to interpret such material as defensive against more pervasive feelings of inadequacy or as a desire for the penis to fulfill feminine needs (such as the wish to be penetrated). Rarely is penis envy interpreted as a primary issue. The concept of primary femininity was not available to Freud. Primary femininity implies an inborn sense of femaleness which predates penis envy, castration anxiety and the Oedipus complex. That is, femininity is innate and, at least in part, biological rather than simply a reaction to a disappointed inability to be masculine. Nonetheless, femininity is still subject to conscious and unconscious conflict and identifications with father as well as mother. Analytic observation of girls had led certain analysts to ask whether the phallic phase occurs at all in girls. If a phallic phase equivalent exists in girls, it is quite different from that of boys.

Penis envy is now recognized as occurring in both sexes. It means different things in boys and girls depending on a variety of factors including biology, environmental experiences with both parents, and fantasy formation. Boys have been observed to suffer from penis envy when they discover that an older male has a larger organ than they do. Some, but certainly not most, girls develop a fantasy that they have been castrated. Penis envy occurs in some girls but not in others. When it does occur it is dependent on the girl's preexisting feminine identity and the experiences that formed it. Restitutive fantasies of a girl's illusory penis can occur in both sexes. Analysts have also wondered whether penis envy can cover a defensive devaluation of an all-powerful mother in both sexes. Penis envy in this context correlates with the feelings of smallness and helplessness with which every child must contend. The universal fantasy of the "phallic mother" can serve to deny castration or helpless vulnerability in a small child. Some analysts have suggested that shifts in fantasy content can be caused by cultural changes so that penis envy will decline and breast and womb envy will increase as gender roles continue to evolve in modern society. In summary, penis envy and narcissistic injury are no longer thought to be necessary factors initiating the girl's entry into the Oedipus complex. Neither is the female superego deemed to be "weak" or deficient. To date, however, penis envy remains part of the clinical vernacular of psychoanalysis though its meaning in girls and boys has been greatly amended and enlarged from Freud's original notions.

Penis envy is not the only aspect of Freud's concept of the Oedipus complex that has been reviewed and revised. New knowledge of gender identity and closer examination of the complexity of both male and female development has raised questions about the concept of the negative Oedipus complex. Freud had posited the negative Oedipus complex originally as a way to reconcile mixed identifications: The child, regardless of gender, identifies with both parents. Unlike penis envy, the negative Oedipus complex is not widely used in clinical contexts. Psychoanalytic writers have speculated that the diminished usage of the concept reflects the fact that it does not easily or even accurately fit observable clinical evidence. Some analysts have studied and questioned the negative Oedipus complex in girls, others in boys. Focusing on the girl, Edgcombe asked whether the negative Oedipus complex was a normal phase of Oedipal development if it existed at all. Others have reassessed negative Oedipal material and found it better explained in terms of a regression from an Oedipal to a pre-Oedipal

level of object relations. What some label negative Oedipal material is seen by others as a wish to be nurtured, fed, and protected by mother: The girl relates on the basis of dyadic pre-Oedipal wishes rather than relating to the mother in an erotic way with rivalrous feelings toward the father. It remains an empirical question whether girls go through a normal negative Oedipal stage of development. Some analysts have reported finding such material only in women with histories of an absent father and a neglectful, depressed mother.

Blos is one of the few analysts who have examined the negative Oedipus complex in boys in his studies of the relationship of boys and their fathers. He prefers to use the terms "isogender dyadic and triadic complex" rather than "negative Oedipus complex." He prefers these terms because he challenges the idea that dyadic relationships are prerequisites for triadic ones. He views early male bonding as more complex than the boy's erotic love for the father as interpreted by concepts such as the Oedipal constellation. Blos emphasized that the boy's early relationship with the father not only consolidates gender identity but also provides a sense of security and safety. Furthermore, the boy's closeness with his father is not necessarily feminine or passive even if it has erotic components. For these reasons he views the term negative Oedipus complex as both misleading and pejorative. Another conceptual problem with the negative Oedipus concept involves whether to consider it as a defense against a positive Oedipus complex, a regression or fixation to a preoedipal level of development, or as pathological in its own right. Complicating the matter is the difficulty of differentiating clinically between oedipal and preoedipal. Furthermore, these two levels of object relatedness can co-exist in a superimposed, simultaneous manner. As a result the concept of the negative Oedipus complex does not appear often in psychoanalytic writings emanating from the United States.

Despite revisions in the way we understand the role of penis envy and negative Oedipus complex, the Oedipus complex remains alive and well in psychoanalytic theory and practice. Many psychoanalysts continue to conceptualize the Oedipus complex and the Oedipal phase as the developmental stage during which the mind either does or does not organize in a new and vital way: namely, a way that is defined as "neurotic." Neurotic mental organization refers to a special and unique structuralization that is thought to occur during the Oedipal phase. Such structuralization is a concept used to describe a reordering of mental functioning. This developmentally advanced mode of organization includes such new capacities as the integration of drives with tri-

adic (rather than dyadic) objection relations, more selective identifications, and a more refined and differentiated sense of morality and authority. It is the most developmentally advanced level of organization available to the human mind. Psychoanalysts believe that the boundary between neurosis and normality is only quantitative, not qualitative. In "good-enough" circumstances, there is a nodal shift from the interpersonal to the intrapsychic that characterizes a neurotic organization. The danger of retaliation for wishes is no longer external but internal. The feared punishment is not in the form of the parent's action or attitude but involves guilt experienced as a failure to adhere to one's internalized ego ideal. This achievement of a capacity for guilt and intrapsychic danger reflects the maturation of the superego as a psychic structure that can regulate the individual's behavior. Most analysts believe that it is through the Oedipus complex, and during the Oedipal phase, that the superego, "heir to the Oedipus complex," is functionally consolidated. Many analysts correlate the formation of the superego with the Oedipus complex and, thus, couple the capacity for neurotic conflict with the Oedipus complex and Oedipal conflict. These analysts tend to view the Oedipus complex as what Spitz called the "fourth psychic organizer."

Spitz described three "critical periods" of psychic organization while applying embryological theory to ego development. These periods were defined by the emergence of new behaviors that Spitz took to indicate that different mental functions were brought into a new relation with one another. The result was new psychological growth manifested not only through a new behavior but also by a new affective expression. The three shifts that Spitz thought signaled a new level in psychic structuralization are: (a) the social smile, (b) stranger anxiety, and (c) the "no" gesture. Those who conceptualize the Oedipus complex as the fourth psychic organizer regard Oedipal conflict as evidence of a new level of organization; the ego now functions "neurotically," making internal compromises and becoming increasingly independent of the external environment. Many psychoanalysts equate Oedipal conflict with neurotic conflict and the infantile neurosis and, consequently, use Oedipal material in the patient's associations to assess whether psychic structure is neurotic or not. Thus, the presence of Oedipal conflicts in the patient's history takes on diagnostic significance. Oedipal content indicates neurotic symptoms or personality traits according to this equation. This diagnosis carries with it the treatment prescription that psychoanalysis is the treatment of choice. Likewise, patients whose conflicts are pre-Oedipal should be treated with psychotherapy according to adherents of this view.

However, child observation suggests that Freud was wrong in the timing of his central Oedipus complex. Not only do the discovery of anatomical differences and gender identity occur long before the emergence of the Oedipus complex, but, so too, does the formation of the superego. Precursors of superego development (along with the capacity for intrapsychic conflict) have been noted in the 2nd year of life, before the phallic and Oedipal phases. Ironically, they can occur during the critical period described by Spitz as the third organizer, “the no gesture.” Occurring at the anal-rapprochement phase (a combination of Freud and Mahler’s developmental theories), “the no gesture” initiates the child’s struggle with compliance to mother’s demands. Compliance indicates the beginnings of internal controls and internalized conflict. Margaret Mahler described the rapprochement subphase as the 3rd in the 4 stages of what she called the separation–individuation process. It is marked by notable ambivalence and the attainment of object constancy. Hence, the early superego arises in the context of ambivalence. When the child begins to say “no” to himself or herself the inchoate makings of the superego are unconsciously at work. If intrapsychic conflict and superego formation can begin in pre-Oedipal years, where does this leave the Oedipus complex? How can Oedipal conflict be a litmus test for presence of the capacity for intrapsychic conflict? Psychoanalysts have begun to wrestle with these questions.

If neurosis is thought to be an indication of superego modulation of intrapsychic conflict, our most recent knowledge of development indicates that neurotic internal structure begins before the appearance of the Oedipus complex. Thus, pre-Oedipal conflicts do not necessarily mean the mind is not organized neurotically. Similarly, the assumption that all Oedipal conflict is evidence of neurotic character structure is problematic. Psychoanalysts regularly bear witness to the fact that all that is Oedipal clinically—including manifestations of an Oedipus complex—is not necessarily indicative of neurosis. Symptomatology that could be viewed as a sign of neurosis (such as phobias or obsessional symptoms) may occur in individuals with borderline or narcissistic character structures. Moreover, Oedipal content can be observed regularly in the thoughts of patients organized at a borderline or psychotic level. It seems most reasonable to conclude, then, that psychoanalysis is indicated when the patient’s symptoms or character traits are part of a personality structured at a neurotic level. Neurotic personality structure is characterized by internalized conflicts that arouse anxiety to which the ego responds with signal anxiety mobilizing appropriate defenses and/or compromise formations.

The content of the wishes, fantasies, or conflicts that would lend themselves best to psychoanalytic treatment may be either Oedipal or pre-Oedipal, about either competing for the opposite-sex parent or seeking the security of mother. Likewise, a transference neurosis, often considered a *sine qua non* of psychoanalysis proper, does not absolutely require that its content be embedded in Oedipal themes. It is the mental structure and not the mental content that is most clinically significant.

In assessing whether to recommend psychoanalysis versus psychotherapy, the psychodynamically trained physician should assess the adaptability of the ego’s functioning, not evidence of an Oedipus complex. One can be led to erroneous treatment recommendations if one looks for signs of Oedipal conflict, castration anxiety, penis envy, rivalrous wishes toward the same-sex parent object, and an eroticized transference. Though it provides one of the most complex conflicts to the developing mind, the Oedipus complex is not always proof of neurosis. Oedipal wishes can be organized in psychosis or borderline ways. The clinician should instead assess for autoplasmic (rather than alloplastic) modes of conflict resolution. Autoplasmic means that the individual’s psychic structure allows for psychic shifts to be made so that conflicts are resolved “internally” rather than by attempting to make the world accommodate to the self (alloplastic). Furthermore, the capacity for affect regulation (specifically signal affects), a sense of self-responsibility, and a superego that controls impulses before they are expressed behaviorally should be looked for as core indicators of neurotic structure.

III. CONCLUSION

In conclusion, although the Oedipus complex and the Oedipal phase of development remain indelible in the history of psychoanalysis, vital to contemporary theory and practice of psychoanalysis, and nuclear to the formation and understanding of unconscious mental structure, the Oedipus complex and Oedipal conflict are no longer necessarily central to the diagnosis of neurosis. The clinician who blindly holds the Oedipus complex as the unshakeable shibboleth of psychoanalysis is in as precarious a position as was Oedipus on the road to Thebes.

time out An intervention in which an individual is removed from sources of positive reinforcement for a specified period of time.

GLOSSARY

differential reinforcement of incompatible behaviors Reinforcement is provided contingent on an individual's engaging in behaviors that are incompatible with an undesirable target behavior.

differential reinforcement of other behaviors Reinforcement is provided contingent on an individual's engaging in behaviors other than an undesirable target behavior.

extinction Decrease in behavior following the removal of reinforcement.

overcorrection An intervention in which an individual is required to improve the setting beyond the way in which it appeared before a disruptive behavior was emitted, or to repeatedly practice behaviors that are alternative to the disruptive behavior.

punishment A contingent relationship between a behavior and a consequence such that the consequence causes the particular behavior to decrease in frequency.

reinforcement A contingent relationship between a behavior and a consequence such that the consequence causes the particular behavior to increase in frequency.

stimulus generalization The spread of the effects of reinforcement to settings different from that in which the original procedure was conducted.

I. DESCRIPTION OF TREATMENT

Omission training is a procedure that is used to reduce or eliminate behaviors that are deemed undesirable. Omission training is typically used to reduce behaviors that occur at a moderate-to-high rate. In general, the procedure requires that a time interval be established, and, if at the conclusion of that time interval, the target behavior has been "omitted," a reinforcer is delivered. Reinforcement is thus provided contingent upon the absence of the target behavior. The name omission training is for this reason often used synonymously with the term DRO schedule, or differential reinforcement of zero rates of the target behavior. As an example, consider an elementary school-aged child who gets up out of his or her seat at a high rate during the teacher's lessons. To implement an omission training procedure, the teacher might first determine the longest duration of time that the child can sit without getting up out of the seat during lesson time and establish this as the specified time interval. The teacher may then observe the child during that time interval, and if the child refrains from getting up out of the seat, the teacher may reinforce the child with a gold star, to be later exchanged for additional recess time. After a sufficient number of reinforcers are earned,

the teacher may gradually and successively increase the length of time for which the child is required to refrain from getting up out of the seat to earn a gold star. This omission training procedure is likely to be effective in reducing the rate with which the child gets up out of the seat during lesson time.

There are a number of advantages associated with the use of omission training. First, because all that is required is that an interval of time be recorded, an observation be made as to whether or not the target behavior occurred, and, if it did not occur, a reinforcer is delivered, this procedure is fairly easy to implement. Teachers, parents, or human service agency staff who wish to reduce a behavior need only a rudimentary understanding of behavioral principles. In 1979, for example, Howard Hughes, Anita Hughes, and Hardy Dial reported the successful use of an omission training procedure by parents of a 4-year-old child who engaged in excessive thumb sucking. Likewise, in 1980 Edward Barton and Jennifer Madsen demonstrated that teachers' aides could effectively use omission training to reduce the extreme drooling exhibited by a child with severe mental retardation.

Second, ethical issues that are raised with other behavior reduction procedures are not of the same magnitude of concern here. Providing reinforcement contingent on the absence of a response is considerably less intrusive than other frequently utilized procedures, such as overcorrection and time out. A third and related advantage is that omission training does not produce the undesirable side effects (such as frustration, aggression, or other emotional behaviors) that are often observed with more intrusive behavior reduction procedures. Fourth, several studies have shown that the deceleration in the rate of the target behavior often occurs rapidly following the onset of an omission training procedure. This makes omission training a desirable procedure to use for reducing behaviors that are particularly disruptive. Fifth, the effects of omission training have been shown to be relatively long lasting, and to generalize to settings other than that in which the original treatment was implemented.

II. THEORETICAL BASES

Omission training as a treatment poses some theoretical difficulties. Specifically, the definition of reinforcement is an increase in the rate of a behavior when that behavior reliably produces some consequence; reinforcement hence describes the contingent relationship between a behavior and its consequence. One might ask, how can this same relationship hold with the absence of a

particular behavior, as is the case in omission training? One way of reconciling this dilemma is by acknowledging that while the individual is refraining from engaging in the target behavior during the specified time interval, that individual is engaging in other behaviors. It is the other behaviors that are correlated with reinforcement, and hence, the other behaviors that increase in rate. For example, in our previous example, while the child is refraining from getting up from the seat, the child may be playing with a pencil, drawing on the desk, or listening attentively to the teacher. The gold star deliveries might serve to increase the rate of these other behaviors. Omission training, then, might conceivably be regarded as differential reinforcement of other, or alternative, behaviors.

Because behaviors occurring during the specified time interval may increase in rate due to their correlation with reinforcement, it is possible for other undesirable behaviors to increase in rate. For example, it would certainly not be beneficial if the omission procedure was successful in reducing the child's getting up out of the seat, but also in increasing the rate of the child's talking to a neighbor. For this reason, it is important to specify socially appropriate behaviors in which it is believed to be beneficial for the individual to engage. If behaviors that were deemed desirable for the individual to engage in during the specified time interval were determined and reinforcement was provided contingent on their omission, an increase in desirable behaviors would occur concomitant with the decrease in the undesirable behavior. This procedure could be conceptualized as a differential reinforcement of incompatible behavior, or a DRI, schedule. For example, if the child was provided with gold stars for listening attentively during specified time intervals, this behavior is incompatible with getting up out of the seat and would be expected to increase in rate. So, it may be useful to gradually fade a DRO schedule into a DRI schedule, so that desirable behaviors are specified and increased. It is also important that the individual's opportunities for reinforcement be maximized. The omission training procedure must begin with a specified time interval during which baseline levels of behavior suggest that the target behavior will not occur. When a certain number of reinforcers have been acquired, the time period can be gradually increased.

III. EMPIRICAL STUDIES

A. Use of DRO to Reduce Self-Injurious Behavior

In 1990, a dramatic demonstration of omission training was reported by Glynnis Cowdery, Brian Iwata, and

Gary Pace. The procedure was used to reduce the frequency of severe self-excoriation (scratching or rubbing) that was displayed by a boy who was not developmentally disabled. Functional analysis results revealed that the boy's self-injurious behavior was maintained by automatic reinforcement. A treatment plan was established in which pennies, tokens, or social praise were delivered following periods of time during which the boy refrained from scratching. Initially, the interval was set at 2 min, which was the longest amount of time the boy had been observed to refrain from scratching. As the boy met the criterion for reinforcement, the time interval was gradually increased to 18 min, and eventually expanded to where the boy was able to leave the facility in which he lived to visit his parents. Four months of treatment were required to reduce the boy's self-injurious behavior to less harmful levels; it was never completely eliminated.

B. Effects of Omission Training as Compared to Extinction

In some situations, caregivers may wish to determine what function a maladaptive behavior is serving, or what specific reinforcer is maintaining the behavior. When that has been identified, it seems reasonable to expect that withdrawing that reinforcer should extinguish the behavior, or cause it to decrease. For this reason, some investigators have compared the effectiveness of omission training to extinction. For example, in 1975, F. Dudley McGlynn, William B. Miller, and John Fancher established a key-pressing response by individuals with chronic schizophrenia. For one half of the participants, key pressing was then put on extinction, while the other one half of the participants received reinforcement contingent on not pressing during specified periods of time. Response rate was shown to decrease more rapidly for participants in the extinction condition; extinction was also shown to result in overall more response suppression than omission training. In 1976, Jeff Topping, Helen Thompson, and Billy Barrios reported slightly different results using a similar procedure with institutionalized individuals with Down's syndrome. Neither procedure was more effective in reducing response rate initially, but greater overall suppression resulted from omission training. The degree to which these results would also be obtained in clinical settings is not clear from either of these reports.

C. Durability and Generality

The effectiveness of an intervention can be evaluated on the basis of durability and generality. Durability refers

to the degree to which the effects of the intervention persist over time after treatment has been terminated. For example, Brian Iwata and Andrew Lorentzson showed in 1976 that the effects of an omission training procedure in controlling seizure-like behavior persisted for 13 weeks following treatment withdrawal. Generality refers to the degree to which the effects of the treatment are shown to generalize to settings different from that in which the original procedure was implemented. In the study described previously by Cowdery, Iwata, and Pace, treatment was conducted in an institutional setting, but the effects were shown to generalize to the child's home when he visited his parents. As with most behavioral interventions, generalization of treatment effects is likely when the settings in which the intervention is performed in are varied, the frequency of reinforcement in the original training situation is reduced sufficiently so that the training situation more closely resembles the natural environment, and when common stimuli are programmed between settings.

D. Side Effects

As mentioned previously, omission training does not produce the worrisome side effects that other procedures might. However, emotional responses may still occur. Cowdery and his colleagues noted that emotional behavior (e.g., crying) did occur when the boy did not earn his scheduled reinforcers. Thus, an individual may experience frustration if scheduled reinforcers are not earned, but such effects would seem to be a by-product of any reinforcement-based intervention. Such effects are presumably of a lesser magnitude than those resulting from more intrusive procedures. It must be noted, however, that there may be clinical situations in which the target behavior poses such concern, either because it is harmful to others or harmful to oneself, such that caregivers do not have time to wait for omission training to take its effect. In fact, more harm may be caused if the behavior is allowed to continue to occur. In such situations, a more intrusive procedure may be warranted.

IV. SUMMARY

Omission training has been shown to be an effective procedure for reducing or eliminating undesirable behavior. It is not as intrusive as other behavior reduction procedures and produces few side effects. Its effects may be seen relatively soon after its onset and may be relatively durable over time. The reduction in the rate of the undesirable behavior can be expected to occur in settings different from that in which the original train-

ing was conducted. Omission training is an easy procedure to implement and will be most successful if opportunities for reinforcement are maximized, and if a DRI schedule is gradually implemented.

GLOSSARY

e-therapy Doing therapy by electronic communication.

online Generally is used to denote the subset of e-therapy done in real time, aiming for pauses between messages that are as brief as those between two people in the same room.

unmet e-therapy E-therapy where client and therapist have not met.

webcam A camera used in conjunction with a personal computer for video communication via the Internet.

E-therapy is doing therapy by electronic communication. At present this means exchanging text messages. Web sites offering e-therapy sometimes do not distinguish between therapy and counseling. E-therapy has evolved empirically because of the availability of technology, which includes both e-mail for communication, and the Internet, where therapists' web sites attract potential clients. There are no controlled studies of efficacy, although anecdotal testimonials abound. It is

derived from older technologies (letters, telephone, facsimiles) that did not achieve the status of distinct therapies. E-therapy has emerged as yet another way the Internet may alter radically the way we do things. Although most professional associations agree e-therapy is not as effective or safe as when the therapist and patient are in the same room, proponents argue it is more convenient and can reach out and involve those who cannot or will not meet a therapist bodily. E-therapy is better than no contact for certain populations and may lend itself to frequent contacts in some forms of therapy. Potential disadvantages abound. Future use is likely as an adjunct to therapy that includes meeting in the same room, but unmet e-therapy depends on the ability to achieve adequate evaluations, and overcoming negative trends in liability, regulations, and reimbursement.

I. DESCRIPTION OF TREATMENT

The Internet, established in 1969 at the University of Southern California for national defense uses, has emerged as a major form of communication, with unanticipated qualities and effects. Electronic mail was used for years among users of terminals of main frame computers. Specialized offers to certain customers date to 1973 with Lexis legal information services available to clients of Mead Data Central. CompuServe began the first online access service for customers in 1979. E-mail has been increasingly accepted

in general medicine, especially for anything a patient might have to write down if told on the telephone, such as test results, written instructions, directions, phone numbers, and so on. E-mail messages can be linked to web sites for patient education. Increasing use has been recommended by the Institute of Medicine's report, "Crossing the Quality Chasm."

E-mail can be contrasted to older technologies, long used in therapy.

A. Letters

An e-mail is basically a letter, the most ancient regular form of communication across distance. Even between people who know and see one another, letters can be used to develop and give a particular form to relationships. Many teenagers have pen pals, often in a distant country, that they do not meet for years. There are published exchanges of letters of people who have and have not met, in which the correspondence was more important than face-to-face encounters. For instance, Tchaikovsky and Najda von Meck corresponded for decades while living in the same city. They chose never to meet by plan, although reacting in their letters to their chance sightings of one another. Numerous examples show the process of therapy in traditional letter writing. Sigmund Freud developed several therapeutic correspondences. There is a rich literature of therapeutic exchanges, which typically took weeks. The big advantages of e-mail over letters are seen at every stage of the process: ease of composition by typing or dictating onto a screen, editing on screen, speed of delivery, ease of retrieval, legibility, ease of response, and storage. Retrieval can be so quick as to allow a conversation in real time, or at one's leisure, which means that the recipient is likely to be in a mindset favorable for communication. Cost per communication is insignificant in that monthly charges through Internet service providers usually provide unlimited e-mail for a monthly fee of \$20 or less. These advantages are so self-evident and overwhelming that no studies have had to be done to quantify these advantages.

B. Telephone

Calls have been used to help people feel better since the invention of the telephone in 1885. They are immediate, and convey nonverbal data through pauses, tone of voice, inflections, and so on. Usually costs are charged by the amount of time taken, so telephone calls tend to be brief. However, therapists have routinely scheduled long sessions with patients when one or the

other is traveling. Unless recorded, they are not retrievable, which may or may not be an advantage. If recorded, playback speedup is essential to achieve evaluation times that can match the ease with which written exchanges can be scanned. Telephone rings tend to be intrusive, and may not catch the recipient in a receptive mind set. Leaving messages on answering machines frustrates the very urgency that led to the call and is complained about as "telephone tag."

There is extensive experience with telephone therapy in the form of suicide prevention centers and other "hot lines." Answerers are always available. The caller and answerer have not met previously. Suicide prevention centers were once publicized extensively and were busy, answering many calls and serving many people in a crisis mode. Studies showed suicide prevention centers did not reduce suicide rates in the cities they served, a phenomenon attributed to the likelihood that more seriously suicidal patients did not call but killed themselves instead. Generally callers used hot lines once or twice. They got support and were urged to go to services where they could be seen and helped. Some of those served did so immediately, others used crisis hot lines and emergency rooms for months or years before getting involved in more regular treatment, and others did not progress beyond use of crisis hot lines. Crisis hot lines are widely used in emergencies and are accepted as one part of the range of services. Some proponents of e-therapy argue from the hot line experience that some people in need of therapy will get involved via the Internet because of its convenience and anonymity. However, web sites offering unmet e-therapy do not resemble crisis hotlines in avoiding diagnosis, treatment, and ongoing relationships.

C. Facsimile Transmission (Fax)

The fax offers a chance to preserve the handwritten, sometimes illustrated, letter format while using the electronic speed of immediate delivery. The novelist Isabel Allende described writing a letter to her mother daily for 30 years, in recent years by fax. She and her mother tie each year's faxes with a ribbon and store them in a closet. Although the writer knows of patients and therapists who communicate by fax, there are no scientific reports. Fax communication is closest to e-mail in that it can occur in real time, but uses the telephone system rather than the Internet and is stored as an image rather than retrievable text. Use of the computer as a facsimile machine may increase as therapists grapple with the regulatory issues described below.

Although the above forms of communication have been available for years, physicians in almost all training programs in all specialties receive no specific education in how to use them.

E-mail poses the following problems:

1. *Junk*: The problem of junk e-mail (spam) can be worse than junk mail, since there is no cost for paper, postage, or handling. For less than \$20, a marketer can purchase a CD with millions of e-mail addresses. In April 2001 more than 10,000 “spam attacks” were launched daily. The estimated annual cost of spam is \$8.5 billion, even though it can be sent without postage to a large number of addresses. Responding to spam, however negatively, actually provokes more, since it shows there is a live person behind the address.

2. *Volume*: Many therapists are on professional and other mailing lists, getting some of 6.1 billion e-mail messages sent daily.

3. *Loss of contact*: E-mail addresses and service providers, which may not reflect a person’s name or location, are changed easily by people, often to avoid getting so much mail. Addresses may be upper or lower case sensitive, multiple (used for different purposes by one or more people), and can change without notice. That mail went undelivered is not always known by the sender; that mail was delivered to the wrong recipient is known by the sender only when the recipient takes the trouble to write back. Most e-mail users report having received someone else’s mail.

These problems can be eased by getting an unpublished address only for e-therapy using a service provider easily accessed from any Internet browser. An ongoing relationship should include ways of contacting the client other than through e-mail.

4. Less easily resolved is *Disinhibition and projection*: The very ease with which e-mail can be sent quickly to anyone results in quick messages and responses before feelings have cooled. The improbability of any local, real-life repercussions in virtual communities on line is disinhibiting. Miscommunication, distortion, emotionality, and projection abound, thought to be a result of the lack of social cues and context. Angry messages constitute a greater percentage of e-mails than of regular letters. “Flaming” and other angry outbursts have led to the development of “netiquette,” which may have its own class distinctions in various settings that provide a further complication. Proponents for e-therapy argue that spontaneity in online therapy is helpful. E-therapists practicing asynchronously garner praise for taking time to think about their responses. E-therapists will have to be able to

write well, expect to be misunderstood, and deal with unexpected feelings stirred up by messages.

E-mail has evolved beyond simple transmission of text. It is possible to send images (e.g., remote art therapy) as an accompanying file, but this is rarely done. Voice dictation is used increasingly, but longer messages tend to slow interaction, and those using it find themselves employing longer words. Some proponents argue that the problem of the lack of physical cues can be overcome by using webcams, but video phones have been available for years without becoming popular. Use of webcams would change the modality to teleconferencing, which has emerged as a clearly defined therapy with limited reimbursement. At present e-mail belongs to the typists. For data gathering purposes this trades whatever can be gained from scrutinizing handwriting, itself the subject of a formidable literature, for legibility and retrievability.

II. GUIDELINES

E-therapy is a subset of patient–therapist electronic communication, so it must proceed within the general guidelines developed for such communication. These have been developed as follows.

The first comprehensive set of guidelines for physician–patient communication was developed by a committee within American Medical Informatics Association and adopted and published in 1998. The guidelines were passed on to the American Medical Association, which modified them slightly and adopted them in its assembly in June 2000. The American Psychiatric Association (APA) assembly adopted the guidelines in November 2000 and requested the APA Board of Trustees to accept the guidelines pending the adoption of APA guidelines. The APA Trustees did so in March 2001. Guidelines have been developed by the Psychiatric Society for Informatics (also highly derivative of the AMIA guidelines) and submitted to the APA. The guidelines adopted thus far are given here in their entirety.

The AMA Board of Trustees recommends:

1. That for those physicians who choose to utilize e-mail for selected patient and medical practice communications, the following guidelines be adopted.

Communications guidelines

A. Establish turnaround time for messages. Exercise caution when using e-mail for urgent matters.

- B. Inform patients about privacy issues. Patients should know:
 - Who besides addressee processes messages during addressee's usual business hours and during addressee's vacation or illness; and
 - That the message may be included as part of the medical record, at the discretion of the physician. [The AMA subsequently stated this decision should be joint between patient and physician, while the Clinton administration privacy guidelines, barely modified (so far) by the Bush administration, offer no choice, stating such messages are to be part of the patient's record.]
- C. Establish types of transactions (prescription refill, appointment scheduling, etc.) and sensitivity of subject matter (HIV, mental health, etc.) permitted over e-mail.
- D. Instruct patients to put the category of transaction in the subject line of the message for filtering prescription: prescription, appointment, medical advice, billing question.
- E. Request that patients put their name and patient identification number in the body of the message.
- F. Configure automatic reply to acknowledge receipt of messages.
- G. Send a new message to inform patient of completion of request.
- H. Request that patients use autoreply feature to acknowledge reading clinician's message.
 - I. Develop archival and retrieval mechanisms.
 - J. Maintain a mailing list of patients, but do not send group mailings where recipients are visible to each other. Use blind copy feature in software.
- K. Avoid anger, sarcasm, harsh criticism, and libelous references to third parties in messages.

Medicolegal and administrative guidelines

- A. Develop a patient-clinician agreement for the informed consent for the use of e-mail. This should be discussed with the patient and documented in the medical record. Agreement should contain the following:
 - Terms in communication guidelines (stated above).
 - Provide instructions for when and how to convert to phone calls and office visits.
 - Describe security mechanisms in place.
 - Hold harmless the health care institution for information loss due to technical failures.
 - Waive encryption requirement, if any, at patient's insistence.

- B. Describe security in place, including:
 - Using a password-protected screen saver for all desktop workstations in the office, hospital, and at home.
 - Never forwarding patient-identifiable information to a third party without the patient's expressed permission.
 - Never using patient's e-mail address in a marketing scheme.
 - Not sharing professional e-mail accounts with family members.
 - Not using unencrypted wireless communications with patient-identifiable information.
 - Double checking all "To" fields prior to sending messages.
- C. Perform at least weekly backups of e-mail onto long-term storage. Define long term as the term applicable to paper records.
- D. Commit policy decisions to writing and electronic form.
 - 2. That the policies and procedures for e-mail be communicated to patients who desire to communicate electronically.
 - 3. That the policies and procedures for e-mail be applied to facsimile communications, where appropriate.
 - 4. That the Board of Trustees [AMA, APA] revisit "Guidelines for Patient-Physician Electronic Mail" when the proposed HIPAA guidelines, encryption, and pertinent federal laws or regulations have been proposed or implemented.

The American Psychiatric Association has issued no statements on e-therapy, but has on telepsychiatry. These guidelines do not deal per se with special demands of the therapeutic process, but do show some of the regulatory burden involved in e-therapy. Subsequently the Health Insurance Portability and Accountability Act (HIPAA) regulations of 2000, themselves the subject of so much controversy as to have generated more comment than any other proposed regulation, have been adopted. They specifically provide for the protection of "notes recorded (in any medium) by a healthcare provider who is a mental health professional documenting or analyzing the contents of a conversation during a private counseling session or a group, joint, or family counseling session" as well as defining "covered professionals" as those who

engage in electronic transactions. As of this writing, the requirement is that all e-mails must be included in the patient's record. The AMA and APA have asked that the physician and patient have the option of including e-mail or not. While protection for such notes is reckoned in advance, it may be difficult for an e-therapist to comply with all parts of the regulation at once.

Although the HIPAA regulations do not distinguish between counseling and psychotherapy notes and counseling in medicine may not be related to psychotherapy and still need to be confidential (e.g., genetic counseling might be of interest to insurers), the term "psychotherapy" has been avoided in statements issued by professional associations. The Ethics Committee of the American Psychological Association (www.apa.org/ethis/stmnt01.html) issued statements in 1995 and 1997 relating to its existing ethics code. While noting that there are no rules prohibiting electronically provided services as such, the statement refers to existing standards on practicing within one's boundary of competence, assessment, therapy, structuring the relationship, informed consent, doing no harm, and others. Most online therapists are marriage and family counselors and psychologists, with almost half possessing PhDs, so it is not surprising that other guidelines refer to counseling, particularly those adopted by the American Counseling Association in 1999 (www.counseling.org/gc/cybertx.htm) and the National Board of Certified Counselors in 2001 (www.nbcc.org/ethics/webethics.htm). "Suggested Principles for the Online Provision of Mental Health Services" were adopted in 2000 by the International Society for Mental Health Online, a self-constituted group of online therapists (mostly psychologists) founded in 1997 in conjunction with the Psychiatric Society for Informatics (mostly psychiatrists) (www.ismho.org/suggestions.html). Requirements include disclosure of credentials, performing an "adequate" evaluation, informed consent, performing within one's general competence (not dealing with any problem online one would not handle face-to-face), procedures to be followed in an emergency (the therapists should have the name of a local health care provider who can be contacted in an emergency), and so on.

The word "therapy" cannot be found in the suggestions or any other document cited earlier, since their framers see psychotherapy as requiring assessments and protections that are not possible without face-to-face meetings. Teleconferencing does not avoid such concerns, having been granted reimbursement mostly for consultations. A California law requires that whatever services are reimbursed when rendered in person

be reimbursed as well when provided electronically, but third-party payers have indicated a willingness to deny claims for e-therapy on the grounds that it is not an equivalent service. Proponents of e-therapy urge reimbursement, but are accused of trying to have things both ways: avoiding liability by describing what they do as counseling, but wanting reimbursement for medically necessary psychotherapy. Persons needing psychotherapy must have some impairment to be reduced by treatment, yet patients with serious problems cannot be evaluated adequately on the basis of remote exchanges of text.

At least one professional organization unequivocally has opposed the practice of unmet e-therapy. The Clinical Social Work Federation voted to do so in its 2001 annual meeting, citing concerns about efficacy, liability, and jurisdiction. Its press release says, in part

This area is totally unregulated and potentially very dangerous for clients and therapists alike. ... This new, very powerful medium blurs all the usual boundaries. Most organizations believe that it cannot or should not be evaluated by well-accepted professional standards. That just is not the case. The standards developed by the U.S. Department of Health and Human Services and Coordinated by the Office for the Advancement of Telehealth, are used by the federal government to assess federal policy on an ongoing basis. ... We have yet to see the first law suits in this area, but we know they're coming. Our concern with establishing a position on the delivery of online therapy services is in absolute alignment with the mission of state licensing boards ... the protection of the consumer. The standards used to analyze the growing area of text-based counseling include principles related to confidentiality, informed consent, quality of treatment, competence of the therapist, and basic ethical and professional requirements. These standards cannot be ensured when the client and therapist know each other only from a text on a screen. Assessment is the first phase of psychotherapy and frequently significant information about the client is based on nonverbal cues. Psychotherapy has at its heart a profoundly human connection, a connection that is, in itself, the major vehicle for change. Healing and restoration occur when the therapist and the client together find the bridge leading back, and forward at the same time, to the true self. Alienation from others and the self will not be healed through a virtual connection in cyberspace, a connection that is fraught with risks and hazards for both clients and clinicians.

Despite these cautions, it is clear that many online therapy practitioners are social workers not bound by

the strictures above. This writer appeared on local television in tandem with a social worker treating a ballerina online for \$80 per hour. They said they did not meet face-to-face because of the inconvenience, although separated only by a few blocks in midtown Manhattan. A marriage and family counselor confidently treated a patient he had never met, as they were separated by 2,100 miles. The press release correctly describes most other professional organizations as neutral about unmet e-therapy, but this does not reflect the intraorganizational debates, which turn on three variables: (1) "adequate evaluation", (2) data reduction, and (3) priorities for the underserved (those who cannot come for meetings in person. There is no controversy about the usefulness of e-therapy where therapist and client meet regularly.

III. DISADVANTAGES OF UNMET E-THERAPY

A. Deception

Michael Lewis has chronicled various deceivers, including teenagers who posed as a stockbroker and a lawyer. The first would pick any obscure stock that struck his fancy, promote it in chat rooms, and sell into the resulting victims's rally. The second passed online as a legal expert until he was exposed, after which demand for his advice continued. Lewis sees these young people as leaders in a populist electronic revolution, but they offer good examples of massive deception and an ongoing demand for advice in a climate that is not likely to be regulated soon. In New York State, as in most, anyone can call themselves a psychotherapist, just as anyone can call himself or herself a fortune teller, astrologist, or palm reader. Periodically newspapers report crimes in which the victim was lured into a meeting after meeting the perpetrator on the Internet. Investigations of those offering online services found many did not give their professional credentials or offered incomplete ones (e.g., "M.S." in a context that implies it is in counseling when it may not be). Similarly, potential clients often give themselves fictional names. Not all deception is deliberate. Couples who met on the Internet have appeared to get married only to discover they mistook one another's sex. Tom Hanks, in the film "You've Got Mail," showed how a person's nature as expressed in e-mail can be very different from that expressed in the face-to-face workaday world. This problem is minimized when the patient and therapist

have met enough in the same room for adequate evaluation and development of a therapeutic alliance.

B. Data Capture

Text-based messages leave out too much to be the sole basis of an evaluation for therapy. The data captured in e-mail are a complete set of a narrow band of communication. Although controlled studies show patients divulge facts more rapidly and completely to computers, most of the studies were done with substance abusers before the Internet and rise of confidentiality concerns. Computer-based assessments have not replaced live interviews because communication of facts still does not convey how a person thinks or feels about them.

C. Confidentiality

E-mails leave copies of themselves in almost all servers through which they pass. In this respect e-mail is less of a sealed letter than a postcard copied at each post office through which it passes. Although the regulations and guidelines included above require attention to confidentiality, they should be understood as raising the bar of difficulty of access to content. It is reasonable to assume that a highly motivated, intelligent person with enough time and other resources can eventually access all files. Thus confidentiality is likely to be sacrificed to the determined hacker.

D. Safety

Although the Internet seems well-enough dispersed to survive most catastrophes, both the Baltimore Tunnel fire and World Trade Center disaster either demolished cables or switching stations that help the Internet and e-mail to flow well. On the other hand, the World Trade Center disaster included such destruction that regular phone lines were out or overcrowded and cell phones highly variable, especially as cell towers atop the buildings were lost. E-mail was extremely effective in reassuring the worried, offering chances to send the same message to many people in one's address book. But systems crash, computers fail, and service can be interrupted by failure of any link in the chain. Other safety issues in e-therapy are, in some cases, a derivative of the deception issue in that text carries so little affect compared to a person's actual presence that most thoughtful therapists fear missing depression, especially suicidal intent. Safety concerns highlight the undesirability of doing e-therapy with a patient not evaluated face-to-face.

E. Liability

As of August 2001 only one lawsuit has been brought, but 31% of state regulatory agencies have had complaints about e-therapists. Not following the guidelines stated earlier would weaken a therapist's defense. Practicing across state lines to patients located where the therapist is not licensed is an added risk, especially as the local means for handling a crisis will also be remote. California legislation, likely to be replicated in other states, requires that anyone providing mental health services to its citizens be licensed in California. Liability is judged in art on the expectations created in plaintiffs, and web sites are careful to avoid statements that diagnosis and therapy are being offered, instead offering help with "problems, stress," and so on. More court tests are likely.

F. Lack of Definition, Standards, and Controlled Studies

This emerging field is not defined. Perhaps it is only a technology, perhaps a new technique, or some blend. It does not have standards per se; professional association standards are cautionary. The International Society for Mental Health Online maintains a web site of reported studies (94 as of September 17, 2001). Most reports are how-to-do-it anecdotes and testimonials to the promise of e-therapy. There are no controlled studies. Although some web sites have been set up by disappointed patients to describe negative experiences with e-therapy, such opinion tends to be reflected more in newspaper articles. In contrast, telemedicine, videoconferencing, telepsychiatry—anything in which video and spoken words are used—is being subjected to controlled studies with random assignment of subjects.

IV. ADVANTAGES OF E-THERAPY

E-therapy is best practiced when the patient and therapist feel comfortable in a progressing relationship that has clearly defined shared goals and objectives. Within this context, the disadvantages cited earlier can be minimized and the following advantages realized.

A. Distance

The Internet and e-mail know no distance, since they are available at any computer, any time, usually for the cost of a local telephone call.

B. Time

E-therapy can be done in real time or through a more leisurely back-and-forth exchange of messages. In real time there is an intensity and density of exchange very much like (although less expensive and slower than) a telephone call. One misses the affect a voice can convey. On the other hand, a record is produced (that must be encrypted for any hope of confidentiality) that can be useful for both patient and therapist later. A more leisurely exchange is more like an exchange of letters and can include elements of a journal kept by the patient with comments by the therapist. Cognitive therapy often proceeds well this way. Supportive therapy is enhanced by the therapist providing another means of access than the telephone, which is more intrusive than e-mail.

C. Convenience

E-therapy can be done without the trouble of travel, dealing with one's appearance, or taking other trouble.

D. Written Record

E-therapy can be used to generate a written record of exactly what texts were exchanged. Present regulations require this or inclusion of e-therapy exchanges in an electronic medical record or computerized patient record.

E. Stigma

There is a general impression that e-therapy carries less stigma because visits to a therapist's office are reduced, and one need not be identified. Because e-mail is fashionable, some of its cachet may spill over to e-therapy.

V. INDICATIONS FOR E-THERAPY

Proponents argue that e-therapy is particularly well-suited for the following:

1. Those who would not otherwise get involved. The Internet indeed attracts many people who are looking online for relationships. One indication is the number of people looking for mates, as evidenced by the membership numbers of the major services: Match.com (1 million), AmericanSingles.com (1.3

million), Matchmaker.com (40,000 new members each week), Jdate (150,000), Blacksingles.com (20,000). The impression that “the Net is packed with depressed people” is supported by at least one study showing an association with heavy Internet use and depression. There are many anecdotes of patients becoming involved in therapy as they developed relationships over the Internet, and outreach programs on the Internet may be useful.

2. Anyone who would benefit from having a written record of patient-therapist exchanges. This writer has routinely given copies of whatever he writes about patients to them. Patients report that it helps them remember what has happened and to see the process of treatment.

3. Those who live in remote places, are physically handicapped, suffer from severe agoraphobia, or communicate already by keyboard, the hearing impaired already communicating by text.

4. Cognitive-behavioral therapy. This form of therapy, which tends to emphasize intellect over affect, with its use of daily journals, labeling and categorizing thoughts, correcting cognitive distortions, and so on, is well-suited for a written record that can be parsed for insight and reinforcement.

5. Supportive therapy. The immediate availability and ease of communication via e-therapy allows ongoing contact as often as indicated and is reassuring.

VI. CONTRAINDICATIONS OF E-THERAPY

Contraindications of e-therapy include:

1. Patients who prefer to have no written record of treatment. Although such patients are rare and always pay themselves without making insurance claims, they have a variety of reasons for wanting no record. A therapist may merely make a note that it was agreed that no record would be kept. Because current regulations stipulate that electronic communication become part of a patient's record, maintaining no record would be a violation.

The following contraindications are “relative” in that they depend on the amount of electronic communication versus the amount of time meeting face-to-face. The crucial variable is maintenance of the therapeutic relationship.

2. Patients for whom nonverbal communication is important. This problem is related not only to patient expressive difficulties but also to what data a therapist

would need to understand what a patient might be feeling. Here the problem is that “high tech” does not substitute for “high touch.” Meeting face-to-face involves many nuances of body language, facial expression, eye movement, and so on. Therapists who can get a good idea of how patients are feeling when meeting with them in the same room often find that patients may not come across as clearly via e-mail, a communication problem resulting from insufficient data.

3. Patients requiring more than text can provide. Anecdotal evidence from therapists who have attempted to provide a presence through electronic communication indicates that it is insufficient for some patients who need to be in the same room as the therapist. This is a therapist problem of matching a high return for patients who need it.

4. Combined psychotherapy and psychopharmacology. Pharmacotherapy requires routine physical assessment of signs, which by definition may be different from the symptoms patients report. It is unethical to prescribe medication without baseline observations and periodic examinations.

5. Psychodynamic therapy. Psychodynamic therapy typically involves mobilization and communication of affect, which is difficult for most people when exchanging texts.

There are many forms of psychotherapy. Those previously mentioned because the special requirements of an approved residency in psychiatry that took effect January 1, 2001 stipulate that a graduate be assessed as competent in each before graduating. It will be interesting to see if the teaching of these forms evolves to include the use of electronic text communication. This may parallel development of the interpersonal and communication skills that are one of the six competencies required of all physicians.

Other forms of therapy available on the Internet include chat rooms, self help groups, and support groups moderated by mental health professionals. Family and group therapy have been reported.

VII. FUTURE OF E-THERAPY

In the late 1990s there were many rosy predictions for what seemed to be an unstoppable Internet revolution that would reach into all aspects of our lives. An example of hype: “the hottest and certainly the most controversial new trend in therapy” with only five therapists practicing on-line in 1996 (a 1997 study found

275) and more than 500 in 2001 (the American Psychological Association panel in August noted many had left the field). Advantages cited include: "It's tailor made for business travelers and employed parents who find it hard to carve out daytime hours or keep appointments in one city. It costs less. E-mails average \$25 to \$50 each. ... Even rates of \$90 an hour fall below typical therapy charges of \$125 to \$165. It can work faster. There is evidence that people self-disclose more quickly to a computer than face-to-face. ... It may attract those too embarrassed to face a therapist: childhood sexual-abuse victims, the obese, those with physical deformities or painful secrets." But many changes predicted as a result of the Internet have not come to pass. Here are some that affect e-therapy.

A. Political Upheaval

Politics seemed changed in 1994 when Thomas Foley, Speaker of the United States House of Representatives with many years of incumbency, was upset by an unknown candidate waging his campaign through e-mail and the Internet. The Internet was touted as democratizing the political process, by offering direct democracy, more information available free to anyone interested, and a venue in which groups unable to afford conventional communication could be heard. However, politics has been documented as relatively unchanged after all, as established political forces have adapted to the new medium and incumbents have continued to be re-elected, often having more resources to devote to the Internet as well as other media. Therapy has its own political upheavals, and an e-therapy revolution connotes a therapeutic revolution, with all sorts of new types of therapy and therapists, a la the heady days of the community mental health center era. This seems no more likely than overall political change.

B. Dot Com Failures

It seemed that e-therapy might be part of the on-line shopping revolution, which fell short as the buying public has continued to want to experience potential purchases up close and making money on the Internet has proved to be difficult. In 1999 there were hundreds of sites offering e-therapy services to anyone who wanted to get involved. Many of these sites are no longer active, including here2listen, which had attracted large amounts of venture capital. Commercial failures in e-therapy have been attributed to unrealistic business plans, difficulty in sustaining growth, massive infrastructure costs, and dif-

ficulty in communicating benefits. However, although businesses have trouble making money on it, the Internet continues to grow and is expected to be a \$20 trillion industry by the year 2020.

C. Paperless Offices and E-Books

Although the rise of the Internet, local area networks, and e-mail were expected to lead to a paperless office, use of paper has been expanding rapidly in the Internet's go-go years. Studies show e-mail, in particular messages over half a page in length, tends to be printed and that people retain roughly 30% more of what they read on paper than on computer screens. Paper documents are easier to annotate and compare. Ink on paper, for example from a laser jet printer at 600 dots per inch, has six times the resolution of computer screens. Hewlett Packard estimates laser jet printers spewed out 1.2 trillion sheets of paper in 2001, a 50% increase in 5 years. Canadian exports of printing and writing paper to the United States grew 14% in 2000.

Although e-books were expected to replace paper, and it was predicted that books published only on the Internet would account for 10% of all book sales by 2005, only one book has been commercially successful when published on the web, and sales of handheld devices for reading such books have been very disappointing. People prefer to be reading something they have in their hands. At least it is unlikely that e-therapy manuals and other materials will exist solely in electronic form and there may be resistance to much use of e-therapy. E-therapy notes will almost certainly be printed and stored as paper, especially with the current interpretation of the need to maintain documentation under HIPAA.

On the other hand, telemedical consultations have mushroomed in specialized sectors and now account for 30% of all consultations done in prisons, where security and incarceration make direct access laborious. Telemedicine is beyond the scope of this article, except to say that (1) the remoteness of the patient from the therapist often leads to e-mail contacts as additional input, and (2) telemedicine and telepsychiatry have gained some reimbursement through being evaluated in controlled studies that find it worthwhile, despite loss of some of the input gained in face-to-face meetings.

The future of e-therapy depends on regulation (too much regulation will put it beyond the reach of all but highly committed therapists willing to invest the resources required to meet the regulatory requirements), clarification (Is it a conversation continuing by other means or separable from other therapies?), and its

eventual reimbursement (present pressures for nondiscrimination [parity] in health insurance may create an atmosphere of cost containment that would preclude reimbursement for e-therapy). Technical advances are likely to take it beyond its present definition.

GLOSSARY

antecedent An event that precedes a behavior.

behavior Any action of a living creature. Behavior can be overt or covert.

consequence An event that follows and is produced by a behavior.

differential reinforcement A procedure used to establish stimulus control in which a particular behavior is reinforced in the presence, but not the absence, of a particular stimulus.

discriminative stimulus An antecedent stimulus that (a) given the momentary effectiveness of some form of reinforcement, (b) increases the frequency of occurrence of a particular behavior because, (c) historically, that kind of behavior was more successful in producing reinforcement in the presence of that stimulus than in its absence.

environment The natural world in its entirety, including all events that occur inside and outside living creatures.

establishing operation An event that alters the reinforcing or punishing value of a consequence.

extinction A procedure (or process) that reduces behavior by failing to reinforce a previously reinforced response.

fading An intervention that is used to transfer stimulus control from one discriminative stimulus to another.

functional assessment Procedures that are used to identify the reinforcer for a problem behavior.

negative punishment A procedure (or process) in which the removal of a stimulus after a behavior weakens (e.g., reduces the likelihood of) that behavior in the future.

negative reinforcement A procedure (or process) in which the removal or postponement of a stimulus after a behavior strengthens (e.g., increases the likelihood of) that behavior in the future.

operant A class of responses that “operate” on the environment to produce particular consequences. These consequences affect the future likelihood of occurrence of members of that response class.

positive punishment A procedure (or process) in which the presentation of a stimulus after a behavior weakens (e.g., decreases the likelihood of) that behavior in the future.

positive reinforcement A procedure (or process) in which the presentation of a stimulus after a behavior strengthens (e.g., increases the likelihood of) that behavior in the future.

response A defined unit of behavior.

rules Overt or covert verbal descriptions of relations among stimuli and responses.

stimulus A physical event.

stimulus control Control of behavior by an antecedent stimulus that is evident when some characteristic of a response (e.g., its rate, magnitude, or probability of occurrence) differs in the presence and absence of a particular stimulus.

stimulus equivalence A phenomenon in which stimuli that share no physical resemblance come to evoke the same behavior. If verbal humans are taught that $A = B$ and $B = C$, the relationship $A = C$ emerges without formal training.

stimulus generalization The spread of the effects of reinforcement (and other behavior-change operations) in the

presence of one stimulus to other stimuli that differ from the original stimulus along one or more dimensions.

token economy A therapeutic consequence system, based on conditioned reinforcement, that is frequently used in hospitals.

verbal behavior A behavioral term for language and related phenomena. The defining feature of verbal behavior is that other people mediate its effects on the environment.

The term operant conditioning does not refer to a specific technique for dealing with behavioral problems. Instead, the term, which was coined and popularized by the late B. F. Skinner, refers to a form of learning, or conditioning, in which behavior is controlled primarily by its consequences. Skinner called the new learned responses *operants* to emphasize that they operate on the environment to change it in some way: that is, to produce consequences.

I. INTRODUCTION

Edward Thorndike's work with cats in puzzle boxes, performed in the closing years of the 19th century, is a good example of operant conditioning. In those experiments, Thorndike placed individual cats in large crates from which they could escape by either pulling a string that was tied to a latch on the crate's door, or by pushing down on a pedal that would likewise open the door. If either response was made, the cats, which were mildly deprived of food, could get out of the box and get food. Thorndike found that all cats eventually made the response that opened the door, and on successive trials, it took progressively less time for the response to occur. Eventually, escape from the box occurred very quickly.

After many experiments with different animals in puzzle boxes yielded similar findings, Thorndike formulated one of the first psychological laws, the law of effect. It stated: Of the many responses made to a situation, the ones that are closely followed by satisfaction will be strongly connected to the situation and will be more likely to recur in that situation, while those that are followed by discomfort will be less likely to recur. The law of effect emphasizes that the historical consequences of a particular behavior in a given context are the primary determinant of current behavior in that context. Cats that previously escaped from a puzzle box and secured food by pulling a string do so rapidly and reliably when placed in such an apparatus. In contrast, cats without that history do not reliably pull the string.

B. F. Skinner did not use puzzle boxes. Instead, he developed a device known as an operant conditioning chamber, or Skinner box. The first such device, used with food-deprived rats, was a small box that contained a metal lever and a small cup into which food pellets could be delivered. Depressions of the lever were counted as responses, and food was delivered as a consequence for such responses. In Skinner's experiments, a rat could press the lever at any time and at any rate, and Skinner manipulated observable variables (e.g., degree of food deprivation, frequency of food delivery) to determine how they affected the rate and pattern of responding. For example, he compared responding when food followed every response and every 20th response, and he observed what happened when food was no longer delivered.

By observing the effect of changes in events before and after specified responses on the rate and pattern of recurrence of such responses, Skinner demonstrated the fundamental orderliness of operant behavior and determined how many different variables affected such behavior. In *The Behavior of Organisms*, published in 1938, Skinner reported the results of his early experiments and described several behavioral processes including reinforcement, extinction, discrimination learning, and punishment. In that book, he also drew a clear distinction between operant and respondent (or classical) conditioning. The fundamental distinction is this: operant behaviors are controlled by their consequences whereas respondent behaviors are controlled by stimulus-stimulus pairings. This distinction may be clarified by contrasting the arrangements used by Skinner to study learning in rats with that used early in the 20th century by the famous Russian physiologist, Ivan Pavlov, to study learning in dogs.

Pavlov observed that food placed in the mouth of a food-deprived dog reflexively elicited salivation. When he arranged conditions so that the sound of a metronome immediately preceded food delivery, after several pairings the sound also elicited salivation, although it did not initially do so. Here, the capacity of the sound to control salivation depended on the pairing of two events, or stimuli: the sound of the metronome and the presentation of food.

Although he did not overlook the importance of respondent conditioning in his well-known book titled *Science and Human Behavior*, Skinner emphasized the importance of operant conditioning in the genesis and maintenance of inappropriate as well as appropriate human behaviors. He also argued that an understanding of operant conditioning provides an excellent basis for

developing rational and effective treatments for a wide variety of behavioral problems. His argument has proven to be valid. From the 1950s to the present time, interventions based on principles of operant conditioning have been demonstrated in controlled studies to benefit people with many different clinical problems. For example, a task force commissioned by Division 12 (Clinical Psychology) of the American Psychological Association reviewed the entire psychological treatment outcome literature. Their findings, which were reported in 1995, indicated that the vast majority of successful interventions were either behavioral or cognitive-behavioral in orientation. Such interventions rely heavily on the principles of operant conditioning.

The fundamentals of operant conditioning are presented in the following sections. The key to understanding operant conditioning is the premise that operant behavior is determined in large part by its historical consequences under particular conditions. Therefore, the probability that such behavior will occur under current circumstances depends on (a) the nature of the historical consequences of the behavior, (b) the extent to which current conditions resemble the historical conditions under which particular consequences occurred, and (c) the current importance to the individual of the events that historically were consequences.

II. THEORETICAL BASES

B. F. Skinner repeatedly pointed out the similarity between operant conditioning and natural selection. In both cases, processes of variation, selection, and retention are apparent. Neither Darwin nor Skinner was able to specify the mechanisms underlying these processes. Skinner believed, however, that changes in physiology were responsible for the control of behavior by its consequences. In recent years, some progress has been made in understanding the physiological processes responsible for positive reinforcement and other principles of operant conditioning. For example, there is evidence that synaptic change is involved in learning via operant conditioning. Future work by neuroscientists may provide a detailed account of the proximal mechanisms that underlie operant conditioning, and in that sense, explain why environmental events affect behavior in particular ways. Some scholars hold the view that there can be no adequate “theory” of operant conditioning until this occurs.

Others, however, hold the view that operant conditioning is itself an adequate theory, insofar as the work

of Skinner and others has led to a system of principles and assumptions that are useful for explaining and predicting behavioral observations. We hold this view. There are a great number of specific interventions based on operant conditioning, and those interventions usually are closely tied to its basic principles. For this reason, in this section procedures are introduced at the time that the behavioral principles that form their basis are explained.

A. Consequences of Behavior

Operant behavior is primarily controlled by its consequences, which are events (stimuli) that are produced by (and follow) such behavior. A behavior's consequence(s) can either increase or decrease the future likelihood of the behavior occurring under similar circumstances. The term reinforcement is used to refer to the former relation (i.e., increased likelihood), whereas punishment is used to describe the latter (i.e., decreased likelihood).

1. Reinforcement

Reinforcement is evident when a response is followed by a change in the environment (reinforcer) and is thereby strengthened. The response-strengthening effects of reinforcement typically involve an increase in the future rate of the response, although other changes in behavior (e.g., an increase in response intensity) may also be indicative of a reinforcement effect. It is important to recognize that, by definition, reinforcement always strengthens targeted behaviors. If a behavior is reliably followed by a consequence and its future likelihood is not increased, then the consequence was not a reinforcer.

Psychologists have traditionally classified reinforcers according to whether they are added to (e.g., presenting food) or subtracted from (e.g., turning off a loud noise) the environment. When a stimulus strengthens behavior by virtue of being presented as a consequence, the stimulus is termed a positive reinforcer, and the outcome is termed positive reinforcement. A spouse who responds with sympathetic statements to a mate's complaints about feeling “down and worthless” is positively reinforcing the occurrence of such statements, if such consequences increase the likelihood of such statements occurring in the future. In this case, the effects of the spouse's attention would be both unintentional and undesirable. Unintentional positive reinforcement frequently plays a role in the development and maintenance of psychopathological behaviors.

Clearly, the “positive” in “positive reinforcement” does not mean “good”; instead, it refers to a stimulus being “added” to the environment. For example, abused drugs (e.g., alcohol, heroin, the nicotine in tobacco) are positive reinforcers for the behavior of people who abuse them, but they cause untold suffering for those individuals and others.

Of course, in many cases, positive reinforcement is used intentionally and to good effect. Praising a young girl when she says “Da Da” when her father picks her up is an example of such positive reinforcement. Here, praise occurs dependent on the child’s vocalization, and the relationship between the response and the outcome constitutes positive reinforcement if the behavior is strengthened as a result of that relationship. A response-strengthening effect probably would not be evident after praise followed “Da Da” on a single occasion, however. The effects of reinforcement are cumulative, and a reinforcer often must be delivered on multiple occasions before behavior changes noticeably. Moreover, once an operant behavior is well established, the effects of reinforcement are primarily to maintain, not to increase, responding. There are obvious limits on how reliably and how rapidly a child can say “Da Da” when picked up by dad and, for most children, those limits are reached fairly quickly.

Like positive reinforcement, negative reinforcement also strengthens behavior, but it does so because behavior (*a*) postpones or prevents the delivery of an otherwise forthcoming stimulus, or (*b*) terminates or reduces the intensity of a stimulus that is currently present. The former relation (*a*) is termed avoidance conditioning and the latter relation (*b*) is termed escape conditioning. A spouse who calls home to say “I’m sorry, but I’ll be working late tonight” before going to a motel with a lover is emitting an avoidance response, if so doing prevents unpleasant interactions on returning home and is for that reason strengthened. A person who terminates aversive questions regarding fidelity by saying “Don’t be silly, you’re the only one I want and love; a bunch of us just stopped for beers after work” is emitting an escape response if the questions stop and such responding is therefore strengthened. Although both responses are incompatible with having an honest and healthy marriage, and may well be maladaptive in the end, their historical short-term consequences are sufficient to maintain them. This is often the case with respect to troublesome operant behaviors, regardless of whether they are maintained by positive or negative reinforcement. Neither positive nor negative reinforcement is intrinsically good or bad. Both processes can foster and

maintain pathological as well as adaptive actions. Moreover, both processes can be used clinically to alter troublesome behaviors that do emerge.

An important early step in the treatment of many troublesome operant behaviors is isolating the reinforcers that maintain those behaviors, as well as any events that reliably precede them. This process, termed functional assessment, can be performed in a number of different ways and provides a basis for developing rational interventions. Consider a child diagnosed with mental retardation who sometimes loudly taps a pencil on a classroom desk. Observation suggests that teachers attend to the child each time this occurs. This relation suggests, but does not prove, that attention from teachers is a positive reinforcer that maintains the troublesome behavior. If this is the case, teaching staff not to attend to the child’s pencil tapping, and to attend to some incompatible and appropriate activity, such as working on assigned materials, might well be an effective intervention.

Although the distinction between positive and negative reinforcement is simple logically (see Figure 1), in practice it can be hard to tell the two apart. For example, does a person adjust the tuning on a blurry television because doing so in the past has produced a clear image (positive reinforcement), or because doing so historically has removed a blurry image (negative reinforcement)? Because of such difficulties, and the possibility of confusing negative reinforcement with punishment, there is good justification for not differentiating positive and negative reinforcement, although the practice remains common.

A variety of environmental changes (i.e., stimuli) can serve as reinforcers. Unconditioned (or primary) reinforcers strengthen behavior in people without any particular history. Many primary reinforcers are of direct biological significance. Air, food, and water are examples of positive reinforcers that fit into this category. Primary negative reinforcers, which organisms will escape (respond to terminate) or avoid (respond to postpone), include high-intensity stimulation in most modalities (e.g., loud noises, extreme temperatures).

In contrast to primary reinforcers, conditioned (or secondary) reinforcers gain their ability to strengthen behavior through learning. Conditioned reinforcers can be established through respondent conditioning, that is, by being paired with (i.e., immediately preceding the delivery of) primary reinforcers or other established conditioned reinforcers. They also can be established through verbal mediation. Money is the prototypical example of a conditioned reinforcer.

	<u>Consequence is presented</u>	<u>Consequence is removed</u>
<u>Behavior is Strengthened</u>	Positive reinforcement	Negative reinforcement
<u>Behavior is Weakened</u>	Positive punishment	Negative punishment

FIGURE 1 Operant Conditioning.

The stimuli that serve as conditioned reinforcers vary substantially across people because of differences in their conditioning histories. For instance, certain kinds of painful stimulation (e.g., being struck with a leather belt) are in some situations positively reinforcing for people labeled as masochists, but not for other individuals. This is probably because such stimulation historically preceded a powerful positive reinforcer, most likely sexual stimulation, for some people, but not for others. Being struck with a belt initially was not positively reinforcing, but it eventually came to be so by virtue of reliably preceding sexual stimulation. Like other conditioned reinforcers, it will maintain its reinforcing ability only if it continues to be paired (actually or verbally), at least occasionally, with some other reinforcer. Once a conditioned reinforcer is no longer paired with another reinforcer, it loses the ability to strengthen behavior.

Although reinforcers typically are construed as stimuli, in some cases it is the opportunity to behave in certain ways that a stimulus affords, not the stimulus per se, that is important. For instance, access to food allows eating and access to a beverage allows drinking. During the 1950s, David Premack developed a response-based model of reinforcement that emphasizes that the opportunity to engage in a more preferred behavior will reinforce a less preferred behavior, a relationship known as the Premack principle. In this context, preference refers to the relative amount of time that an individual will engage in the behaviors if unconstrained. If, for example, an eighth-grade student is given a

choice between playing basketball and doing math problems and spends more time playing basketball, then that behavior is the more preferred one. If this is so, then according to the Premack principle the opportunity to play basketball (the more preferred behavior) will be an effective reinforcer for solving math problems. Parents could use this relation to increase the time that their child spent working on math. That is, in order to play basketball for a given period, the child first must solve a specified number of math problems.

Environmental events may reinforce responses that precede them even if the response does not actually produce the reinforcer. For instance, a pool player shooting the nine ball may say “roll fast, sweetheart” as the nine ball slowly approaches a pocket. The player is apt to repeat the phrase under similar conditions in the future if the ball drops, winning the game, even though there is no plausible mechanism whereby the verbal response could influence the ball or table. This type of reinforcement, termed superstitious or adventitious, may control behaviors that appear counterintuitive. It should be noted, however, that explaining a behavior as being superstitiously reinforced begs the question of how the behavior is actually controlled, unless the nature of the superstitious reinforcement is apparent.

a. Variables That Influence the Effectiveness of Reinforcers Several factors affect the degree to which reinforcing consequences strengthen behavior. Four factors are especially important.

1. The quality and magnitude of the consequence. Stimuli differ in their effectiveness as reinforcers across people and within people across circumstances. Isolating effective reinforcers for clients often is an important part of therapy, and specific procedures have been developed for identifying reinforcing objects and activities. For example, objects that will positively reinforce behavior in a person with mental retardation can be isolated by presenting putative reinforcers (e.g., a car, a whistle, and a toy dog) and determining which, if any, object the person contacts. If, for instance, a child regularly selects and plays with the stuffed dog, it is reasonable to assume that the toy will serve as a positive reinforcer for that person's behavior. The car and whistle might do likewise, but they probably will be less effective as reinforcers. In general, reinforcer effectiveness tends to increase with the magnitude or intensity of a given stimulus. For example, \$20 is a more effective reinforcer than \$2 for most people's behavior. Ultimately, however, reinforcer effectiveness must be directly assessed, not simply inferred.

2. The level of motivation relevant to the consequence. The importance of this variable, which is discussed in detail later, is evident if one considers the reinforcing effectiveness of a given kind of food (e.g., a hamburger) as a function of how recently and how much one has eaten.

3. The delay between the response and its consequence. In the absence of verbal mediation, delaying consequences substantially reduces their effectiveness as reinforcers.

4. The schedule of delivery of the consequence. Many different relations, termed *schedules* (or, if behavior is strengthened, *schedules of reinforcement*), can be arranged between consequences and the events that produce them. For example, under a continuous reinforcement schedule every response produces the reinforcer. Behavioral interventions are typically implemented initially on continuous schedules and eventually the schedule is changed to some type of intermittent reinforcement schedule. The term *intermittent reinforcement* indicates that some instances of the behavior result in reinforcement whereas others do not. Most human interactions occur under intermittent schedules. For example, the gambling of individuals who play slot machines is maintained under an intermittent reinforcement schedule. Not every coin dropped into the slot results in a payoff. In fact, most do not; but eventually one of the coins is followed by a reinforcing payoff. Casino operators program this arrangement, which would be technically described as a *variable-ratio schedule*, because it generates a high rate of responding that persists for a relatively long time, even if no reinforcers are forthcoming.

The schedule of reinforcement that is arranged is one variable that determines response effort, which is the amount of force, exertion, or time required to execute a response, or to earn a reinforcer. Research has shown that (a) response rates generally decrease as response effort increases, (b) behavior weakens more rapidly during extinction as effort increases, (c) individuals will escape from situations that require particularly effortful responding, and (d) individuals prefer lower-effort responding to higher-effort responding. Knowing these effects of response effort can be of benefit in dealing with clients' troublesome behaviors.

As a case in point, broken health care appointments are a major problem in medicine. Something in the neighborhood of 10 to 30% of appointments are broken, and in such cases patients fail to receive needed services, and the schedules of service providers are disrupted. One strategy for reducing the number of appointments that patients miss is to reduce the effort required to keep an appointment. This tack was taken in the 1980s by Pat Friman and his associates, who mailed a parking pass and a reminder to patients who had scheduled appointments at pediatric clinic. Their notion was that the reminder made it easier to remember the appointment and the parking pass made it easier to park, therefore, the effort required to keep the appointment was reduced. This cheap and simple intervention was effective, insofar as it reduced missed appointments by approximately 20%.

As the preceding example illustrates, understanding of schedules can be used to good advantage in dealing with some clinical problems. Consider as a second example, a child diagnosed with autism who often flaps his hands in front of his face during school sessions. The behavior is considered undesirable because it interferes with educational activities. A possible strategy for reducing hand flapping to acceptable levels is to arrange conditions such that access to some reinforcing activity or object depends on the passage of a specified interval during which hand flapping does not occur. If the response occurs, the interval is reset. Initially, only a short time without hand flapping is sufficient to earn reinforcement. Over time, and only when hand flapping is adequately controlled, the interval without responding required for reinforcement is increased. Such procedures, which often are termed *differential-reinforcement-of-other-behavior* (DRO) schedules, have been used to good advantage in reducing various problem behaviors.

But how is it that behavior can be reduced by reinforcement, which by definition always strengthens behavior? The answer is that the unit of behavior that is

reinforced under DRO schedules is an interval of not responding. For instance, if the child in our example were exposed to a DRO 5-min. schedule, 5 min. must elapse without hand flapping for the reinforcer (e.g., teacher attention) to be delivered. If the child is sensitive to this arrangement, 5-min. (or longer) intervals without hand flapping will increase in frequency. When this occurs, incidents of hand flapping will decrease. People can learn through reinforcement to omit as well as to emit particular responses.

2. Punishment

When laypeople think of learning-based procedures for reducing responding, they often think of punishment. Punishment occurs when behavior is weakened by its consequences, which are termed punishers. Many psychologists differentiate between positive and negative punishment, and the basis for the distinction is the same as that for distinguishing between positive and negative reinforcement (see Figure 1). If behavior is weakened because such responding adds something to an individual's environment, positive punishment is involved. If, however, behavior is weakened because such responding removes (or decreases the intensity of) some stimulus, the procedure is termed negative punishment.

Like reinforcers, punishers can be conditioned or unconditioned. The same processes that establish stimuli as conditioned reinforcers are also effective in establishing neutral stimuli as conditioned punishers. A common example of a conditioned punisher is the word "no." Without any prior training, a toddler will not have any specific reaction to "no." However, early in the life of most English-speaking people, the word is paired with unconditioned punishers and is thereby established as a conditioned punisher. For example, a young child may touch an electrical outlet in the presence of his parents. A quick, forceful grab of the child's arm (an unconditioned punisher), accompanied by a stern "no," will likely decrease the probability of the child touching outlets in the future. It will also be an initial step toward establishing "no" as an effective punisher. Of course, several pairings with another punisher may have to occur before the word alone has a response-reducing function. Once it does, the word can be used as a positive punisher to reduce various undesirable behaviors emitted by the child.

Relatively few people object to parents saying "no" to prevent their child from electrocution. But there has been considerable controversy about the use of punishment in therapeutic settings. Many therapists advocate the use of reinforcement-based procedures and consider

punishment-based procedures unnecessarily intrusive. Others maintain that clients have a right to effective interventions and, if reinforcement-based procedures have failed, then other interventions that have been proven efficacious in similar cases, including punishment, should be used. A substantial literature documents the efficacy of punishment-based procedures when other interventions have failed, although applications have been largely limited to dangerous behaviors, such as self-injury, exhibited by people with developmental disabilities in controlled settings. When punishment is used, it typically is incorporated into an intervention package that also includes reinforcement procedures.

In general, negative punishment is better accepted than is positive punishment. When negative punishment is arranged, the consequence of an undesired behavior is that a person loses access to something of value. For example, exceeding the speed limit may result in a financial loss when the cost of a speeding ticket is paid. If the person is less likely to speed in the future as a result of receiving a ticket, negative punishment has occurred.

Two common procedures based on negative punishment are timeout and response cost. Timeout refers to the removal of access to positively reinforcing objects and activities for a preset time when a specified behavior occurs. For instance, when a child has broken a family rule (e.g., hit a sibling), the parents may arrange timeout by placing the child in a corner of the room with no access to interaction or toys for 3 min. If the behavior is weakened, negative punishment has occurred. Response cost typically involves removal of a specified amount of a reinforcer when an unwanted behavior occurs. Being fined for a traffic violation as described earlier is an example of response cost.

Overcorrection is another procedure based on punishment principles. It is based on the notion, originally advanced by David Premack and sometimes included as part of the Premack principle, that forcing an individual to engage in a less preferred behavior as a consequence of a more preferred behavior will punish the more preferred behavior. As an example of overcorrection, a child who has had a tantrum and thrown food on the dining room floor (a more preferred behavior) might be required to pick up the food and scrub the floor (a less preferred behavior). This procedure is apt to reduce the future likelihood of food being thrown and is appealing to many people because it is restitutional in nature—the child repairs the damages caused by inappropriate behavior. The primary problem with overcorrection is that it can be difficult to force people to engage in nonpreferred activities.

Critics sometimes argue that the effects of punishment are short lived. This may or may not be true and depends on specifically how punishment is arranged. Moreover, the effects of reinforcement also are short lived, in the sense that the changes in behavior produced by reinforcement eventually disappear when reinforcement no longer occurs. In general, operant conditioning procedures affect behavior only so long as they are in place, regardless of the specific nature of the procedures.

Other criticisms are that punishment produces undesirable emotional behavior, as well as escape from and avoidance of the individual who delivers the punisher. In addition, punishment may produce a generally passive and unresponsive individual. Although all of these adverse effects may occur, they are most probable with severe positive punishment. Mild punishment, both positive and negative, is a common and accepted part of human interactions that also occurs in many therapeutic contexts. For instance, a therapist treating a depressed client may say, “no, that’s no really true – you’re not that way at all” when the client describes him- or herself as helpless and unwanted. The intent is to reduce the future likelihood of the client making such statements. If the intent is realized, punishment has occurred, and the client has probably benefited.

In general, the same kinds of variables that influence the effectiveness of reinforcement also determine the effectiveness of punishment. Therefore, maximal response reduction is apt to occur when strong punishers are delivered after each occurrence of an undesired response. Making available an alternative and appropriate response that produces the same reinforcer that maintains the undesired response also increases the effectiveness of punishment. In practice, it often is difficult to arrange effective punishment for troublesome behaviors. For example, many people drive over the speed limit, although doing so may result in expensive tickets. They do so because the likelihood of receiving a ticket for a given instance of speeding is low, and the cost of the ticket is not great relative to most people’s income. If every motorist received a ticket costing one month’s pay each time they drove over the speed limit, and if this relation were assured, there would be few speeders.

3. Extinction

As long as a behavior produces an effective reinforcer, that behavior will recur. However, when responding no longer produces the reinforcer that once maintained it, the behavior eventually ceases. This process, and the pro-

cedure used to arrange it, is called extinction. The example described previously in which a child’s striking of a desk with a pencil was eliminated by having teachers stop attending to the behavior is an example of extinction. Reducing abusers’ intake of heroin by treating them with the drug naltrexone is another example of extinction. Here, naltrexone blocks the subjective and physiological effects of heroin, so that when a person takes the drug, there are no reinforcing consequences. Under these conditions, heroin self-administration eventually ceases. A serious problem, of course, is that individuals can stop taking naltrexone, ending the pharmacologically induced extinction.

Responses that have an extended history of reinforcement are likely to persist for a substantial period despite failing to produce a reinforcer. In fact, when extinction is first implemented, an individual may respond at higher rates or intensities than usual. This is known as extinction-induced bursting. Emotional responding and increases in the variability of behavior also commonly occur during extinction. As examples of these phenomena, consider what happens when a person puts a dollar in a vending machine, pushes a button in a manner that historically has produced a favored soda, and gets nothing. She or he is likely to curse, pound the machine, and push other buttons. The individual may even put more money in the machine. Eventually, however, machine-related behavior ceases.

The overall persistence of responding when reinforcement is no longer available is called resistance to extinction and is one measure of response strength. Even when responding falls to near-zero levels during extinction, the behavior remains in the organism’s repertoire and may return quickly to previous levels if reinforcement once again becomes available. More interesting, when motivation relevant to a particular kind of reinforcer is high and responses that recently have produced that reinforcer are unavailable or ineffective, previously extinguished responses often occur. This phenomenon is termed resurgence.

Avoidance responses often persist for long periods, even indefinitely, in the face of extinction. In large part, this is because it is difficult for an individual to ascertain that conditions have changed. Successful avoidance responses prevent an event from occurring, and that event does not occur during extinction, unless extinction is arranged so that the event that served as a negative reinforcer is now presented repeatedly regardless of whether the historical avoidance response occurs or not. Under the latter condition, responding weakens relatively quickly.

4. Complex Consequence Systems: Token Economies

Both in everyday and therapeutic settings, consequences typically do not occur as single events in isolation. Instead, complex consequence systems may be implemented for several different behaviors simultaneously. One of the most common and effective therapeutic consequence systems is the token economy. Ted Ayllon and Nathan Azrin developed token economies in the mid-1960s as an intervention for chronic psychiatric patients. Since then, token economies have become widely accepted and are included as a standard part of many inpatient hospital treatment programs. A token economy typically allows a person to earn rewards and privileges (positive reinforcers) for emitting appropriate behaviors, such as attending therapy sessions and attending to personal hygiene. Typically, privileges are lost (i.e., negative punishment is arranged) when inappropriate behaviors, such as hoarding items or stealing, occur.

A token economy has three vital components: (a) tokens, (b) backup reinforcers that can be obtained with a certain number of tokens, and (c) schedules for reinforcement, punishment, and token exchange. The tokens function as conditioned reinforcers. Conditioned reinforcers have no intrinsic value, but they acquire the capacity to function as positive reinforcers because they can be exchanged for highly preferred items or for access to preferred activities. Generally, a person may earn tokens throughout a day or week and then trade them in for backup reinforcers at a preset exchange time and rate. Once appropriate behavior is established under stringent conditions, schedules can be altered to better approximate those that clients will encounter outside the inpatient setting.

B. Antecedent Influences on Behavior

The previous sections have considered how events that occur after operant behaviors (i.e., consequences) affect such responding. The following two sections discuss how operant behaviors are affected by prior, or antecedent, events.

1. Stimulus Control

As Thorndike suggested with the law of effect, the effects of reinforcers and punishers are relatively situation specific. That is, the behavioral effects of reinforcement (or punishment) that occurs in one context may not be evident in another context. Because of this, an individ-

ual's behavior often differs substantially across settings. Consider our previous example of a girl who has learned to say "Da Da" when picked up by her father. Initially, the same response might occur when another person, perhaps her mother, picked her up. However, before long mom would not evoke "Da Da," although dad would continue to do so. Another verbalization, probably "Ma Ma," might well occur when the mother picked up the daughter. In this situation, the person who holds her determines what the baby says and the child's verbal behavior is controlled by an antecedent stimulus, that is, by an event (i.e., the presence of the father or mother) that occurs before the behavior.

In general, stimulus control is evident when some characteristic of a response (e.g., its rate, magnitude, or probability of occurrence) differs in the presence and absence of a particular stimulus. Stimulus control can be excitatory or inhibitory. In the former case, the likelihood of the response occurring is higher in the presence of the stimulus than in its absence. In the latter, the likelihood of the response occurring is lower in the presence of the stimulus than in its absence.

Stimulus control is ever present in everyday life. It can be established through respondent conditioning, but most of the stimulus control that is evident in human behavior occurs as a result of operant conditioning, in which the consequences of behavior differ in the presence and absence of a stimulus. For example, in the example of the girl responding differently to her two parents, saying "Da Da" was reinforced (probably by attention, praise, and cuddles) in the presence of the father, but not the mother. Saying "Ma Ma," in contrast, was reinforced when mom, but not dad, picked up the child. As a result, the two people evoked different responses in their daughter.

In the context of operant conditioning, excitatory stimulus control typically occurs with discriminative stimuli. The term discriminative stimulus (S^D) is used to refer to a stimulus that (a) given the momentary effectiveness of some form of reinforcement, (b) increases the frequency of occurrence of a particular behavior because, (c) historically, that kind of behavior was more successful in producing reinforcement in the presence of that stimulus than in its absence. The mother and father are S^D s in our example of the child learning to talk. Other examples of S^D s controlling behavior include saying "4" when presented with " $2 + 2 = __$," beginning to play a musical instrument when a conductor's baton is raised, and taking food from an oven when the timer rings. In each case, doing so has "paid off" (i.e., been reinforced) in the past. A history of success in the presence

of an S^D gives that stimulus the capacity to control behavior. Behaviors controlled by S^D s continue to be so controlled only if reinforcement is at least occasionally arranged for those behaviors. If not, stimulus control eventually disappears.

If the historical consequences of behavior are punishing in the presence of a particular stimulus, then that stimulus is likely to acquire inhibitory control over such responding. Consider, for instance, two college students at a party who are talking about their favorite TV show. An influential professor, who in the past has criticized (punished) their comments about TV, approaches them, and they stop talking about TV. This is inhibitory stimulus control—if the professor were not around, comments about TV would occur more frequently. Stimuli present during extinction, as well as during punishment, also may acquire inhibitory control over behavior.

In clinical situations, it is often important to identify the S^D s that operate in a client's environment and, if possible, to manipulate those stimuli to evoke appropriate behavior. Assume, for instance, that a functional assessment revealed that a child made rude noises in class primarily because the student sitting in the next seat laughed appreciatively when such sounds occurred. Given this, it is reasonable to assume that the laughter reinforces the noisemaking, and that the child who laughs is an S^D for the other child's disruptive behavior. If so, moving the noisemaker to a seat where the other child could not be readily seen would be a simple, and probably effective, intervention. It would be made even stronger if the noisemaker was seated beside another classmate who was an S^D for working quietly on tasks.

In some cases, establishing appropriate stimulus control is an important therapeutic goal. Consider, for example, the treatment of a convicted date rapist. It may be the case that such an individual has not learned to respond appropriately to social stimuli, such as a potential partner moving away, or saying "that's enough." Persisting in the face of such stimuli may have resulted in sexual gratification in the past. Establishing appropriate stimulus control of sexual behavior would be a necessary part of the treatment of the rapist. Practical and ethical considerations, however, probably would make this task relatively difficult to accomplish, and verbal mediation or contrived feedback in controlled settings, not direct exposure to consequences in a dating setting, would have to be used to establish stimulus control. A potential problem with such procedures is that the stimulus control established in the therapeutic setting might not generalize to actual dating situations.

In some cases, simply presenting a stimulus under conditions where responding is reinforced may be insufficient to establish stimulus control. Suppose you were trying to teach a child how to learn math facts with flashcards. Your instruction might include presenting a flashcard (e.g., $10 \div 2 = \underline{\quad}$), requesting the answer, and providing error correction or praise, depending on the response. You would probably consider the child successful if the answer were correct following three consecutive presentations of the card. In addition, you would probably assume that the child "knew" the answer to " $10 \div 2$." Suppose, however, that the child merely guessed at the correct answer initially and subsequently provided it not in response to the actual numbers printed on the card, but instead in response to the size and color of the numerals. Therefore, the answer "5" would be given to any set of two black numbers printed in 12-point font, not just to " $10 \div 2 = \underline{\quad}$." This example illustrates the problem of "attention" in stimulus control. Individuals occasionally respond to unintended features of an antecedent stimulus, such that effective stimulus control is not developed. To counteract this effect, it is crucial to correlate differential consequences with the presence of the specific antecedent stimulus features that should control the behavior. In our example, the child would need to be exposed to other flashcards bearing problems different from " $10 \div 2 = \underline{\quad}$," but of the same size and color. The response "5" would be reinforced only when it was appropriate to the numbers presented, and in this way attention could be focused on that dimension of the flashcard, which is the sole relevant dimension in this example.

As this example illustrates, discrimination training can be used to establish behavior so that it only occurs in the presence of a specific S^D . In discrimination training, only instances of the target behavior that occur in the presence of the target S^D are reinforced. All other behaviors are placed on extinction in the presence of the S^D . In addition, the target behavior is placed on extinction in the presence of all antecedent stimuli except the S^D . The degree to which you reinforce only the target behavior determines how "tight" the stimulus control becomes (i.e., the degree of stimulus discrimination). For example, a classroom in which student questions are answered following both hand raising and calling out would most likely appear somewhat chaotic. If, however, the instructor only answered the questions of students whose hands were raised, and the answers were reinforcing, then the class would appear more orderly. In other words, tight stimulus control over the students' behavior would be achieved.

In some cases, consequences occur only when two or more stimuli, or stimulus dimensions, are present, and as a result a conditional discrimination is formed. For example, a child asking (behavior) his parents (antecedent) for money (consequence) only on or after payday (conditional antecedent) constitutes a conditional discrimination. The behavior occurs only when both antecedents (i.e., parents and payday) are present because, historically, that was the only time that the behavior was reinforced.

2. Antecedent Stimulus Classes

The stimulus control of human behavior is subtle and complex. In many cases, a number of different stimuli control equivalent behaviors in the same person. That is, they are members of the same stimulus class and are functionally equivalent.

One way in which different stimuli can acquire the same function is through stimulus generalization, which can be conceptualized as the counterpart to stimulus discrimination. Generalization occurs when antecedent stimuli that share a physical resemblance with an established S^D control the behavior evoked by that S^D . For example, suppose a child learns to say “dog” in the presence of a dog. The child might later say “dog” in the presence of a cat, not because this behavior was previously reinforced, but instead because dogs and cats share certain physical similarities (e.g., four legs, fur, tails).

A second way in which stimuli can come to control the same behavior is by being correlated with the same consequences for that behavior. For example, a stop sign, a red traffic light, and a traffic control officer with an outstretched palm may constitute a functionally equivalent class of S^D s for stopping a car. These physically different antecedents acquired the same stimulus control properties because of a shared history of reinforcement for stopping.

A third way in which functionally equivalent stimuli can be established is through a phenomenon known as stimulus equivalence. Stimulus equivalence is thought to be a product of learning certain conditional discriminations. Specifically, individuals learn that $A = B$ and $B = C$. As a result of such learning, the transitive relation “ $A = C$ ” automatically emerges, although it is not specifically trained. After the relation emerges, the stimuli A and C are functionally equivalent. For example, a person may learn that Jessie is a Harvard graduate, which can be construed as learning $A = B$ (Jessie = Harvard graduate). That same person may also learn that Harvard graduates are exceptionally intelligent people, which can be construed as $B = C$ (Harvard

graduate = very intelligent person). As a result of learning these two relationships, the person would “automatically” know that Jessie was a very intelligent person and would respond to her by emitting whatever behaviors that person historically had learned to emit in the presence of “very intelligent people.” Similar behaviors would be occasioned by anyone described as a Harvard graduate and, depending on the history of the person responding to them, a wide range of behaviors may occur in their presence. Some people, for instance, learn to avoid highly intelligent people. Others ridicule them, whereas some seek them out as companions. Stimulus equivalence plays an extremely important role in determining how humans behave, and researchers have demonstrated the relevance of the concept to areas as broad as language development and adult psychopathology.

3. Fading

A common intervention that achieves its effects due to stimulus control is fading. The purpose of fading is to transfer stimulus control from an S^D that currently evokes the desired behavior to a new S^D that should evoke the behavior. In a fading procedure, the S^D for a particular behavior is gradually removed while the new S^D is gradually introduced. Thus, the target behavior occurs throughout the procedure, only the S^D s are altered. This can be beneficial in that the individual frequently contacts reinforcement for the behavior. There are two general categories of fading.

Prompt fading occurs when a response prompt is physically removed from an individual’s environment. For example, an individual in rehabilitation for a traumatic brain injury might initially require physical assistance to walk. In this case, the individual is walking, although dependently, at the onset of rehabilitation. As therapy progresses, the physical assistance is gradually removed so that the patient walks independently. In this example, stimulus control was transferred from the S^D of physical guidance to the S^D of physical independence through prompt fading.

Stimulus fading occurs when a stimulus prompt is physically removed from an individual’s environment. For example, a teacher might use ruled (lined) paper when teaching a child how to write. The lines could eventually be lightened and/or spaced closer together such that the child learns to write smaller and straighter text. In this case, the child’s writing is reinforced throughout the fading procedure. Stimulus control was transferred from the S^D of dark/wide lines to lighter/narrower lines through stimulus fading.

4. Motivational Control

One factor mentioned, but not discussed, in the section dealing with variables that influence the effectiveness of reinforcers, is the level of motivation relevant to the consequence. In operant conditioning, “motivation” is often explained in terms of a behavior’s reinforcer. That is, if an individual is “motivated” to perform a behavior, then there is most likely a reinforcer available for that behavior. Although this approach has been useful, an adequate account of motivation must include antecedent influences on behavior. The previous section described how events that occur immediately before behavior can influence responding. However, some events that occur immediately or long before a response can also affect its occurrence, as well as the value of its consequences (i.e., motivation). Such events are the focus of the next section.

5. Establishing Operations

In general, an establishing operation (EO) is an antecedent event that produces two effects. One is a function-altering effect, which momentarily changes the value of a reinforcer or punisher. The other is an evocative effect, which momentarily alters the likelihood of occurrence of behaviors that have been previously reinforced or punished. As an example of a function-altering effect, a period without any interpersonal interactions might make a conversation more reinforcing. In other words, we might say that deprivation (i.e., lack) of social interaction establishes a conversation as a reinforcer. Social deprivation probably also would have an evocative effect: in addition to establishing conversation as a reinforcer, it also increases the probability of behaviors that have been previously reinforced with attention (e.g., making a telephone call to a friend). Thus, EOs alter the effectiveness of reinforcers (or punishers) and alter the likelihood of occurrence of behaviors that have produced those reinforcers in the past.

It is important to note that an EO can make an event either more or less reinforcing (or punishing). For example, food deprivation increases the reinforcing effectiveness of food, but free access to food reduces its reinforcing effectiveness. It is also important to note that an EO’s effects usually are not permanent. EOs characteristically produce relatively short-lived effects; such is the nature of “motivation.”

EOs can be either conditioned or unconditioned effects. Unconditioned establishing operations (UEOs) produce their effects in the absence of any particular learning history. A clinically relevant example of a UEO is the duress that a person who is physically dependent

on heroin experiences during withdrawal from the drug. During the highly unpleasant withdrawal syndrome, the effectiveness of heroin as a positive reinforcer increases, as does the likelihood of occurrence of behaviors that have produced heroin in the past.

In contrast to UEOs, conditioned establishing operations (CEOs) are developed through several different associative processes. That is, they are learned. An example of a CEO is the host of a TV game show saying to the audience, “I’ll give \$1,000 for every broken pencil you can show me.” Following that statement, but not prior to it, broken pencils would have substantial reinforcing value. Behaviors likely to produce broken pencils (e.g., rummaging through purses), therefore, would be far more likely to occur.

One example of a clinical intervention that most likely achieves its effects via EOs is noncontingent reinforcement (NCR). NCR has recently been used to treat the undesired behavior (e.g., self-injury) of individuals with developmental disabilities. Before NCR is implemented, the reinforcer responsible for maintaining the behavior is identified through functional assessment. This reinforcer is subsequently delivered to the individual on a time-based schedule regardless of whether or not the undesired behavior occurs. In other words, the individual receives “free” access to the reinforcer. Hence, the “motivation” to engage in the behavior is reduced. In this case, the free delivery of the reinforcer is an EO that results in a reduced probability of undesired behavior.

Methadone maintenance treatment of heroin abusers is another example of a treatment with an EO component. Methadone “substitutes” for heroin, reduces the likelihood of withdrawal occurring, and decreases the reinforcing value of heroin and the likelihood of occurrence of behaviors that in the past produced heroin. Because many of those behaviors are harmful to the heroin abuser, as well as to other members of society, this is a desirable effect. So, too, is reduced contact with heroin.

C. Verbal Behavior

Humans are like other animals in many regards, but verbal behavior makes humans unique. Verbal behavior is the term that B. F. Skinner used to refer to what many people call language. In his 1957 book, *Verbal Behavior*, and in other writings, Skinner emphasized that talking, writing, and signing is operant behavior that affects the world indirectly, through the mediation of someone else’s behavior. In contrast, nonverbal operant behavior affects the world directly. For example, consider a thirsty 3-year-old girl who is sitting in the living

room playing with her father. She can gain access to water by walking to the kitchen, getting a glass, and filling it with water from the tap. She can achieve the same outcome by saying, "Dad, please get me a glass of water." In the first case, the girl's actions directly produce water. Therefore, her behavior is nonverbal. In the second case, the girl's actions cause her father to behave in a way that produces water. Because of this mediation by another person, her behavior is verbal.

Verbal behavior is like nonverbal operant behavior in that it is acquired and maintained as a result of its effects on the environment. The specific environment that is affected by verbal behavior is a social one comprising other people. Verbal behavior is developed and maintained because it is reinforced by the actions of a social community that is taught, although not formally, to reinforce such behavior. Because different people reinforce different patterns of verbal responding, relatively strong audience control of verbal responding is common. As an example, consider how differently most people talk to friends, parents, lovers, employers, clergy, and police officers.

In general, verbal behavior allows speakers to ask for things (e.g., "Please get me a glass of water") and to describe the environment for others (e.g., "The tap in the kitchen isn't working"). Asking for things benefits the speaker, who often gets them, and may benefit the listener, insofar as they provide an indication of how the speaker is likely to behave. A speaker's description of relations observed in the environment, however, is apt to be especially useful for listeners. These descriptions may involve only stimuli ("When the stove is red, it's very hot"), antecedent stimuli and responses ("When the phone rings, answer it"), or antecedent stimuli, responses, and consequences ("When you hear a Beatles' song, be the first person to call in, and win \$5,000"). Skinner called descriptions of relations among stimuli and responses rules.

Rules specify relations among stimuli and responses and usually change the behavioral function of those stimuli. For instance, after hearing a disc jockey say, "When you hear a Beatles' song, be the first person to call in, and win \$5,000," a person who hears a Beatles' tune may well call the radio station. Absent the announcement, however, calling the station is highly unlikely. In this example, the announcement gives the Beatles song a capacity to control behavior similar to that of an S^D . The song is not an S^D , however, because the person has no previous history of calling in and winning. What she or he has, instead, is a history wherein following rules is generally productive. Whether or not a par-

ticular rule is followed by a given individual depends in large part on her or his prior experience with respect to the rule giver (and similar people) and the accuracy of similar rules provided in the past. We learn through operant conditioning to follow rules or to refrain from following them. For instance, a parent says to a child, "Don't touch the stove; it's hot and you'll get burned." Despite the rule, the child touches the stove and gets burned. As a result of the correspondence between real and described consequences, the future likelihood of rule following increases. If, however, the child touches the stove but is not burned, the future likelihood of rule following decreases.

The most important characteristic of rules is that listeners can learn from them. For example, a person can acquire new behavior, with very little effort, through rules such as "To get to the barbeque at my house, turn left on Main, turn left at the second light, and it's the fourth house on the right, 3117 Market Street." Without the rule, the listener would have to learn appropriate behavior through direct exposure to the environment. Imagine how difficult it would be to find 3117 Market Street in a large city with no map or directions. A rule makes doing so much easier. In fact, rules mimic the effects of classical and operant conditioning by allowing people to be affected by environmental relations that they have never directly experienced. Rule-governed behavior is of crucial importance to humans because it (a) provides for very rapid behavior change and (b) enables people to behave effectively without requiring direct exposure to environmental events that might prove harmful or ineffectual. Rules also can increase the effectiveness of delayed consequences. These are important, and often beneficial, effects.

Rules can interact with the consequences of behavior in three major ways. First, as noted earlier, rules can alter the behavioral function of consequences. A person who is exercising to improve health in the presence of a personal trainer may be told, "No gain without pain, make it hurt" while doing bench presses. This rule might alter the function of mild pain in the pectorals from punishing to positively reinforcing. In many cases, people who behave in the face of what appear to be unpleasant consequences are following rules that modify the behavioral function of those consequences.

Second, rules can alter the range of behaviors that are available to contact naturally occurring consequences. A depressed person who is repeatedly told to "Call your sister; she'll be glad to hear from you" probably is more likely to make the call, during which any of a variety of desirable verbal responses might be reinforced.

Third, rules can alter a person's sensitivity to consequences that are contacted. In general, if a rule accurately specifies the consequences of a particular kind of behavior, then sensitivity to those consequences increases. If, however, the rule is inaccurate with respect to actual consequences, then sensitivity to those consequences decreases. Rules can foster a kind of behavioral rigidity, wherein a person responds in a manner consistent with the rule, almost regardless of the consequences of so doing. Because of this, it is crucial that accurate descriptions of operant interventions be provided before those interventions are put in place. A token economy, for example, is apt to produce faster and greater improvements if the schedules it comprises are clearly stated to participants than if they are not.

Rules can be covert as well as overt; "talking to one's self" is behavior that is not fundamentally different from talking aloud. Rules also can be self-generated as well as provided by others. In either case, they sometimes provide inaccurate descriptions of relations among events in a person's environment. For instance, a person with anorexia may say, "When I weigh over 100 pounds, people think I'm fat and ugly." In fact, this is untrue. People think (i.e., say) that the client is seriously underweight at 100 pounds and that 130 would be a far better, and more attractive, weight. Were the higher weight to be attained, the actual consequences are very different from those described by the client. By following an erroneous rule, however, the client will never encounter those consequences. Moreover, even if they are encountered, other "bad" rules might change their function. If, for instance, the client got up to 125 pounds and several friends offered compliments, the client might well say "Everyone humors a fat person," or "That's what they say to my face; behind my back they're laughing." Either rule would prevent the compliments from functioning as a reward.

Most humans are verbal organisms, and most outpatient therapies are based heavily on verbal interactions between patients and therapists. In many cases, the aim of those interactions is to alter the client's rule-governed behavior, although they are not always conceptualized in this manner. In recent years, Steven Hayes and his colleagues have developed a comprehensive analysis of the role of verbal behavior, and of rules specifically, in human psychopathology. For example, Hayes and Ju offer the following explanation of suicide:

The purposeful act of taking one's own life is an instance of rule-governed behavior based on derived relations involving time and the verbal construction of

expected consequences of action ... For example, "death" can participate in if ... then verbal relations with many other events that have acquired desirable functions both directly and through the transformation of stimulus functions tied to direct events, such as, "If I am dead, I will no longer suffer, everyone will be happier, they will all be sorry for what they've done to me, I will finally be at peace," and so on ... [Death therefore] becomes a verbal consequence of importance ... Once death becomes a verbal consequence of importance, rules can be followed that give rise to it ... However, the impact of such rules as "If I die, then I will be at peace" depends upon the degree to which they conflict with other functional rules, such as "Suicide is an offense against God." It is for this reason that the psychotherapies and religious institutions around the world strive to create meaning, values, and purpose in the lives of individuals.

Hayes and his colleagues have developed a therapeutic technique, "acceptance and commitment therapy" (ACT), that is intended to overcome unhealthy forms of verbal control and to foster healthy forms. Although relatively new, ACT appears to hold promise for treating a variety of serious behavioral problems in clients for whom direct control of the environment is impossible.

Although altering the rules that an individual generates and follows can be a valuable therapeutic technique, it is important to realize that these activities are themselves influenced by their consequences. If there is nothing in a client's everyday social or nonsocial environment to support (i.e., reinforce) appropriate rule-governed behavior, then such behavior usually will not endure over long periods. In some cases, naturally occurring consequences in the client's everyday environment are sufficient to support appropriate behaviors that emerge. In other cases, however, contrived consequences may be needed. A significant problem in providing treatment for outpatients is arranging such consequences.

III. APPLICATIONS AND EXTENSIONS

The behavior of essentially all people is sensitive to operant conditioning, and procedures based on operant conditioning have proven useful in dealing with an enormous range of problems in clients with a wide variety of diagnostic labels. Many of the early therapeutic applications of conditioning principles involved children or people with developmental disabilities, and a few skeptics have argued that consequences do not

affect the behavior of verbal adults. This contention is patently untrue. What is true, however, is that it often is difficult or impossible to arrange effective consequences for the behavior of adult humans unless they are in tightly controlled settings (e.g., inpatient treatment wards), which rarely occurs. Procedures based on operant conditioning obviously can be effective only when they can be consistently implemented, and they cannot be effectively implemented for some clients in some settings. When this occurs, therapists must attempt to alter rule-governed behavior and hope that naturally occurring consequences are sufficient to maintain any appropriate behaviors that are generated.

Moreover, in verbal individuals rules can diminish sensitivity to consequences. This may make it appear that these individuals are not affected by the consequence of their actions but, in fact, they are—the primary reason that they follow rules today is that behaving in similar fashion paid off in the past. Rule-governed behavior, which is indirectly controlled by consequences, is just as important as is behavior directly controlled by its consequences. Effective therapists work to change the two in parallel.

With certain clients, procedures based on operant conditioning may be more effective as adjuncts than as primary treatments. For example, antipsychotic drugs typically are first-choice treatments for schizophrenia and related conditions, even though operant interventions are useful in dealing with specific behavior problems in individuals with these conditions. Combined pharmacological and conditioning treatments also are useful in treating behavior problems in people with conditions other than schizophrenia, including depression and attention-deficit/hyperactivity disorder (ADHD).

Client diversity is not a consideration with respect to procedures based on operant conditioning in general, although appropriate sensitivity to this issue is required to evaluate the acceptability and probable effectiveness of specific interventions. Some clients object to interventions based on the manipulation of consequences as unnatural, controlling, or contrived, and such objections must be overcome if treatment is to have any hope of success.

IV. EMPIRICAL STUDIES

A great deal has been written about operant conditioning and clinical interventions based on it, and many research articles have been published. For example, a recent search of the psychological literature

(using the PsycINFO database) with the keywords “operant conditioning” yielded 7,844 publications. It is very difficult to summarize this vast literature, save to point out that procedures based on operant conditioning are useful in treating a wide range of behavioral problems in many different kinds of clients in a variety of settings. As noted previously, results of a 1995 evaluation of the entire treatment outcome literature in clinical psychology indicated that the vast majority of successful interventions rely heavily on the principles of operant conditioning.

Such interventions have been used to good avail in dealing with behavioral problems in children and adults without diagnostic labels, in people with developmental disabilities, and in individuals with various mental disorders (e.g., ADHD, schizophrenia, depression, anxiety disorders, eating disorders). People with brain injuries and other medical problems (e.g. obesity, hypertension) also have responded favorably to operant interventions. Of course, not all clients respond favorably to a given intervention, and no client is helped by an ill-conceived treatment, regardless of its alleged theoretical basis. Over the years, poorly trained and misguided caregivers have placed children in closets for long periods as a kind of “timeout.” Others, equally misguided, have deprived people with mental retardation of clothes and food, which they had to work to earn back, as a kind of “reinforcement.” Such treatments cannot be justified and would not be recommended by any legitimate clinician.

V. CASE ILLUSTRATION

Jack is a 15-year-old male diagnosed with ADHD. He currently participates in outpatient therapy with his parents to address a variety of their concerns regarding his behavior. The presenting concerns include inappropriate behaviors at home (e.g., noncompliance, disrespectful language, breaking curfew) and at school (e.g., noncompliance, fighting, failure to complete homework). Most of these inappropriate behaviors have developed and worsened in the 2 years since Jack started high school.

The behavior therapist has decided to use a token economy to both increase appropriate behaviors (e.g., homework completion, compliance) and decrease inappropriate behaviors (e.g. fighting, breaking curfew). The token economy includes the following components: (a) tokens, (b) backup reinforcers, and (c) schedules for token delivery and removal and an exchange

rate. In addition, the token economy provides consequences for clear, observable behaviors and provides unambiguous criteria for delivering those consequences. The token economy was developed through collaboration among the parents, therapist, and Jack. Jack's parents had final approval on the details of the treatment program.

The tokens used for Jack are points recorded in a check register by his parents. Only his parents can deliver or remove points, and they keep track of all delivery and exchange. Jack can earn a preset number of points each time he completes certain behaviors and he can lose a preset number each time he engages in other behaviors (see table 1). Points are exchanged on Saturday morning for a variety of activities and privileges (i.e. backup reinforcers) for Saturday and the next week. The list of these backup reinforcers was generated by having Jack provide a list of items and activities for which he would like to work, which ensured a variety of potentially effective reinforcers. His parents then either eliminated items (e.g. a new stereo) or approved items (e.g., watching movies) from Jack's list and established a point exchange rate for the Saturday exchange (see table 1). Each week in session the therapist reviewed the targeted behaviors and assessed Jack's progress and helped the family make changes in the token economy when necessary. Jack's progress was tracked by counting the number of points earned each week and counting the number of appropriate and inappropriate behaviors occurring each week.

The baseline condition indicates that Jack had high rates of problem behavior before the implementation of the token economy. The first week of the operant treatment resulted in a decrease in problem behavior and an increase in appropriate behaviors. Jack earned several points and was able to trade them in on the first Saturday for a delayed curfew (60 min.) on Saturday night and the opportunity and funds to see a movie. His progress continued in the next 3 weeks of treatment with even greater decreases in problem behaviors. The family continued to use a version of this token economy successfully and eventually Jack's behaviors remained at a satisfactory level as the treatment system was stopped.

Several principles of operant conditioning are evident in this case example. First, there is a schedule of reinforcement included in the token economy. Occurrences of an appropriate target behavior resulted in a positive reinforcer in the form of points delivered under a specified schedule. These points are conditioned reinforcers because they have no inherent reinforcing value but acquire such value because they can be exchanged for the backup reinforcers (i.e., items from the menu). A

TABLE 1
Token Economy Targets, Point Schedule,
and Reinforcer Menu

<i>Target behaviors</i>	
A. <i>Complete homework assignment</i> : An assignment is defined as all task materials due the next day in one particular class (e.g., algebra, biology). The assignment must be completed by 9:30 p.m.	
B. <i>Meeting curfew</i> : Jack must be inside the house by 9 p.m. with no arguing, complaining, or prompting from his parents.	
C. <i>Following instructions</i> : If Jack is instructed to do something (e.g., set the table, clean up your room, put away your shoes, lower the stereo), he will complete the task (e.g., turn down the stereo) or initiate completion of the task (e.g., cleaning room) within 5 min.	
D. <i>Fighting</i> : Fighting is any activity that is called fighting by school personnel.	
E. <i>Using respectful and disrespectful language</i> : Respectful language includes "please," "thank you," "yes/no maam/sir," and other phrases in an appropriate tone and volume of voice. Disrespectful language includes name calling and agreed-on statements (e.g., "shut-up," "leave me alone," "no way.")	
<i>Point schedule</i>	
<i>Appropriate behavior</i>	<i>Points earned</i>
Completion of each homework assignment	1
In house by 9 p.m. (curfew)	3
Following instructions within 5 min.	1
Respectful language	1
<i>Inappropriate behavior</i>	<i>Points lost</i>
Fighting	15
Disrespectful language	5
<i>Back-up reinforcer menu</i>	
<i>Item/activity</i>	<i>Point cost</i>
Extended curfew (1 hour/1 day)	40
Movie (paid by parents)	25
Driving range with Dad on Sunday	25
\$5 and trip to video arcade	25
Rent 2 movies	15
(This menu will be edited every 2 weeks)	

variety of reinforcers, selected by Jack, is available to ensure high quality reinforcers and to prevent satiation (i.e. maintain motivation). The number of points gained or lost for performing a behavior depends on the importance of that behavior. Because each occurrence of an inappropriate target behavior resulted in the immediate

removal of points, a schedule of negative punishment is in effect. Finally, the relations between behavior and its consequences are explained carefully to Jack in the interest of generating appropriate rule-governed behavior and maximizing the sensitivity of his behavior to its consequences.

VI. SUMMARY

“Operant conditioning” does not refer to a single therapeutic technique. Instead, the term refers to an important form of learning, or conditioning, in which behavior is primarily controlled by its consequences. The consequences of a particular kind of behavior in one setting can either increase or decrease the probability of such behavior occurring in similar settings in the future. Descriptions of the consequences of behavior, called *rules*, can have similar effects. A great deal is known concerning how consequences affect behavior, and this knowledge has been put to good use in designing interventions shown to be effective across a wide range of client populations, behavior problems, and settings.

quences of traumatic injuries to the brain (such as an injury sustained in a motor vehicle accident, or as a result of a gunshot wound). TBI is contrasted with other forms of brain pathologies, such as tumors, strokes, infections, and degenerative conditions, that do not result from a sudden, violent event, although the latter's consequences can be no less traumatic to the individual.

GLOSSARY

cognitive therapy/remediation Refers to several forms of rehabilitation/treatment addressing the cognitive and behavioral consequences of brain damage. This treatment involves procedures that address impaired functions by using a variety of computer programs, as well as other exercises. In addition, cognitive therapy involves the teaching of a variety of compensatory strategies to increase functioning despite residual impairments. Cognitive therapy may include supervised practice of real-life situations outside the office. Cognitive therapy refers to treatment of individuals with brain damage and is distinguished from the psychotherapeutic technique by the same name.

organic brain syndromes (OBS) Refer to dysfunctions in the intellectual/cognitive, behavioral, social or emotional spheres, whose primary effective cause is brain pathology. These syndromes are defined in contrast to dysfunctions in the same spheres, whose etiology is believed to be primarily emotional or psychological.

traumatic brain injury (TBI) A category of OBS, used to describe the cognitive, emotional, and behavioral conse-

I. OVERVIEW OF ORGANIC BRAIN SYNDROMES

The term organic brain syndrome (OBS) refers in the literature to both organic mental disorder and organic brain disorder. This reflects the dualist mind-body distinction, which gave rise to it. That is, it implies a distinction between "physical" and "mental" causes of behavioral-emotional-cognitive dysfunction. The latter are also known by the general term psychopathology, but can there be an organic mental disorder, or even normal behavioral/cognitive functioning that is not related to brain function (try functioning without it)? And can there be a brain disorder that is not "organic," in the sense that it refers to something other than normal or impaired function of brain tissue? Current knowledge suggests a negative answer to both questions. There is a long tradition of dualism in psychiatry of "functional" and "organic" disorders (expressed in the diagnosis of OBS) that reflects the belief that some behavioral abnormalities originate in brain pathology, whereas others result from "psychological" or "functional" factors, such as

maladjustment in the domains of emotional, social, and familial function.

Today it is recognized that a variety of medical conditions can cause the full range of psychiatric syndromes and symptoms. Therefore, many diagnostic categories of psychiatric symptoms resulting from specific medical conditions are recognized and are typically classified together with other clinical entities with similar clinical manifestations. When applied judiciously, OBS has important diagnostic, prognostic, and therapeutic implications: it implies that the appropriate strategy for dealing with the symptoms is to attend to the underlying brain pathology, whereas the behavioral-affective manifestations may be of secondary concern. To the extent that OBS is secondary to some underlying brain pathology, and to the extent that this pathology is treatable, the treatment of choice is medical intervention. However, for various forms of OBS (for example, degenerative disease), medical intervention may be limited to the pharmacological management of symptoms related to behavioral problems. For other subcategories of OBS, such as mild to moderate TBI or strokes, medicine offers little beyond symptomatic relief, and it is left for other professions to provide rehabilitation of impaired functions. It is therefore important that practicing clinicians consider the various forms of OBS in their differential diagnoses, because brain pathology can give a spectrum of psychiatric symptomatology, and because many of these disorders may be reversible with medical intervention. For similar reasons, the presence of documented brain pathology, in the context of psychiatric symptoms, may preclude common psychotherapeutic approaches. Thus, for example, insight-oriented psychotherapy for a patient whose insight is impaired by frontal lobe damage is quite ineffective.

As brain tissue does not regenerate to an appreciable extent, damage resulting in OBS, is in a sense "irreversible." Thus, many forms of OBS result in permanent dysfunction. In cases of degenerative conditions, the dysfunction gets worse. But in many other forms, such as in cases of TBI, various infections, and strokes, when occurring in the context of otherwise healthy individuals, where some form of new learning can still take place (which may be well into the 7th or 8th decades of life), functional improvement can take place. In such cases, motivation to exert the effort required, therapeutic intervention and environmental support are the main ingredients in turning the consequences of OBS around, and returning the individual back to his or her premorbid level of functioning, as

quickly as possible. In this article, the focus is on the consequences and treatment of TBI, but it should be emphasized that these are appropriate for all other forms of OBS where there is a potential for recovery.

II. DESCRIPTION OF TRAUMATIC BRAIN INJURY

Traumatic brain injuries (TBI) do not form a well-defined category of symptoms, as injuries vary in their severity and location within the brain. This category of syndromes is the leading cause of OBS among young people and is the form of OBS most likely to come to the attention of psychotherapists. TBI include a large variety of syndromes, with varying degrees of disabling symptoms and pathologies. There is a considerable body of research on the topic, and space allows for only introductory discussion. TBI can result in a wide range of psychiatric and cognitive symptoms. No two traumatic injuries are alike, and the clinical picture following brain injury, as well as long-term adjustment, are always a combination of premorbid personality, psychological adjustment, intelligence, and the extent and location of the injury, together with the availability and quality of treatment and the patient's social support system. Thus, any prior history of drug or alcohol abuse, in itself a risk factor for TBI, may complicate both diagnosis and return to "normal" functioning. In part due to the age of the population with head injuries, there is typically significant recovery, albeit rarely back to the premorbid level of functioning.

Brain traumata are usually classified into cases of severe, moderate, or mild injuries, according to scores on the Glasgow Coma scale (GCS, a 15-point assessment tool, using measures of verbal, motor, and eye-opening responses), and on the length of time the individual has been unconscious. Roughly speaking, loss of consciousness for less than 20 min and a GCS of 13 to 15 are considered to reflect a "mild" injury. Any history of coma beyond 6 hr with a GCS of 3 to 8 is considered to indicate "severe" injury. However, there are substantial variations in the severity of symptoms and outcomes that do not respect the classification described earlier. Most often the injured person has amnesia for the injury, and depending on the severity of impact to the brain, there is often retrograde amnesia as well (amnesia extending from the onset of injury backward in time). The length of retrograde amnesia varies among injuries but does not correlate well with severity. There is often posttraumatic amnesia as well, referring to the

period following onset of injury, during which the patient is alert but for which the patient later exhibits amnesia. Posttraumatic amnesia provides a measure of the severity of the impact to the brain and gives some indication of the prognosis (although variations are common). In addition, short-term memory deficits and impairment in new learning following brain injury are ubiquitous and are referred to as anterograde amnesia.

Traumatic brain injuries can result from a penetrating foreign body (as from a gunshot wound). They can result from acceleration–deceleration of the head, as in cases of motor vehicle accidents, falls, or from a blunt blow to the head, in which case they are referred to as closed head injuries. The mechanism of injury to brain tissue is different in each type, and from one situation to another. In some cases intracerebral bleeding occurs, and in some cases focal tissue damage can be seen on brain imaging. But almost always there is diffuse injury as well, involving disruption of cell membranes, especially in the brainstem and shearing of neuronal processes (axons). In addition to actual tissue damage, TBI may result in other pathological processes that may affect cognition, such as tissue swelling (edema). TBI can result in clinical pictures ranging from persistent vegetative state to a seeming absence of residual neurological symptoms. When the injury is severe, the individual usually does not return to premorbid functioning and may need lifelong assistance in all aspects of living, even after a long course of rehabilitation. In moderate and mild cases, a fast return to functioning is often possible, although residual deficits may, and often do, remain for the rest of the person's life, as damaged brain tissue does not regenerate.

Occasionally, the brain injury impairs the patient's insight (expressed as the inability to monitor and judge one's own behavior and/or thought process), so that the patient is not aware of the deficits and may even deny them altogether. This impairment makes intervention and rehabilitation much more difficult, as the patient sees no reason for the rehabilitation efforts, and cooperation may be limited. Nevertheless, intervention with the aim of improving overall functioning may still be necessary. Needless to say, when insight is impaired by TBI, or any other brain damage, any attempt to treat the disorder with insight-oriented therapy is doomed to failure (see later for more details on treatment).

Mild TBI can present a challenge to the clinician, because such injuries are often dismissed as representing either exaggeration of symptoms for secondary gains (especially when litigation is involved), or outright malingering. Such cases often received psychiatric di-

agnoses in the past, because the typical symptoms were headaches, concentration problems, memory loss, depression, mood lability, and even personality changes, among others. Nevertheless, research over the past 30 years indicates that between 5 to 10% of mild TBI, despite only brief loss of consciousness, or merely short alteration in consciousness, and without any symptoms of major impairment in thought processes, intellectual ability, or language skills, do not return to normal functioning. This symptomatology has been supported by techniques of functional imaging of the brain, such as positron emission tomography, and by research in patients who are not involved in litigation, where financial incentive may seem the basis for the complaints. Such disability was found to be due to residual symptoms of poor short-term memory, reduced attention/concentration (especially on tasks of divided attention), impaired organization, and reduced speed of cognitive processing, together interfering with cognitive performance. This clinical presentation is known as the postconcussion syndrome (PCS). This subtype of TBI can be seen in the absence of litigation, and there is evidence that microscopic changes do take place in the brains of these individuals, such as axonal shearing. The microscopic changes, however, are too subtle to be visualized by any imaging technique, and most often a general neurological evaluation produces no focal findings.

Deficits associated with the PCS can only be documented on comprehensive neuropsychological testing. In addition to the cognitive deficits mentioned earlier, patients with the PCS often suffer from headaches for many months, sleep disturbances, fatigue, and depression. Occasionally, a change in personality is noted, and symptoms of anxiety, irritability, dizziness, and apathy are present. Individuals who had been high functioning prior to the injury are particularly disturbed by PCS, even when their test performance is still in the normal range for the general population. That is due to their intact insight, so they are acutely aware of their deficits. Patients with the PCS frequently have the added burden of “convincing” their families that something is wrong with them; it is not obvious, given the relative minor nature of their injury, that they indeed sustained a lasting injury to their brain (see later for further discussion of treatment and diagnosis of PCS).

Recovery from any TBI is most rapid in the first 6 months following the injury, with continuing noticeable recovery up to about 1 year. Over the first year, the rate of recovery decreases gradually. Beyond 1 year, additional recovery may still take place, albeit at a frus-

tratingly slow pace. Depending on the age at the time of the TBI, patients have shown recovery for several years postinjury, especially with regard to increased independent functioning. However, the latter depends to a significant extent on the social support system of the patient, availability of rehabilitation, and motivation.

One of the most significant, and almost universal, consequences of TBI and any other form of brain damage is affective disturbance. Most commonly, depression is seen, but other mood disorders can result as well. Thus mood swings, anxiety, phobias, hypomania and even posttraumatic stress disorder have been reported following TBI. Sometimes mood disorders reflect the effects of brain damage directly; in other cases, affective symptoms (mostly depression) are secondary and reactive to the cognitive deficits. A combination of both etiologies together is also possible. Mood disorders themselves in TBI can impair normal functioning, and therefore they require professional attention.

III. DIAGNOSTIC ISSUES

In cases of severe TBI, there is little question as to the presence of underlying brain damage. However, in cases of mild to moderate head injuries, especially where brain imaging reveals no positive findings of damage, and the neurological evaluation also produces no pathological findings, the diagnosis of TBI requires a different approach. Such diagnosis is crucial when litigation is involved, as motivation becomes part of the clinical question of diagnosing brain damage. It is also essential when the injury is mild, but the individual complains of persisting problems in function.

The most effective approach to identify the presence of cognitive deficits and determine their extent, to date, is the neuropsychological evaluation. The neuropsychological assessment, through the use of standardized tests, provides the most accurate, noninvasive, picture of the functional status of the individual, which in turn allows the inference of brain dysfunction, if present. Neuropsychological testing utilizes a comparison between the estimated premorbid, intact intellectual function of the individual, against his or her present performance on cognitive testing. This comparison is done under the assumption that the overall cognitive performance on different cognitive tasks of a given individual is fairly uniform within a certain range of variations. Therefore, an observed large deviation from the expected performance in a given skill, relative to the estimated intellectual functioning of the individual,

raises the suspicion of impairment. If such a deviation is consistent with similar findings in other cognitive skills, the latter known from research to be readily affected even by mild brain damage, a diagnosis of TBI (or PCS) is made. Because TBI involves, by definition, pathology of brain tissue, it is likely that even if the presenting symptoms of TBI seem to be psychiatric (say, depression, mood swings, or poor concentration), some cognitive deficits will be present as well. These are most likely to be short-term memory and attentional deficits. In fact, despite the prevailing notion that depression results in cognitive deficits on testing, recent research on this topic has found little, if any, correlation between scores on neuropsychological tests and depression. Problems with daily and occupational functions, however, can be and often are seen with depression. As neuropsychological assessment identifies the presence or absence of brain pathology, positive findings on neuropsychological testing greatly increase the likelihood that the underlying cause of the patient's complaints is brain pathology. Neuropsychological testing is appropriate in mild to moderate cases of TBI, and where brain damage is known to be present (e.g., in cases of severe TBI with damage seen on brain imaging). The neuropsychological assessment should also be used to determine the extent of dysfunction and to aid in developing an optimal treatment plan.

IV. THEORETICAL BASIS OF TREATMENT

The World Health Organization formulated a part model to conceptualize deficits following TBI: impairment, disability, and handicap. Impairment refers to deficits in the actual underlying cognitive skills (such as memory, attention, fluency, inhibition of action). Impairments are detailed on the neuropsychological evaluation. Disability refers to deficits noted in the injured individual's function in everyday life (for example, memory impairments may cause problems in carrying out the task of shopping for food, keeping appointments, etc.). Handicap refers to difficulties imposed on the injured person by the demands of the outside world (e.g., a return to work may be impossible due to disability in dealing with more than one thing at a time). Within this framework, improvement in disabilities may not necessarily result from improvement in impairments: using a list for shopping can lead to improvement in performance of this task without any change in the underlying memory impairment. Nor is

an improvement in a disability by itself a guarantee for progress of a handicap: the use of a list may not suffice to overcome the memory demand required by taking an oral examination at school. The goals of treatment in TBI are improvements in both disabilities and handicaps, although often impairments are targeted as well, especially within the initial phase of treatment.

Any therapeutic approach must be based on the presumption of a potential for recovery. Indeed, it is a common observation that people after TBI recover to some extent or other, often even spontaneously, in the absence of intervention. What does this recovery represent in terms of brain functions? TBI results in several pathophysiological (i.e., abnormal) processes in brain tissue that have been identified experimentally. Some of them (e.g., swelling, or edema) in and of themselves may cause disruption in normal functions beyond the effect of the brain damage itself. Thus, when swelling resolves, for example, it is accompanied by some recovery of TBI symptoms. As brain tissue does not regenerate, further functional recovery involves, most likely, (1) some measure of reorganization in tissue functions (perhaps the assumption of function by a healthy tissue heretofore not specialized for the impaired function), combined with (2) the residual function of damaged neuronal networks. But beyond the recovery of basic perceptual, conceptual, memory, attention, and motor skills, functional recovery observed can, and often does, reflect (3) the development of compensatory strategies. Various combinations of these three processes most likely form the basis for observed improvement following injury.

What we know from functional brain imaging about the neuroanatomical substrate of recovery is that reorganization takes place shortly after an injury to brain tissue. New neuronal networks seem to take over functions that premorbidly were subserved by the now-damaged tissue. But in addition, new learning can take place in neurologically intact individuals even into the seventh decade of life, albeit at a reduced rate and extent. Thus, there are good reasons to believe that as long as healthy, viable tissue remains after trauma, the individual may still be able to learn new tasks, or be capable of doing old tasks in new ways (i.e., compensation for deficits). Such new learning involves, quite likely, formation of new synapses (contacts among nerve cells), changes in membrane properties and firing characteristics of nerve cells, as is the case with learning in general. It is true, however, that even mild TBI is likely to reduce the overall capacity of the nervous system, so that any new learning requires more time and effort, depending on the extent of injury.

The general principles forming the basis for recovery outlined earlier cannot provide detailed guidelines for addressing a specific impairment or disability in a specific way. As individuals present with different injuries, different premorbid abilities, occupational background and adjustment, as well as varying psychosocial and familial contexts, treatment must be tailored to the individual needs of the patient. Individualizing treatment implies that long-term goals and specific treatment plans are synthesized from all the factors known to affect the outcome of treatment. Treatment approaches may include, in addition to individual therapy, group treatment when appropriate. Group therapy, whether as a form of cognitive treatment or psychotherapy, can have an important role in promoting recovery. Indeed, several rehabilitation programs around the world are based on group treatment approach (see later for details). Another implication of the knowledge we have on reorganization in the brain is that initiation of therapy should be as soon as the injured individual can participate in treatment. When treatment is initiated early, reorganization can incorporate easier new approaches to old tasks, and patients better adapt to new learning. During the first year following a TBI, the majority of recovery takes place. Beyond that, progress is far slower. Individuals with TBI who begin treatment a year following onset or later, may actually have to unlearn ineffective compensatory strategies they have acquired on their own during the initial phase following injury. This is an unnecessary burden.

V. COGNITIVE THERAPY AND PSYCHOTHERAPY IN ORGANIC BRAIN SYNDROMES

A. Cognitive Treatment

Cognitive treatment (CT) must address the complete range of skills involved in normal functioning, in the context of psychosocial, cognitive, occupational, and emotional readjustment. In reality, cognitive, occupational, physical, group, and psycho -therapies are intertwined in the process of assisting an injured individual to negotiate a return to normal functioning. Improvement in functioning can be observed even when test performance of basic skills does not change. This happens when treatment aims to improve the actual functioning in the context of real-life occupational and psychosocial settings.

In general, CT is said to be “restorative” when it addresses cognitive impairments directly by, say, rote

repetitions of tasks involving impaired skills. Therapy is regarded as “compensatory” when new skills are taught to patients, such as procedures designed to reduce disabilities despite persistent cognitive impairments. Cognitive treatment follows the general knowledge acquired through more than half a century of research on principles of cognitive learning. Examples include strategies in improving memory functions (e.g., through the use of mnemonics), attention and visual scanning training, the utility of distributed versus concentrated practice, and so on. These principles are used but extended beyond the clinic in CT, through generalization into real life situations.

Any systematic activity that requires the purposeful use of the brain can be utilized as CT, as long as it is part of an effort to reduce impairment, disability, or handicap. Thus, anticipating and responding to a target on a computer screen, making a supervised trip from the home to the clinic using public transportation, interacting socially in a group moderated by a therapist, are all forms of cognitive treatment. Cognitive treatment might take the form of sensory stimulation for a partially comatose patient and ends with assisting an injured lawyer with strategies for reading and preparing legal briefs. A great deal of material exists commercially which can be used for CT: computer software, videos, tapes, workbooks, reading material, games, puzzles, and so on. Elaborate guidebooks and materials for addressing specific areas of problems can be purchased commercially (such as, for example, the Attention Process Training designed by McKay Moore Sohlberg & Catherine Mateer, 1989, and many other computer-based programs). But the resources are limitless, as many other, even daily encountered objects and situations can serve the same purpose of increasing functioning. Thus the home environment may be modified to provide an injured person with the structure necessary to stimulate recovery and reduce disability. Material from the patient’s premorbid occupation may serve as context for developing specific compensatory strategies for skills needed for work; so can environmental objects serve the same therapeutic purpose for better functioning in daily life. For example, the pictures at a museum may serve to exercise both attentional and expressive purposes; searching topics on the Internet can provide exercises of attention, reading, visual-spatial and abstract skills, and so on. In short, the range of tools used in cognitive treatment is only limited by the therapist’s imagination. In our center, for example, it is not unusual for patients to go shopping with a therapist, play a musical instrument, practice

the use of public transportation, or attempt work at a local store, all as part of an individualized treatment plan. The only requirement is that any therapeutic activity is aimed at specific functional goals, appropriate for the individual’s needs, and that it is executed with sights on actively challenging the patient.

Cognitive therapy must be performed at a specific level for the individual TBI patient: it cannot be too easy, as boredom will be quick to set in. Equally problematic is CT that aims too high for the patient: frustration and even a catastrophic reaction may ensue. Treatment must be just challenging enough for the individual, within a rather narrow window of difficulty, so that progress will take place without undue negative reactions. This requires constant, careful monitoring of both the mood and performance of the patient. For this reason, treatment plans for a CT session can never be rigidly adhered to. Fluid movement from one level of difficulty to another, or from one task to another may be required when unanticipated reaction from the patient renders the plan obsolete. It must be emphasized that individuals with brain damage may often exhibit not only shorter attention span than intact people, but also lower tolerance for frustration and a more rigid approach to problem solving. These abnormal reactions in themselves may become the focus of treatment.

Although the therapist–client relationship is somewhat different in the context of CT than it is in regular psychotherapy, rapport and trust are important elements of treatment. Eliciting cooperation requires, at times, a great deal of skill on the part of the therapist. For instance, clients may be profoundly depressed and feel hopeless, anxious, embarrassed or they may believe nothing is wrong with them. All these reactions to brain damage, and many more, may result in minimal motivation to cooperate in treatment. Cajoling a TBI patient to participate in therapy may call for the most elaborate inducements and reinforcements. Often it is necessary to recruit the assistance of family or significant others to promote participation. Group treatment can also be effective, provided the discrepancy in patients’ abilities within the group is not too large. Thus, symptoms of impaired social functioning can be addressed in a group setting, where members’ interactions provide both stimulus for and context of therapy. Other cognitive symptoms can be addressed well in a group settings, such as expression and comprehension skills, attentional deficits, sequencing, self-monitoring, and turn taking. Needless to say, psychosocial issues, such as acceptance of deficits, can be addressed well in group therapy (see later for more on this issue).

Survivors of brain damage present with an infinite variety of symptoms, and no two patients are quite alike. Premorbid adjustment and psychosocial factors influencing recovery are never at the control of the therapist. Therefore, understanding the totality of both symptomatology and psychosocial background must form part of the treatment plan. Whether a TBI patient lives alone, with parents or with spouse, will have bearing on the goals of treatment. Therefore it is always important to involve the family, or significant others, in the therapeutic process. At times, CT may take the form of educating the injured person's family regarding the altered cognitive status, the abilities and disabilities of their loved one. A family may hinder or facilitate the individual's recovery process, depending on their attitude toward the cognitive/behavioral changes they face.

B. Psychotherapy

Throughout human development, changes from infancy to childhood, into adulthood, and later maturation into old age are gradual. The process is slow, allowing ample opportunity for making such adjustments so as to preserve some sense of the individual's continuous identity. Thus, a person perceives himself or herself as possessing the same identity across significant changes in size and cognitive abilities. Brain damage, in contrast, is abrupt in TBI, and the demand for readjustment is both substantial and immediate, and always in the direction of reduced capacity (that is, it results typically in negative emotional response). Therefore, brain damage is a devastating event in all spheres of human experience, creating bewilderment and often a sense of loss. It may profoundly shake the person's sense of identity. Even in cases of mild impairments, awareness of reduced cognitive proficiency can injure the individual's sense of self. The experience, common after mild brain damage, of forgetful episodes, difficulties with handling more than one thing at a time, or reduced stamina, will require significant adjustment on the part of the patient. Typically, the more severe the damage, the more adjustment will be required; not only in terms of recovering of premorbid functions, but in the demand for emotional adjustment in the face of irreversible changes.

The most common presentation of psychological reaction to brain damage is problems of acceptance. These problems may appear as lack of awareness of deficits (especially with more severe injuries), over which the patient has no volitional control. In cases where awareness is intact, accepting the changes fol-

lowing brain damage presents a serious challenge, as it entails viewing oneself as less competent than before. High- and overachievers have particular difficulties with this kind of readjustment, which requires psychotherapeutic intervention. Reduced self-esteem and depression are very often the consequence of awareness of cognitive deficits. The role of psychotherapy is, then, to facilitate acceptance and the readjustment process, so that recovery and return to functioning are maximized. Without acceptance, people with brain damage can rarely negotiate the compensation needed for good adjustment. The process of acceptance includes grieving, as in a real sense individuals with brain damage must deal with the loss of part of their identity.

Psychotherapy should include educating patients concerning the effects of brain damage, so as to reassure them that their experience of changes is not unique. For example, mood swings, irritability, fatigue, bursts of uncontrolled anger (all common symptoms following TBI) in heretofore friendly and patient individuals can be very alarming, but understanding of such symptoms in and of itself can have a calming effect. Supportive psychotherapeutic techniques should be combined with more directive approaches to assist patients with the use of new strategies to deal with changes. For example, using a behavioral self-monitoring log to comprehend and control undesired anger outbursts can be taught to individuals exhibiting such symptoms. Families, when available, must be part of the adjustment process, as they, too, need education regarding the changes in their loved ones, support, and guidance in assisting the injured family member. Several approaches have been used with reported positive results, such as the cognitive therapy of Aaron Beck in addressing depression, cognitive-behavioral therapy, and even psychodynamically based intervention. Often psychotropic medications, such as antidepressants, are indicated and should be used as an adjunctive to psychotherapy.

In some cases of impaired insight, behavioral management techniques with the injured individual may be the only effective intervention. In such cases, substantially reduced abstract thinking ability and limited awareness render insight-oriented psychotherapy totally ineffective. As in dealing with individuals with dementia, in such cases it is the caregivers who are usually the focus of intervention, through counseling and teaching them behavioral management techniques to facilitate life at home.

Group therapy is quite effective in affecting what Irvin Yalom called "universality": the feeling that one is

not unique in his or her experience of cognitive deficits. Group therapy is also useful in creating a context for social support from others who understand the changes following brain damage. It provides an opportunity to try new compensatory behaviors in a safe environment, with immediate supportive feedback. Patients who require relearning of social skills will do so better in a group setting.

Unlike traditional psychotherapy, the therapist working with individuals with brain damage must take a more directive role in the therapeutic process, as noted earlier. In addition to educating the client, the therapist may provide alternative approaches to a variety of problem-solving demands on the client, who may now be showing deficits of insight, initiative, and abstract abilities. Thus, not only is the patient devastated emotionally in the face of catastrophic changes, the patient now lacks efficient means of dealing with them. Merely supporting and facilitating grieving of loss, although important in the initial stages of recovery, may not be sufficient in the stages of returning to society at large.

Cognitive deficits do not have to prevent a survivor from returning to work. Thus, memory and attentional deficits can be circumvented using a variety of compensatory strategies. But, as noted earlier, to utilize these strategies, it is crucial for the individual to accept this new condition and recognize the necessity for compensation. For example, in our center we commonly recommend the use of organizers (electronic or not), as a compensatory strategy of dealing with memory deficits. But to make it useful, the individual must use the organizer. Again and again we observe patients who superficially accept the strategy but do not implement it in daily life. Using it presupposes accepting the need for it and, therefore, admitting to reduced cognitive ability.

It is very common to encounter individuals with mild brain damage who think "they are going insane" due to the perceived changes in function. This is especially common following TBI where patients are told they will get better in about 6 to 8 weeks, but no relief is experienced. In such cases, psychiatric referral may result, with the unfortunate implication that the patient has "neurotic" problems, or else, when litigation is involved, is greatly exaggerating the symptoms for financial gains. When the latter is not the case, such implications only serve to exacerbate emotional symptoms and hinder recovery.

Although the consequences of brain damage will be expressed in many forms, both cognitive deficits and emotional problems are often seen. Whereas mood dis-

orders can result directly from impairment to the brain processes involved with affective responses, they can also be secondary to awareness of cognitive deficits. In turn, these psychological symptoms will intensify the symptoms of dysfunction that originally resulted from damage to brain tissue. Thus, it is necessary to treat both the cognitive and psychological symptoms observed in individuals with brain damage as they are inextricably entangled following injury. For this reason, overall improved functioning can be seen in survivors of brain damage when either cognitive or psychological symptoms improve.

VI. REVIEW OF TREATMENT EFFICACY

What is the role of cognitive therapy in promoting the rate of recovery and its final steady state? There are inherent methodological difficulties in assessing outcome of cognitive treatment. To mention a few, it was already noted that no two individuals with brain damage are alike, either in their life history, premorbid adjustment, support system, extent, and location of injury. In addition, defining and measuring outcome is very difficult, in a manner similar to that encountered in research on the effectiveness of psychotherapy. Recovery may be measured on a neuropsychological test battery, or in terms of returning to work and/or function in the family or the community. Each aspect of recovery has its place but may not correlate highly with each other, thus making the study of treatment outcome very complex. Despite the difficulties, the research evidence to date provides general support for the efficacy of cognitive treatment (CT). Thus large, multicenter studies indicate that rehabilitation in general will result in better functional recovery, higher rate of return to gainful employment, and better psychosocial adjustment, even when residual symptoms remain. In contrast, studies on the effect of CT that addresses just the basic cognitive processes, outside the context of functional utilization in the real world, are not as encouraging. The inference is that treatment should focus on disabilities in real life, that is, at work and in the psychosocial environment.

The efficacy of psychotherapy in the population with brain damage has not been well studied on a large scale, but many rehabilitation centers report positive effects of therapy in many, although not in all, individuals with brain injuries. This might be expected, given that patients with brain damage do not choose to receive

psychotherapy, as do clients who turn to psychotherapy on their own. Such patients do not always recognize their own needs as a result of the injury, nor do they always have the cognitive wherewithal to form therapeutic alliance and benefit from the psychotherapeutic process. Often the effects of brain damage require pharmacological intervention before any adjuvant psychotherapy can have any effect. At other times, impaired memory, attention, and concentration do not permit good carryover from one session to the next, requiring a repetition of material dealt with before.

For these reasons, and due to the variability of the population with brain damage in general, no definitive information on efficacy is available. Yet any one who works in treatment with persons with brain injuries can attest to the dramatic positive responses, the improvement in psychosocial functions exhibited by some patients, with less remarkable effectiveness in others. Given the effects of brain damage on psychosocial functions, and the negative effects of the emotional consequences of brain damage on functioning, it would be unethical to await results of large-scale efficacy study of psychotherapy, and not provide intervention as needed.

VII. SUMMARY

Brain damage results in a wide variety of cognitive, affective, psychosocial, and occupational symptoms. Depending on the location and extent of damage, as well as on the developmental history, premorbid adjustment, overall intelligence, motivation, and available support system, the consequences can range from mild impairments with a full return to function, to total disability. Therapy for the symptoms must address the needs of the individual in all possible spheres, as they overlap and interact to produce a clinical picture of disability. Therefore, cognitive treatment, psychotherapy, psychosocial and vocational intervention all must form

part of a comprehensive treatment plan if positive outcome is to be achieved. A return to normal function does not require a complete remission of deficits, something rarely achieved in this clinical population. Instead, it is contingent on acceptance of irreversible changes, emotional adjustment, and the integration of compensatory strategies that allows functioning despite residual impairments. For this purpose, the totality of the injured person's cognitive, social, physical, and emotional spheres (in short—the identity) must be readjusted in the process of treatment, to accommodate the new changes in the most adaptive fashion within the individual's life.

GLOSSARY

expectancy effects Responses that follow a treatment but are not specific results of the treatment but are placebo responses due to the participant's expectancy of improvement. They can be difficult to exclude from specific effects in studies of psychological therapies that use placebo procedures as controls, because the treatment may appear to the participants to be more likely to be effective than the placebo.

multiple-baseline design Employed in single-case studies with the aim of demonstrating that the change following a treatment is a specific effect of the treatment. Frequency or intensity of a number of behaviors is assessed at baseline. Treatment aimed at changing only one of the behaviors is introduced. If that behavior and none of the others change following treatment it is considered that the treatment has specifically produced the change. The procedure can be repeated with a treatment aimed at changing a second behavior and so on. The design will not control for expectancy effects if the treatment appears to the participant to be more likely to affect the behavior targeted than the other behaviors.

I. DESCRIPTION OF TREATMENT

Orgasmic reconditioning, also termed masturbatory reconditioning, was introduced for the treatment of participants seeking modification of their sexual preference. In early studies they were mainly homosexual men but in last two decades they have been mainly male sexual offenders. In their 1991 review, Laws and Marshall described four forms of orgasmic reconditioning that had been reported in the literature. Combinations of the four could be regarded as a fifth form.

A. Thematic Shift

In thematic shift the participant is instructed when he masturbates to use his habitual "inappropriate" or deviant fantasy to produce an erection and to maintain sexual arousal. At the point of ejaculatory inevitability he is instructed to switch his fantasy to one of an "appropriate" nature, thus pairing that fantasy with orgasm. Over time the participant is to introduce the nondeviant fantasy earlier and earlier during masturbation. If following the thematic shift he begins to lose arousal he is to shift back briefly to the deviant fantasy to regain high arousal and then shift again to the nondeviant fantasy. Ultimately he is expected to always masturbate using appropriate fantasies.

B. Fantasy Alternation

It was considered by some workers that as thematic shift was usually carried out by the participant without direct supervision he may not maintain the required temporal relationships between deviant and nondeviant fantasy. They changed the procedure to make it easier for the participant to follow. Rather than shift the thematic content in each session of masturbation, he was instructed to use alternate sessions, in one of which he used deviant fantasies exclusively and in the other, nondeviant fantasies exclusively.

C. Directed Masturbation

With this form of orgasmic reconditioning, the participant was instructed to masturbate exclusively to nondeviant fantasies and to totally avoid masturbating to deviant themes.

D. Satiation

In satiation as described by Marshall and Lippens in 1977 and subsequently termed verbal satiation by some authors, the participant under auditory supervision masturbated continuously beyond ejaculation for a prolonged period, usually about an hour, while fantasizing aloud every variant he could think of on his deviant activities.

Subsequently it was reported the procedure could also be carried out by the participant at home, where he recorded his verbalizations, for the therapist to check he was following the instructions.

E. Combined Directed Masturbation and Satiation

A subsequent development was for the participant to commence with directed masturbation until ejaculation and then employ satiation. This was further modified by the participant repeating directed masturbation until he was completely unresponsive to sexual stimuli and then commencing satiation while masturbating a flaccid penis. Laws and Marshall commented that duration of satiation with this procedure was brief, usually 20 min. Another variant was for the participant to initially masturbate to slides and audiotapes considered appropriate, then following ejaculation, to masturbate a second time while listening to a relaxation tape under instructions to avoid any sexual fantasy, then masturbate a third time when refractory, while exposed to deviant slides and audiotapes for 1 hr.

II. THEORETICAL BASES

Thorpe, Schmidt, and Castell in their 1963 report of the treatment of a homosexual man by showing him the picture of an attractive scantily dressed woman as he reached orgasm, described the procedure as a positive conditioning technique. Presumably it was expected that the sexual arousal associated with orgasm would by conditioning occur to women. Laws and Marshall in their 1991 review considered orgasmic reconditioning was based on the assumption inherent in conditioning accounts of sexual deviation that the content of masturbation fantasies guided the overt expression of sexual behavior. They stated that Marquis in 1970, though not the first to use the technique of thematic shift, provided the first theoretical rationale for its employment. The aim was to maintain the nondeviant fantasy as continuously as possible throughout the masturbatory sequence until ejaculation. The repeated pairing of sexual arousal and orgasm with appropriate fantasies was expected to initiate conditioning processes that would alter sexual desires in an appropriate direction. Thoughts of appropriate sexual acts with appropriate partners would become attractive. In addition, through the discontinuation of pairing deviant thoughts with masturbation, deviant acts would lose their attraction by simple extinction. Laws and Marshall commented of directed masturbation that it was not clear if it was expected to reciprocally reduce deviant arousal. However, as with the procedure, participants avoid masturbating to deviant themes, simple extinction should operate to reduce this arousal as with thematic shift.

Laws and Marshall stated that satiation was based on the concept that continuous unrewarded repetition of an undesired behavior will lead to its extinction. They cited the 1977 report of Marshall and Lippens that many of their clients had told them their masturbatory fantasies often became boring and they changed them to maintain arousal. Marshall and Lippens reasoned that the continued repetition of favored masturbatory themes during a period when the client was in a low state of sexual arousal should lead to a reduction in the arousing properties of those themes.

III. EMPIRICAL STUDIES

A. Penile Circumference Response Assessment of Outcome

Most of the empirical studies of orgasmic reconditioning report its use in one or a few patients with no or

inadequate controls. They usually rely for assessing change in the individual participant's sexual preference by measuring his penile circumference responses (PCRs) to appropriate and deviant stimuli prior to and following the procedure. The validity of these responses as measures of sexual preference has been increasingly questioned. As early as 1971 Bancroft reported that though the mean PCRs of 30 homosexual men as a group were greater to pictures of nude men than nude women, in only 14 of the 30 as individuals were correlations between their "erection" and ratings of arousal statistically significant. In 1975 Mavisakalian, Blanchard, Abel, and Barlow found the mean PCRs to pictures of a nude young woman failed to discriminate as groups, six homosexual from six heterosexual men. In articles published by McConaghy in 1989 and 1991 and reviewed along with further evidence in 1998 the lack of consistent findings in studies attempting to discriminate groups of rapists or pedophiles from controls by their mean PCRs to deviant stimuli was pointed out. Evidence was also advanced of the ability of their penile volume responses unlike their PCRs to discriminate heterosexual and homosexual men as individuals rather than as groups.

To support the validity of PCR assessment Lalumiere and Quinsey in 1994 reported that meta-analysis of the findings of selected studies investigating the PCRs of rapists demonstrated that the assessment did discriminate rapists from nonrapists, as groups. Hence it was necessary to combine the responses of several groups of rapists and nonrapists by meta-analysis to obtain convincing statistical evidence that PCR assessment discriminated the two groups. This indicated it could weakly discriminate as groups men who differed in sexual preferences, but certainly not as of individuals.

Nevertheless the authors considered the result supported the use of the assessment in individual men. In 1996 Marshall commented that

for a test to have merit, it must be shown that it is in a standardized form that is broadly acceptable, that it is reliable and valid, and that either it is resilient to faking or faking can be reliably discerned. Unfortunately, the available data on phallometric assessments (i.e. PCR assessment of sexual preference) do not meet any of these empirical and technical requirements ... the wisest course of action may be to withdraw its clinical use until more adequate data are available.

Subsequently in 1998 Lalumiere and Harris decided it was unclear whether changes in participants' PCRs following treatment should be thought of as changes in

sexual preference or changes in men's ability to control arousal, a suggestion made previously by Quinsey and Earls in 1990.

In their 1991 review Laws and Marshall accepted that changes in PCRs of individual men to pictures of nude males and females were valid measures of change in their sexual preference that demonstrated the effectiveness of orgasmic reconditioning. Penile volume assessment though consistently demonstrated to validly assess the sexual preference of individual men has not been used to evaluate orgasmic reconditioning.

B. Thematic Shift

In their 1963 report of thematic shift orgasmic reconditioning of a homosexual man Thorpe and his colleagues stated that following the procedure his masturbatory fantasy remained entirely homosexual. The procedure was then alternated with electrical aversive therapy to pictures of nude males, after which he reported great reluctance to use homosexual fantasy with masturbation. Following treatment he had "occasional homosexual patterns" of behavior but continued the new pattern of masturbating to female pictures and fantasies. In a subsequent study Thorpe and colleagues used directed masturbation, instructing a homosexual man to masturbate as often as possible using heterosexual fantasies only. Initially he took a long time to reach orgasm, but later the time decreased, and he reported satisfying fantasy. He was then treated with aversion relief. The participant was said to have experienced heterosexual interest for the first time in his life during and following treatment.

In their 1991 review Laws and Marshall pointed out that unlike these and other early studies in which orgasmic reconditioning required some form of aversive therapy to dampen the attractiveness of the deviant stimuli, in his 1970 study Marquis reported its effective use alone. In the uncontrolled study 12 of 14 participants treated for a variety of sexual deviations reported that they were much improved or cured. Marshall relied on use of PCR assessment in a 1973 study that included thematic shift in 12 clients of mixed diagnoses but pointed out that as aversive therapy was used also causal inferences could not be made.

Ten years after introduction of orgasmic reconditioning Conrad and Winzce in 1976 pointed out the evidence of its efficacy had not gone beyond the case study level. They investigated use of thematic shift in three homosexual men who received this procedure alone and one in whom its use was followed by aversive therapy.

In evaluating their results they attached importance to failure of the participants' reported improvement, PCRs, and their written records of sexual feelings to change in relation to the periods of withdrawal and reintroduction of the treatments. As discussed by McConaghy in his 1977 review expectation that treatment effects would disappear when treatment was withdrawn was accepted at the time in applied behavior analysis theory. That this meant that treatment effects would be evanescent was overlooked. McConaghy concluded the study could be considered an uncontrolled report of a positive response to orgasmic conditioning in three patients, and a negative response in a fourth, who subsequently responded to aversive therapy. Conrad and Winzce accepted the validity of the individual participants' PCR assessments and considered they may have reported changes they did not feel and that both treatments were unsuccessful. Laws and Marshall in their 1991 review decided the study was the only well-controlled study of thematic shift and accepted the authors' interpretation that it failed to demonstrate any effects for the procedure.

C. Fantasy Alternation

Laws and Marshall reviewed the use of fantasy alternation in studies with one to four subjects that used self-report and PCR assessment as outcome measures. Some studies attempted to causally relate the treatment to outcome using a multiple-baseline design. This design relies on demonstrating that the introduction of the treatment targeting one behavior modifies only that behavior and not others that were not targeted. If this occurs it is accepted that the modification is a specific effect of the treatment. This methodology ignores the possibility that the targeting of one behavior has induced an expectancy effect in regard to that behavior and not the others not targeted. In any case in a study cited of a bisexual pedophile, though arousal to female children was targeted and declined, that to male children declined without having been targeted. Laws and Marshall attached significance to one study of four confused, apparently ego-dystonic homosexuals, in two of whom the procedure produced increase rather than decrease in deviant arousal as assessed by their PCRs. They also pointed out that from the theoretical basis of orgasmic reconditioning use of masturbation to deviant fantasies as in fantasy alteration would increase rather than decrease the ability of such fantasies to excite sexual arousal. They con-

cluded it was hard to see any justification for further investigation of the procedure.

D. Directed Masturbation

Laws and Marshall considered there was some evidence that directed masturbation might be effective. At the same time they raised the issue of whether it was appropriate to attempt to reduce men's sexual arousal to deviant fantasies by encouraging them to masturbate exclusively to nondeviant fantasies if they were already strongly sexually aroused by such fantasies. The evidence they cited supporting the procedure was again that of single-case uncontrolled studies using either self-report and/or PCR circumference assessments. It is difficult to see how this evidence was stronger than that supporting the efficacy of thematic shift, which they considered inadequate.

E. Satiation

Laws and Marshall cited single-case studies evaluating satiation, which were also uncontrolled and used participants' self-report and PCR changes as outcome measures. In one a multiple-baseline design was used in which PCR assessed reductions in sexual arousal occurred to stimulus categories targeted in sequence by the satiation procedure. Laws and Marshall did not discuss the possible confounding influence of expectancy effects and/or the ability of the participant to consciously or unconsciously modify his penile responses. Men's ability to modify their PCRs had been well documented by the time of their study. They considered satiation was clearly responsible for the reduction in inappropriate arousal that they considered had been demonstrated by the change in the participant's PCRs. The participant's assessed arousal to adult females showed only a modest increase. In another participant satiation produced marked decline in deviant arousal and a modest increase in arousal to adult women, as assessed by his PCRs. The participant had previously failed to respond to self-esteem enhancement and electrical aversive conditioning. Laws and Marshall criticized single-case studies evaluating combinations of directed masturbation and satiation as providing inadequate data concerning the outcome, or lacking appropriate control. Gray in 1995 reported a comparison study of verbal satiation alone and directed masturbation followed by ammonia aversive therapy in 28 participants, 14 nonrandomly allocated to one or other procedure. Outcome was assessed by participants' PCRs to audiotapes of sexual interactions with adults

and children. Seven of those who received satiation and six of those who received the combined procedure showed reduction in assessed arousal to appropriate stimuli, a finding not discussed by the author. Significant reduction in assessed arousal to deviant stimuli followed the procedure incorporating aversive therapy but not satiation, and it was concluded the former was more effective.

F. Conditioning Theory Basis of Orgasmic Reconditioning Questioned

Accepting the theoretical basis of orgasmic reconditioning that pairing of sexual cues with orgasm would increase sexual arousal, Marshall and Eccles in 1993 concluded concerning pedophiles that

Each time the offender has sex with a child, he obviously pairs heightened sexual arousal with vivid, realistic visions of children and the proprioceptive stimuli produced by his own actions. These contacts provide powerful conditioning trials, and if repeated often enough, should entrench a growing attraction to sex with children even in the absence of masturbating to children.

Evidence that would appear to question this belief was provided by McConaghy in a 1978 study that has been consistently ignored. Using the valid penile volume assessment of the sexual preference of individual men, the arousal to moving films of nude men as compared to that to films of nude women was determined in 181 men seeking treatment for compulsive homosexual feelings. Married men who had repeatedly experienced orgasm in the presence of female cues, namely their wives, but had not had intercourse with other women showed no evidence of increased penile volume arousal to films of women or decrease to films of men, compared to single men with no history of heterosexual intercourse. If all the married men utilized exclusive homosexual fantasies during their intercourse with their wives, it could be argued that these fantasies inhibited the effect of any physical cues from the bodies of the women with whom they were in intimate physical contact. However fewer than 20% of these men reported that they used homosexual fantasy during intercourse with their wives. All had sought treatment to cease homosexual activity and wished to continue the relationship with their wives with whom they frequently stated they were in love. Most said they were sexually aroused by thoughts of their wives, though they felt no sexual

attraction to other women. It is possible that in men who report no sexual arousal to women generally, the repeated experience of heterosexual intercourse with one woman does condition sexual arousal to her, but it does not generalize to other women.

G. Need for Penile Volume Response Assessment of Effects of Orgasmic Reconditioning

The finding that the orgasmic reconditioning procedure experienced regularly by married homosexual men produced no change in their validly assessed sexual preference strongly indicates the need for valid empirical evidence of the ability of the procedure to modify the sexual preference of sex offenders, in whose treatment it remains widely used. The empirical research evaluating it in uncontrolled case studies using self-report and PCR assessment has been conducted in participants most of whom wish to experience or to report changes in their sexual orientation either for their own emotional comfort or to impress therapists who may be influential in regard to legal decisions concerning them. Given the superior validity of penile volume responses to films of nude males and females in assessing sexual preference, studies utilizing it to evaluate the various forms of orgasmic reconditioning used in current sex offender programs would seem urgently required. As stated earlier, Lalumiere and Harris suggested in 1998 that treatments which induce change in PCR assessments may do so not by changing men's sexual preference but by increasing their ability to control inappropriate arousal. If so, orgasmic reconditioning procedures that involve prolonged or repeated masturbation on instruction would seem to require comparison with more acceptable procedures that increase this ability. These include alternative behavior completion (imaginal desensitization), demonstrated in placebo-controlled studies to do so. The conclusion of Laws and Marshall that the combination of directed masturbation and satiation needs to be evaluated in a systematic study could stimulate a randomized controlled comparison of the combination with alternative behavior completion. Unfortunately this seems unlikely.

H. Incorporation of Orgasmic Reconditioning in Multimodal Approaches

As various forms of orgasmic reconditioning are now usually combined with a variety of treatments in multi-

modal approaches, research evaluating any forms alone is unlikely to be carried out. Quinsey in 1986 reported the response of self-referred sex offenders treated with covert sensitization and masturbatory satiation, cognitive restructuring, social and assertiveness skills and sex education; 89% of 44 contacted at 6 months and 79% of 19 contacted at 12 months under confidential conditions reported no recidivism. Travin, Bluestone, Coleman, Cullen, and Melella in 1985 reported a somewhat lower rate of recidivism over a shorter follow-up period with similar therapy in more highly selected sex offenders. These results were not superior to those reported by McConaghy and colleagues in 1985 and 1988 with therapy using alternative behavior completion combined with brief nonstructured counselling carried out during follow-up interviews. However comparisons of the results of these studies cannot be accepted to be meaningful in view of the lack of control of participant differences. McConaghy and colleagues treated all participant who sought treatment for deviant urges they could not control in a cost-free program tailored to allowed those employed to continue to work. The selection procedures and cost of the other programs was not specified, as is common. A further indication that research evaluating individual behavioral procedures is unlikely to be conducted is implicit in the comment of Quinsey and Earls in 1990. They considered that cognitive therapies for sex offenders may not require the addition of behavioral approaches, as the variety of behavioral treatments used to modify sexual arousal patterns all appeared to be at least somewhat effective, and hence all may act nonspecifically.

IV. APPLICATIONS AND EXCLUSIONS

Orgasmic conditioning procedures would appear to have been abandoned in the management of participants reporting problems in relation to homosexual feelings by some therapists because they consider that changing sexual preference by these and other methods is impossible, and others because they consider such attempts are unethical. The American Psychiatric Association in 1998 issued a statement opposing reparative therapy, that is, attempts to change homosexual preference. Currently orgasmic conditioning procedures are used in men with paraphilias, mainly sex offenders. Such men are under considerable social and often legal pressure to comply with treatment. The use of procedures that encourage them to masturbate particularly

for long periods would seem likely to be experienced as demeaning by many such participants whose self-esteem is usually already low. In view of the lack of evidence of the effectiveness of the procedures in changing the sexual preference of men with paraphilias in an appropriate direction, they would seem unlikely to encourage them to form appropriate social relationships. It would seem acceptable to encourage men with paraphilias when they do masturbate to attempt not to use deviant fantasies. However to instruct them, particularly if they are under legal pressure to comply, to masturbate as a therapeutic procedure could be considered unethical when no acceptable evidence has been advanced of its value.

V. SUMMARY

Orgasmic reconditioning aims to change participants' sexual preference so they are more aroused by persons deemed appropriate in age, sex, and ability and willingness to consent, and less by those deemed inappropriate. The various forms that are or have been used are described, and their theoretical bases discussed. Associating pictures, verbal descriptions, or fantasies of appropriate persons with orgasm was considered to act by conditioning to increase arousal to the group to which such persons belonged. Associating similar representations of inappropriate persons with reduction of sexual arousal by repeated masturbation producing satiation was considered to inhibit arousal to the group to which such persons belong. Empirical research considered to support the value of the procedures lacked validity as it was based on self-report and/or change in treated participants' penile circumference responses to representations of appropriate or inappropriate subjects. Penile circumference responses unlike penile volume responses lack validity as measures of individual men's sexual preference. Using penile volume to assess their sexual preference, it was no different in married homosexual men who had repeatedly experienced orgasm with their wives compared to single homosexual men who have never had heterosexual intercourse. This finding casts considerable doubt on the theoretical basis of orgasmic reconditioning and indicates a need for valid research evaluating the procedures that remain in widespread use in the treatment of sex offenders. Until such evidence is produced as the procedures could be experienced by the subjects treated as demeaning, their use particularly by legal compulsion could be considered unethical.

GLOSSARY

clinical significance Refers to the relevance or meaning of change for the individual client. This is in contrast to statistical significance, which refers to the differences between group means on a measure.

efficacy research Designed to determine the success of specific treatment interventions for a particular disorder.

effectiveness research Intended to discover the overall success of interventions with typical clients in the usual clinic setting.

patient-focused research Centers on observing the individual client's progress throughout the course of therapy to determine how that particular client is responding.

reliable change index The least number of units a score can change on a measure to be certain that the change was not a chance fluctuation due to measurement error inherent from the reliability of the instrument.

Outcome measures are procedures used to document client functioning before, during, and after participat-

ing in psychotherapy. These can include self-report questionnaires, therapist and clinician rating scales, scales completed by the clients' relatives, or even records such as school, medical, insurance, or employment history.

I. THE PURPOSE OF OUTCOME MEASURES

The accurate measurement of clients' responses to psychotherapy is vital in order to (1) improve psychotherapy services both at the individual clinician level and at the level of establishing viable treatment protocols for specific disorders; and (2) demonstrate the effectiveness, including cost-effectiveness, of clinical interventions to interested parties (i.e., consumers, clinicians, researchers, third-party payers, administrators, and those who develop policy).

II. MULTIDIMENSIONAL NATURE OF CLIENT CHANGE

The accurate measurement of client response to psychotherapy is complex due to the multidimensional nature of change. For example, a group of clients who meet the diagnostic criteria for depression may experience to a different degree each of the clinical symptoms (i.e., sadness, suicidal ideation, and so forth). In addition to these distinctions, clients may also experience

variations in other areas such as interpersonal difficulties, physical problems, financial concerns, work impairment, or substance abuse. These various difficulties are frequently the focus of therapeutic interventions, and proper assessment of a client's response to therapy requires that these areas also be evaluated. Hence, outcome measures by necessity must focus on many different areas of performance to give a complete picture of client functioning. Various researchers have proposed that outcome measures could conceivably evaluate aspects of client functioning such as (1) psychological symptoms, (2) interpersonal functioning in close relationships, (3) social role functioning in work or school, (4) physical health, (5) the cost of care and treatment utilization, (6) reduction in public health and safety threats, (7) client satisfaction, and (8) global well-being or quality of life.

III. EXPERIMENTAL DESIGN AND OUTCOME MEASURES

The purpose of an outcome study influences the type of outcome measures used. Efficacy research is designed to determine the relative success of specific treatment protocols for a particular disorder. This type of research uses experimentally controlled conditions with homogeneous populations. Different treatment interventions are given to the experimental and control groups. The responses of the experimental and control groups to the different interventions are measured with scales designed for that population and/or disorder. For example, a study exploring the response of clients to different interventions for depression might use the Beck Depression Inventory (BDI, a short self-report instrument that the client completes), the Hamilton Depression Rating Scale (HDRS, a rating scale completed by a clinician), a structured diagnostic interview, a client self-report scale to assess cognitive distortions, and so on. Differences between the experimental group and the control group on such scales are compared. Conclusions concerning the relative efficacy of interventions are based on tests of statistical difference between the means of the experimental and the control groups.

Effectiveness research measures the mean response of a more heterogeneous group of clients in naturalistic clinic settings. This type of research is designed to discover the overall success of interventions with typical clients in the usual clinical environment. Outcome measures in such studies often evaluate a wider range

of difficulties because clients are not screened and come with more diverse problems. Examples could include instruments with a wider range of symptoms such as the Symptom Checklist 90-Revised (SCL-90-R, a 90-item self-report instrument completed by the client), program evaluation surveys, or client satisfaction questionnaires.

Patient-focused research centers on observing the individual client's response throughout the course of therapy and afterward. This approach determines how each particular client is responding in therapy. Outcome measures that sample a wide range of symptoms are also appropriate for this kind of study. Patient-focused research concentrates on the clinical significance of the individual client's responses to interventions rather than just the statistical significance of differences between group averages as is common in efficacy and effectiveness studies. Establishing the clinical significance of change reveals not just the magnitude of change but also the meaning of change for the individual client.

The most commonly accepted method of defining clinical significance has two components. First, a cutoff point that distinguishes between the "normal" and "dysfunctional" populations on the outcome measure is established. For example, the cutoff point could simply be defined as one standard deviation above the mean of the "normal" group on the measure (or below, depending on which way is more dysfunctional). The second step is to determine the reliable change index (RCI). The RCI is the minimal number of units the client's score must change between administrations to reliably say that the change is not due to chance fluctuation. The RCI is calculated by dividing the absolute change between two scores on the same instrument by the standard error of measurement for that instrument. For a clinically significant positive change to occur by this two-part definition, a client's change in score between the initial administration and subsequent administrations of the scale would have to (1) move from the "dysfunctional" side of the cutoff point into the "normal" range, and (2) move at least as many units as the RCI to ensure that the change was not due to measurement error. Cutoff points and RCIs have been established for many of the most commonly used outcome instruments. For example, on the BDI a client's total score after the initial administration would have to be under 14 (the cutoff score to be in the "normal" population), and would have to be at least 7 points lower than the initial administration in order to comply with this definition of a clinically significant change.

IV. BRIEF HISTORICAL REVIEW AND COMMON OUTCOME MEASURES

The theoretical orientation of researchers has historically influenced the type of instruments used to measure client change. For example, due to the influence of Freudian dynamic psychology, early measures such as the Thematic Apperception Test and the Rorschach Ink Blot Test attempted to measure changes in unconscious processes as a result of participation in psychotherapy. Later, measures such as the Q-Sort Technique were used because of their congruence with client-centered theory. Such procedures are no longer used due to poor psychometric qualities, dependence on inference, and the amount of time and cost required to administer and score them. Measures consistent with behavioral theory (behavioral monitoring) and cognitive theories (e.g., Irrational Beliefs Inventory) have also been used with interventions consistent with those theories.

Early efforts to document client outcome also relied heavily on unstandardized procedures and therapists' ratings of the clients' general improvement in one dimension. More recent efforts have focused instead on measuring outcome in many areas of functioning from a variety of viewpoints. This could include samples from the client, outside observers, relatives, physiological indices, and institutional information such as employment of school records. Current outcome measures have also improved in that they focus on specific symptoms without being theory-bound. Some measures can be used to examine patterns of change over time because they are brief and can be repeated many times through the course of therapy.

Several reviews have demonstrated which instruments have been most frequently used in outcome studies over the past three decades. The most frequently used standardized self-report measures include the State-Trait Anxiety Inventory (STAI), the Minnesota Multiphasic Personality Inventory (MMPI), the Rotter Internal-External Locus of Control, the S-R Inventory of Anxiousness, the BDI, and the SCL-90. A more recent measure, the Outcome Questionnaire-45, (OQ-45, a 45-item self-report questionnaire that measures the clients symptoms and self-distress, functioning in close interpersonal relationships, and social role functioning in society) has been used in a variety of studies to examine patterns of change in psychotherapy. The Hamilton Rating Scale for Depression (HRSD) is the most common scale used by therapists or expert raters, and the Locke-Wallace Marital Adjustment In-

ventory has been used most frequently with significant others to describe changes in relatives participating in therapy.

Unfortunately, researchers studying client outcome in psychotherapy have more frequently created their own unstandardized measures to study client response to treatment. The use of unstandardized measures results in difficulty in communicating, interpreting, and integrating findings between treatment approaches and across studies. Many researchers have therefore proposed the notion of individualizing outcome measures. This usually entails creating specific treatment goals for clients and rating their progress on a graded series of possible outcomes from least to most desirable. The Target Complaints Measure and Goal Attainment Scaling are examples of this type of approach. These approaches have not yet produced valid, reliable, unbiased measures of outcome with findings that are easily integrated across studies.

V. CATEGORIZING OUTCOME MEASURES

As has been mentioned, client outcome to psychotherapy is complex due to (1) the different purposes of outcome research and the resulting variations in research design (efficacy, effectiveness, and patient-focused research; statistical vs. clinical significance); (2) the multidimensional nature of client change; (3) the diversity in psychological theories and approaches to treatment (4) the lack of consistent use of standardized instruments; and (5) the need to evaluate outcome from a variety of viewpoints (such as the therapist, patient, and significant others). One way to bring order to this complexity is to categorize outcome measures on four dimensions: content, temporality, source, and technology. It is possible to categorize any outcome measure on each of these dimensions.

The content dimension refers to the aspect of functioning that is being sampled. This could include intrapersonal events (affect, cognitions, behaviors, symptoms), interpersonal events within close relationships, and the fulfillment of social roles through the client's interaction with society at large (i.e. work and/or school performance).

The temporality category refers to two aspects of a measure. First, it can reflect whether the instrument measures unstable state-like constructs that are expected to show change as a response to psychotherapy versus stable trait-like constructs that are more likely to remain

consistent. Second, the temporality category also calls attention to the number of times the researcher uses the instrument during the course of the study. Some researchers administer an instrument both before and after therapy, whereas others utilize repeated administration throughout the course of therapy to establish a pattern of change both during and following treatment.

The source dimension refers to who completes the instrument: the client, the therapist, relevant others, trained observers, or a social where records are maintained. This dimension is a continuum moving from those most involved with therapy to those least involved. A robust finding is that studies using measures of outcome from different sources do not always yield consistent results. For example, treatment of a phobia may produce a reduction in behavioral avoidance as rated by observers, but it may not produce a decrease in levels of self-reported discomfort. This highlights the need for careful consideration of the source of outcome data in discerning the true impact of therapeutic intervention.

The technology dimension refers to the method or process of data collection. For example, this could include subjective global retrospective ratings of improvement at the end of therapy by the therapist or the client, more careful descriptive procedures that pinpoint specific symptoms at the time of the assessment, frequency counts of observed behaviors by trained observers, or measures of physiological status (e.g., electrodermal response, heart rate). The type of technology used influences the findings of outcome studies. For example, studies using measures that are more open to bias, such as posttherapy retrospective global ratings of change, will produce larger treatment effects than studies that use measures that are less susceptible to rater bias. Scales that are less susceptible to bias, such as those requiring descriptions of specific symptoms at the time of the administration of the instrument, lead to smaller estimates of treatment effect sizes. Thus researchers and consumers of outcome research need to consider carefully the type of technology used in the study when interpreting the findings.

The most common outcome instruments sample intrapersonal content (symptoms or distress) with descriptive technology (assessing current functioning at the time of administration) using self-report as the source. On the temporality dimension, the instruments are usually used as both pre- and posttherapy measures, and are intended to measure state-like client characteristics that hopefully change as a response to therapy. This means that the typical outcome instrument requires that the client rate his or her own behavior, feelings, and symptomatic distress on a

paper-and-pencil measure. This would include instruments such as the BDI, the SCL-90-R, or the OQ-45.

VI. CHARACTERISTICS OF GOOD OUTCOME MEASURES

Researchers have often called for the creation of a “core battery” of outcome instruments to facilitate the comparison and integration of research findings. No such battery has materialized, but the following guidelines in outcome research and the use of instruments have evolved: (1) Specify clearly what is being measured to facilitate replication; (2) examine client functioning from diverse perspectives; (3) use a variety of type of scales and methods; (4) utilize symptom-based atheoretical instruments; (5) examine patterns of change over time with repeated administrations of the measure; (6) instruments should be inexpensive, and should be easy to score and administer; (7) scales should be appropriate for clients with a variety of diagnoses; (8) instruments must be psychometrically sound (standardized, reliable, and valid) and be sensitive to change; (9) instruments must be less susceptible to bias by focusing on the current functioning of the client; (10) they should have enough items in the “normal” and “dysfunctional” range to correct for possible floor and ceiling effects; and (11) they should sample a variety of content areas such as symptoms, interpersonal functioning, and performance in social roles.

VII. FUTURE RESEARCH POSSIBILITIES

With cutoff points and reliable change indexes available on many of the most commonly used instruments, clinicians can now use repeated administrations of brief symptom-oriented measures to see how well clients are progressing in therapy. Both clients and clinicians could be given feedback on how the client is responding, and studies could examine how such immediate feedback improves the outcome and process of therapy. In addition to this, normal patterns of change or “recovery curves” that typify the usual progress of clients during therapy could be formulated for specific outcome instruments. The progress of the individual client could then be compared with the usual progress of clients with the same initial level of disturbance. If patients are not progressing as well as their cohorts, therapists could use that information to reassess and restructure therapeutic interventions.

With sound outcome measures, therapeutic effectiveness could be established for specific disorders, interventions, programs, and even individual providers. Questions concerning “dosages of therapy” for different patient subtypes or disorders could be explored. Further work could be performed linking client outcome with the process of psychotherapy. It would be possible to correlate client progress with specific behaviors during therapy. It would also be possible to study the relationship between clients’ pretherapy characteristics and their distinct responses to therapeutic interventions. This would help answer the question of which types of clients respond best to which kinds of interventions or processes.

With sound outcome measures, the target of defining cost-effective treatment becomes more attainable. This would entail identifying which interventions, therapists, and therapeutic processes result in the best outcomes for which kinds of clients suffering from which kinds of disorders for the least expenditure in time and money.

The wise use of solid outcome measures can give feedback to clinicians about how to help improve their own practice. Master clinicians who repeatedly produce better outcomes can be studied so that other practitioners can learn from their procedures.

VIII. SUMMARY

Outcome measures examine the client’s response to psychotherapy. The use of such measures can improve psychotherapy services and can inform the decisions made by all parties involved in the process. Client change is multidimensional (i.e. personal distress, interpersonal functioning, social role fulfillment), and needs to be assessed from a variety of viewpoints (such as the therapist, the client, and significant others).

Different experimental designs (efficacy, effectiveness, patient-focused research) have different purposes and require different types of outcome measures. Patient-focused research centers on the clinical significance of a change for the individual client rather than on the statistical significance of a difference between group means on a scale score. One definition of clinical significance is that (1) the client move from the “dysfunctional” to the “functional” range on the measure; and (2) the client’s change is greater than a chance fluctuation due to the measurement error of the instrument (is greater than the reliable change index).

Early outcome measures were linked more heavily to theoretical trends of the day, and may have relied more

heavily on therapist global retrospective ratings of client improvement. More recent measures are atheoretical, pinpoint a wider variety of specific symptom complaints at the time of the administration, are brief, and can be administered repeatedly to examine patterns of change. The widespread use of unstandardized measures in the past has resulted in difficulty coordinating and integrating findings.

Outcome measures can be classified according to the dimensions of content (the aspect of client functioning sampled), temporality (the degree to which the measure focuses on state or trait characteristics, and the utility of the instrument in being administered repeatedly), source (who completes the instrument), and technology (the process by which the information is gathered). The type of instrument chosen influences the reported effect sizes of the interventions. Careful researchers need to pick the type of outcome measure that will best answer their research question, and that will most clearly add to the body of growing outcome literature. “Core batteries” of outcome measures have not been established, but the characteristics of a good outcome measure have been identified. As good measures are utilized, future research could more clearly examine what interventions work best with which types of clients and disorders. Cost-effectiveness of interventions can be more clearly investigated, client progress can be monitored during the course of therapy, and clinicians can more easily learn from each other.

GLOSSARY

graduated guidance Adjustment of the amount of force applied to the client's body to provide the minimum amount of physical assistance necessary for completion of required movements.

manual guidance Therapist placement of hands on the client's body to physically assist the client through required movements.

stereotyped behavior Repetitive acts that have no apparent functional effect on the environment.

Overcorrection is a diverse set of treatment techniques that involve contingent delivery of aversive consequences following undesirable behavior. The unique element of overcorrection is that the aversive consequences involve correct forms of behavior directly related to the undesirable act. This use of topographically similar responses is regarded as the critical feature that distinguishes overcorrection from other punishment techniques.

I. DESCRIPTION OF TREATMENT

Overcorrection procedures involve the contingent use of aversive consequences that are directly related in form (i.e., topographically similar) to the undesirable behavior they follow. In a 1982 review of overcorrection research, Richard M. Foxx and D. R. Bechtel identified several other important features of overcorrection.

1. The client is made to experience the effort that would be required of other individuals to correct the personal or environmental effects of the client's undesirable behavior.

2. The client also is required to rapidly perform overcorrection procedures, thereby increasing the effort involved.

3. Physical or manual guidance is employed to ensure client cooperation with, and completion of, the overcorrection procedures.

4. Manual guidance is graduated in that it is adjusted according to the degree to which the client voluntarily responds to directions to perform the required overcorrection acts.

The sequence of procedures used in overcorrection involves several important steps. Initially, the client is informed of his or her inappropriate action. Then the client receives brief verbal instruction regarding the overcorrection responses required. If the client does not immediately initiate the instructed responses,

graduated guidance is provided. Finally, graduated guidance is terminated when the client complies with and/or completes the overcorrection procedure.

Originated in the early 1970s by Nathan H. Azrin and Richard M. Foxx, overcorrection procedures were classified by their developers as consisting of either restitutional or positive practice procedures. Restitutional overcorrection is employed in the treatment of maladaptive behaviors that result in disturbance to the environment (including harm to the client). Such procedures require an individual who demonstrates a maladaptive target behavior to restore the environment and him- or herself to a state that is vastly improved in comparison with conditions prior to the maladaptive behavior. The objective of overcorrecting environmental effects is achieved after first identifying the specific and general disturbances created by the misbehavior and identifying the behaviors needed to greatly improve the consequences of the disturbance. The individual then is required to perform corrective actions in the appropriate context whenever the undesirable behavior occurs. Useful examples of restitutional overcorrection procedures from Foxx and Azrin's initial studies include procedures referred to as oral hygiene training and household orderliness training. Oral hygiene training was employed as a consequence for repetitive mouthing, a behavior that may cause self-infection. The procedure involved verbal instruction and physical guidance directing the client to cleanse the teeth, gums, and lips with mouthwash for a period of 10 min. Household orderliness training was employed as a consequence for acts involving property damage. After throwing or overturning furniture, the client was required to spend 30 min or more wiping tables, emptying ashtrays, and rearranging magazines as well as returning the furniture to its original position.

Positive practice overcorrection is employed in the treatment of maladaptive behaviors that result in no apparent disturbance to the environment or harm to the client. Positive practice procedures require the individual who demonstrates a maladaptive target behavior to repeatedly practice appropriate responses that are relevant to the maladaptive behavior and the context in which it occurred. This objective, repeatedly practicing correct forms of relevant behavior, is achieved after first identifying appropriate behaviors that should be practiced. The client then is required to perform the correct behaviors after each occurrence of the target behavior. In Azrin and Foxx's initial applications, positive practice overcorrection procedures referred to as functional movement training were used to treat forms of self-

stimulatory behaviors such as stereotyped head weaving and repetitive hand clapping. The procedures involved physically restraining either the client's head or hands and then verbally instructing and physically guiding the client through a series of head or hand movements for a period of 5 min.

Overcorrection procedures have been employed in the treatment of self-injurious behaviors, inappropriate toileting, and undesirable social and academic behaviors, as well as inappropriate oral behaviors, aggressive-disruptive behaviors, and self-stimulatory behaviors such as those cited in the preceding examples. Incorporating correct forms of behavior that are topographically similar to a wide range of target behaviors, numerous procedural variations of restitutional and positive practice overcorrection have been developed. In addition to oral hygiene training, household orderliness training, and functional movement training procedures, clinicians have developed overcorrection procedures labeled as medical assistance training, cleanliness training, quiet training, personal hygiene training, personal appearance training, social apology/reassurance training, required relaxation, hand control and awareness, autism reversal, and theft reversal.

Due to potential confusion that may arise from the various procedural labels used to characterize overcorrection treatments, Richard Foxx and D. R. Bechtel have recommended the elimination of all procedural terms and labels, including restitution and positive practice. These authors contended that overcorrection procedures consist of consequences that should be individually designed for each specific target behavior. Accordingly, overcorrection procedures should be described on a case-by-case basis, thus limiting the usefulness of procedural terms and labels.

Foxx and Bechtel noted that the use of the term positive practice has resulted in erroneous inferences regarding the inclusion of negative practice and positive reinforcement as components of overcorrection. It is important to recognize that overcorrection procedures do not include either of these elements. Overcorrection procedures are different from negative practice, a procedure whereby the client is asked to repeatedly practice the undesirable behavior. Moreover, the inclusion of positive reinforcement as a component in overcorrection procedures would alter the aversive nature of these procedures and possibly lead to increases in the target behavior. In those overcorrection studies in which positive reinforcement has been employed, such reinforcement was administered for appropriate behaviors that occurred during times when overcorrection

was not delivered, rather than for correct forms of behavior that were required as part of the overcorrection sequence.

II. THEORETICAL BASES

As aversive stimuli that produce decrements in the behaviors they follow, overcorrection techniques clearly function as punishment procedures. When delivered immediately following undesirable behavior, overcorrection also includes timeout from positive reinforcement, as the client's ongoing behavior is interrupted and opportunities to obtain reinforcement from the environment are eliminated during overcorrection. Negative reinforcement, in the form of removal of manual guidance and termination of the overcorrection procedure, also occurs for the individual's compliance with and completion of the required overcorrection acts.

Overcorrection procedures have been regarded as unique compared with other punishment procedures because of their use of correct forms of behavior that are topographically similar to the maladaptive target response. Whether this element of topographical similarity results in behavioral outcomes that are different from outcomes of other punishment procedures is a question that has not been adequately addressed. Several studies have demonstrated that variations of overcorrection that employ topographically dissimilar forms of behavior can also produce suppression of target behaviors. Moreover, few studies have included data or anecdotal reports of increases in appropriate behavior associated with the use of topographically similar overcorrection procedures. Accordingly, Foxx and Bechtel have recommended the elimination of terms referring to the "educative" and "training" functions of overcorrection. Thus, researchers are left with the question of whether overcorrection entails anything more than an elaborate, albeit effective (as is discussed in the next section), set of punishment procedures.

III. EMPIRICAL STUDIES

Although overcorrection procedures have been utilized most commonly with persons with mental retardation in institutional settings, these procedures also have been employed in the treatment of autism, emotional disturbances, and behavior disorders in a variety of settings. Although many of the treatment studies have focused on children, significant numbers of studies have

been conducted with adults as well. In their 1982 review of 97 overcorrection studies, Foxx and Bechtel classified the maladaptive behaviors treated with overcorrection techniques into categories of aggressive-disruptive behaviors, self-stimulatory behaviors, self-injurious behaviors, toileting behaviors, inappropriate oral behaviors, and educational-social development behaviors. Historically, the vast majority of applications of overcorrection have occurred with aggressive-disruptive, self-stimulatory, and toileting behaviors.

The initial application of overcorrection procedures occurred as a method of toilet training individuals with mental retardation in institutional settings. An extensive set of procedures known as dry-bed training was used following bowel and bladder accidents. The procedures usually consisted of mopping the floor, cleaning wet and soiled items, redressing oneself in clean clothing and replacing bed linens, and repeatedly walking to the toilet and performing a series of responses (pulling pants down, sitting, etc.) involved in appropriate toileting. These procedures later were modified for application to normal children with greater emphasis placed on the positive practice component (i.e., repeatedly walking to the toilet and rehearsing appropriate toileting behaviors). Similar procedures have been applied to children diagnosed with enuresis or encopresis. Despite some variation across studies and populations treated, the duration of overcorrection with toileting behaviors usually has been 30 min or greater, often ranging up to 45 min. Because overcorrection procedures usually have been combined with other effective procedures such as Mowrer and Mowrer's bell-and-pad training and reinforcement for appropriate voiding, it is not possible to determine the relative contribution of overcorrection to the successful outcomes reported in such multicomponent treatment programs. However, reductions of greater than 80% in wetting and/or soiling usually have been reported, with near 100% reductions often being achieved within 1 to 3 months and maintained at 2- to 18-month follow-up.

With aggressive-disruptive behaviors, overcorrection has been employed rather extensively in treating relatively mild problems, such as out-of-seat behavior or talking out, as well as in treating more extreme acts, such as hitting, biting, and assaultive sexual behavior. Typical overcorrection procedures for aggressive-disruptive behaviors include picking up thrown or ripped items, apologizing to the victim, and/or assisting in medical care of the victim. In a few studies, overcorrection has involved requiring the aggressor to lie down, to pat and stroke the victim, or to engage in a series of arm

movements. The duration of these overcorrection procedures has ranged from less than 1 min to 2 hr, with the most frequent durations being 5 to 10 min. In relatively few of these studies has overcorrection been used as the only treatment procedure. Instead, many studies have combined overcorrection with procedures such as verbal warnings and positive reinforcement during periods when the client was not engaged in overcorrection acts. Using DRI (differential reinforcement of incompatible behaviors) or DRO (differential reinforcement of other behaviors) procedures, positive reinforcement has been made contingent either on responses that are incompatible with the target behaviors or on the absence of aggression or disruption for specified intervals. In investigations of overcorrection treatments, reductions of greater than 85% have been observed within 2 weeks to 2 months for most aggressive-disruptive behaviors, with a large number of researchers reporting reductions of near 100%. Maintenance of behavior change has been reported in most studies, with follow-up periods ranging from 5 weeks to 1 year.

In a large number of studies, overcorrection has been used to treat a variety of self-stimulatory behaviors including hand flapping and posturing, stereotyped vocalizations, rocking, hair pulling, and mouthing objects. Behaviors most frequently treated have been hand flapping, rocking, and mouthing. The most commonly used overcorrection procedures for these responses consist of required movement of the body parts involved in the self-stimulatory behaviors. Other common procedures have included enforced toy play and required toothbrushing. The duration of the overcorrection procedures for self-stimulatory behavior has ranged from 30 sec to 20 min, with a typical duration of 2 min. Relatively few treatments for self-stimulatory behaviors have employed overcorrection alone, as most combine overcorrection with other procedures. Additional treatment procedures have included verbal warnings, prevention of self-stimulatory behavior by physical restraint or other means, and/or positive reinforcement (i.e., DRI or DRO procedures). Nearly all investigators reported reductions in target behaviors of greater than 80%, with near 100% reductions observed in the majority of studies. However, follow-up data have been reported in very few studies, with maintenance of behavior reductions rarely reported for longer than 1 to 3 months.

Self-injurious behaviors, such as face slapping, head banging, hand biting, and eye poking and gouging also have been the focus of a relatively small number of overcorrection studies. The most frequently treated

self-injurious behaviors have been head banging and biting. Overcorrection procedures for these behaviors usually have consisted of required movement of the body part involved in the self-injury, sometimes combined with required toothbrushing for self-biting, hair combing for head banging, required bed rest, and applying medication or cream to the affected area. The duration of these overcorrection procedures typically has ranged from 5 to 10 min. Overcorrection has been utilized as the only treatment procedure in most studies but has been combined with positive reinforcement of alternate behaviors in a few instances. Reductions in self-injurious behaviors of 95 to 100% have been reported in less than 1 week of treatment for most cases. The majority of studies have reported follow-up data, with maintenance of treatment effects being demonstrated for 4 to 33 months posttreatment.

A handful of investigations have addressed maladaptive oral behaviors in individuals with mental retardation. This category of behaviors includes drooling, vomiting, rumination (the repeated rechewing and swallowing of regurgitated food), pica (the ingestion of nonnutritive substances such as paper or cigarette butts), and coprophagia (the ingestion of fecal material). Overcorrection procedures have consisted of picking up trash, required practice in correct vomiting, cleaning of vomited matter from various surfaces including walls and floors, and required handwashing, toothbrushing, and mouth wiping. Durations for such procedures have varied considerably, often involving periods of less than 2 min for rumination, drooling, and pica as contrasted with 20 min to 2 hr for coprophagia and vomiting. Brief durations of overcorrection have been used most often combined with other procedures such as DRO and positive reinforcement for appropriate behaviors. Except for drooling, near 100% reduction in these maladaptive oral responses has been reported at posttreatment. The majority of studies conducted follow-up assessments and reported maintenance of these reductions at 3 to 12 months posttreatment.

A limited number of studies have addressed various responses identified by Foxx and Bechtel as educational-social development behaviors. Maladaptive responses in this broad category include errors on academic-related tasks (e.g., oral reading, spelling, writing proficiency, manual signing) and failure to comply with directions/demands to stay on-task, attend class, share with other children, make eye contact, vocalize, eat appropriately, and perform tasks with adequate speed. Overcorrection procedures for these behaviors typically have consisted of requiring

clients to repeatedly correct academic errors, complete written academic tasks, comply with verbal instructions, and engage in required movements of specific body parts (e.g., hand movements with eating utensils or puzzle pieces, head movements in the direction of the therapist). Modeling and reinforcement procedures often have been included as treatment components in these studies. Combinations of these procedures usually have resulted in significant decrements in maladaptive responses, as well as significant improvements in compliance with instructions and accurate responding. However, relatively few studies examining the use of overcorrection procedures with social-academic behaviors have addressed issues of maintenance of behavior change.

As with other punishment procedures, the literature on overcorrection is replete with numerous reports (usually anecdotal in nature) of positive and negative side effects. The majority of studies that have provided data-based observations of side effects have examined stereotyped behaviors of a self-stimulatory or self-injurious nature. Associated with overcorrection have been reported increases in prosocial behaviors such as compliance, cooperation, and appropriate toy play, as well as increases in negative responses such as aggression, emotional outbursts, and nontargeted self-stimulatory behaviors.

IV. SUMMARY

In general, overcorrection represents a response-suppression method that has been demonstrated as highly effective in the treatment of a variety of maladaptive behaviors. Especially when combined with treatment procedures that promote appropriate behaviors, overcorrection has resulted in near elimination of aggressive and disruptive behaviors, self-injurious behaviors, inappropriate oral behaviors, and inappropriate toileting, as well as impressive decrements in self-stimulatory be-

haviors. Brief (i.e., 5 min or less), as well as extended, administrations of overcorrection have been demonstrated to suppress maladaptive behaviors with nearly equal effectiveness. As with most punishment procedures, many studies have reported positive and/or negative side effects with the use of overcorrection. Although a number of single case studies suggest the superiority of overcorrection when compared with other behavioral treatments, methodological problems inherent in these studies severely limit the conclusions that can be drawn from such comparisons. For this reason as well as ethical and practical considerations, inclusion of brief durations of overcorrection are recommended as a component of treatment protocols that provide positive reinforcement for incompatible responses and for alternate forms of appropriate behavior.

ment of pain a priority for all hospitalized patients. Clinicians treating pain need to consider factors such as the duration and intensity of the pain, its psychosocial context, and its associated psychiatric comorbidity. This article will examine the treatment of pain in a biopsychosocial framework, concentrating on psychotherapy as a tool to help treat the pain patient.

GLOSSARY

- acute pain** Pain from an obvious nociceptive source. It is generally self-limited and short-lived.
- automatic thoughts** Spontaneous and rapid, often inaccurate, interpretation of a situation.
- biofeedback** The technique of making unconscious, physiological processes perceptible to the senses through the use of a monitoring device in order to manipulate them by conscious mental control.
- chronic pain** Over 6 months, the original nociceptive cause can no longer explain the duration or severity of the pain.
- continuous pain** Long-standing pain from an obvious source (e.g., cancer pain).
- hypnosis** Induction of a state of selective attention, usually through a combination of imagery and relaxation techniques.
- nociceptor** A specialized peripheral nerve receptor the function of which is to receive pain stimuli.

The treatment of pain is a difficult challenge for all physicians. Recently, JCAHO has made adequate treat-

I. TYPES OF PAIN

A. Overview

Pain was initially perceived as being purely a sensory event, resulting from tissue damage. The fact that patients respond to the same pain-generating stimulus in vastly different manners suggests that such an explanation is much too simplistic. Pain should more appropriately be viewed as a perceptual phenomenon rather than a sensory one. In a perceptual framework, both sensory and psychological factors are incorporated, and there is a much greater recognition of the importance of the attentional, cognitive, affective, and social components to the pain experience.

Physicians often question whether their patients are experiencing “real pain” or not. Such concern is generally useless, as it views pain solely as a sensory rather than a perceptual experience. Accepting patients’ pain complaints as real is important; treatment can then be based on the sensory and psychological experience unique to that patient. Pain is often described as acute,

continuous, or chronic in nature. Table I examines the differences between these types of pain.

B. Acute Pain

In most instances, the treatment of acute pain is uncomplicated. Adequate pharmacological analgesic relief is the first guiding principle. Physicians have often been leery of using narcotic medications even for severe pain because of a fear of the patient becoming addicted. This fear is grossly exaggerated, and narcotics can be used when clinically appropriate with minimal risk of addiction. Patients occasionally do not respond as well as expected to standard pharmacological analgesic treatment, and, in these instances, psychiatric consultation is sometimes requested. Psychosocial components to the pain should be explored in depth, and nonpharmacologic interventions can often be quite helpful. Many of these interventions will be described below.

C. Continuous Pain

Patients suffering from continuous pain pose very different challenges. For example, a patient with bone metastases may suffer some degree of pain no matter how aggressively he or she is treated with narcotic medications. The goal in managing pain in these patients is to help the patient learn to accommodate to the pain. A variety of psychotherapies can accomplish this task and may also permit the patient to decrease the dose of pain medication, minimizing the overall side effect burden. Biofeedback, cognitive-behavioral therapy, and hypnosis have all been demonstrated to be effective in such patients and will be described in further depth below.

D. Chronic Pain

Psychiatric consultation is most frequently requested for patients suffering from chronic pain. In these pa-

tients, the original nociceptive cause of the pain is no longer sufficient in explaining the current level of pain that the patient is experiencing. Pain behavior demonstrated in chronic pain patients often leads the physician to question the veracity of the pain complaints. The patient may complain of being in agonizing pain, but appear quite comfortable, or he may only cry out in pain only when the health care professional walks past his hospital room. Such behavior happens when the patient begins adapting to the pain. If the physician questions whether the pain is real because of this, then the patient may feel he needs to prove that his pain is real. Often, the disruption of the doctor-patient relationship that may ensue in such instances may further complicate the treatment. Patients need to be assured that their pain is real, and that the request for a psychiatric consult does not mean that the physician believes the pain is "all in their head." The consulting psychiatrist should emphasize that the goal of treatment is not cure of the pain, but instead to help the patient deal with it better. Aggressive treatment of underlying psychiatric conditions such as depression or anxiety that are often present in patients with chronic pain is necessary. Pharmacologic treatment must address both the pain and the underlying psychiatric issues to be successful. Psychotherapy interventions must do the same.

II. COGNITIVE-BEHAVIORAL THERAPY FOR PAIN DISORDERS

A. Overview

Cognitive-behavioral therapy has been shown to be effective in patients suffering from either continuous or chronic pain. Patients are taught skills such as distraction, imagery techniques, and calming self-talk, and learn to decrease negative, catastrophizing thoughts that are present in pain patients. Restructuring the patients'

TABLE I
Differences in Pain Types

<i>Pain type</i>	<i>Obvious nociceptive source</i>	<i>Response to narcotics</i>	<i>Time course of symptoms</i>	<i>Associated with psychological symptoms</i>
Acute	Yes	Good	Short, generally 1 month or less	No
Continuous	Yes	Good	Over 6 months	Sometimes
Chronic	No	Fair to poor	Over 6 months	Frequently

cognitive approach to pain is important. Beliefs about their condition, their expectations for the future, and cognitive distortions must all be examined. A catastrophic, overly negative view of the future has been found to be correlated to more intense pain reports. Helping the pain patient to have a more realistic assessment of the future may enable him or her to deal with the pain in the present.

B. Automatic Thoughts

Discovering the automatic thoughts that are present can enable them to be replaced with more realistic thoughts. For example, when the pain becomes worse, an automatic thought may be triggered such as “I’m never going to get better” or “I can’t do anything.” Such automatic thoughts often lead to more emotional distress, and increased physical and psychological dysfunction. Challenging the patients’ inaccurate automatic thoughts can provide the patient with a more realistic and adaptive view of the problem. These same cognitive-behavioral techniques can also be used to treat the comorbid depression and anxiety that are often found in patients with pain.

C. Homework

Homework assignments are always an important part of cognitive-behavioral therapy. In patients with pain disorders, homework assignments may include asking patients to keep track of which specific thoughts, actions, and behaviors exacerbated or helped the pain. Homework can also be used to aid the patient in utilizing the coping strategies discussed in the therapy session. Homework should start easier and get progressively harder as the therapy continues. When easier tasks can be accomplished, the patient is more likely to be motivated to attempt to accomplish the more difficult tasks.

D. Relaxation Training and Imagery

Relaxation training and imagery are important components of cognitive-behavioral therapy for pain patients as well. Progressive muscle relaxation, stretch-based relaxation, and breathing relaxation are all techniques that have been shown to be beneficial. Progressive muscle relaxation involves tensing a muscle group for several seconds, passively focusing on how the tensed muscle feels. The tensed muscles are then released, with passive focus of attention on how the muscles feel as the relaxation

takes place. This sequence is then applied to the major muscle groups of the body.

Stretch-based relaxation is utilized when tensing muscle groups exacerbates the pain. In stretch-based relaxation, series of muscles are very gently stretched without the tensing and relaxing techniques utilized in progressive muscle relaxation. For patients immobilized by their pain, stretch-based relaxation rather than progressive muscle relaxation is often utilized. Once patients become more mobile, progressive muscle relaxation techniques can begin to be used in combination with a stretch-based program.

Breathing relaxation focuses on slow, patterned abdominal breathing. Patients are instructed to inhale slowly and deeply through the nose, allowing the abdomen to expand. With inhalation, the abdomen rises, and the diaphragm moves downward. As the breath continues, the lower part of the chest expands and eventually the upper part of the chest does so as well. When the breath is completed, the patient is instructed to hold the breath for approximately 1 second, and then begin exhaling. The process is reversed with exhalation. The breath is slowly released as the abdomen is drawn back in and the diaphragm is lifted back up. The previously expanded chest now relaxes and exhalation is completed. The empty lungs are held this way for 1 second, and the cycle is again repeated. The entire process should take approximately 8 to 10 seconds, with inhalation and exhalation each lasting 3 to 4 seconds, and pauses following the completion of inhalation and exhalation lasting 1 second.

The use of imagery is often a part of cognitive-behavioral treatment as well. Patients can imagine returning to a calm, relaxing place. For pain patients, this allows their attention to be taken away from their pain. Imagery can also be more specific to the pain. The patient who suffers stabbing, intense trigeminal neuralgia pain, may imagine a knife stabbing into his cheek and can then be guided in therapy into imagining the knife becoming duller, and then ultimately becoming a blunt piece of wood. Other patients may be asked to focus intently on their pain, paying particular attention to its character. Pain does not remain at a constant level, but worsens significantly at times. When the patient becomes more aware of the pain and its inconstant nature, they can be more successful in utilizing imagery to help decrease the pain.

E. Coping Skills

Cognitive-behavioral therapy also involves the practical application of techniques enabling better coping

with day-to-day pain. Diversional techniques such as reading or listening to music can be encouraged. Finding an appropriate pace for activities is equally important. Patients frequently alternate between doing too much, then being nearly immobilized from pain as a result. Encouraging activity, but in a restrained manner that is not likely to exacerbate the pain, is crucial for these patients. Other patients may be too inactive for fear of worsening their pain. Setting concrete, attainable goals may enable them to slowly become more active.

Cognitive-behavioral groups are utilized frequently in hospital-based pain programs. These groups often have a coping skills training component. Coping skills emphasized in such groups often emphasize assertiveness training, acknowledging and expressing feelings appropriately, and self-acceptance. When patients can hear from other fellow pain patients possible coping strategies, they are more likely to utilize them. Groups also offer the benefit of allowing patients to realize that they are not facing their problem alone.

F. Relapse Prevention

Relapse-prevention and maintenance of the learned skills in dealing with pain is an important part of cognitive-behavioral therapy as well. When patients have a flare-up of pain, especially when they have been relatively pain-free for a while, they will often become quite distressed, and feel that they need to “start all over” or that they will never get better. They frequently can forget the coping strategies and cognitive-behavioral techniques described above and can benefit from a short “refresher course.” Emphasizing that one bad day does not undo all the good days that came before it is important as well. Patients can often benefit from a systematic approach to identifying the cause of the increased pain and discovering ways to prevent future flare-ups.

III. OTHER THERAPIES

A. Operant-Behavioral Therapy

In the operant-behavioral approach to the patient with pain, the goal is simply to change behavior by reinforcing well behavior and ignoring pain behavior. The operant model pays particular attention to the role that the patient's family may play in contributing inadvertently to pain behavior. Pain behavior may have been reinforced by providing attention, or permitting the patient to avoid undesirable activity. The family of

the pain patient is told to ignore pain behaviors such as lying in bed moaning, while even small steps toward increased function are strongly reinforced. Homework assignments for both the patient and the family are often a part of the treatment. When both the family and the treating physician are involved, the benefits of this approach are magnified. An operant-behavioral approach to pain is often used in conjunction with a cognitive approach for additional therapeutic benefit.

B. Biofeedback

Biofeedback has often been used for a variety of pain complaints, including chronic tension headaches, low back pain, temporomandibular pain, fibromyalgia, and arthritis pain. Patients undergoing biofeedback become adept at monitoring physiological processes such as heart rate, muscle tension, and galvanic skin response. Patients learn to control these processes and thereby control overall physiological arousal. Biofeedback treatment often involves 10 to 20 sessions in which a physiological monitoring device is attached to the patient. The patient is then instructed to do whatever possible to alter the physiological parameter (e.g., skin temperature) in the specified direction. Biofeedback training typically includes training in specific relaxation strategies, such as progressive muscle relaxation or diaphragmatic breathing to aid patients to better control their physiological processes. The success of biofeedback is greatly dependent on the patient continuing to use the techniques learned in the biofeedback sessions at home.

C. Hypnosis

Hypnosis can also be a useful psychotherapeutic tool in the management of the pain patient. It has been shown to be effective in alleviating the chronic pain associated with cancer, irritable bowel syndrome, tension headaches, temporomandibular disorders, and a variety of other chronic pain disorders. Hypnosis is defined as the induction of a state of selective attention, typically through relaxation and imagery techniques. Hypnosis has both presuggestion and postsuggestion components. The presuggestion component involves attentional focusing through the use of imagery, distraction, or relaxation, and has features quite similar to relaxation techniques discussed earlier. During the suggestion component, the specific goal is introduced (e.g., a change in the nature of the pain from intolerable to mildly annoying). The postsuggestion phase involves continued use of the new behavior after hypnosis is terminated.

The hypnotherapist can, at times, teach patients to hypnotize themselves. Self-hypnosis has the potential to be an effective method for controlling both acute and chronic pain as well, especially for the motivated patient that will practice the technique at home. While not all patients can master this technique, benefits for those who can may include an increased sense of control over their illness and less dependency on the health care system. As with any pain treatment technique, hypnosis works best when it is employed early in the pain cycle, before the pain has become severe enough to impair concentration.

Meditation serves a similar function to hypnosis or self-hypnosis for patients but does not involve suggestion, autosuggestion, or the induction of a trance state. Mindfulness meditation focuses on development of an awareness of bodily sensations and mental activities in the present moment to allow the body to relax and the mind to calm. Chronic pain patients generally feel at the mercy of their illness and are quite frustrated by how much their pain controls their life. Offering tools such as meditation and self-hypnosis that patients may utilize on their own empowers them and allows patients to feel that they are once again in control of their life.

Biofeedback, hypnosis, and meditation are often used in conjunction with cognitive-behavioral therapy. As described earlier, the relaxation techniques utilized in cognitive-behavioral therapy are used in biofeedback to aid the patient in garnering more control over physiological processes, and used in the presuggestion phase of hypnosis. There is an underlying presumption in cognitive-behavioral therapy, biofeedback, and hypnosis that it is possible to attenuate the effects of pain through the use of the mind. Each of these therapies requires active intervention on the part of the patient, especially when self-hypnotic techniques are added to regular hypnotherapy. The patient must take not only an active part in his or her therapy, but must continue

to do so once at home to ensure that gains made will be sustained. Table II describes the similarities and differences in cognitive-behavioral therapy, operant-behavioral therapy, biofeedback, and hypnosis.

IV. COMBINED TREATMENT OF PAIN AND PSYCHIATRIC DISORDERS

Patients with pain disorders often have comorbid psychiatric disorders. Patients who have either continuous or chronic pain are very likely to develop depression. Other psychiatric disorders, including anxiety and somatoform disorders, can frequently be found as well. The psychotherapist treating the patient who has a pain disorder must be alert to the likelihood of psychiatric disorders and ensure that they too are aggressively treated. A better treatment outcome is likely when both the comorbid psychiatric illness and the pain disorder are treated, rather than exclusively focusing on one or the other.

Many of the therapeutic methods utilized to treat the comorbid psychiatric illnesses can also be helpful in treating the pain disorder. Pharmacologic approaches such as antidepressants are often used as adjunctive agents in the treatment of pain disorders, as well as being a primary method in the treatment of depression. Anticonvulsant medications such as carbamazepine and gabapentin have often been used in a variety of pain disorders and are considered useful as augmenting agents in the treatment of anxiety or depression.

Cognitive-behavioral therapy techniques useful in the treatment of pain disorders are also helpful in the treatment of depression and anxiety. Relaxation therapy techniques utilized in the treatment of pain disorders are also frequently used in the treatment of anxiety disorders. Other cognitive-behavioral techniques, such

TABLE II
Therapies for Pain Disorders

Therapy	Automatic thoughts	Relaxation techniques	Homework	Family involvement	Monitor physiological process	Induction of state of selective inattention
Cognitive-behavioral	Yes	Yes	Yes	Yes	No	No
Operant-behavioral	No	No	Yes	Yes	No	No
Biofeedback	No	Yes	Yes	No	Yes	No
Hypnosis	No	Yes	No (except in self-hypnosis)	No	No	Yes

as cognitive restructuring and changing automatic thoughts, are common to the treatment of pain disorders, depression, and anxiety. The patient who has learned these techniques in one context should be able to more easily apply them when the other illness is being treated.

When treatment for the comorbid psychiatric illness is initiated, the therapist must be careful not to imply that this means that the therapist feels that the illness is “all in the patient’s head.” Most patients will readily accept the concept that psychiatric illness and pain disorders amplify each other’s effects. For example, when a patient’s pain becomes worse, this will often worsen a depression. A worsened depression makes it even harder to handle the pain, and this can lead to further pain, and even more depression. If the depression can be treated, then the patient’s capacity to tolerate pain may increase as well.

In a similar vein, anxiety disorders must be appropriately treated as well. Patients with anxiety disorders frequently suffer from muscle tightness and have a constant low-grade muscle tenseness. For the chronic pain patient, this constant tension can be a source of additional discomfort. Treatment of anxiety with psychotropic medications or psychotherapy is necessary for complete treatment of the underlying pain.

V. SUMMARY

The treatment of the patient with a pain disorder poses a significant challenge for any clinician. Patients often resent being referred to a mental health professional, and are hesitant to accept that there may be an emotional overlay to their pain complaints. Clinicians need to take care not to suggest that the pain experienced is anything less than real, but also need to treat the comorbid psychiatric illnesses that are often present in the chronic pain patient population.

Psychotherapeutic approaches that have been shown to be effective in the treatment of patients with pain disorders include cognitive-behavioral therapy, operant-behavioral therapy, biofeedback, and hypnosis. Relaxation techniques such as progressive muscle relaxation are often used in cognitive-behavioral therapy, biofeedback, and hypnosis and are an important component of the treatment of pain disorders. Patients with psychiatric disorders such as anxiety or depression can often benefit from a psychotherapeutic approach that utilizes many of the features found in the treatment of pain disorders.

GLOSSARY

agoraphobia Significant anxiety about places or situations from which escape might be difficult or in which help might not be easily available in the event of having a panic attack. Approximately one-third of patients with panic disorder meet this additional diagnosis.

panic disorder An anxiety disorder that is characterized by recurrent and unexpected panic attacks, which are discrete episodes of intense fear that are accompanied by a number of typical somatic and cognitive symptoms. Approximately 3% of the population is affected by this disorder over the course of a lifetime.

This article presents the therapeutic techniques, the theoretical basis, and the empirical evidence of cognitive-behavior therapy, an empirically supported intervention for the treatment of panic disorder and agoraphobia.

I. DESCRIPTION OF TREATMENT

The most effective psychological treatment for panic disorder with agoraphobia to date is cognitive-behavior

therapy (CBT). This treatment is usually delivered in 12 weekly 60-min individual treatment sessions but can also be conducted in a small group format consisting of two therapists and between four and seven patients. Between each session, the patients are given clearly specified “homework” assignments to practice the newly acquired skills that are discussed in treatment. In addition, patients are expected to complete daily monitoring forms in order to identify specific panic attack triggers. These monitoring forms also serve the purpose of monitoring the patients’ progress throughout treatment and of enhancing the patients’ sense of predictability and controllability.

One of the best-studied CBT manuals for panic disorder is the Panic Control Treatment protocol (PCT) developed by David H. Barlow and his colleagues. The treatment consists of the following components: (a) education about the nature of anxiety and panic; (b) training in slow breathing; (c) cognitive restructuring; (d) interoceptive exposure exercises; and (e) *in vivo* situational exposure exercises for individuals with high levels of agoraphobia.

A. Education about the Nature of Anxiety and Panic

During the first two sessions, patients are taught about the nature and function of fear and its nervous system correlates. The fear response is presented as a normal and generally protective state that enhances the individual’s

ability to survive. Panic attacks are conceptualized as inappropriate fear reactions arising from spurious, but otherwise normal, activation of the body's fight-or-flight response system. Like other fear reactions, panic attacks are portrayed as alarms that stimulate the person to take immediate defensive action. Because the individual normally associates the fight-or-flight response with the presence of danger, panic attacks typically motivate a frantic search for the source of threat. When none is found, the treatment model assumes that the person looks inward and interprets certain bodily symptoms as signs of a physical or psychological catastrophe (e.g., "I'm dying of a heart attack," "I'm losing my mind").

In addition to normalizing and demystifying panic attacks, the educational component of PCT provides patients with a model of anxiety that emphasizes the interaction between the mind and body and provides a rationale and framework for the skills to be taught during treatment. A three-component model is utilized, in which the dimensions of anxiety are grouped into physical, cognitive, and behavioral categories. The physical component includes bodily changes (e.g., neurological, hormonal, cardiovascular) and their associated somatic sensations (e.g., shortness of breath, palpitations, lightheadedness). The cognitive component consists of thoughts, images, and impulses that accompany anxiety or fear (e.g., thoughts of dying, images of losing control, impulses to run). The behavioral component contains behaviors that are associated with anxiety (e.g., pacing, carrying a safety object, or simply avoiding or escaping the situation). These three components are described as interacting with each other, often with the result that anxiety is heightened. The therapist then explains that the goal of treatment is to learn skills for controlling each of the three components of anxiety. To manage some of the physical aspects of anxiety, such as sensations due to hyperventilation (e.g., lightheadedness and tingling sensations) or muscle tension (e.g., trembling and dyspnea), patients are taught slow, diaphragmatic breathing. To reduce anxiety-exacerbating thoughts and images, patients are further taught to critically examine, based on past experience and logical reasoning, their estimations of the likelihood that a feared event will occur, the probable consequences if it should occur, and their ability to cope with these consequences. In addition, they are assisted in designing and conducting behavioral experiments to test their predictions.

B. Breathing Retraining

Beginning with Session 3, patients are taught a breathing technique that encourages slow, diaphragmatic

breathing over fast chest breathing. When introducing this treatment component, the patients are usually asked to first voluntarily hyperventilate by standing and breathing fast and deeply, as if blowing up a big balloon, for approximately 1 min. This exercise typically induces intense and unpleasant bodily sensations (e.g., racing heart, dizziness, tingling sensations in hands and feet), which often resemble some of the sensations that patients experience during a panic attack. Once the symptoms have abated, the therapist educates the patients about the physiological basis of hyperventilation and suggests that this may often be associated with panic attack episodes. It is then suggested that chronic hyperventilation, which may be caused by relatively fast and shallow chest breathing, might lower the threshold and therefore increase the risk for experiencing recurrent panic attacks.

In the next step, the therapist introduces a breathing control technique, which encourages patients to rely on the diaphragm rather than on chest muscles when breathing. In addition, patients are instructed to concentrate on their breathing by counting their inhalations and thinking the word "relax" on exhalations. The therapist models the suggested breathing patterns and then provides corrective feedback to patients while they practice this technique in the office setting. In Session 4, patients are further taught a technique to slow the rate of breathing with the goal of comfortably spanning a full inhalation and exhalation cycle over 6 sec. Again, the therapist models and then provides corrective feedback as practice is conducted during the session. As part of the homework assignment, patients are instructed to practice diaphragmatic breathing at least two times a day, for at least 10 min for each of the remaining sessions.

C. Cognitive Restructuring

The PCT manual introduces this treatment component in Session 4 by suggesting that thoughts are hypotheses or guesses rather than facts. The therapist explores the patients' thinking errors that are typically associated with panic attacks. Two main types of cognitive errors are described. The first error is probability overestimation, or jumping to negative conclusions and treating negative events as probable when in fact they are unlikely to occur. The second error is catastrophic thinking, or blowing things out of proportion.

The method for countering overestimation errors is to question the evidence for probability judgments. Typical probability overestimations are: "The feeling of dizziness are caused by a brain tumor," or "the feeling

of breathlessness is a sign of a heart attack.” Patients are encouraged to examine the evidence for these predictions, while considering alternative, more realistic hypotheses. This is best done in a Socratic style (i.e., leading questions) so that patients examine the content of their statements and reach alternative explanations.

Similarly, the method of countering catastrophic thinking is best done by using Socratic questions. This type of error typically arises from viewing an event as “catastrophic” when, in actuality, it is not. Typical kinds of catastrophic thoughts are “If I faint people will think that I am weak and this would be unbearable,” or “If people notice my anxiety, I will make a fool of myself and I could not deal with this.” By challenging and modifying these catastrophic thoughts (“decatastrophizing”) the patients begin to realize that the actual occurrences are not as “catastrophic” as originally assumed because there are ways to cope with these situations.

D. Interoceptive Exposure

To change maladaptive anxiety behaviors, patients learn to engage in graded therapeutic exposure to cues they associate with panic attacks. The exposure component (interoceptive exposure) focuses primarily on internal cues, specifically, frightening bodily sensations. The rationale for needing to perform interoceptive exposure exercises is very important for facilitating generalization from in-session practices to daily exposures. For this purpose, the therapist explores the way in which avoidance of feared sensations serves to maintain fearfulness. Activities that are avoided because of the associated physical sensations may not be immediately obvious to patients. They may include physical exercise, emotional discussions, suspenseful movies, steamy bathrooms, drinking coffee, and other arousing activities.

The purpose of these interoceptive exposure exercises is to repeatedly induce sensations that are feared and to weaken the fear response through habituating and learning that no actual danger results. In addition, the repeated inductions allow practice in applying the cognitive techniques and breathing strategies. As a result, fear of physical sensations that occur naturally is significantly reduced.

During exposure, patients deliberately provoke physical sensations like smothering, dizziness, or tachycardia by means of exercises such as breathing through a thin cocktail straw, hyperventilating, spinning, or strenuous physical exercise. These exercises are done initially during treatment sessions, with therapist modeling, and subsequently by patients at home. As patients become less afraid of the sensations, more naturalistic activities

are assigned, such as drinking caffeinated beverages, watching suspenseful movies, or going to a sauna.

E. In Vivo Situational Exposure

An optional situational exposure component can be added for patients with significant agoraphobic avoidance. As currently administered, exposure therapy typically begins with the construction of a hierarchy of feared situations, which the patients are encouraged to enter repeatedly, starting with easier ones, and remain until anxiety diminishes. Sometimes the therapist accompanies the patients initially, but ultimately they are expected to do the task alone.

The most challenging aspect of this treatment component is to motivate the patients to engage in these exposure exercises without using any avoidance strategies. Before conducting the exercises, the therapist needs to thoroughly explore any forms of avoidance and anxiety-reducing strategies that patients typically use, some of which might be more obvious (e.g., carrying medication or a cell phone) than others (e.g., carrying quarters for a public phone, sunglasses, or chewing gum). Ideal situations at the beginning of the exposures are situations that are under the therapists’ control and in which escape and avoidance strategies are difficult (e.g., leaving patients alone in a shopping mall). Once the patients have successfully mastered those situations, the therapist will then choose situations that are less controllable by the therapist (e.g., driving long distances in the car alone).

II. THEORETICAL BASES

A. History of Diagnosis and Treatment Models

Panic disorder was first officially recognized as a distinct diagnostic entity after a series of pharmacological experiments conducted by Donald Klein and his collaborators in the late 1950s and early 1960s. Klein and his colleagues observed that imipramine, an antidepressant, was effective against spontaneous panic attacks, but not against chronic and anticipatory anxiety. Klein concluded that panic and anticipatory anxiety reflect two qualitatively different underlying biological processes. By the 1980s, the efficacy of pharmacological treatment with imipramine in patients with panic disorder had been well established, and imipramine became the pharmacological criterion standard for the treatment of panic disorder for more than 20 years, until the emergence of the selective serotonin reuptake inhibitors.

Prior to including panic disorder as a distinct type of anxiety disorder in *DSM-III* in 1980, psychological therapies tended to focus primarily on the behavioral pattern of situational avoidance that frequently occurs in patients with panic attacks. During the 1960s and 1970s, systematic desensitization, consisting of imaginal exposure to feared situations paired with muscle relaxation, was the principal form of treatment. That approach was preferred to *in vivo* exposure, because it was thought the latter might engender too much anxiety for patients to manage. However, subsequent studies showed that *in vivo* exposure was superior to systematic desensitization for treating agoraphobia. During the 1980s, paralleling with the increasing recognition of the importance of fear of panic attacks as a factor in the development and progression of panic disorder, investigators began to experiment with treatments aimed more specifically at patients' experiences of anxiety related to panic and somatic sensations. These treatments are now called exposure therapy, behavior therapy, cognitive therapy or cognitive-behavioral therapy, depending on the theoretical orientation of the clinician or the emphasis placed on the treatment components, although in practice there is considerable overlap among them.

Researchers today generally agree that a combination of cognitive and behavioral strategies is the most effective psychological treatment for panic disorder and agoraphobia. Some researchers believe that exposure therapy primarily targets agoraphobic avoidance, whereas CBT either enhances the efficacy of exposure therapy or specifically addresses the panic attacks and associated features. Others assume that the treatment effects are primarily due to either exposure therapy or CBT.

B. Contemporary Psychological Models

The most popular psychological model of panic and agoraphobia today is the cognitive model. This model assumes that preexisting beliefs about the harmfulness of bodily sensations predispose people to regard them fearfully. Panic attacks are therefore viewed as resulting from the catastrophic misinterpretation of certain bodily sensations, such as palpitations, breathlessness, dizziness, and so on. An example of such a catastrophic misinterpretation would be a healthy individual perceiving palpitations as evidence of an impending heart attack. The vicious cycle of the cognitive model suggests that various external stimuli (i.e., the feeling of being trapped in a supermarket) or internal stimuli

(i.e., body sensations, thoughts or images) trigger a state of anxious apprehension if these stimuli are perceived as threatening. It is assumed that this state is accompanied by fearful bodily sensations that, if interpreted in a catastrophic fashion, further increases the apprehension and the intensity of bodily sensations. Moreover, this model states that the attacks appear to come from "out of the blue" because patients fail to distinguish between the triggering body sensations of the subsequent panic attack and the general beliefs about the meaning of an attack.

Another popular psychological model is the anxiety sensitivity hypothesis by Steven Reiss and Richard J. McNally. Anxiety sensitivity denotes the tendency to respond fearfully to anxiety symptoms and is based on beliefs that these symptoms lead to harmful consequences. Similar to the cognitive model, the anxiety sensitivity hypothesis assumes that beliefs about the harmfulness of bodily sensations predispose people to respond fearfully. In contrast to the cognitive model, however, the anxiety sensitivity hypothesis does not require that patients misconstrue anxiety as something else (such as a heart attack). Instead, the model assumes that people with high anxiety sensitivity may be well aware of what causes the feared bodily sensations. Rather, patients believe that the high arousal itself might eventually lead to heart attacks, insanity, or other catastrophes.

C. Contemporary Biological Models

Biological models of panic assume that the disorder is associated with the dysregulation of a number of different biological systems. One of the most popular biological models today is the suffocation alarm hypothesis by Donald Klein. This model assumes that panic disorder is characterized by a pathologically low threshold for firing of an evolved "suffocation alarm," which can be activated by a number of biological (e.g., carbon dioxide inhalation) and psychological challenge procedure (e.g., feeling of being trapped) that signal impending loss of oxygen.

III. EMPIRICAL STUDIES

The efficacy of CBT has been demonstrated in numerous clinical studies. For example, it has been shown that PCT is superior to a relaxation condition or alprazolam, a frequently prescribed benzodiazepine to treat panic attacks. More recently, the PCT protocol was compared to imipramine, an antidepressant, which is often considered to be the gold standard pharmacological

treatment for panic disorder. This study compared the efficacy of imipramine, a pill placebo, and combinations of PCT with imipramine or a pill placebo in a large, multicenter trial conducted by David H. Barlow and his colleagues. A total of 312 panic disorder patients with mild or moderate agoraphobia were randomly assigned to imipramine, PCT, PCT plus imipramine, PCT plus placebo, or placebo only. Participants were treated weekly for 3 months. In addition, responders were seen monthly for 6 months and then followed up for an additional 6 months after treatment discontinuation. The results of this study showed that combining imipramine and CBT had limited advantage acutely but more substantial advantage in the longer term: Both imipramine and PCT were superior to placebo on some measures for the acute treatment phase and even more pronounced after the 6 monthly maintenance sessions. Six months after treatment discontinuation, however, people were more likely to maintain their treatment gains if they received PCT, either alone or in combination with a pill placebo. Individuals who received imipramine were more likely to relapse than those who did not receive the antidepressant.

Similar results were also reported with a CBT protocol that focuses more on cognitive restructuring. For example, a study by David M. Clark and his colleagues compared cognitive therapy, applied relaxation, imipramine, and a wait-list control group. At posttreatment, 75% of the cognitive therapy patients were panic free, compared with 70% in the imipramine condition, 40% in the applied relaxation condition, and 7% in the wait-list control condition. Cognitive therapy was superior to the wait-list control group on all panic and anxiety measures, whereas imipramine and applied relaxation were better than the wait-list control group on approximately one-half of the measures. At 9-month follow-up, after imipramine had been discontinued, the panic-free rates were 85% for cognitive therapy, 60% for imipramine, and 47% for applied relaxation. These results are consistent with reviews and meta-analyses of treatment outcome studies utilizing *in vivo* situational exposure, suggesting that 60 to 75% of treatment completers experience clinical improvement with fairly stable treatment gains at treatment follow-ups.

It is not known at present which components of CBT are most important for treatment efficacy or whether they all contribute uniquely to efficacy. Panic patients with high levels of agoraphobia seem to respond best to *in vivo* situational exposure. Patients with moderate or mild agoraphobia seem to respond best to CBT protocols that combine cognitive restructuring, psychoedu-

cation, interoceptive exposure exercises, and breathing retraining and relaxation exercises. Unfortunately, except for the use of a relaxation control condition in some studies, direct comparisons of the various components are lacking. However, there is some indication in the literature that repeated interoceptive exposure practices alone are effective in reducing panic attacks even without any explicit cognitive restructuring techniques. Similarly, *in vivo* situational exposure practices seem to be effective in treating panic disorder and agoraphobia without explicit cognitive interventions. Thus, although CBT for panic disorder and agoraphobia is clearly effective, little is known about the most important active ingredients in treatment and the mechanism of treatment action.

IV. SUMMARY

Panic disorder is a debilitating disorder that is characterized by recurrent and unexpected panic attacks. Approximately 3% of the population is affected over the course of a lifetime, and one-third of those individuals also develop agoraphobia, usually within 1 year of the initial occurrence of the panic attacks.

A number of biological and psychological models of the disorder have been proposed. A prominent biological model, the suffocation alarm hypothesis, assumes that panic disorder is the result of a pathologically low threshold for firing of a "suffocation alarm." The two most prominent psychological models are the cognitive model and the anxiety sensitivity model. The cognitive model assumes that panic attacks result from the catastrophic misinterpretation of certain bodily sensations. The anxiety sensitivity hypothesis does not assume that all panic attacks are caused by catastrophic beliefs. Instead, this hypothesis is based on the assumption that individuals with panic disorder have inherited a tendency to respond fearfully to anxiety symptoms.

CBT and *in vivo* exposure therapy are the most effective treatments for panic disorder with agoraphobia. A typical CBT protocol combines education about the nature of panic attacks, controlled breathing procedures, cognitive restructuring, interoceptive exposure exercises, and situational exposure practices. The treatment is usually delivered in 12 weekly 60-min individual sessions. The efficacy of this treatment protocol is well documented. Controlled studies show that this intervention is more effective than relaxation techniques and at least as effective as alprazolam or imipramine. Cognitive restructuring, interoceptive exposure practices, and

in vivo situational exposure exercises all seem to be important components for the treatment of panic disorder and agoraphobia. However, it remains unclear which component is most effective for treating the disorder and what the mechanism of action of treatment is.

GLOSSARY

fear-of-fear The concern that anxiety will result in the experience of negative physical consequences; these consequences can range from life threatening (e.g., cardiac arrest) to seemingly innocuous (e.g., perspiration).

logotherapy An existential approach to psychotherapy—developed by Viktor Frankl—that postulates meaning in one's life is a basic human need and that the failed search for such meaning underlies much neurotic distress.

recursive anxiety An extreme form of social phobia that is based on the concept of fear of fear and the additional suggestion that a self-maintaining process contributes to the experience of excessive anxiety.

reframe A common therapeutic procedure that involves changing the valence of a reported event from negative to positive without changing the facts.

Although paradoxical intention has been popularly identified with Frankl's logotherapy, and with family therapy, more recently the procedure has gained some

favor with behavior therapists. As a behavioral strategy, it is typically presented as a directive by the therapist to an individual who is experiencing a problem associated with activity of the sympathetic nervous system—usually within a social context. For example, a person may complain about perspiring in public. In general, the behavioral difficulty is exacerbated by the anxiety about the effects of anxiety (i.e., fear of fear) and with the attempt to take voluntary control of this anxiety to avoid these unwanted effects. The paradoxical intention directive generally contains two elements common to most other paradoxical procedures: It is unexpected and counterintuitive (i.e., contrary to common sense) and it requires the individual to maintain the discomforting focal behavior as it is presently being experienced. Thus, an effected person might be told to seek as many opportunities as possible in which he or she might expect to perspire and, once in the situation, to try to become anxious and perspire.

I. DESCRIPTION OF TREATMENT

Paradoxical intention (PI) is one of a group of—not easily differentiated—techniques and strategies all of which are classified under the rubric of therapeutic paradox. It is an approach employed in a variety of schools of psychotherapy, especially family and Gestalt therapy—although its name was coined by Viktor Frankl whose use of the technique in logotherapy, an existential

approach to psychotherapy, predates these. This article is confined to its use as a behavioral procedure.

Paradoxical intention is generally employed with responses that are impeded by recursive anxiety—a concept associated with fear of fear. A typical example would involve individuals complaining of anxiety when giving a public address. If a behavioral analysis suggested that discomfort were associated exclusively with factors external to the speaker (e.g., the size of the audience, aspects of the attendees, effect of the speaker on those assembled), then conventional behavioral procedures would be appropriate (e.g., systematic desensitization *in vivo*). In contrast, if discomfort were largely related to internal factors associated with anxiety, then paradoxical intention would be the treatment of choice. A characteristic complaint would be “I am afraid that when giving a public address, I will become very anxious and my heart rate will increase to the point that I will have a heart attack.” The core instruction administered to such a client—provided within the context of a behavioral program, which would include procedures designed to support the paradoxical intervention—would be to make a presentation while focusing on, and attempting to augment, the most salient aspect of sympathetic activity—in this case, “try to increase your heart rate.”

The role of PI is that of assisting individuals with recursive anxiety to enhance their desired performance by circumventing the goal of remaining calm. To do this, clients are directed to enter those situations in which they experience recursive anxiety, focus on the most salient aspect of sympathetic discomfort, and attempt to augment that process. Then they are instructed to remain in the situation until they have regained their composure. Thus a person who is afraid of blushing in front of others at work would be asked to participate in as many of these discomforting circumstances as possible and “really try to blush—turn as red as a traffic light—become so bright red that people will have to turn away to avoid being blinded by the light.”

Naturally, a great deal of collateral work must be done to support these individuals in engaging in behavior that may at least be seen as dreadfully embarrassing and at most, life threatening. Frankl, and before him, Allport, discussed the role of humor in neutralizing anxiety. They believed that neurotic clients had taken a significant stride toward their therapeutic goals when they could laugh at their neurotic complaints. Frankl therefore considered humor to represent an important part of PI with respect to both its administration and its effectiveness. In fact, one of the components of PI that

is a necessary part of humor is the opposition to expectation: the element of surprise. Practically speaking, before individuals consult a psychotherapist, they generally seek formal and informal guidance from a variety of acquaintances, both nonprofessional and those in relevant professions (e.g., a family physician). The longer the problem is extant, the more advice and counseling they accumulate. They combine all this information with their own preconceived notions and bring the result to the therapist. The therapist, applying PI gives them instructions that are counter to that which they expect, that is, in essence: Remain the way you are, stop trying to change.

Of course, as with most therapeutic procedures, considerable rapport must first develop. In addition, the manifestation by the therapist of great confidence in the procedure is necessary. These are the very minimal aspects required to form a supporting basis for the successful use of PI in the behavioral approach to recursive anxiety. Finally, paradoxical procedures have commonly been employed to enhance cooperation. In this context, clients are generally not provided with information about the techniques. In contrast, PI when utilized as the behavioral treatment of choice for problems associated with recursive anxiety requires, like any conventional behavioral technique, that the therapist provide the client with as many details as possible regarding the operation of the procedure (e.g., suitability of PI for the specific problem, available research, the experience of the therapist with the procedure, full instructions on intersession self-administration). The client and therapist are seen as equally important members of the team that must first formulate and then administer treatment to a successful conclusion. Therefore, the client must be as informed as is the therapist.

II. THEORETICAL CONSIDERATIONS

The myriad descriptions of the effective use of paradoxical interventions as a group, and especially PI, that are replete throughout the literature of psychotherapy are accompanied by an equal abundance of explanations for this efficacy. Because the scope of this article does not permit a survey of these hypotheses, discussion is confined to an explanation of the operation of PI from a behavioral perspective. Within that context, PI is presented as the treatment of choice for behavior that is impeded by recursive anxiety.

Fear of fear refers to concern about possible negative physical effects of anxiety on oneself. This phenomenon

is typically associated not with all anxiety but with that experienced in specific locations or situations. Such an individual who is afraid of crowded places may notice an increase in cardiac rate at such times and can become afraid that the anxiety experienced under these circumstances will result in a rising cardiac rate that eventually reaches a level that produces a heart attack. So although most people with phobias attribute their anxiety to aspects of the external environment on which they remain focused, those with fear of fear shift their attention from external factors to internal stimuli and to the effects of anxiety on the functioning of certain physiological processes.

Recursive anxiety that is based on the concept of fear of fear adds two additional complications. The first concerns the sympathetic mechanism that maintains these individuals at a high level of anxiety. Suppose that circumstances require the person in the earlier example to participate in an event that involves a crowd. This individual will become apprehensive and will begin to focus on that aspect of the sympathetic syndrome that is of most concern. In the case of individuals who fear having a heart attack, that sympathetic component would be heart rate. As the time for the presentation draws near, anxiety will increase and the cardiac rate will be elevated. This in turn will be associated with a further increase in anxiety and a consequent additional elevation of the cardiac rate. The resulting pernicious circle is self-maintaining because it is based on this recursive process.

The second complication associated with recursive anxiety refers to observations of Michael Ascher, Tom Borkovec, Diane Chambless, and Alan Goldstein, among others, who have written about processes related to recursive anxiety. They have emphasized the significant role of social anxiety and have suggested that *in vivo* exposure to the social environment is of considerable importance. Ascher has further hypothesized that no matter what the person with recursive anxiety initially reports fearing—heart attack, passing out, losing bladder control, going crazy—the basic concern is loss of control. Such loss of control will result in emitting embarrassing behavior that will engender the negative evaluation of observers. The consequence will be a significant negative life change.

Individuals with recursive anxiety generally exhibit low-self esteem. They focus on what they believe to be substantial deficits in the qualities or skills necessary to maintain significant aspects of their lives. Because of their perceived inadequacies, people with recursive anxiety feel that they must depend on others for sup-

port and therefore place a great deal of importance on these interpersonal relationships.

At work, for example, affected people may attend to negative aspects of their skill, education, or performance profile, infusing these presumed inadequacies with disproportionate importance. They believe that by maintaining themselves in their positions they are perpetrating a fraud—no matter what evidence exists to the contrary. They, like Blanche DuBois, must rely on the kindness of strangers or, in this example, colleagues, both to assist them in the performance of their responsibilities and to maintain their—self-determined—fraudulent facade.

Thus, the person in our example who is anxious in crowds may be concerned that while participating in a business meeting at which the attendance of a large number of people is required, he or she will become very anxious and, fearing a heart attack, may run out of the room at an inopportune time. The horrible soap opera continues with all of those in attendance assuming that the departure had negative associations (e.g., “_____ was obviously psychotic.” or “_____ is certainly not “executive material” and should leave the firm”), and the CEO will demand resignation from their highly compensated position. In the final scene, the loss of this income and status results in the rapid deterioration of lifestyle, divorce, and finally descent into alcoholism and homelessness.

Because of their perceived dependency on these relationships, individuals with recursive anxiety will devote extraordinary effort to developing and nurturing associations with people deemed to have a significant role in their lives. They do this by advancing themselves as “nice” people and will do all that is necessary to support this perception. They believe that people who are “nice” are more likely to garner assistance when necessary and to have their shortcomings overlooked.

All individuals who perform goal-directed behavior have as their object the satisfactory achievement of the ostensible purpose of these actions. Those giving public addresses, for example, aim to educate or influence their audience in an entertaining manner. Or, supermarket shoppers wish to fill their grocery lists as efficiently as possible. Again, individuals driving across bridges simply want to get from one side to the other without encountering any difficulties or delays. Of course, those with recursive anxiety aim for the same goals as everyone else. However, they also have a second goal that is of more immediate concern: that of remaining calm while attempting to accomplish the ostensible goal.

They must remain calm to avoid the hypothesized disastrous consequence (e.g., heart attack, going crazy, looking foolish to others). This latter objective is difficult, if not impossible to accomplish. Moreover, in any case, attempts to remain calm subvert the professed aim of the performance by diverting the attention and effort necessary for accomplishing the ostensible goal.

Recursive anxiety represents a significant impediment over and above that resulting from simple phobias (i.e., those that are confined to aspects of the environment external to the individual). Thus people who exhibit simple public-speaking phobia are uncomfortable when giving a public lecture, but they remain largely concerned about the quality of their performance and direct their effort toward improving their presentation. Those with public-speaking phobia complicated by recursive anxiety initially attend to external aspects of their performance. But, at high levels of anxiety, they shift their focus to internal stimuli and begin to worry about the possibility of emitting some embarrassing behavior in front of an audience (e.g., freezing, vomiting, losing bladder control). They believe that this would be disastrous, and it therefore becomes vital that they remain free of anxiety to preclude this disaster. Remaining calm, then, becomes their primary commitment.

A number of hypotheses have been offered in an attempt to explain the efficacy of this procedure with recursive anxiety. Most recently, Ascher has advanced a proposal that combines his position on recursive anxiety with some of the formulations of Daniel Wegner. To understand Ascher's suggested explanation, it is first necessary to briefly describe Wegner's view of cognitive control.

Wegner describes the process of cognitive control by postulating a bimodal system. When individuals wish to exercise cognitive control (e.g., when there is a wish to inhibit specific classes of disconcerting, distracting thoughts in order to fall asleep or study or work on last year's taxes), activity on the part of the "operating" system (OS)—the active, effortful cognitive regulator—is initiated to ensure this control. A complementary "monitoring" system (MS) is an effortless component that is constantly searching for cognitions in opposition to the desired state of control. When the MS detects an errant thought it acts to bring this thought into the focus of attention of the OS and initiates the OS to control the incompatible cognition. In the normal individual, under ordinary circumstances, cognitive control by the OS generally occurs smoothly and effectively.

In contrast, when the person is under cognitive stress, the OS can become overloaded and increasingly

less effective. In addition, if sufficiently bereft of resources, the OS will be able to do nothing with the incompatible thought that has now been released into the individual's focus of attention. In this way, a thought that is in opposition to the specific goal of cognitive control is very likely to be expressed.

Ascher hypothesizes that the difference between individuals who experience phobias with and without a recursive anxiety component is that the former attempt to control their cognitive state, whereas the latter are more concerned with the characteristics of the external situation. In addition, when recursive anxiety is associated with the phobic system, the result is the development of a "fundamental" fear of a significant negative life change. This would seem to add a considerable degree of stress and, therefore, cognitive load, relative to those exhibiting a simple or "common" phobia.

Thus, individuals with a simple public-speaking phobia, for example, would be absorbed in monitoring and enhancing their performance while observing audience response to measure their success. In contrast, those with recursive anxiety complicating their public-speaking phobia would be engaged in controlling their cognitive environment. They would attempt this by monitoring their thoughts and related emotional experiences in an effort to minimize stimuli incompatible with their objective of remaining calm. The more significant they deemed this goal of calmness to be—this depends on the details of the hypothesized disastrous consequence—the more cognitive load is generated, and the weaker becomes the OS. The result would be an increasing frequency of incompatible thoughts brought by the MS to the attention of the powerless OS that would be permitted to remain unmodified. This bimodal explanation of cognitive control is also compatible with the self-maintaining recursive component of the fear-of-fear process. That is, awareness of incompatible, anxiety-provoking thoughts increases cognitive load and decreases the ability of the OS to control them, thus permitting further discomforting thoughts, additional cognitive load, and continuing deterioration of the OS.

Combining the bimodal explanation with PI suggests the utility of the procedure with recursive anxiety. Paradoxical intention is based on instructions—to relinquish control and to accept whatever cognitive and physical experiences are present, but primarily—to try to protract the duration and the degree of discomfort of the most unpleasant of these symptoms. In such cases, the MS would be engaged in seeking thoughts that are incompatible with the goal of attempting to generate

more profound discomforting symptoms—that is, thoughts of calmness and control, and also neutral, distracting thoughts. These cognitions enter the OS and become the focus of attention because these individuals begin their presentations with an already weakened OS. The thoughts that are incongruous with the PI are compatible with diminished stress and reduced cognitive load in situations that are uncomfortable for the individual with a public-speaking phobia and recursive anxiety. The result is a more positive experience for these affected individuals.

III. APPLICATIONS AND EXCLUSIONS

As a conventional behavioral procedure, PI for disorders associated with recursive anxiety and similar processes is appropriate for most groups of individuals. However, because of its counterintuitive nature, it may not be practical for those with cognitive developmental disabilities. At the very least, considerable repetition of instructions will be necessary. In addition, supervision of the *in vivo* practice conducted by family members, or others, can be a valuable adjunct to therapy and increase the probability of success with this population.

Although a careful behavioral analysis is the necessary preparation for the administration of any behavioral program, when the therapeutic program includes PI as its central focus, the behavioral analysis takes on an even more crucial role. As Ascher has written on several occasions, and demonstrated in his recent study with public-speaking phobia (described in the next section), it is important to differentiate between those experiencing simple phobias and those whose phobias are complicated by recursive anxiety. Simple phobias are adequately addressed by systematic desensitization, and covert conditioning, among a host of conventional behavioral strategies. But, the use of PI with simple phobias has been shown not only to be less useful than the established treatments of choice, but actually to impede the course of therapy and thereby protract its length in many cases.

In contrast, when the phobia is complicated by recursive anxiety, then PI becomes the treatment of choice, behavioral procedures devoid of the *in vivo* exposure to the interpersonal milieu tend to provide less satisfactory results.

Finally, it seems almost unnecessary to caution against the use of paradoxical procedures with individuals who are severely depressed or suicidal or with

those attempting to control maladaptive approach responses (e.g., sexually offensive behavior, difficulties with alcohol, drugs, or tobacco).

IV. EMPIRICAL STUDIES

Since Viktor Frankl began writing about PI in the 1920s, many case studies have been published demonstrating its effectiveness with a wide variety of behavioral problems. Of course, uncontrolled case studies are of very limited value, at best.

In 1978, Michael Ascher and Jay Efran published the first controlled investigation of the procedure. They used a multiple-case study design with clients whose latency to sleep onset did not diminish as the result of a standard 10-week behavior therapy program appropriate for this problem. Subsequent to this 10-week segment, these clients were exposed to PI instructions. By the end of the next 2-week period, all clients reported that their sleep onset latency had reached a satisfactory level.

Rather than presenting an exhaustive review of the numerous experiments that followed the work of Ascher and Efran, many based on designs incorporating sophisticated controls, this section is intended to present a survey of studies that exemplify the research associated with paradoxical intention.

The first study to utilize the random assignment of subjects to groups in testing the efficacy of paradoxical intention was conducted in 1979 by Ralph Turner and Michael Ascher. In this study, PI was compared to two treatments of choice for reducing clinically significant levels of latency to sleep onset (relaxation, stimulus control). Two control groups were also included (attention-placebo and waiting-list). Analysis of the results failed to find any significant differences among the three treatment groups, each of which was significantly superior to the control groups. No differences were found between the two control groups. In a partial replication of their study, Ascher and Turner in 1979 confirmed the efficacy of PI with sleep onset insomnia.

When administered like any conventional behavioral technique, all aspects of the procedure and its goals are fully disclosed to the client. However, when used in other contexts (e.g., family therapy) this is not always the case. Then, PI, used to reduce resistance, is presented in a more obscured manner. In 1980, Ascher and Turner investigated the relationship of these two methods for administering PI. They randomly assigned volunteers who complained of clinically significant levels

of sleep onset insomnia to all groups. These conditions included two treatment groups (PI with veridical or obfuscated instructions) and two control groups (attention-placebo and waiting-list). Clients receiving the veridical instructions showed significantly greater treatment effects than did the group from whom the purpose of the procedure was obscured.

Ascher went on to conduct controlled multiple-case study investigations of PI with the travel restriction associated with agoraphobia and with psychogenic urinary retention. The results of these studies supported the hypothesis that PI, when administered as a conventional behavioral procedure, could be an effective component of a treatment program.

Subsequent to Ascher's study, Matig Mavissakalian, Larry Michelson, and a number of co-workers conducted a series of large-sample randomized groups experiments. Their target behavior was agoraphobia, and one of the treatment strategies in which they were interested was PI. This research extended from 1983 through 1986 and produced variable results with all treatment groups. One conclusion that might have been drawn from their final study was that although randomized assignment of clients to groups was a powerful method of control, it might have distorted the actual relationship of the treatment with the specific clinical profile of the client. That is, were a clinician to assign individuals with agoraphobia to treatment groups following a behavioral analysis, the results might have been more consistent, and of more benefit to the individual. Such clinically focused assignment might also reduce the variability of the resulting treatment data.

In 1999, Ascher tested this hypothesis with groups that had public-speaking phobias. Using a 2x2 design, he randomly assigned individuals with a simple phobia or with a phobia complicated by recursive anxiety to one of two treatment groups. One treatment condition involved a standard behavioral approach to public-speaking phobia, the other, added PI to the standard behavioral program. The results supported the idea that a better outcome was possible when clients are paired with treatment on the basis of clinical criteria as opposed to random assignment. Those with simple public-speaking phobia showed significantly greater improvement when the standard behavioral treatment program did not include PI. When this technique was added, the course of therapy was greatly protracted. The reverse was the case with clients exhibiting recursive anxiety. When their treatment included PI, their performance improved significantly relative to those

who did not receive PI instructions. Of course, this selective assignment is fraught with design problems that can only be adequately addressed with sophisticated controls. However, a more valid picture of clinical operations may possibly be the outcome.

The body of research investigating the efficacy of PI from Ascher and Efran's study in 1978 through the mid-1980s grew in frequency and in sophistication of design. It generally suggested that PI was an effective procedure with a variety of behavioral complaints. The results were not uniform, nor were they based on designs that were above criticism. The data do support the impression that in the hands of an experienced clinician, PI viewed as a conventional behavioral procedure can be a useful and effective addition to the behavior therapist's repertoire.

V. CASE ILLUSTRATION

A 30-year-old, married, white male complained of becoming anxious and experiencing tremors at inopportune times. He was a psychologist who worked in the student health center of a private university. Each morning all members of the counseling section were required to participate in a meeting whose general focus was case presentation and case management. During the course of these meetings, coffee and cake were available; the coffee was served in ceramic cups on saucers (it was a well-endowed university). It was under these daily circumstances that the client experienced the most disconcerting occurrence of the problem.

He was afraid that if he were experiencing tremors when he removed his cup from the saucer, the resulting tapping would be noticed by others. On the basis of this behavior, the other members of the counseling team would conclude that the client had a serious mental health problem that would preclude him from continuing to work in the center. This information would become available to those in the mental health field at large, and he would be permanently denied employment in his profession.

He had been at the student health center for more than one year. He enjoyed his work and seemed to be doing well. He was popular with his student clients, had been commended by his supervisor on several occasions, and appeared to have the respect of his colleagues. Yet he felt that he could not quite meet the standard that was expected by these colleagues. As he explained it, this deficit was because all the professionals in the center had degrees in clinical psychology

whereas his was in counseling psychology—which he deemed to be inferior.

Each workday he would be awakened early by what he described as an anxiety attack. He would monitor himself for tremors, squeezing his hands tightly into fists or around objects in an effort to moderate these attacks. His anxiety would remain fairly high until he entered the conference room for the morning meeting, whereupon his anxiety would increase markedly. Along with the anxiety would appear sporadic, mild intention tremors. His thoughts would shift from strategies for dealing with these tremors to their catastrophic consequences. He attended most meetings and did not generally leave before their conclusion. However, each meeting was an ordeal that never seemed to diminish.

Because the social phobic component of these complaints was immediately manifest and clear to the client, a good deal of the preparation generally necessary with cases involving recursive anxiety was precluded. The PI instructions are greeted by most people as counterintuitive and anxiety provoking. They are not only told to do something that may be in opposition to what they thought would be useful but are directed to do exactly what they fear. Here again, the client's professional training proved to be helpful. He was able to grasp the reason for the paradoxical suggestion and, rather than viewing it as counterintuitive, could understand its underlying logical structure.

With the assistance of the client, the therapist composed a hierarchy of anxiety-provoking, social situations. Emphasis was placed on those circumstances in which the client had experienced tremors or feared that he might have such an experience. Of course, the top of the hierarchy was occupied by the daily clinic meetings. The client was then encouraged to enter a situation that was of a lower degree of discomfort and to "try to become anxious. Practice exhibiting your tremors." He was not to exaggerate them, but to attempt to display them as realistically as possible. He first practiced them in the office but had a great deal of trouble making the tremors look realistic. They were jerky and spastic, and he devoted considerable effort to producing authentic tremors that, in so doing, served to create a good deal of attendant entertainment for both the client and the therapist. The client left the office in apparent good spirits and with a professed sense of confidence based on his new perspective.

On returning the following week, the client reported that he had practiced the procedure in a social situation, midway on the hierarchy, and he indicated his pleasure with his performance. He went with the expectation of acting as though he had tremors, he felt

quite calm, and found it difficult to produce them in a realistic fashion.

It is important when using PI with recursive anxiety that the therapist not reinforce clients for success, because an effusive response on the part of the therapist will generally serve to impede progress. The reasons for this vary with the client. One common possibility is that it places additional pressure on acquiescent clients to meet what they consider to be the expectations of their therapists. The safest thing for the therapist to do is to reflect clients' positive emotion associated with their demonstration of efficacy. In this way, the therapist can remain relatively neutral and thereby reduce his or her role in client's *in vivo* activities. In the present case, the therapist encouraged the client to discuss his uncharacteristic comfort in the party that he had attended, and how it contributed to his enjoyment of the evening. In another effort not to bring the client's expectations to an unrealistic level, the therapist cautiously introduced the point that the client still had a good deal of work to do in this area, and that although it was pleasant that he was able to begin with a successful experience, impediments and setbacks were certain to appear sporadically. The instructions were repeated, and the client selected his next target.

During the next three sessions, the client continued to report improvement, but on the fourth session, he described an encounter that resulted in considerable anxiety and what the client described as a failure. The therapist reframed the event to support a more positive view and suggested that perhaps the client went into the situation with too much confidence. Possibly he was not prepared to allow his anxiety-free reign and to display his tremors. Maybe he thought that he was "cured" and was no longer in need of such preparation. The therapist reaffirmed the idea that the client should assume that he would be employing the paradoxical strategy in social situations for a considerable length of time. This seemed to have the desired effect, because the client's progress in dealing with his social anxiety resumed its positive trend in subsequent weeks.

With regard to his comfort during the morning meetings at the student counseling center, the client began to feel more comfortable after his first reported success in another social context. For some time, however, he was unwilling to take the chance of "trying to become anxious" in that most difficult setting. Finally, after some weeks, having gained some confidence in the PI procedure, and experiencing somewhat less anxiety at these morning meetings, he began to apply the procedure in the counseling center and found it to be quite helpful.

The focus of this case description was intended to rest on the administration of PI with recursive anxiety. Naturally, substantial ancillary activity was necessary to support the paradoxical intervention. In addition, other significant aspects of the client's life were addressed. Very often in the past, case studies illustrating the efficacy of PI emphasized this procedure to the point that its role in the therapeutic process was unrealistically exaggerated. PI as a conventional behavioral treatment of choice for recursive anxiety is, like other behavioral procedures, administered in an appropriate behavioral context.

VI. SUMMARY

Paradoxical intention as described in this article is a conventional behavioral treatment of choice for recursive anxiety—a phenomenon associated with fear of fear that reflects extreme social anxiety. Individuals who complain of anxiety about exhibiting the secondary aspects of anxiety in public (e.g., flushing, perspiration, tremors, urinary frequency or retention) represent good examples of this behavior. The paradoxical instruction, administered within the context of a standard behavioral program, requires clients to increase the frequency of that which they would prefer to inhibit, or to inhibit that which they would prefer to increase. Thus, a woman who has been avoiding public places for fear of being embarrassed by blushing would

be advised to seek as many opportunities as possible to blush in front of others. Such suggestions often have the effect of reducing some of the anxiety that the person associates with interpersonal contact.

PCIT, which draws from both attachment theory and social learning theory in teaching parents to interact with their child in new ways to change the child's behavior. Finally, we review the PCIT outcome studies and the directions for future research.

GLOSSARY

clinically significant The extent to which the effect of an intervention makes an important difference to the individual or has practical or applied value.

negative reinforcement The removal of a negative stimulus (e.g., child whining) contingent on the occurrence of a behavior (e.g., parent yelling), which causes the behavior to occur more often.

prevalence rate Percentage of cases in the general population at one time.

Parent–child interaction therapy (PCIT) is a psychosocial treatment for preschoolers with conduct problems and their parents. In this article we describe the assessment procedures that guide the course of treatment and the treatment procedures in each major phase of treatment: (1) the child-directed interaction (CDI) phase in which parents learn play therapy skills, and (2) the parent-directed interaction (PDI) phase in which parents learn discipline skills. We address the significance of conduct problem behavior for children and families and present the theoretical foundation of

I. DESCRIPTION OF TREATMENT

A. Assessment in PCIT

Parent–child interaction therapy is an assessment-based treatment in which progression through treatment is guided at every point by the data. To begin treatment, the PCIT therapist must have a thorough understanding of the child's problem behaviors and the context in which they occur. This information is obtained by an assessment approach that involves multiple methods and informants, including parent interviews, parent and teacher ratings scales, and behavioral observations in the clinic and school or day care setting.

The initial clinical interview with the parent is designed to establish rapport and obtain information about the child's family that will impact treatment planning, including the parents' attitudes and beliefs about child rearing and their goals and expectations for treatment. Family factors known to present barriers to treatment, such as transportation problems for low-income families, are discussed with the family as well, so that they can be resolved immediately. Following the clinical

interview, a structured diagnostic interview is conducted to determine whether the child meets criteria for oppositional defiant disorder. Children whose behavior problems are less severe may not require a treatment as intensive as PCIT. The diagnostic interview is also important for the identification of comorbid disorders that must be considered in tailoring PCIT to the specific needs of the child and family.

The Eyberg Child Behavior Inventory (ECBI) is a 36-item parent rating scale of disruptive child behavior used initially as a baseline measure and regularly throughout PCIT to assess the child's progress. Richard Abidin's parent self-report scales, the Parenting Stress Index—Short Form and the Parenting Alliance Measure, are given as baseline measures at the initial assessment session as well, to enable assessment of the effects of treatment on the parents' functioning.

The Dyadic-Parent Child Interaction Coding System-II, developed by Sheila Eyberg and colleagues, is used to assess parent–child interactions during three brief, structured play situations in which the degree of control required by the parent is varied. These initial observations provide baseline data for comparison throughout treatment, and specific situations are coded at the beginning of the treatment coaching sessions to monitor change in the parents' skills, to provide direction for the coaching, and to determine when the parents are ready to move to the next phase of treatment.

For children who present behavior problems at school or day care as well as at home, their teachers are asked to complete the Sutter-Eyberg Student Behavior Inventory—Revised, a measure of oppositional and inattentive behavior in the classroom. In addition, classroom observations are often conducted to assess disruptive behavior using the Revised Edition of the School Observation Coding System (REDSOCS). These measures are repeated at the end of treatment to assess the degree of generalization of treatment effects to the school.

B. The Format of PCIT

Treatment sessions begin as soon as the initial assessment is completed. PCIT is typically conducted in 1-hour weekly sessions and is usually completed within 9 to 16 weeks. The first phase of treatment, CDI, is focused on developing the parents' use of prosocial skills, and the second phase of treatment, PDI, emphasizes the parents' use of consistent disciplinary techniques. The principles and skills of each interaction are first presented to the parents alone during a single didactic session using modeling and role-play, and the subsequent sessions in each phase involve direct coaching of

the parents to use the skills with their child. During these coaching sessions, the parents take turns being coached by the therapist as they interact with their child while the other parent observes the coaching.

1. Child-Directed Interaction

In CDI, parents learn to follow their child's lead in play by avoiding commands, questions, and criticism, and using the nondirective "PRIDE" skills: Praising the child, Reflecting the child's statements, Imitating the child's play, Describing the child's behavior, and being Enthusiastic during the play. The parents learn to manage the child's behavior by directing the PRIDE skills to the child's appropriate play and ignoring the child's inappropriate behavior. Parents are asked to practice CDI skills at home for 5 minutes each day. Handouts summarizing the CDI skills are given to parents for their review (see Table 1), and additional handouts on topics of relevance to individual families, such as social support or modeling appropriate behavior, are provided to parents during the course of CDI as needed.

Each of the CDI coaching sessions begins with a 5-minute observation of the interaction, coded by the therapist, which indicates the primary focus of the session. During coaching, the therapist prompts and reinforces the parents' use of the PRIDE skills and points out their positive effects on the child's behavior. The therapist uses this time to encourage and shape reciprocal interactions and responsive parenting. The CDI phase of treatment continues until the parents meet criteria for skill mastery: 10 behavioral descriptions, 10 reflective statements, 10 labeled praises, and no more than 3 questions, commands, or criticisms within the 5-minute interval. The criteria also include ignoring the child's inappropriate behavior.

2. Parent-Directed Interaction

During PDI, parents continue to use their CDI skills, but they also learn to direct their child's behavior using effective commands and specific consequences for compliance and noncompliance. Parents first teach the child to mind using "running commands," which are commands to perform a specific behavior immediately. Parents are taught the eight rules of effective commands (see Table II) and the precise steps that must be followed after a running command is given to the child (see Fig. 1). Parents are taught to give a labeled praise if the child obeys or to initiate the time-out procedure if the child disobeys.

During the PDI didactic session, the entire time-out procedure is role-played with each parent, and the parents are asked to review handouts summarizing PDI techniques prior to the next session. Parents are

CDI Skills Handout

Child		
Rules	Reason	Examples
Praise your child's appropriate behavior	<ul style="list-style-type: none"> • Causes your child's good behavior to increase • Lets your child know what you like • Increases your child's self-esteem 	<ul style="list-style-type: none"> • Good job of putting the toys away! • I like the way you're playing so gently with the toys.
Reflect appropriate talk	<ul style="list-style-type: none"> • Shows your child that you are listening • Demonstrates that you accept and understand your child • Improves your child's speech 	<ul style="list-style-type: none"> • Child: The doggy has a black nose. • Parent: The dog's nose is black.
Imitate appropriate play	<ul style="list-style-type: none"> • Shows your child that you approve of the activity • Shows that you are involved • Teaches your child how to play with others and take turns 	<ul style="list-style-type: none"> • Child (drawing circles on a piece of paper) • Parent: I'm going to draw circles on my paper just like you.
Describe appropriate behavior	<ul style="list-style-type: none"> • Shows your child that you are interested • Teaches your child concepts • Models speech for your child • Holds your child's attention on the task 	<ul style="list-style-type: none"> • You are putting together Mr. Potato Head. • You put the girl inside the fire truck.
Be Enthusiastic	<ul style="list-style-type: none"> • Lets your child know that you are enjoying the time you are spending together • Increases the warmth of the play 	<ul style="list-style-type: none"> • Parent: You are REALLY being gentle with the toys.
Avoid Commands	<ul style="list-style-type: none"> • Takes the lead away from your child • Can cause unpleasantness 	<p><i>Indirect commands:</i></p> <ul style="list-style-type: none"> • Could you tell me what animal this is? <p><i>Direct commands:</i></p> <ul style="list-style-type: none"> • Please sit down next to me.
Avoid Questions	<ul style="list-style-type: none"> • Leads the conversation • Many questions are commands and require an answer • May seem like you are not listening to your child or that you disagree 	<ul style="list-style-type: none"> • We're building a tall tower, aren't we? • What sound does the cow make? • What are you building? • You're putting the girl in the red car?
Avoid Criticism	<ul style="list-style-type: none"> • Often increases the criticized behavior • May lower your child's self-esteem • Creates an unpleasant interaction 	<ul style="list-style-type: none"> • That wasn't nice. • I don't like it when you make that face. • Do not play like that. • That animal doesn't go there.
Ignore negative behavior (unless it is dangerous or destructive)	<ul style="list-style-type: none"> • Helps your child to notice the difference between your responses to good and bad behavior • <i>Consistent</i> ignoring decreases many behaviors 	<ul style="list-style-type: none"> • Child: (sasses parent and picks up toy) • Parent: (ignores sass; praises picking up)
Stop the play time for aggressive and destructive behavior	<ul style="list-style-type: none"> • Teaches your child that good behavior is required during special play time • Shows your child that you are beginning to set limits 	<ul style="list-style-type: none"> • Child: (hits parent) • Parent: (CDI STOPS.) Special play time is stopping because you hit me.

TABLE II
Eight Rules for Effective Commands

Rule	Reason	Examples
1. Commands should be <i>direct</i> rather than indirect	<ul style="list-style-type: none"> Leaves no question that child is being told to do something Does not imply a choice or suggest parent might do the task for child. Is not confusing for young children 	<ul style="list-style-type: none"> Please hand me the block. Put the train in the box. <i>instead of</i> Will you hand me the block? Let's put the train in the box.
2. Commands should be <i>positively stated</i>	<ul style="list-style-type: none"> Avoids criticism of child's behavior Provides a clear statement of what child should do 	<ul style="list-style-type: none"> Come sit beside me. <i>instead of</i> Don't run around the room!
3. Commands should be given <i>one at a time</i>	<ul style="list-style-type: none"> Helps child remember the command Helps parent determine if child completed entire command 	<ul style="list-style-type: none"> Put your shoes in the closet. <i>instead of</i> Put your shoes in the closet, take a bath, and brush your teeth.
4. Commands should be <i>specific</i> rather than vague	<ul style="list-style-type: none"> Permits child to know exactly what is to be done 	<ul style="list-style-type: none"> Put this lego in the box. <i>instead of</i> Clean up your room.
5. Commands should be <i>age-appropriate</i>	<ul style="list-style-type: none"> Makes it possible for child to understand the command 	<ul style="list-style-type: none"> Draw a square. <i>instead of</i> Draw a hexagon.
6. Commands should be given <i>politely and respectfully</i>	<ul style="list-style-type: none"> Increases likelihood child will listen better Teaches child to obey polite and respectful commands Avoids child learning to obey only if yelled at 	<ul style="list-style-type: none"> Child: (Banging block on table) Parent: Please hand me the block. <i>instead of</i> Parent: (Said loudly) Hand me that block this instant!
7. Commands should be explained <i>before</i> they are given or <i>after</i> they are obeyed	<ul style="list-style-type: none"> Avoids encouraging child to ask "why" after a command as a delay tactic Avoids giving child attention for not obeying 	<ul style="list-style-type: none"> Parent: Go wash your hands. Child: Why? Parent: (Ignores, or uses time-out warning if child disobeys). Child: (Obeyes) Parent: Now your hands look so clean! It is so good to be all clean when you go to school!
8. Commands should be used <i>only when necessary</i>	<ul style="list-style-type: none"> Decreases the child's frustration (and the amount of time spent in the time-out 	<ul style="list-style-type: none"> Child: (Running around) Parent: Please sit in this chair. (Good time chair)to use this command) <i>instead of</i> Parent: Please hand me my glass from the counter. (Not a good time to use this command)

instructed to spend the following week faithfully practicing their CDI skills at home, so that the child's first "time-outs from CDI" will be especially salient. Parents are coached through their first PDI with the child in the clinic so that the therapist will be avail-

able to provide the parents with emotional support during the initiation of the time-out procedure.

As the family progresses in PDI, the child's rate of compliance increases rapidly. Parents' homework assignments gradually expand their use of running com-

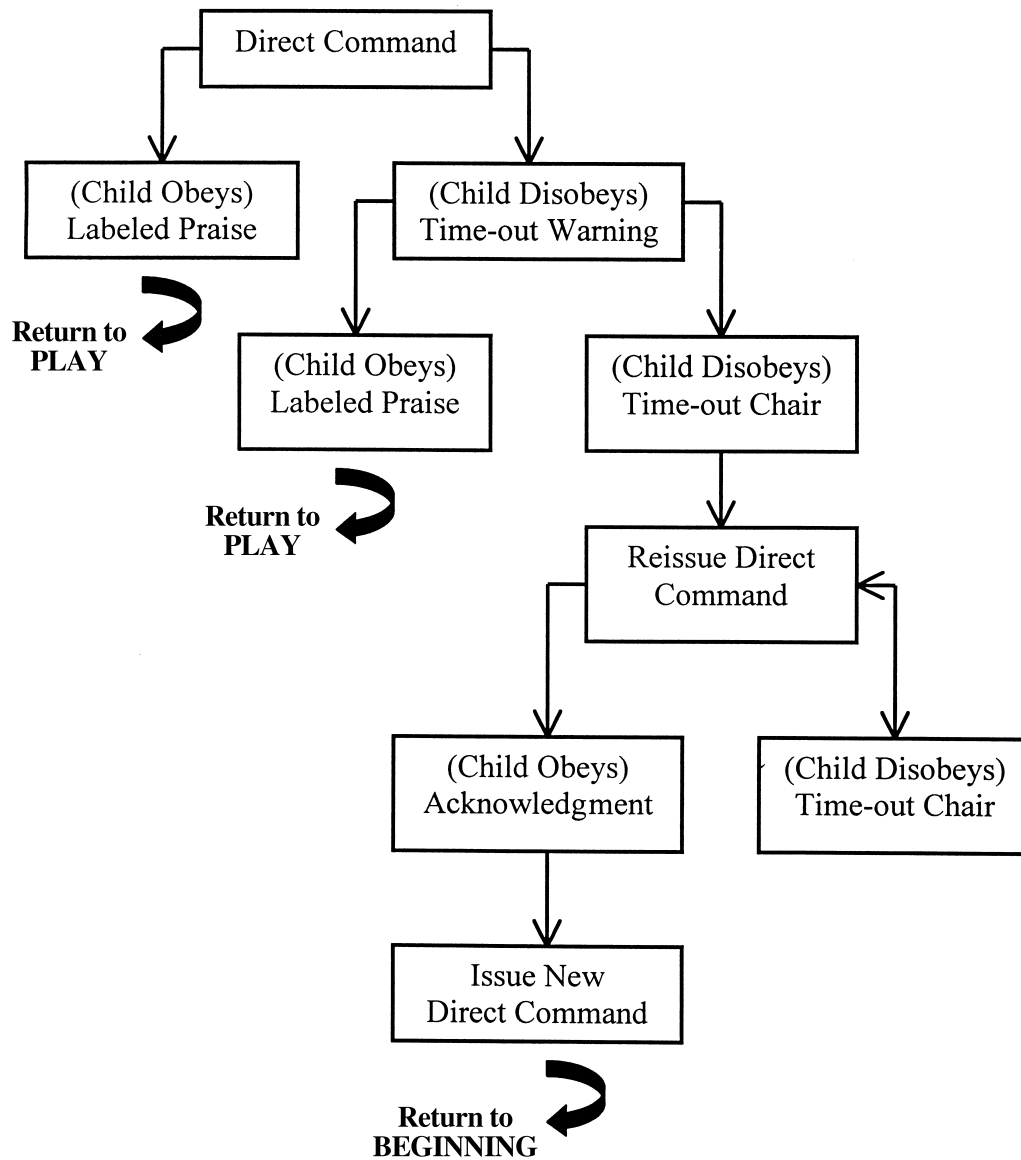

FIGURE 1 Parent-directed interaction diagram. (Copyright Sheila Eyberg, 2000).

mands to address specific problems that were identified during the assessment. For example, to encourage the child's use of words to indicate wants, the parent might give a command directing the child to say the name of the object the child is pointing to, and then follow the child's compliance with an enthusiastic labeled praise that explains the reason that the behavior is important, such as, "Nice job of using your words! Now that I know you want me to hand you the hat, I can give it to you really fast without guessing."

3. House Rules

As they progress in PDI, parents frequently want help with their child's aggressive behavior that is not decreased by parental ignoring and is not easily corrected with running commands. After a child's compliance to running commands is under control, parents may be introduced to the house rules procedure, which is a "standing command" variation of PDI. In teaching this procedure, parents are instructed first to label the target behavior problem for the child for 3 days to en-

sure that the child is aware of the label and the specific behavior it refers to, before a house rule to decrease that behavior is put into effect. For example, each time the child hits another person, the parent would say "You are hitting. Starting on Sunday, each time you hit, you will go to time-out." Once a house rule is in effect, the parent must use the time-out procedure when the targeted behavior occurs and must praise the child for behaviors incompatible with the target behavior, for example, "Good job of keeping your hands to yourself when she messed up your track." Parents keep a record of each house rule and the daily frequency of rule violations so that the effectiveness of the technique can be evaluated by the therapist. A new house rule may be added when the child shows improvement in an earlier target behavior, although a child should have no more than two active house rules at a time.

4. Public Behavior

Toward the end of PDI, another problem that may remain for some children is disruptive behavior in public places. To apply the PCIT principles to this situation, parents are advised to describe to the child their expectations for the child's behavior prior to entrance into the public area. Parents are then prompted to think of ways to give positive attention to the child's appropriate public behavior and ways to implement a time-out procedure for unacceptable behavior that cannot be ignored. The parent is given the opportunity to practice the new strategy with coaching as the therapist accompanies the family to public areas, such as a waiting room or parking lot.

Mastery of the PDI skills is demonstrated during clinic observations when 75% of the parents' commands are effective commands that allow the child time to obey, and when the parent follows through correctly at least 75% of the time after the child responds to a command, either with praise after compliance or initiation of time-out after noncompliance. The final PCIT session includes specific discussion of ways to maintain treatment gains and methods to deal with setbacks or new problems that arise in the future.

5. Follow-Up

Follow-up strategies are important to ensure the maintenance of parenting skills and the child's improved behavior. Maintenance techniques range from letters from the therapist reminding the family of the importance of daily practice sessions, to booster sessions in the clinic. One promising model of maintenance treatment currently under empirical study is an aftercare model in

which the therapist continues contact with the parent with short, monthly telephone calls to monitor maintenance and determine the level of intervention indicated, if any. Three levels of intervention are used during the maintenance period, with Level 1 consisting of supportive services. A Level 2 intervention includes the components of Level 1 in addition to the implementation of a problem-solving approach for an identified problem. A Level 3 intervention is a clinic session and is indicated for significant problems or crisis situations. The components of a Level 3 intervention include support, problem solving, clinic observations of parent-child interactions followed by coaching, and the development of a plan for problem resolution. The goal of the maintenance model is to monitor treatment gains and intervene immediately at the first sign of new or recurrent problems so as to prevent relapse.

II. THEORETICAL BASES

A. Conduct Problem Behavior in Preschoolers

In young children, the prevalence of clinically significant conduct problems is thought to be rising. Recent studies have found as many as 23% of preschool children in the general population score in the clinically significant range on parent-rating scales of externalizing behavior problems. Not surprisingly, conduct problems are the most common reason for referral to child mental health services.

Although once dismissed as a transient phase of children's development, we now know that, without treatment, conduct problem behavior that begins in early childhood tends to persist and worsen with time. Evidence indicates that early parent-child interactions have a powerful influence on the development of conduct problems, particularly in children with difficult temperaments, and parenting practices continue to play an important role in the maintenance of conduct problem behavior throughout the child's development. Fortunately, evidence has also shown that parent training interventions with young conduct-disordered children can reverse their behavior and may produce lasting change.

Parent training programs for young children with conduct problems have historically taken either a relationship enhancement approach, as exemplified by Bernard Guerney in 1964, or a behavioral approach, as exemplified by Robert Wahler in 1965. In relationship enhancement therapies, parents are trained to use

nondirective play therapy techniques to strengthen the parent–child bond, foster greater independence and self-acceptance on the part of the child, and increase parental acceptance of the child. In contrast, behavior therapies train parents in the application of learning principles to alter specific child behavior problems. In 1969, Constance Hanf developed a behavioral model of therapy that focused on coaching parents *in vivo* as they played with their child. Her treatment consisted of two stages, in which parents were first taught to change their child's behavior by using differential social attention, which involves ignoring inappropriate behavior and attending to positive behavior. In the second stage, parents were trained to change their child's behavior by giving direct commands, praising compliance, and punishing noncompliance with time-out.

Parent–child interaction therapy is a parent–child treatment for young children with behavior problems that places a dual emphasis on relationship enhancement and behavioral parent management training. The goal of PCIT is to create a nurturing, secure relationship by teaching parents to increase their child's prosocial behaviors while decreasing their child's inappropriate behaviors. Like the Hanf model, PCIT includes two primary phases in which parents are coached in the treatment skills as they play with their child. Goals of the first phase, CDI, are to strengthen the parent–child relationship, increase positive parenting, and increase child prosocial behavior. Goals of the second phase, PDI, are to decrease child noncompliance and defiance by improving parents' ability to set limits and be fair and consistent in disciplining their child. PCIT is most distinct from the Hanf model in its emphasis on teaching parents to use traditional play therapy techniques and the skills of reciprocal interaction in the first phase, and, in the second phase, on teaching parents to use problem-solving skills to apply general discipline paradigms to problem behavior, with an overarching objective to improve the quality of parent–child interactions.

B. Theoretical Underpinnings of PCIT

PCIT draws on both attachment and social learning theories. Children's optimal emotional, behavioral, and social development is enhanced by a secure, stable attachment and healthy interaction patterns with their parents. Attachment theory asserts that attentive and sensitive parenting during infancy leads children to develop a cognitive-affective model that their parents will be responsive to their needs. Children whose parents

are cold, distant, and unresponsive to their child's needs are likely to develop a maladaptive attachment with their parents and peers, display increased aggression, and have poor self-esteem, coping skills, and social competence. The CDI emphasizes responsive parenting to establish or strengthen a secure attachment relationship as the foundation for establishing effective child management skills.

Gerald Patterson's coercion theory also provides a transactional account of early disruptive behavior in which children's conduct problems are inadvertently established or maintained by negative reinforcement in the parent–child interaction. Dysfunctional interactions must be interrupted by a change in parent behavior involving clear limit-setting that is consistently enforced early in the child's life. PDI incorporates these social learning principles by teaching parents a highly structured algorithm of positive and negative consequences to follow once they have issued a command or set a rule in place.

III. EMPIRICAL STUDIES

Parent–child interaction therapy outcome research has demonstrated significant findings in the treatment of conduct-disordered behavior of preschool children, including improvements in children's behavior at the end of treatment on parent and teacher rating scales and direct observation measures and significant changes on parents' self-report measures of psychopathology, personal distress, and parenting locus of control. Important changes in the interactional styles of fathers and mothers in play situations with the child, such as increased reflective listening, physical proximity, and decreased criticism have also been demonstrated at treatment completion. Treatment effects have been found to generalize to the school setting and to untreated siblings. Comparison studies have found PCIT superior to wait-list control groups and other treatments including parent group training.

Several studies have addressed the issue of maintenance of behavioral improvements following completion of PCIT by examining the short- and long-term recurrence of conduct problems for study participants in later childhood. In a study conducted by Toni Eisenstadt and her colleagues in 1993, short-term maintenance of treatment effects for 14 families was found on parent ratings of behavior problems, activity level, and maternal stress, and observational measures of parenting skills and child compliance. Two years later, 13 of

these families were located for follow-up, and 9 (69%) of these families had maintained treatment gains on measures of behavior problems, activity level, and parenting stress at the same level as found at the end of treatment. Most of the children (7 of 13 or 54%) also remained free of diagnoses of disruptive behavior disorders. Recently, maintenance of treatment gains in child behavior and parenting confidence at 4 to 6 years after treatment have been found.

Daniel Edwards and colleagues examined differences in long-term outcomes between 23 PCIT dropouts and 23 PCIT completers. Ten to 30 months after their pre-treatment assessment, mothers of children who dropped out of PCIT reported significantly more symptoms of the disruptive behavior disorders and higher levels of parenting stress than did those who completed treatment. The follow-up scores for dropout families showed no differences from their scores before treatment started, whereas follow-up scores for the families who completed treatment showed no differences from their scores at the end of treatment. These data suggest that PCIT can alter the developmental path of disruptive behavior for those young children and families who complete treatment, and they also highlight the problem of attrition.

Addressing attrition must become a research priority. The rate of attrition from PCIT has ranged from 0 to 32% in recent studies, which compares favorably to the average 40% to 60% attrition rate typically found in child clinic samples. Neither the poorest families nor the children with the most severe problems drop out more than other families, but maternal distress has been identified as a significant predictor of dropout from PCIT. Such findings indicate the necessity of addressing broader contextual issues in treatment to prevent attrition in the high-stress families of conduct-disordered children. In particular, attention to the parents' personal concerns will need even greater emphasis in PCIT.

Further attention to treatment maintenance is a second research priority. Although long-term maintenance of PCIT effects has been documented, the effects of treatment do not last for every family. Given the persistent and recurrent nature of early-onset conduct disorder, it may be unrealistic to expect that the current models of short-term treatment, which end immediately on initial resolution of the presenting problems, will lead to lasting changes in child and family behavior as the child develops and the family faces new challenges. In addition to testing promising models of maintenance treatment, it will be important to examine both the course and the predictors of long-term maintenance to identify the factors related to long-term be-

havior change, which will help in designing more effective interventions for all families.

IV. SUMMARY

Parent-child interaction therapy is a treatment for preschool-age children with conduct problems and their families. This treatment is theoretically based, assessment driven, and empirically supported. During PCIT sessions, parents play with their child while the therapist coaches them to use specific skills to change their child's behavior. In the first phase of treatment parents learn the CDI skills, designed to strengthen the parent-child attachment relationship and to increase positive parenting and the child's prosocial behavior. In the second phase, parents learn the PDI skills, designed to decrease child noncompliance and aggression by improving parents' ability to set limits and be fair and consistent in disciplining. Treatment ends when parents demonstrate mastery of these relationship enhancement and child management skills with the child and report that the child's behavior problems are within normal limits on standardized measures. Studies have clearly demonstrated the effectiveness of PCIT in decreasing disruptive behavior and increasing prosocial behavior of the child and improving the psychological functioning of the parents. The early long-term follow-up studies suggest that the changes seen at the end of treatment tend to last for most children and families, although further study of both maintenance and attrition is imperative.

GLOSSARY

anaclitic A developmentally-oriented perspective on traits, behaviors, capacities, psychological structures, and psychopathological configurations that emphasizes relatedness, interpersonal relations, and attachments across the spectrum of maturity. The term is derived from the idea of “leaning upon.”

introjective A developmentally-oriented perspective on traits, behaviors, capacities, psychological structures, and psychopathological configurations that emphasizes the establishment and maintenance of a sense of self. It literally means, “to take in.”

Psychotherapy research usually assumes an homogeneity among patients and treatments. A number of research methodologists and psychotherapy investigators have questioned these assumptions and have noted the need to differentiate among patients and to examine systematically the role of the patient in the treatment process. As observed by the distinguished research

methodologist, Lee Cronbach almost a half century ago, differences in the effects of various forms of therapeutic intervention may be a function of the congruence of certain characteristics of the patient with particular aspects of the treatment process. Rather than assuming that all patients respond to treatment in the same way, it may be more productive to distinguish among patients and to examine interactions between types of treatment and types of patients expecting some patients to respond more effectively to one form of treatment whereas other patients might respond more effectively to another form of treatment. Jerome Frank, a major figure in initiating systematic psychotherapy research, noted in 1979 that research consistently suggests that “major determinants of therapeutic success appear to lie in aspects of the patients’ personality and style of life.” He saw as crucial the development of better criteria for the assignment of different types of patients to different therapies. He suggested that patients who conceptualize their subjective worlds in greater complexity might do better in unstructured situations whereas less conceptually complex patients may respond better to a more structured therapy. Mardi Horowitz and colleagues, in a study of brief therapy for bereavement in 1984, found that patients with developmentally more advanced levels of self-concept had better outcome in insight-oriented treatment, whereas patients with developmentally lower self-concept responded better to supportive techniques.

In an analysis of data from the National Institute on Mental Health (NIMH) sponsored Treatment of Depression Collaborative Research Program (TDCRP), Stuart

Sotsky and colleagues in 1991 identified several pretreatment characteristics of patients that were predictive of treatment outcome. Higher social functioning predicted a generally favorable outcome (completion of treatment and reduction of severity of depression at termination), particularly in responsiveness to interpersonal therapy (IPT). Higher cognitive functioning also appeared to predict good outcome, (i.e., reduction of severity of depression), especially to cognitive-behavior therapy (CBT). Patients with both impaired social and work functioning responded best to medication (imipramine) plus clinical management (i.e., reduction of depression severity and completion of treatment). These findings led the authors to suggest that “each psychotherapy relies on specific and different learning techniques to alleviate depression, and thus each may depend on an adequate capacity in the corresponding sphere of patient function to produce recovery with the use of that approach.” Patients with relatively good social functioning are better able to take advantage of interpersonal strategies in IPT to recover from depression, whereas patients with relatively less cognitive impairment are better able to utilize cognitive-behavioral techniques to reduce depression. In a 1994 review of attempts to predict therapeutic outcome from a host of patient personality variables (e.g., rigidity, ability to feel deeply, ego strength, coping capacities, extroversion, and neuroticism), assessed via both objective and projective procedures, Sol Garfield concluded that “although a number of investigations have reported some positive findings, most of the relationships secured between personality variables and outcomes have been of limited strength.”

The study of the interactions of patient characteristics with process and outcome variables in psychotherapy research was initially proposed by Lee Cronbach in 1952 in his demonstration that differential efficacy of various teaching procedures was a consequence of the congruence of particular educational procedures and teacher's style with characteristics of the individual student. As Cronbach noted, these findings not only have implications for educational psychology, but they have important implications for psychotherapy research in their suggestion that the investigation of patient-treatment (PT) and patient-outcome (PO) interactions may provide a more productive methodology for psychotherapy research. The investigation of the interaction between patient characteristics with aspects of the treatment process might facilitate the investigation of the efficacy of various types of treatment, as well as the exploration of possible differences in treatment outcome and process. Different types of treatment may not only be differentially effective with different individuals, but different individuals may

experience different, but equally desirable, outcomes with the same therapeutic intervention. The identification of patients' characteristics that interact with particular therapeutic modalities and different outcomes could provide fuller understanding of important aspects of the therapeutic process.

The view that different types of patients might have differential responses to different types of therapy has been discussed since Cronbach's initial observations, more recently emphasized in a 1991 special issue of the *Journal of Consulting and Clinical Psychology* devoted to this topic. Donald Kiesler noted in 1966 that among the most salient obstacles to the development of methodologically sophisticated psychotherapy research are the assumptions of “patient and therapist uniformity.” Patient uniformity is based on the assumption that “patients at the start of treatment are more alike than they are different.” Kiesler stressed the need to abandon these uniformity myths in favor of “designs that can incorporate relevant patient variables and crucial therapist dimensions so that one can assess which therapist behaviors are more effective with which type of patients.” Later in 1991, Larry Beutler called for more specific operational definitions of therapy and of patient characteristics if we are to develop effective predictive models. However, he stressed that the inclusion of PT and PO interactions in psychotherapy research requires conceptual models to identify the personality variables that might mediate the responses to different types of treatment and result in different types of therapeutic outcome.

The primary difficulty in developing this line of research is the identification of certain qualities, out of the infinite array of possible personal characteristics of patients, that might be relevant to the treatment process. Research not guided by theoretically derived or empirically supported principles could lead investigators into a “hall of mirrors” because of the complexity of the potential interactions. Cronbach noted in 1975, “One can avoid entering (this) hall of mirrors by exploring the interactions between theoretically meaningful ... variables” that are grounded in conceptual models. The choice of patient qualities needs to be theory driven and include dimensions relevant to the processes that are assumed to underlie psychological change. One possible model for introducing patient variables into psychotherapy research is the theory of personality development and psychopathology that articulates two primary dimensions in personality development—interpersonal relatedness and self-definition—and notes their differential role in different forms of psychopathology as well as their possible impact on the treatment process.

Sidney Blatt and colleagues beginning in 1974 proposed a theoretically derived and empirically supported model of personality development and psychopathology that has the potential to facilitate the introduction of patient variables into psychotherapy research. Blatt and colleagues conceptualized personality development as involving two fundamental developmental lines: (a) a relatedness or anaclitic line that involves the development of the capacity to establish increasingly mature and mutually satisfying interpersonal relationships, and (b) a self-definitional or introjective line that involves the development of a consolidated, realistic, essentially positive, differentiated, and integrated self-identity. These two developmental lines normally evolve throughout the life cycle in a reciprocal or dialectic transaction. An increasingly differentiated, integrated, and mature sense of self is contingent on establishing satisfying interpersonal relationships, and, conversely, the continued development of increasingly mature and satisfying interpersonal relationships is contingent on the development of a more mature self-concept and identity. In normal personality development, these two developmental processes evolve in an interactive, reciprocally balanced, mutually facilitating fashion throughout life.

These formulations are consistent with a wide range of personality theories ranging from fundamental psychoanalytic conceptualizations to basic empirical investigations of personality development. Sigmund Freud, for example, observed in *Civilization and Its Discontents*, that

the development of the individual seems ... to be a product of the interaction between two urges, the urge toward happiness, which we usually call "egoistic," and the urge toward union with others in the community, which we call "altruistic." ... The man who is predominantly erotic will give the first preference to his emotional relationship to other people; the narcissistic man, who inclines to be self-sufficient, will seek his main satisfactions in his internal mental processes.

Freud also distinguished between object and ego libido and between libidinal instincts in the service of attachment and aggressive instincts necessary for autonomy, mastery, and self-definition. Hans Loewald, a distinguished psychoanalytic theorist, noted that the exploration of

these various modes of separation and union ... [identify a] polarity inherent in individual existence of individuation and "primary narcissistic union"—a polarity that Freud attempted to conceptualize by various approaches but that he recognized and insisted upon

from beginning to end by his dualistic conception of instincts, of human nature, and of life itself.

John Bowlby from an ethological viewpoint considered striving for attachment and separation as the emotional substrate for personality development. Michael Balint, from an object-relations perspective, also discussed these two fundamental dimensions in personality development—a clinging or connectedness (an ocnophilic tendency) as opposed to self-sufficiency (a philobatic tendency). Shor and Sanville, based on Balint's formulations, discussed psychological development as involving a fundamental oscillation between "necessary connectedness" and "inevitable separations" or between "intimacy and autonomy." Personality development involves "a dialectical spiral or helix which interweaves these two dimensions of development." A wide range of more general personality theorists including David Bakan, David McClelland, and Jerry Wiggins have also discussed relatedness and self-definition as two primary dimensions of personality development.

Various forms of psychopathology can be conceptualized as an overemphasis and exaggeration of one of these developmental lines and the defensive avoidance of the other. This overemphasis defines two distinctly different configurations of psychopathology, each containing several types of disordered behavior that range from relatively severe to relatively mild forms of psychopathology. Based on developmental and clinical considerations, anaclitic psychopathologies are those disorders in which patients are primarily preoccupied with issues of relatedness, ranging from symbiotic and dependent attachments to more mature relationships, and utilize primarily avoidant defenses (e.g., withdrawal, denial, repression) to cope with psychological conflict and stress.

Anaclitic disorders involve a primary preoccupation with interpersonal relations and issues of trust, caring, intimacy, and sexuality, ranging developmentally from more to less disturbed, and include non-paranoid schizophrenia, borderline personality disorder, infantile (or dependent) character disorder, anaclitic depression, and hysterical disorders. These patients utilize primarily avoidant defenses like denial and repression. In contrast, introjective psychopathology includes disorders in which the patients are primarily concerned with establishing and maintaining a viable sense of self ranging from a basic sense of separateness, through concerns about autonomy and control, to more complex and internalized issues of self-worth. These patients utilize primarily counteractive defenses (projection, rationalization, intellectualization, doing and undoing, reaction formation,

overcompensation) to cope with conflict and stress. Introjective patients are more ideational and concerned with establishing, protecting, and maintaining a viable self-concept than they are about the quality of their interpersonal relations and achieving feelings of trust, warmth, and affection. Issues of anger and aggression, directed toward the self or others, are usually central to their difficulties. Introjective disorders, ranging developmentally from more to less severely disturbed, include paranoid schizophrenia, the schizotypic or overrideational borderline, paranoia, obsessive-compulsive personality disorders, introjective (guilt-ridden) depression, and phallic narcissism.

The distinction between these two broad configurations of psychopathology can be made reliably from clinical case records. In contrast to the atheoretical diagnostic systems established in the diagnostic and statistical manuals of mental disorders developed by the American Psychiatric Association based primarily on differences in manifest symptoms, the diagnostic differentiation between anaclitic and introjective pathologies is based on dynamic considerations, including differences in primary instinctual focus (libidinal vs. aggressive), types of defensive organization (avoidant vs. counteractive), and predominant character style (e.g., emphasis on an object vs. self-orientation, and on affects vs. cognition).

The theoretical model of personality development and psychopathology based on the polarity of relatedness and self-definition provides a theoretically grounded, empirically supported, conceptual framework for introducing personality variables into psychotherapy research. Differences in the nature of therapeutic outcome and in the treatment process between anaclitic and introjective patients were examined in three different research programs: (a) in the study of therapeutic change in the long-term, intensive, psychodynamically oriented inpatient treatment of patients who are seriously disturbed and treatment resistant (the Riggs-Yale Project), (b) in the comparison of the therapeutic efficacy of psychoanalysis and long-term supportive-expressive outpatient psychotherapy (the Menninger Psychotherapy Research Project), and (c) in the comparison of four different, brief (16-week), outpatient interventions for major depression (the NIMH-sponsored TDCRP).

Sidney Blatt and colleagues demonstrated that the distinction between anaclitic and introjective patients facilitated the identification of important differences in the processes of clinical change in long-term intensive treatment with both inpatients and outpatients. The results of these two studies indicate that anaclitic and in-

trojective patients have different needs, respond differentially to different types of therapeutic interventions, and demonstrate different treatment outcomes. Analyses of the data in these two studies based on more conventional diagnostic differentiations (e.g., psychosis, severe borderline, and neurotic psychopathology) were not as effective in identifying differences in change over the course of treatment. This conclusion is consistent with earlier findings that patient characteristics based on psychodynamic indices, as compared to symptomatic and descriptive distinctions, seem to have greater utility in predicting aspects of the therapeutic process and outcome.

I. THE AUSTEN RIGGS-YALE STUDY

Therapeutic change was studied in young adult inpatients who were seriously disturbed and treatment resistant in long term (at least 1 year), intensive, psychodynamically oriented treatment, including at least four times weekly individual psychoanalytic psychotherapy, in an open therapeutic facility. The differentiation of anaclitic and introjective patients was based on a review of admitting clinical case reports prepared during the first 6 weeks of hospitalization. Two judges made this differentiation from the case records at a high level of reliability. Systematic differences were found in the response of anaclitic and introjective patients on a number of measures of therapeutic change reliably derived from clinical case records and independent psychological test protocols that had been obtained at the outset of treatment and again after, on average, 15 months of inpatient treatment and, on average, 10 months prior to discharge from the clinical facility. Patients generally demonstrated significant improvement across these multiple independent assessments. Introjective patients, however, had greater overall improvement than did anaclitic patients on many of the measures. Independent of the degree of therapeutic gain, anaclitic and introjective patients expressed their therapeutic change (progression and regression) in different ways. Introjective patients expressed therapeutic change primarily through changes in their clinical symptoms, as reliably rated from clinical case reports and in their cognitive functioning, as independently assessed on psychological tests—in thought disorder on the Rorschach and in intelligence as assessed on the Wechsler Adult Intelligence Test. In contrast, anaclitic patients expressed change primarily in the quality of their interpersonal relationships, as reliably rated from clinical case reports, and in their representation of the human form on the Rorschach. Thus, anaclitic and introjective patients

changed primarily in the dimensions of their basic concerns and preoccupations. Anaclitic patients changed primarily on measures of interpersonal relatedness; change in introjective patients was found primarily in measures of cognitive functioning and of clinical symptoms.

II. THE MENNINGER PSYCHOTHERAPY RESEARCH PROJECT (MPRP)

The Menninger Psychotherapy Research Project compared the therapeutic response of outpatients in 5-times weekly psychoanalysis with patients in long-term, psychodynamically oriented, twice-weekly, supportive-expressive psychotherapy. Extensive prior analyses of the clinical evaluations and psychological test assessments, conducted both before and after treatment, have repeatedly failed to find any significant differences in the therapeutic response of patients to these two types of therapeutic intervention. Significant differences between psychotherapy and psychoanalysis, however, were found when patient variables were introduced into the data analyses. Anaclitic and introjective patients were reliably differentiated by two judges who reviewed the pretreatment case reports. Independent evaluation of psychological test data gathered at the beginning and the end of treatment indicated that anaclitic patients had significantly ($p < .05$) greater improvement in psychotherapy than they did in psychoanalysis. Introjective patients, in contrast, had significantly ($p < .05$) greater improvement in psychoanalysis than they did in psychotherapy. Not only were these differences between the two types of treatment significant within each type of patient, but the patient-by-treatment interaction was a significant ($p < .001$) cross-over interaction. Thus, the relative therapeutic efficacy of psychoanalysis versus psychotherapy was contingent, to a significant degree, on the nature of the patient's pathology and pretreatment character structure. It seems consistent that the dependent, interpersonally oriented, anaclitic patients were more responsive to a therapeutic approach that provided more direct interaction with the therapist. It also seems consistent that the more ideational introjective patients, preoccupied with separation, autonomy, and independence, would be more responsive in psychoanalysis.

The findings of both these studies—the comparison of outpatients in two different forms of treatment and the therapeutic response of inpatients who are seriously disturbed and treatment resistant in long-term, intensive treatment—clearly indicate that aspects of patients' personality interact with dimensions of the

therapeutic process to determine the nature of therapeutic change and the differential response to different therapeutic modalities. Patients come to treatment with different types of problems, different character styles, and different needs, and respond in different ways to different types of therapeutic intervention.

III. THE TREATMENT OF DEPRESSION COLLABORATIVE RESEARCH PROGRAM (TDCRP)

The availability of the empirical data from the large-scale, multicenter, treatment program for depression, the TDCRP, sponsored by The National Institute of Mental Health (NIMH), provided opportunity to explore the role of patient dimensions in the brief outpatient treatment of depression. The NIMH TDCRP was a comprehensive, well designed, carefully conducted, collaborative, randomized clinical trial that evaluated several forms of brief (16-week) outpatient treatment for depression. Two hundred thirty-nine patients were randomly assigned to one of four treatment conditions: cognitive-behavior therapy (CBT), interpersonal therapy (IPT), imipramine plus clinical management (IMICM) as a standard reference, and pill placebo plus clinical management (PLA-CM)¹ as a double-blind control condition. It seemed particularly appropriate to explore patient differences in the TDCRP with regard to the fundamental polarity of relatedness and self-definition, given the considerable evidence by Aaron Beck in 1983 and Sidney Blatt in 1974 that indicated the reliability and validity of the distinction between anaclitic and introjective forms of psychopathology, especially in the study of depression.

Patients were nonbipolar, nonpsychotic, seriously depressed outpatients who met RDC criteria for major depressive disorder and had a score of 14 or greater on a modified, 20-item, Hamilton Rating Scale for Depression (HRSD). Among patients who began treatment, 70% were female, 38% were definitely endogenous by RDC criterion, and 64% had had one or more prior episodes of major depression. The average age was 35.

Patients were systematically assessed at intake, at 4-week intervals until termination at 16 weeks, and again at three follow-up evaluations conducted 6, 12, and 18 months after termination. Assessments included an interview and a self-report measure of depression HRSD

¹ Clinical management (CM) was a 20-min nonspecific supportive interaction.

and Beck Depression Inventory [BDI], respectively), an interview and a self-report measure of general clinical functioning (Global Assessment Scale [GAS] and Hopkins Symptom Checklist [HSCL-90], respectively), and an interview assessment of social adjustment, the Social Adjustment Scale (SAS). In addition, patients, therapists, and independent clinical evaluators (CEs) rated various aspects of therapeutic progress during treatment, at termination, and at the three follow-up assessments (therapists did not participate in the follow-up assessments). Prior analyses of the TDCRP data indicated some differences in therapeutic outcome at termination among these brief treatments for depression; IMI-CM and IPT, but not CBT, were more effective than PLA-CM, but only with patients who were more severely depressed. Though at midtreatment, IMI-CM resulted in more rapid reduction of symptoms than CBT and IPT, no significant differences in the extent of symptom reduction were found among the three active treatment conditions in the TDCRP (CBT, IPT, and IMI-CM) at termination. In addition, no significant differences in the intensity of symptoms were found among all four treatment condition at the three follow-up assessments conducted at 6, 12, and 18 months. However, Blatt and colleagues found significant differences between the two psychotherapy conditions and the medication condition at the follow-up evaluations in the degree to which patients thought treatment had a constructive impact on their development of adaptive capacities to deal with interpersonal relationships and their experiences and symptoms of depression.

The development of these adaptive capacities early in the follow-up period, at the 6-month follow-up assessment, significantly moderated the degree to which subsequent stressful life events resulted in increases in depressive symptoms at the final follow-up assessment conducted 18 months after the termination of treatment. Thus, despite frequent claim of the efficacy of the medication condition in the TDCRP, analyses of data from all three follow-up assessments, including the last assessment conducted 18 months after termination, indicate that patients in the two psychotherapy conditions, CBT and IPT, reported greater satisfaction with their treatment and that their treatment had significantly greater positive effect on their life adjustment in a number of important areas—in their ability to deal with interpersonal relationships and their experiences and symptoms of depression than did patients in the medication condition. The development of these adaptive capacities decreased patients' vulnerability to subsequent stressful life events. These findings raise questions about the relative value of

reduction in symptoms versus reduction of vulnerability as measures of therapeutic progress.

A. Impact of Patient Variables on Therapeutic Outcome

To introduce patient variables into analyses of data from the TDCRP, an experienced judge reviewed the intake clinical evaluations to see if he could differentiate anaclitic and introjective patients but found that these clinical case reports contained primarily descriptions of patients' neurovegetative symptoms and lacked sufficient detail about aspects of the patients' lives to allow the judge to discriminate reliably between anaclitic and introjective patients. Fortunately the Dysfunctional Attitudes Scale (DAS) had been included in the TDCRP protocol, primarily to assess the effects of treatment on dysfunctional cognitions. A factor analysis conducted on the pretreatment DAS in the TDCRP data set, consistent with several prior studies, indicated that the DAS is composed of two primary factors—need for approval (NFA) and perfectionism (PFT) or self-criticism. Prior research indicated that NFA factor on the DAS assesses primarily the relatedness or anaclitic dimension whereas the PFT factor in the DAS assesses primarily the self-definitional or introjective dimension. Thus, the pretreatment DAS provided the basis for introducing differences among patients on the dimensions of relatedness and self-definition into analyses of data from the TDCRP.

Pretreatment PFT significantly ($p = .032$ to $.004$) predicted negative outcome, assessed by all five primary measures of clinical change in the TDCRP (HSRS, BDI, GAS, SCL-90, and SAS across all four treatment groups. Factor analysis of the residualized gain scores of these five outcome measures at termination revealed that these measures all load substantially ($p > .79$) on a common factor with an eigenvalue of 3.78, accounting for 75.6% of the variance, indicating that this factor is a consistent measure of therapeutic change. Pretreatment PFT had a highly significant ($p < .001$) negative relationship to this composite residualized gain score at termination. NFA, in contrast, had a marginal, but consistently positive, relationship to treatment outcome as assessed by each of these five outcome measures and by the composite outcome measure ($p = .11$).

Pretreatment PFT also had a significant negative relationship to outcome ratings made by therapists, independent CEs, and the patients at termination. This negative impact of perfectionism on the therapeutic process persists even as late as the last follow-up assessment, 18 months after termination. Pretreatment

PFT correlated significantly with follow-up ratings by CEs of poorer clinical condition and a need for further treatment, and with ratings by patients of dissatisfaction with treatment. Perfectionistic patients gave poorer ratings of their current condition, said that they experienced less change in treatment, and said that treatment had less impact on their general life adjustment and their coping skills (i.e., dealing with relationships and their ability to recognize and deal with their symptoms of depression).

It is important to note that not only did patients with elevated pretreatment PFT feel subjectively less satisfied with treatment and report less impact of treatment on the ability to develop adaptive capacities, but ratings by the therapists (at termination) and CEs indicated a significant negative relationship between patients' pretreatment PFT scores and ratings of the degree to which they thought the patients improved at termination and at the 18-month follow-up, independent of the type of treatment the patient had received. Thus, introjective personality traits significantly interfered with patients' capacity to benefit from short-term treatment, whether the treatment was pharmacotherapy (IM-ICM), psychotherapy (CBT or IPT), or placebo. These findings of impaired response of introjective (perfectionistic) patients in short-term treatment stand in contrast to the findings of more positive responses of introjective patients in the long-term, intensive treatment of inpatients who are seriously disturbed at the Austen Riggs Center and in the long-term, intensive treatment of outpatients evaluated in The Menninger Psychotherapy Research Project.

B. Impact of Patient Variables on the Therapeutic Process

The extensive data gathered as part of the NIMH TDCRP also provided Blatt and colleagues the opportunity to examine some of the dynamics of brief treatment and to identify when and how introjective personality characteristics interfere with the therapeutic process.

Therapeutic gain in the TDCRP was assessed every 4 weeks until termination, and thus it was possible to evaluate when in the treatment process pretreatment PFT began to disrupt therapeutic outcome. PFT significantly disrupted therapeutic progress primarily in the last one half of the treatment process. Until midtreatment at the 8th week, no significant differences were found in therapeutic gain between patients at different levels of PFT. Beginning at midtreatment, however, only patients in the lower one third of the distribution

of PFT continued to make significant progress. When two thirds of the patients, those with higher pretreatment levels of perfectionism, approach the end of treatment, they seem to experience a sense of personal failure, dissatisfaction, and disillusionment with treatment. Even further, perfectionistic (introjective) individuals are very concerned about maintaining control and preserving their autonomy. Thus, another factor that may disrupt the therapeutic progress in the last one half of the treatment process of the more perfectionistic (introjective) patients in the TDCRP may be the unilateral, external imposition of an arbitrary, abrupt termination date.

Not only were we able to identify when introjective personality qualities began to disrupt therapeutic progress, but we were also able to discover some of the mechanisms through which this disruption occurs. Janice Krupnick and colleagues in 1996 had used a modified form of the Vanderbilt Therapeutic Alliance Scale (VTAS) to assess the contributions of patient and therapist in establishing an effective therapeutic alliance in the TDCRP. Judges rated videotapes of the 3rd, 9th, and 15th treatment sessions. They found that the VTAS comprised two factors: (a) a patient factor that assessed the extent to which the patient was open and honest with the therapist; agreed with the therapist about tasks, goals, and responsibilities; and was actively engaged in the therapeutic work; and (b) a therapist factor that assessed the extent to which the therapist committed self and skills to helping the patient and the degree to which the therapist acknowledged the validity of the patient's thoughts and feelings. The contribution of patients to the therapeutic alliance, but not that of the therapist, significantly predicted treatment outcome. Therapeutic outcome across treatment groups was predicted by the degree to which the patient became increasingly involved in the treatment process.

Using these ratings of the therapeutic alliance made by Krupnick and colleagues, David Zuroff and colleagues recently explored the impact of the pretreatment levels of PFT on the development of the therapeutic alliance and found that PFT significantly impedes the capacity of patients to develop a therapeutic alliance, particularly in the latter one half of treatment. Thus, not only were we able to identify when in the treatment process perfectionism disrupts therapeutic progress, but we also discovered how introjective personality traits impede patients' capacity to gain from the brief treatment of depression. Patients who make therapeutic progress usually become increasingly involved in a constructive collaborative relationship with their therapist,

but this increased involvement in treatment is moderated by the patient's pretreatment level of perfectionism, independent of the treatment they were receiving. Increases in therapeutic alliance were significantly smaller or absent in patients at higher levels of perfectionism, particularly in the latter one half of the treatment process.

Perfectionistic individuals generally have limited capacities for developing open, collaborative relationships, and therefore it may take a more extended period of time for them to establish an effective therapeutic alliance. The effects of pretreatment PFT on therapeutic outcome is not only moderated by the quality of the therapeutic alliance, but, as Golar Sharar and colleagues demonstrated, it is also moderated by the extent to which patients are able to establish and maintain external social support during treatment and the follow-up period. Thus, the disruptive effects of pretreatment PFT on the treatment process is primarily the consequence of the disruptive effects of perfectionism on interpersonal relatedness both in the treatment process and in interpersonal relationships more generally.

Blatt and colleagues in 1996 also tried to identify aspects of the treatment process that could facilitate treatment outcome with these patients who are more difficult and highly perfectionistic. The TDCRP research team, using the Barrett-Lennard Relationship Inventory (B-L RI), asked patients, at the end of the second treatment session, to rate the degree to which they thought their therapist was empathic and caring. The B-L RI includes subscales to assess patient's perception of the therapist's emphatic understanding, level of positive regard, and congruence—qualities of the therapist that Carl Rogers believed were the necessary and sufficient conditions for therapeutic change. Prior studies demonstrated that the B-L RI was significantly related to treatment outcome at termination.

Overall, the degree to which patients in the TDCRP perceived their therapist as empathic and caring at the end of the second treatment session had a significant ($p < .05$) positive relationship to therapeutic outcome. However, this facilitating therapeutic effect of the patients' early view of the therapist as empathic and caring was very much contingent on the patients' level of perfectionism. An initial positive view of therapist had only marginal effects on treatment outcome at low and high levels of PFT ($ps < .10$ and $.15$, respectively). Patients who are highly perfectionistic did relatively poorly in treatment whereas patients low in perfectionism had relatively better outcome, independent of how they perceived the therapist early in treatment. However, at the middle level of PFT, the patient's early view of the therapist

had a highly significant ($p < .001$) impact on treatment outcome. At the middle level of perfectionism, an early view of the therapist as empathic and caring significantly reduced the disruptive effects of perfectionism on treatment outcome, whereas a negative view of therapist significantly compounded these disruptive effects. Thus at the middle level, the effect of perfectionism on treatment outcome is significantly contingent on the degree to which the patient, very early in the treatment process, perceived the therapist as empathic and caring.

In sum, analyses of brief treatment of depression in the TDCRP indicate that therapeutic outcome is significantly influenced by pretreatment characteristics of the patient—by pretreatment level of perfectionism or self-criticism—independent of the type of treatment provided. This negative effect of pretreatment PFT on outcome occurs primarily in the second one half of the treatment process, as patients approach termination. This impact of pretreatment PFT on outcome occurs in large part through interference with patients' capacity to continue to be involved in interpersonal relationships both in the therapeutic alliance, particularly as termination approaches, as well as in interpersonal relations external to the treatment process. This negative impact of perfectionism on treatment outcome is significantly reduced, but only at middle levels of perfectionism, if the patient initially perceives the therapist as empathic and caring.

IV. SUMMARY

A fundamental polarity of relatedness and self-definition, central to many of Freud's theoretical formulations, as well as to those of many other psychoanalytic and non-psychoanalytic investigators, provides a basis for articulating a model of personality development: A model that involves a complex, mutually facilitating, dialectic transaction between the development of interpersonal relationships and of self-definition throughout the life cycle. This polarity also provides a basis for identifying two major types of depression: an anclitic or dependent and introjective or self-critical depression. This polarity also provides a way for understanding a wide range of psychological disturbance, from schizophrenia to the neuroses, as emerging from disruptions in the dialectic development of the two fundamental developmental lines of relatedness and self-definition. This differentiation of two primary configurations of psychopathology—anaclitic and introjective—is based, not on differences in manifest symptoms, but on fundamental dimensions of personality organization: differences in primary instinctual focus (sexuality vs.

aggression), type of defensive organization (avoidant vs. counterphobic), and personality style (e.g., emphasis on relationships vs. a self-orientation and an emphasis on feelings and emotions versus cognition). This conceptual model of two major configurations of psychopathology developed by Blatt and colleagues facilitates an appreciation of the continuities between personality development and normal variations in personality or character style, as well as among various forms of psychopathology.

This conceptual model of personality development and psychopathology facilitated the introduction of personality dimensions into the study of therapeutic outcome and process in both short- and long-term treatment. These analyses demonstrated that anaclitic and introjective patients come to treatment with different capacities, needs, and problems, are differentially responsive to different types of treatment, and change in different, but equally, desirable ways. These theoretical formulations about a fundamental polarity of relatedness and self-definition provided a fuller understanding of personality development and the nature of psychopathology and facilitated a fuller exploration of important aspects of the therapeutic process and the nature of therapeutic change.

The introduction of patient variables into research on therapy outcome and process enables investigators to begin to identify factors that impede or facilitate therapeutic change. Even further, the inclusion of patient characteristics in research designs enables investigators to examine more systematically aspects of the therapeutic process and to identify when and how in the treatment process particular characteristics of the patients facilitate or impede therapeutic progress as well as identify particular aspects of the therapeutic process that can facilitate therapeutic change with patients who are treatment resistant.

GLOSSARY

aversive A nontechnical term often used to refer to punishment and negative reinforcement procedures.

conditioned punisher An event that acquires its capacity to serve as a punisher through learning.

negative punishers Punishers that involve removing something from an individual's environment.

negative punishment A procedure (or process) in which responding is weakened by its consequences, which involve removing something from an individual's environment.

negative reinforcement A procedure (or process) in which behavior is strengthened as a function of its consequences, which involve terminating a stimulus that is present or postponing (or preventing) the delivery of an otherwise forthcoming stimulus.

positive practice overcorrection A procedure that reduces the frequency of undesired behavior by having an individual emit appropriate relevant behaviors repeatedly each time the troublesome behavior occurs.

positive punishers Punishers that involve adding something to an individual's environment.

positive punishment A procedure (or process) in which responding is weakened by its consequences, which involve adding something to the individual's environment.

Premack principle A lower-probability behavior may be reinforced by allowing an individual to engage in a higher-probability behavior after the lower-probability behavior occurs. Conversely, a higher-probability behavior may be punished by requiring an individual to engage in a lower-probability behavior after the higher-probability behavior occurs.

punishers Consequences that weaken behavior.

punishment A procedure (or process) in which responding is weakened by its consequences, which are termed punishers.

respondent conditioning A procedure in which a previously neutral stimulus comes to control behavior by virtue of reliably preceding a stimulus that controls behavior at the onset of and throughout stimulus–stimulus pairings.

restitutional overcorrection A procedure that reduces the frequency of undesired behavior by requiring a person to repair the damage done by that behavior and to make the relevant parts of the world better than before the misdeed occurred.

simple correction A procedure that reduces the frequency of undesired behavior by having an individual emit appropriate relevant behaviors a single time after the troublesome behavior occurs.

stimulus An environmental event.

unconditioned punisher An event that does not require learning to serve as a punisher.

Many people consider punishment to be any attempt at disciplining a person by harming that individual, either physically or psychologically, when misbehavior occurs. When it is defined in this way, whether punishment increases, decreases, or has no effect on the future

likelihood of occurrence of the misbehavior is irrelevant. Thus, spanking a child for cursing would be considered as punishment, regardless of whether the child curses more, less, or equally often after being spanked. When punishment is construed in this way, the behavioral function of the procedure is unclear and what stands out is that punishment is intended to hurt the person exposed to it. Not surprisingly, people who view punishment in this way typically object to its therapeutic use, although they may support it as retribution for heinous misdeeds.

To increase clarity and to avoid the negative connotations associated with “punishment” as the term is used in ordinary language, many behavioral psychologists define punishment not in terms of the intent of the person who implements it, but instead in terms of the nature of the operation and its effects on behavior. Specifically, punishment occurs when behavior is weakened by its consequences, which are termed *punishers*. The nature of those consequences, the intent of the person who administers them, and whether they harm the individual exposed to punishment are irrelevant to this definition, which we prefer. What is relevant is that the consequences of a particular behavior make it less likely that such behavior will occur in the future.

I. DESCRIPTION OF TREATMENT

It is convention to distinguish between positive and negative punishment. Positive punishment occurs when a response adds something to an individual's environment and is therefore weakened. If, for example, a parent says “don't poke your brother” when an older sibling jabs a toddler, and the subsequent rate of jabbing decreases as a result of this consequence, then the procedure is positive punishment. Negative punishment, in contrast, occurs when a response takes something away from an individual's environment and is therefore weakened. If, for example, the older sibling loses access to TV after poking the toddler, and the subsequent rate of jabbing decreases as a result of this consequence, then the procedure is negative punishment. In almost all cases, as in these examples, the response-weakening effects of punishment involve a decrease in the rate of responding. Other changes in behavior, however (e.g., an increase in response latency), can also be indicative of the response-weakening effects of punishment.

Positive punishment procedures can be divided into two general categories, those that involve presenting an external stimulus to a client and those that entail re-

quiring the client to engage in nonpreferred (i.e., low-probability) behaviors. It is usual practice to refer to events that serve as positive punishers as “aversive” stimuli and to consider punishment as an “aversive” intervention. Unfortunately, these same terms also are often applied to negative reinforcers and negative reinforcement procedures, respectively, which is a source of confusion. Negative reinforcers are events that, when removed as a consequence of a particular kind of behavior, strengthen that behavior (e.g., pressing the “off” button on an alarm clock is strengthened by removal of the sound). Reinforcers always strengthen behavior, punishers always weaken it, and events that serve as negative reinforcers do not always serve as positive punishers. In addition, in everyday language “aversive” means “unpleasant” or “noxious,” but the subjective effects of punishment are not a part of its technical definition. Punishment is defined functionally, in terms of how it affects behavior (i.e., it weakens it), not in terms of how it makes people feel. For these reasons, little is gained by labeling punishment as “aversive,” although the practice is very common.

Positive punishment by presenting an external stimulus to a client when misbehavior occurs requires two steps. First, an effective positive punisher must be isolated and, second, conditions must be arranged so that this stimulus consistently and immediately follows the behavior that is to be reduced.

Positive punishers can be unconditioned (unlearned, or primary) or conditioned (learned, or secondary). Unconditioned punishers, which include events that provide extreme stimulation of any sensory system (e.g., loud sounds, bright lights, extreme cold or heat, strong pressure on the skin), suppress behavior automatically. That is, their delivery following a behavior reduces the likelihood that such behavior will recur in similar settings regardless of the history of the person in question. Events that serve as unconditioned positive punishers are similar across people. Moderate to intense electrical stimulation (shock) applied to the skin is a good example of such a punisher.

Unlike unconditioned punishers, conditioned positive punishers acquire their capacity to reduce responding through learning. This can occur through respondent conditioning when an established punisher reliably and shortly follows a neutral stimulus. For example, if a tone of moderate intensity that is not initially punishing occurs just before a person is shocked on a number of occasions, the tone eventually will acquire a punishing function. This function will be maintained so long as the tone is at least occasionally paired with the shock.

Conditioned punishers also can be established through verbal mediation. Consider, for instance, a music teacher who is giving voice lessons to a highly motivated student who is practicing singing on-key. The teacher says, “When you go too high, I’ll raise my forefinger.” By virtue of a unique learning history, the student is motivated not to sing at a pitch beyond that targeted by the teacher, that is, to “not go too high,” and doing so is punishing. So is any indication that this is occurring, like the teacher’s raised forefinger. Barring the teacher’s explanation, the raised finger would not punish (i.e., reduce the future likelihood of) singing off-key in this student. In addition, unless their histories were similar to that of the student in our example, the teacher’s raised finger would not serve as a positive punisher for the behavior of other people.

Once an effective unconditioned or conditioned punisher that is practical and ethically acceptable is isolated or established—which is an essential first step that can be difficult to accomplish—effective reduction of the targeted behavior is most likely to occur if:

1. The punisher immediately follows each occurrence of the behavior that is to be reduced.
2. The punisher is introduced at its optimum intensity initially, rather than being gradually increased in intensity over time.
3. The conditions of punishment are explained accurately to the client, if she or he has the verbal skill to understand them.
4. The reinforcer that maintains the troublesome behavior is made available for an alternative, desirable response.

As explained in later sections, positive punishment through the delivery of an external stimulus is not a common therapeutic procedure. More common, although still controversial, is requiring an individual to engage in a low-probability behavior when a high-probability, but troublesome, behavior occurs. This form of punishment is based on the Premack principle, which was devised by David Premack in the 1950s. It states that (a) the opportunity to engage in a higher-probability behavior will reinforce a lower-probability behavior, and (b) the requirement of engaging in a lower-probability behavior will punish a higher-probability behavior.

Premack measured the probability of different incompatible behaviors by allowing an individual unconstrained opportunity to engage in them and measuring the amount of time spent in each activity. For example, a middle-school student on the playground during a

30-min recess would be given the opportunity to play soccer or softball, two independent activities that cannot occur together. If the student spent 24 min playing softball and 6 min playing soccer, then playing softball is the higher-probability, or preferred, activity. The Premack principle suggests that one could increase the amount of time the child played soccer by requiring this behavior to occur before the opportunity to play softball was provided. Conversely, the amount of time spent playing softball could be reduced if the child was required to play soccer for a considerable period after playing softball for a short time. In this case, however, neither behavior is necessarily undesirable and, unless they loved soccer and loved softball, there would be no reason for parents or teachers to punish playing softball in this manner. In other cases, however, the higher-probability behavior is clearly undesirable and the lower-probability behavior desirable (or innocuous), and the Premack principle of punishment can be used to good advantage. This is the case with overcorrection, a procedure that Richard Foxx and Nate Azrin developed in the early 1970s to reduce aggressive and other disruptive behaviors exhibited by clients with mental retardation living in an institutional setting.

In essence, overcorrection requires a client to engage in a low-probability (nonpreferred) behavior each time a higher-probability, but troublesome, behavior occurs. Two versions of overcorrection are distinguished, depending on the nature of the nonpreferred behavior that the client is required to perform. In positive practice overcorrection, the client is required to emit appropriate relevant behaviors repeatedly each time the troublesome behavior occurs. For example, a child who kicks a chained dog passed on the way to school might be required to walk the block on which the dog lives 10 times without approaching (or kicking) it.

A procedure similar to positive practice overcorrection is simple correction, in which the individual is required to emit appropriate relevant behaviors once after the undesired behavior occurs. For instance, the hypothetical child who kicks a chained dog would be required to walk past the dog once without approaching it.

In restitutive overcorrection, or restitution, each time the problem behavior occurs the client is required to repair the damage done by that behavior and to make the relevant parts of the world better than before the misdeed occurred. If, for instance, a child spits on the kitchen floor, she or he would be required to not only clean up the spittle, but also to mop and dry the entire kitchen floor. An advantage of restitution is that it has an educational, as well as a punishing, function.

Although they are not typically construed as overcorrection, a number of other interventions make use of the Premack principle to reduce inappropriate responding. One such procedure is contingent exercise, where a client who rarely exercises is required to do so when an undesired response occurs. Another is guided compliance, where a client who misbehaves while performing a task is physically guided through the task until it is completed. If, for instance, a child who is asked to turn off and put away a tape player begins to whine and argue (the undesired behavior), the parents may physically guide the child in performing the requested activity. Here, as in all cases involving punishment by requiring clients to engage in nonpreferred activities, when physical guidance is provided the stimulation resulting from such guidance may be punishing.

In some cases, it is difficult or impossible to get an individual to engage in nonpreferred activities, and attempts at doing so can create a host of problems. Among them are inconsistent application of the intervention and physical harm to the client, the therapist, or other people. In general, punishment based on the Premack principle is best used with compliant and easily managed individuals. One would not, for instance, attempt to physically guide a large, strong, and angry client in performing a task she or he abhorred.

II. THEORETICAL BASES

As discussed in the entry for operant conditioning, operant conditioning has been likened to natural selection in that both involve processes of variation, selection, and retention. Punishment “selects out” operants that produce certain consequences. Studies by neuroscientists may reveal the physiological mechanisms through which this occurs and, if so, contribute to a comprehensive theory of punishment. No such theory is currently available, which perhaps has contributed to widespread misunderstanding of what punishment entails.

Psychologists have been concerned with punishment from the discipline’s early days. Although Edward Thorndike made no mention of what we now call punishment in the earliest versions of his well-known law of effect, by 1905 when his book *The Elements of Psychology* appeared, he recognized that the consequences of behavior could have bidirectional effects. That is, they could make it either more or less likely that such behavior would recur. Thorndike wrote:

Any act which in a given situation produces satisfaction becomes associated with that situation, so that

when the situation recurs the act is more likely than before to recur. [This is reinforcement.] Conversely, any act which in a given situation produces discomfort becomes disassociated from that situation, so that when the situation recurs the act is less likely than before to recur. [This is punishment.]

Later in life, Thorndike came to believe that punishment was not effective in reducing behavior. This belief was fostered by the results of studies conducted with college students learning to match English words with Spanish synonyms. Thorndike found that saying “Right” after correct matches facilitated learning, therefore, reinforcement was effective. But saying “Wrong” after incorrect matches had no effect on subsequent performance, therefore, punishment was ineffective. Although Thorndike’s results are subject to alternative explanations, his view of punishment as ineffective was popularized in the lay press with respect to child-rearing practices.

B. F. Skinner greatly extended Thorndike’s research and theorizing regarding the effects of consequences on behavior. Skinner acknowledged punishment as a principle of behavior, but throughout his life he argued that the effects of punishment are short lived and that, in general, punishment should not be used therapeutically or in the culture at large. Skinner’s position regarding the short-lived effects of punishment were supported by his research findings with rats, and by the findings of his student, William Estes. In one study, Estes initially rewarded (reinforced) rats’ lever presses with food. After the response was occurring reliably, food was no longer available, and each lever press produced an intense electric shock delivered to the rat’s feet. This procedure reduced responding to near zero levels. If, however, a substantial period of time passed without the rats being tested, they would resume lever pressing. Thus, punishment did not eliminate behavior but only suppressed it so long as the punishment procedure was in effect.

Results such as these, as well as philosophical considerations, caused Skinner to have strong negative opinions regarding positive punishment. For example, the chapter in his 1953 book *Science and Human Behavior* that deals with punishment is titled “A questionable technique.” He argues therein that (a) punishment does not produce lasting effects, (b) punishment often is used abusively, (c) punishment often engenders strong and negative emotional responding, (d) punishment engenders escape from and avoidance of stimuli associated with the experience, and (e) viable alternatives to punishment are available. He acknowledged,

however, that relatively little research had been conducted on the effects of punishment and suggested that further work in the area was necessary.

Laboratory research concerning punishment by the delivery of aversive stimuli increased dramatically during the 1960s, but interest in the area soon waned. The studies that were conducted revealed a great deal about the variables that influence the degree of response suppression produced by positive punishment and also provided evidence that punishment could eliminate, or substantially reduce, behavior over long periods. In fact, after summarizing the research literature, Nate Azrin and William Holz concluded in 1966 that:

As a reductive procedure, punishment appears to be at least as effective as most other procedures for eliminating responses. . . . If we have not overlooked the effects of [important] variables, there is every reason to believe that our punishment procedure will be completely effective in eliminating the undesired response. The emotional state or enduring behavioral disruption of the punished subject are not necessarily undesirable outcomes of punishment, nor are the severity of the response reduction or the behavioral generalization of the punishing effects undesirable.

They suggest that disruption of social interactions, caused by the tendency of the individual exposed to punishment to avoid or react aggressively toward the person who inflicts punishment, is the major disadvantage of using punishment. Although Azrin and Holz' influential chapter is by no means a glowing endorsement for therapeutic applications of positive punishment, the studies reviewed therein make it clear that punishment can be effective in reducing behavior. These laboratory studies, which dealt with the application of external stimuli as punishers, provided an empirical basis for therapeutic applications of positive punishment during the 1960s and 1970s.

Although many theoreticians construe punishment as a process that is similar to reinforcement, but with opposite effects on behavior, there is an alternate view. From this perspective, the response reduction produced by punishment is due to passive avoidance responding. That is, organisms learn that emitting certain responses produce undesired (i.e., punishing) consequences and, because of this, they withhold such responses even though variables are present that would otherwise cause those responses to occur. Behavioral psychologists do not agree as to whether or not experimental data provide solid support for either the passive avoidance or direct response reduction theory of pun-

ishment. Although the issue is of theoretical significance, it does not appear to have important implications for clinical applications of positive punishment.

Most basic laboratory research in the area of positive punishment has involved delivery of aversive stimuli, and most theorizing has concerned the effects of such stimuli. There have, however, been some extensions of Premack's work concerning punishment by requiring the performance of low-probability (nonpreferred) activities. It is now generally accepted that forcing an individual to engage in a higher-probability behavior can punish a lower-probability behavior, so long as the individual is forced to engage in the higher-probability behavior for a longer period than would occur normally. Although this finding is interesting, it is of little clinical significance.

III. APPLICATIONS AND EXCLUSIONS

Restrictions on the use of positive punishment depend on the specific procedure under consideration. In general, ethical and legal considerations severely limit the use of positive punishment as a primary intervention in therapeutic settings. There is, however, debate about whether positive punishment should ever be used with protected populations (e.g., children, people with mental retardation).

No legitimate therapist recommends positive punishment as a first-line intervention, and advocates of "non-aversive" interventions contend that the procedure should never be used. Advocates of the right to effective treatment also acknowledge that positive punishment is a restrictive (harmful) intervention. They contend, however, that it may be appropriate to use the procedure to deal with serious behavioral problems that have not responded favorably to other, less restrictive, interventions. In fact, some argue that it is unethical to withhold a potentially valuable, although momentarily unpleasant, intervention if doing so maintains the client in a dangerous or uncomfortable state.

As a rule, the use of unusual unconditioned punishers (e.g., electric shock, aromatic ammonia) is more strongly restricted than are procedures that deliver common conditioned punishers (e.g., verbal reprimands) or that require clients to perform generally accepted, but (for them) low-probability behaviors. For instance, in 1990 the American Association on Mental Retardation condemned "aversive procedures which cause physical damage, pain, or illness" and procedures "which are

dehumanizing—social degradation, verbal abuse and excessive reactions.” Common forms of conditioned punishment, as described in the example of the music teacher’s raised finger, are common in many human interactions, including therapeutic interchanges in which clients and therapists talk to one another. Such interchanges are not, however, based primarily on punishment or generally considered as punishment procedures.

If punishment is to be used systematically as a part of therapy, it is important that appropriate safeguards be put in place to protect both clients and staff. In general, a clear decision-making process regarding the use of punishment should be in place. This process should recognize that punishment is a restrictive (harmful) intervention and adhere to the doctrine of the least restrictive alternative intervention. This doctrine states that other, less restrictive, interventions must be evaluated and found ineffective before punishment is considered.

Clear guidelines must be established regarding the exact nature of the punishment procedure, including who is to implement it and the specific standards of accountability. Input from clients and client’s advocates, as well as behavior-change experts, should play a crucial role in determining the details of punishment, including who is to administer it and how its effects are to be monitored. Unambiguous rules regarding the behavioral data that will support continuation, modification, and termination of punishment must be established by a vigilant, expert, and caring treatment team before punishment is implemented, and these rules must be followed unless the good of the client dictates otherwise in the opinion of the team. Whenever possible, positive punishment should be avoided entirely.

IV. EMPIRICAL STUDIES

Most of the published studies of therapeutic applications of positive punishment involve attempts to reduce harmful behaviors in people with mental retardation and other developmental disabilities. A well-known example of research in this area concerns Ivaar Lovaas’s successful use of electric shocks during the 1960s to reduce pernicious self-injury in children with autism. Other researchers replicated his findings concerning the effectiveness of electric shock punishment in reducing self-injury and also demonstrated that the procedure could be used to reduce other harmful behaviors to acceptable levels.

Several unconditioned primary punishers have been evaluated in published studies, including water mist

sprayed in the face, ice cubes placed against the jaw, lemon juice squirted in the mouth, and aromatic ammonia held close enough to the client to be smelled. These stimuli have proven to be effective in reducing self-injury and other troublesome behaviors when presented immediately after such behavior occurred. In short, published studies provide clear evidence that punishment via the delivery of aversive stimulation can provide rapid, strong, and enduring suppression of target behaviors.

Even people who argue strongly against the use of punishment via the delivery of aversive stimuli generally acknowledge the procedure’s efficacy. They point out, however, that the procedure can produce several harmful side effects, including aggression, undesirable emotional responses (e.g., crying), establishment of the person who delivers the punisher as a conditioned punisher, and general suppression of behavior. Although such effects certainly can occur, reviews of the research literature suggest that punishment is at least as likely to produce positive side effects, such as increases in social behavior, improved affect, and reductions in the problem behavior outside the treatment setting. Nonetheless, negative side effects remain a real concern.

So, too, is the possibility that caregivers may use punishment excessively and inappropriately in treating people with developmental disabilities, and that children who see punishment being used are likely to use punishment themselves. Such effects are documented in the literature, although they do not inevitably occur. Finally, because punishment is generally recognized as restrictive and is considered by many people as intrinsically dehumanizing, efficacy alone does not justify its use. When nonaversive alternatives are available, they are preferable. Although it is clear that such procedures have been used to manage a wide range of problem behaviors in protected populations, there is ongoing debate as to whether effective nonaversive alternatives to punishment via the delivery of an aversive stimulus are always available.

Positive punishment by requiring an individual to engage in nonpreferred activities has been evaluated in a substantial number of studies, most concerned specifically with overcorrection. In brief, such procedures, used alone or in combination with other strategies, have been effective in reducing a substantial range of behaviors emitted by a wide variety of persons in diverse settings. Among the behaviors that have been successfully controlled are self-injury, aggression, stereotypy, disruption, in-class masturbation, oral reading errors, oral spelling errors, writing errors, and failure to make eye

contact. Although positive side effects, including decreased crying and increased smiling and social interactions have been observed in some studies, negative side effects also have been reported. These include aggression, avoidance of the setting in which the procedure is applied, screaming, and stereotypical responding. As noted previously, difficulties can arise in getting a client to perform low-probability behaviors. Moreover, selecting appropriate low-probability behaviors can be difficult in some settings.

Positive punishment by requiring individuals to engage in nonpreferred activities has engendered some controversy but appears to be generally accepted so long as the required behaviors are appropriate and the measures taken to get clients to perform them are humane. Positive punishment by the delivery of aversive stimuli, in contrast, is highly controversial and is best viewed as a treatment of last resort. Nonetheless, various forms of positive punishment are ubiquitous in everyday life and in therapy. They may teach people what not to do and be of value for that reason. But they do not establish appropriate behaviors, and they are unpleasant, and for these reasons many thoughtful people minimize their use.

V. CASE ILLUSTRATION

A study published by Thomas Sajway, Julian Libet, and Stuart Agras in 1974 provides a straightforward example of positive punishment through the delivery of an aversive stimulus. They treated a severely malnourished and dehydrated 6-month-old girl who regurgitated each time she was fed. As they described it, after being given food (e.g., milk in a bottle), she “would open her mouth, elevate and fold her tongue, and vigorously thrust her tongue backward and forward,” which caused her to throw up the food she had just ingested. There was no sign of duress during these activities, and physicians could isolate no cause for their occurrence.

To reduce regurgitation, Sajway, Libet, and Agras squirted unsweetened lemon juice into the girl’s mouth immediately after the tongue movements occurred. This procedure rapidly reduced regurgitation and, after 12 days of exposure to it, the vigorous tongue movements and regurgitation had totally disappeared. As a result, the girl’s weight increased dramatically—by 50% in 2 months—and she became healthy. No untoward effects were observed, and it is no exaggeration to say that exposure to the mild punishment procedure saved the girl’s life.

A study published by Richard Foxx and Nate Azrin in 1972 clearly illustrates punishment by requiring a person to emit nonpreferred behaviors. The client in this study was a 50-year-old woman with mental retardation who lived in an institution. Prior to treatment, for over 30 years she regularly (more than 10 times per day) upset furniture and engaged in other destructive acts on her ward. To reduce these destructive and high-probability behaviors, Foxx and Azrin used a restitutional overcorrection procedure in which the woman was required to correct immediately any damage caused by her actions and, in addition, to emit other behaviors that improved the quality of the ward. For instance, if she upset a bed, she was required to set it upright and make up the covers, and also to fluff the pillows on all of the other beds in the ward. (These were low-probability activities for the woman.)

Overcorrection rapidly reduced destructive acts. Within 1 week, fewer than four acts occurred per day. After 11 weeks of overcorrection, the behavior was totally eliminated. No adverse effects of the procedure were noted. Here, a behavioral problem that had existed for over 3 decades was solved by requiring the client to make amends for the damage caused by her inappropriate actions.

VI. SUMMARY

Positive punishment refers to a procedure in which a particular kind of behavior is weakened (decreased in rate) because a stimulus is presented, or the individual is required to engage in nonpreferred activities, as a consequence of that behavior. Positive punishment is effective in reducing a wide range of behaviors, but ethical and practical objections broadly restrict its therapeutic use.

GLOSSARY

chaining Reinforcing discrete responses in sequence so that all the behaviors occur as a single cohesive unit.

conditioned reinforcers Stimuli that acquire reinforcing properties through learning.

differential reinforcement of incompatible behavior A procedure in which a desired behavior that is incompatible with an undesired behavior is reinforced. The procedure is used to decrease undesired behavior and simultaneously increase desired behavior.

differential reinforcement of other behavior A procedure in which a reinforcer is delivered when a prespecified period passes without occurrence of an undesired response. The procedure is used to decrease undesired behavior.

primary positive reinforcers Stimuli that have reinforcing capacity in the absence of a special learning history.

prompt A verbal or physical antecedent that indicates to an individual how to respond in order to obtain reinforcement.

shaping Reinforcing successively closer approximations to a terminal, desired response.

Desirable as well as undesirable human behaviors often are operant responses, that is, they primarily are controlled by their consequences. Consequences are events (stimuli) that follow and are produced by a particular behavior. When the consequences of behavior make it more likely that such behavior will occur in a similar future context, or otherwise strengthen the behavior, the consequences are termed reinforcers and the process whereby responding is strengthened is termed reinforcement. Negative reinforcers strengthen behavior when responding removes them from the individual's environment, or prevents their occurrence. Positive reinforcers, in contrast, strengthen behavior when responding leads to their presentation.

Positive reinforcers can be learned (called conditioned or secondary) or unlearned (called unconditioned or primary). Stimuli that serve as primary positive reinforcers typically are of direct biological significance (e.g., food, water). Stimuli that serve as conditioned reinforcers do so because they precede the delivery of other reinforcers, or because of verbal mediation. Because people differ in their learning histories, the stimuli that serve as conditioned reinforcers differ substantially across people.

In a general sense, positive reinforcement comprises all procedures in which operant behavior is strengthened through the response-produced presentation of an object or event. Procedures based on positive reinforcement are useful in treating many kinds of behavioral problems in a wide range of client populations.

Moreover, understanding the role of reinforcement in the genesis and maintenance of inappropriate behavior is critical for understanding human psychopathology and for treating it effectively.

I. DESCRIPTION OF TREATMENT

Troublesome human behaviors generally can be categorized into those that involve the presence of inappropriate responses and those that involve the absence of appropriate responses. Because reinforcement by definition increases, or otherwise strengthens, responding, procedures based on positive reinforcement have an obvious role in treating individuals who fail to emit desired behaviors. To deal with such problems, a clinician typically begins by defining the desired behavior and selecting a measurement system that allows the behavior to be accurately quantified. Goals for performance of the desired behavior also are established at this point.

Next, a determination is made as to whether the absence of desired behavior involves a skill deficit or a performance deficit. In the former case, the client has not learned to perform the response. In the latter case, the client knows how to perform the response, but fails to do so. Often, the reason is that the desired behavior is not consistently reinforced in the client's everyday environment.

In many cases, planned reinforcement is used to treat performance deficiencies. For instance, an adult with mental retardation living in a group home may not regularly dress herself, even though she knows how to perform the task and does so on occasion. Making something valuable to the woman—perhaps tokens that can be exchanged for favored objects and activities—available only if she dresses herself appropriately each morning would in all likelihood lead to consistent self-dressing.

Treating a skill deficit typically begins with a task analysis, which involves breaking a complex behavior into its component parts. Dressing one's self, for example, begins with recognizing and laying out appropriate clothes and ends with fastening the final accouterment in place. Between the beginning and end of this chain of responses are many specific actions that depend on exactly what the person will be wearing. Several different procedures, all involving positive reinforcement, might be used in teaching a person to perform a new behavior, like dressing herself. Among them are shaping, modeling, prompting, chaining, and providing verbal instruction.

In shaping, successively closer approximations to the desired response are reinforced until the target (desired)

behavior emerges. To teach a person to pull up a zipper, for instance, one might ask the person to do so then observe their performance. If they grasped the tab and pulled the zipper halfway up, praise (a positive reinforcer) would be provided. On the next trial, however, praise would be withheld until the zipper was pulled more than halfway up. This process would be repeated until the zipper was fully closed. At that point, another response in the self-dressing sequence would be taught.

In prompting, physical or verbal guidance in performing a desired response is provided. If the woman in our example were verbal, the therapist might say, "Keep pulling hard," as the zipper was raised. The therapist might also place a hand over the client's hand and help her to pull the zipper. In modeling, someone performs the target (desired) response while being observed by the individual who is to learn that behavior. Our therapist might operate a zipper one or more times before asking the client to do so.

In chaining, discrete responses are reinforced in sequence to form complex behaviors that eventually occur as a single cohesive unit. The completion of one response provides a cue (i.e., a discriminative stimulus) for performing the next response in the sequence and, eventually, reinforcement is provided only when the chain of responses is complete. By the time the client has learned to dress herself, she might earn praise only at the end of a long and integrated sequence of responses.

Verbal instructions can serve as prompts but also can specify relations among stimuli (events and objects) and responses, thereby changing the function of those stimuli and responses. The therapist might, for instance, tell the client "Your green top and your black slacks really go well together—I love how you look in them." This statement might establish the top and slacks combination as a positive reinforcer, which the client values and will work to get to wear. Absent the therapist's statement, or given another kind of statement, such as "Your green top and your black slacks look crappy together—I hate how you look in them," wearing the top and slacks together would not serve as a positive reinforcer.

In many cases, a behavior that is appropriate in one context is not appropriate in another. Therefore, once new behavior is established under conditions where it is appropriate, steps often must be taken to ensure that it does not generalize to other, inappropriate, contexts. This can be accomplished through differential reinforcement, which entails reinforcing behavior in contexts where the behavior is appropriate, and failing to reinforce that behavior in other contexts. Teaching multiplication tables to a child labeled with a learning disability in mathematics provides a good example of differential

reinforcement at work. The child's saying "ten" is correct, and positively reinforced with praise ("that's right, good") when the child is reacting to " $5 \times 2 = \underline{\quad}$." But that response is incorrect and is followed by corrective feedback that is not reinforcing ("no, that's wrong") when the child is reacting to " $3 \times 2 = \underline{\quad}$." In this fashion, " $5 \times 2 = \underline{\quad}$ " is established as a discriminative stimulus for the verbal response "10." Differential reinforcement is used to establish stimulus control such that a particular response appears in the presence of appropriate stimuli, but not in their absence. In verbal humans, descriptions of appropriate stimulus control can sometimes be used as a substitute for actual differential reinforcement.

Positive reinforcement always strengthens the behavior that is reinforced, therefore, it may seem odd that procedures based on positive reinforcement can be used successfully to weaken undesirable behaviors. Two procedures that are frequently used in this way are called differential reinforcement of incompatible behavior (DRI) and differential reinforcement of other behavior (DRO) schedules. The DRI schedule makes use of the fact that some behaviors cannot occur simultaneously, therefore, increasing the rate of occurrence of one of these behaviors by reinforcing it also reduces the rate of occurrence of the other behavior. A client with a phobia cannot, for instance, simultaneously walk toward and avoid a feared object. So, by reinforcing approach responses, one can reduce avoidance responses.

The DRO schedule provides a reinforcer dependent on the passage of a specified period of time during which the behavior to be reduced does not appear; each time the behavior does occur, the interval is reset. If, for example, a DRO 5-min schedule is arranged to reduce self-stimulatory hand flapping by a person with autism, some positive reinforcer (perhaps a point on a counter that later could be exchanged for access to preferred music) would be delivered each time five consecutive minutes passed without a hand flap. This procedure should reduce the frequency of hand flaps relative to the preintervention level. But how can this be a reinforcement effect? The answer is that the unit of behavior that is strengthened is an interval of 5 min or longer without a hand flap. These units increase under the DRO and, as a result, incidents of hand flapping are reduced.

II. THEORETICAL BASES

A great deal is known about positive reinforcement. As discussed in the entry for operant conditioning, B. F. Skinner compared the selection of behavior by its con-

sequences to natural selection and emphasized that both entail processes of variation, selection, and retention. Studies by neuroscientists may reveal the physiological mechanisms through which these processes allow behavior to be strengthened by its consequences. Attempts have also been made to explain at other levels of analysis why certain stimuli are positively reinforcing under certain circumstances. None of these attempts is universally accepted.

Be that as it may, over the past 50 years thousands of studies have documented the importance of positive reinforcement in controlling behavior in nonhumans in laboratory settings, and in humans in laboratory settings, in everyday life, and in clinical applications. Positive reinforcement directly or indirectly plays a crucial role in the production of an incredible variety of human behaviors, both healthy and pathological. The variables that influence positive reinforcement have been studied extensively and clinical applications of positive reinforcement are for the most part based on the resultant knowledge. Put simply, there is unequivocal theoretical support for the clinical application of procedures based on positive reinforcement.

III. APPLICATIONS AND EXCLUSIONS

As noted in the previous section, positive reinforcement can be used in a variety of ways to increase desired behaviors and to arrange for those behaviors to occur only in appropriate contexts. Arranged in other ways, positive reinforcement can be used to reduce or eliminate undesired behavior. Given this breadth of application, positive reinforcement is potentially useful in dealing with the behavioral problems of all clinical populations. Issues of client diversity do not limit the general use of positive reinforcement, which is widely accepted, but particular cultures and individuals may object to specific procedures based on positive reinforcement. Moreover, cultures may vary with respect to the behaviors that they deem acceptable and unacceptable, and in the objects and events that serve as positive reinforcers.

Some individuals object to contrived reinforcement procedures, that is, those that do not occur naturally, as a form of bribery. Bribery is rewarding an individual so that she or he will behave in a corrupt way that benefits the person who delivers the reward. Therapeutic applications of positive reinforcement are intended to benefit the person whose behavior is reinforced, and the behavior that is reinforced is appropriate responding,

not unethical conduct. Positive reinforcement is not equivalent to bribery.

But, even if positive reinforcement is not bribery, certain critics claim that the purpose of using it is to control people's behavior, which to the critics is objectionable. It is true that the sole intent of therapists who use positive reinforcement, or, for that matter, any other psychological or psychiatric intervention, is to improve and in that sense "control" the client's behavior. But the control effected is such that the client's behavior, and as a result the quality of his or her life, improves. Moreover, the targeted changes in behavior characteristically are selected in consultation with the client, if she or he has the capacity to participate meaningfully in such decisions. If positive reinforcement is unacceptable because it controls clients, so are all therapeutic strategies.

Related to the foregoing concern is a third criticism of positive reinforcement, which is an ethical objection to rewarding people for doing "what they should do anyway." For example, Steve Higgins and his colleagues recently have had good success in treating cocaine abusers by paying them to produce drug-free urine samples. Although the procedure is relatively cheap as well as effective, some detractors claim that it is wrong to pay people not to engage in illegal behavior. People who raise this concern typically believe that individuals have the freedom to behave as they choose, and that those who behave inappropriately are ethically flawed and should be punished, not rewarded, for their shortcomings. Although this conception of human behavior has precedent in Western philosophy, theology, and jurisprudence, people who emphasize that much of human behavior is learned see it as little more than "blaming the victim."

A fourth criticism of positive reinforcement, one made popular by Edward Deci, is that the use of extrinsic reinforcers reduces an individual's "intrinsic motivation" to emit appropriate behavior. Such an effect has been demonstrated in a small number of studies in which children performed a task with no systematic reinforcement, then were reinforced for performing the task, and finally were retested with no systematic reinforcement. They worked less hard in the third condition than in the first, which is taken as evidence that extrinsic rewards (or reinforcers) reduced intrinsic motivation. In fact, the "intrinsic" motivation was acquired in large part as a result of prior reinforcement—people learn to do what they are asked to do because, historically, doing so was reinforced. In addition, the overwhelming majority of studies provide no evidence that positive reinforcement reduces people's intrinsic interest in tasks.

If the criticisms of positive reinforcement discussed earlier have little merit, why were they accorded so

much space? Only because behavior-change interventions based on positive reinforcement should be used even more widely than they are. Paul Chance makes this point very nicely in an anecdote related in his 1998 book, *First Course in Behavior Analysis*:

Once, when I was at a PTA meeting, the parents and teachers were discussing the problem of what to do about student misbehavior, which was getting worse and worse each year. The discussion focused on the kinds of punishment to provide for various offenses. They had compiled a list of student offenses and the consequences each offense should have. I made an innocent observation. "No one," I offered, "has said anything about what happens when a student behaves well. What about providing some *positive* consequences for *good* conduct?"

Some parents strongly opposed the idea. "Nobody gave *me* anything for behaving myself when I was in school," said one. But the fact that schools haven't been very good about reinforcing desirable behavior does not mean that they should not do so now. Their schools never used to use computers, but that hasn't kept us from putting them in the schools.

IV. EMPIRICAL STUDIES

A very large clinical literature has documented the efficacy of positive reinforcement, alone and in combination with other strategies, in treating behavior disorders. Because of the size of this literature, and because positive reinforcement plays a role in such a wide range of interventions, it is impossible to provide a simple and meaningful summary of the efficacy of "positive reinforcement procedures." It is, however, the case that procedures based primarily on positive reinforcement have been shown to be effective with a wide range of settings, target behaviors, and client populations.

A good understanding of the principles of operant conditioning is required to design effective positive reinforcement procedures. Although they are rarely reported in the literature, failed attempts at using positive reinforcement are common in the everyday world of education and clinical practice. These attempts fail when the events selected as positive reinforcers do not, in fact, have this function, and when the intervention team cannot control the delivery of events that do serve as reinforcers. They also fail when reinforcement is too delayed or too inconsistent, and when the rules that a person follows regarding the consequences of his or her behavior reduce sensitivity to these consequences. Occasionally, positive reinforcement procedures fail because of

their “side effects,” that is, the negative emotional responding, aggression, escape, and avoidance that poorly designed procedures can engender. Although people characteristically enjoy positive reinforcement, such adverse reactions can occur when response requirements are substantial and reinforcers are few.

V. CASE ILLUSTRATION

Positive reinforcement is an equal opportunity employer. In other words, it is responsible for maintaining both appropriate and inappropriate behaviors. When the natural environment fails to provide sources of reinforcement for appropriate behaviors, inappropriate behaviors may emerge through the same mechanisms that govern adaptive behaviors. That is, the same behavioral processes that support appropriate behaviors may engender inappropriate behavior. This is the case in the following example that, although fictitious, is representative of many studies demonstrating the reinforcing properties of social attention in the classroom.

Imagine a second-grade classroom where children are busily filling out their math worksheets. The teacher is going around the room, checking on the children’s work and assisting them as they need help. All of a sudden, there is an outburst. One of the children yells, “Give that back to me!” The teacher looks up and quickly becomes exasperated. Once again, Tommy is bothering another child. This time, he took Sarah’s pencil. Tommy looks in the direction of the teacher. The teacher says, “Tommy, you give that back to Sarah right away! Get back to work!” A sly grin crosses Tommy’s face. He complies, however, giving the pencil to Sarah and turning toward his paper. Tommy then looks at his blank paper. The numbers are almost as foreign to him as the crosses and dashes next to the numbers. He couldn’t write the correct answer even if he wanted to.

After about 2 min, Tommy gets out of his seat. The teacher is on him this time. He is barely one step away from his desk when the teacher yells, “Get back in your seat! You know that you are not allowed out of your seat without my permission.” Tommy begins to argue. He says, “My pencil is broken and I need to go to the bathroom,” whereupon many of the other students snicker audibly. The teacher responds by reciting the rules for Tommy. She then comes over to his desk to make comments about his incomplete school work. In some cases, a scenario like this can last all day long. It is no wonder that teachers reach their frustration limits sometimes. An understanding of the variables controlling Tommy’s behavior, however, may help

Tommy to get his work done and reduce his class disruptions. It also will probably make the teacher’s life easier if she is able to come up with an intervention that weakens or counteracts the primary controlling variable, social attention.

In this case, Tommy’s inappropriate behavior is strengthened by teacher attention, which functions as a positive reinforcer. Unfortunately, virtually all of the attention given to Tommy is dependent on inappropriate behavior. In the scenario described earlier, there was not a single instance where social attention followed appropriate behavior. Every instance of inappropriate behavior, in contrast, produced attention. Therefore, we can conclude that Tommy’s disruptive behavior is maintained by positive reinforcement in the form of teacher attention, and perhaps peer attention. One common, erroneous assumption is that positive reinforcement is “positive” in an evaluative sense. It is not.

In the case example, if the teacher is reflective or refers to a consultant who is knowledgeable about principles of behavior, she might be able to distribute her attention differently to promote more productive classroom behaviors. For example, she might praise Tommy for attempts to solve problems while ignoring (i.e., arranging extinction for) his inappropriate behaviors. In the process, she will probably discover that Tommy can’t do the problems without assistance. Therefore, some additional instruction may be necessary. If she is consistent and if Tommy receives social attention for appropriate behaviors (e.g., numbers written on the page, holding his pencil appropriately) frequently enough to compete with the reinforcing effects of peers’ attention for inappropriate behavior, the teacher may witness an increase in appropriate behavior and a decrease in inappropriate behavior.

It will be important for the teacher to keep in mind that Tommy’s problem behaviors were strengthened over time and that they may be resistant to extinction for a period. In fact, they may increase briefly if the teacher stops providing social attention for inappropriate behavior. This fact alone is often the reason why adults stop an intervention quickly and conclude, “I tried that but it didn’t work.”

VI. SUMMARY

Positive reinforcement comprises all procedures in which behavior is strengthened through the response-produced presentation of an object or event. Such procedures can be used to increase desired behavior and to cause it to occur only in appropriate circumstances.

They also can be used to decrease undesired behavior. Thousands of studies document their efficacy with a wide range of clients and target behaviors in many different settings. Although they are not panaceas, positive reinforcement procedures are widely and effectively used by applied behavior analysts and other clinicians.

GLOSSARY

cognitive-behavioral therapies A wide range of programs including anxiety management, exposure treatments, cognitive restructuring, and combinations of these.

cognitive processing therapy A treatment designed especially for female sexual assault victims and uses features of exposure therapy and cognitive therapy.

diagnostic and statistical manual A manual of psychiatric diagnoses and statistics that has been published in multiple editions by the American Psychiatric Press, Inc.

eye-movement desensitization/reprocessing therapy A treatment in which trauma survivors are asked to recall disturbing elements of the trauma while the therapist invokes saccadic eye movements.

exposure therapy A form of therapy that consists of exposure to anxiety-provoking stimuli.

impact of events scale A scale that assesses PTSD symptoms.

stress inoculation training A treatment in which patients learn to manage anxiety that is conditioned at the time of the trauma and then generalized to many situations.

I. INTRODUCTION

The diagnosis of posttraumatic stress disorder (PTSD) was introduced into the *Diagnostic and Statistical Man-*

ual (DSM) as an anxiety disorder in 1980. In the current *DSM* (fourth edition), there are six major diagnostic criteria for PTSD. First, the person must be exposed to a traumatic event in which they experienced or witnessed an event that involved the threat of death or serious injury, and the individual must have experienced significant fear, helplessness, or horror in response to the event. The major symptom criteria are persistent reexperiencing of the event, persistent emotional numbing and avoidance of stimuli associated with the trauma, and persistent arousal symptoms. The duration of the symptoms must be 1 month or more and must cause significant distress or impairment.

Traumatic events occur more often than one might expect. For example, it has been estimated that 7% of the U.S. population is exposed to a major trauma on an annual basis. Lifetime trauma exposure rates in populations are often 50 to 80%. Those who have been exposed to a traumatic event are at risk for developing PTSD and other major psychiatric disorders. Epidemiological studies have found that one-third of women who were sexually assaulted experienced PTSD at some point in their lifetime. Similar rates were found for lifetime PTSD in Vietnam veterans.

A variety of treatments have been used for PTSD. Recent neuroimaging, neurophysiological, and neuroendocrine studies have suggested that PTSD creates biological alterations. These findings have prompted clinicians to investigate the usefulness of pharmacological interventions. However, psychotherapy remains

the primary treatment of most PTSD, particularly acute PTSD. This chapter focuses on psychotherapeutic interventions for PTSD. Work on group psychotherapy and debriefing are less systematic and are not reviewed.

II. PSYCHODYNAMIC THERAPIES

A. Description of Treatment

In their 2000 review, Harold S. Kudler, Arthur S. Blank Jr., and Janice L. Krupnick summarized the theoretical basis and research findings of the use of psychodynamic psychotherapy in the treatment of PTSD. They note that brief psychodynamic therapy, as developed by James Mann, can be particularly useful in work with trauma survivors to explore issues of separation and loss. Mardi Horowitz developed a brief psychodynamic psychotherapy specifically for the treatment of trauma survivors. It is a transference-based, 12-session model that focuses on the ways in which the trauma survivor's preexisting personality style and psychological defenses interact with the traumatic experience to affect relationships especially in the context of the therapeutic relationship. Later, Charles Marmar and Michael Freeman developed a brief treatment based on Horowitz's ideas to manage narcissistic regression in the face of trauma. Also building on Horowitz's work, Daniel Brom, Rolf Kleber, and Peter Defares developed a manual on brief psychodynamic psychotherapy for PTSD. Horowitz recently revised his manual on brief psychodynamic therapies for stress response syndromes. His technique is a multimodal brief approach. In this model, systematic case formulations guide decisions on when to use behavioral techniques, cognitive techniques, and/or supportive and expressive dynamic techniques.

In supportive psychotherapy, which is built on the principles of psychodynamic psychotherapy, the therapist's knowledge of defensive structures and transference informs his or her work with PTSD. The defenses against intrusive withdrawal and arousal are strengthened through education, identification of successful defense operations, and attention to interpersonal withdrawal.

Interpersonal therapy is a time-limited, manualized treatment, which incorporates supportive elements into a psychodynamic approach. Rather than focusing on the transference, the therapist explores the patient's relationship with other people as the avenue to identify distress and interpersonal withdrawal. Work is underway to use interpersonal therapy as a group treatment for women with PTSD following sexual or physical assault/abuse.

B. Theoretical Bases

Josef Breuer and Sigmund Freud, in their 1895 *Studies in Hysteria*, proposed that psychological trauma can create psychiatric illness. They hypothesized that if the traumatic memory could be found and removed, the patient would be cured. Later, Freud speculated that hysterical patients defended against their traumatic memories by maintaining them outside of conscious awareness (repression). Physical and psychological symptoms represented a compromise that partially expressed the memory and also expressed the ego's defense against the memory and the feelings accompanying it. Influenced by World War I, Freud attributed psychological trauma to a breakdown in a psychic stimulus barrier in *Beyond the Pleasure Principle*. Trauma survivors' intrusive and avoidant symptoms (essential features of PTSD) were viewed as biphasic attempts to cope with the trauma. Freud hypothesized that survivors repeated the memories in the hope of mastering them (repetition compulsion). Both world wars compelled many therapists to further develop theoretical models and treatments. Abreactive techniques using sodium amytal and hypnosis were paired with support and psychoeducation to treat combat fatigue. Henry Krystal and Robert Jay Lifton documented that overwhelming life events could result in a kind of "death in life." Krystal developed an information-processing model of trauma that postulated that overwhelming events can disable the psyche's ability to use anxiety as a signal for the mobilization of defense. Once this system is disrupted, anxiety and other affects fail to serve psychic needs. Affect may become muted, overwhelming, or inappropriate. The ego, without its normal signal processing, is virtually defenseless. One possible outcome described was alexithymia (a profound disconnection between words and feelings).

More recent approaches focus on psychodynamic psychotherapy's attempt to understand and work through the meaning of symptoms. Reminders represent meaningful fears. Psychodynamic therapy also focuses on the experience of guilt, shame, and interpersonal avoidance. These feelings usually carry associated memories of early life experiences that have become attached to the recent events. Even events after the traumatic event, such as a diagnosis of cancer, can enter the meaning network and become a primary source of sustaining the PTSD symptoms. Attention to the meaning network and its anxiety, defense and transference patterns can aid in dissecting the symptoms from their sources. Attention to the complex countertransference responses

of the therapist when treating trauma victims is a major theoretical perspective adopted by all psychotherapies of PTSD.

C. Empirical Studies

Empirical studies of psychodynamic psychotherapy of PTSD are few. During 1993–1995, Mardi Horowitz and his colleagues published work that examined the hypothesis that trauma survivors experienced heightened intrusive and avoidant symptoms related to traumatic memories and themes. The brief psychodynamic psychotherapy that was provided was manualized. They found that when a topic linked to the traumatic event was discussed, it was accompanied by intrusion and avoidance, warding off behaviors, stifling of facial emotional expression, emotionality, and fragmentation of important ideas.

In 1997, Susan Roth and Ronald Batson evaluated a year-long psychodynamic treatment of six adult female survivors of childhood incest with PTSD. There was significant clinical improvement in their diagnoses, trauma themes, and PTSD symptoms.

In 1989, Daniel Brom, Rolf Kelber, and Peter Defares compared the efficacy of trauma desensitization, hypnotherapy, and a brief psychodynamic therapy (based on Horowitz's model) in reducing PTSD symptoms of intrusion and avoidance in 112 survivors of associated traumas and wait-list controls. One limitation of the study was that not all subjects met *DSM-III* criteria for PTSD. They found a reduction in symptoms on the Impact of Events Scale (IES) using desensitization that was higher than the improvement in the other treatments, but was not statistically significant.

D. Clinical Studies

In 1988, Jacob Lindy reported on 37 Vietnam combat veterans, who were treated for PTSD that met *DSM-III* diagnostic criteria. The participants' psychological function and combat experience were assessed. These combat veterans were compared to a volunteer sample of Vietnam veterans who were recruited from clinical and nonclinical sources ($n = 200$). There was no placebo comparison group, and assignment was not randomized. Treatment was manualized and consisted of opening, working through, and termination phases. Twenty-three of the participants completed the treatment. Significant changes were noted on the Psychiatric Evaluation Form (based on clinical ratings made by independent clinicians, on global ratings made by

both patients and therapists), and on the Symptom Checklist-90, the Impact of Events scale, and the Cincinnati Stress Response Schedule).

In 1993, Daniel S. Weiss and Charles Marmar described a 12-session, manualized psychodynamic treatment for adult survivors of single traumatic events. Systematic outcome measures were not used. They reported on results in work with over 200 patients.

E. Summary

Psychodynamic psychotherapy remains a major part of the psychotherapy of PTSD, particularly complex chronic PTSD in which meanings of the trauma have been generalized to the individual's past and present. The unique focus of psychodynamic psychotherapy on the complex countertransference experience with PTSD patients has been widely adopted across all psychotherapies. Psychodynamically informed supportive psychotherapy is perhaps the most widely used form of treatment in severe chronic PTSD with multiple comorbid disorders and in which psychopharmacologic agents are important symptom-reducing factors.

III. COGNITIVE-BEHAVIORAL THERAPIES

Cognitive-behavioral therapies (CBT) have been used widely in the treatment of PTSD and are the most rigorously studied to date. CBT encompasses a wide range of programs, including anxiety management, exposure treatments, cognitive restructuring, and combinations of these. Edna Foa has been instrumental in the use of CBT for PTSD and strengthening research methodologies of psychotherapeutic treatment of PTSD.

A. Exposure Therapy

1. Prolonged Imaginal and in Vivo Exposure Therapy

a. Description of Treatment Exposure therapy consists of exposure to anxiety-provoking stimuli. The core feature of all these methods is that the person is confronted by the frightening stimuli until his or her anxiety dissipates. There are a number of different techniques, which vary in terms of whether the stimulus is real or imaginal; whether the length of the exposure is short or long, and how much anxiety the subject experiences during the exposure (e.g., high for flooding, moderate to low for desensitization). Generally, a

hierarchy of anxiety-causing stimuli is developed. Two types of exposures are employed, imaginal and *in vivo*. Imaginal exposure generally consists of the patient talking about the trauma as if it is happening in the present. In contrast, *in vivo* exposure entails the patient confronting situations that are objectively safe, but have been avoided due to fear generalized from the original trauma. For example, if a person were robbed on the subway and continued to avoid it, the goal of exposure would be for the person to ultimately return to the subway. Flooding begins with exposure to the strongest anxiety-provoking item, whereas other systematic desensitization begins with items of low intensity. Exposure therapy is often used in combination with other components such as relaxation training.

b. Theoretical Basis Exposure therapy is based on learning theory. It has been used very successfully in the treatment of phobias. Because PTSD shares features of phobic disorders, it was hypothesized that exposure therapy would be of benefit for PTSD. Elements of PTSD are believed to be conditioned. Using the classical conditioning paradigm, the trauma (unconditional stimulus) is paired with a neutral stimulus, for example darkness. The previously neutral stimulus, darkness, now becomes a conditioned stimulus associated with a conditioned fear response. Operant conditioning maintains the fear as the traumatized individual used avoidance (e.g., not going out after dark) to diminish anxiety and fear. The avoidant behavior, itself, perpetuates the fear and anxiety. By forcing the traumatized individual to face the conditioned stimulus (threat), the patient learns that the conditioned stimulus no longer needs to be avoided.

c. Empirical Studies There have been 12 studies on the use of imaginal and *in vivo* exposure therapy for PTSD, 8 of which meet the most stringent criteria for methodology. Four well-controlled studies and two uncontrolled studies of the use of exposure therapy with Vietnam veterans have been conducted. All found positive results. There have been two well-controlled studies examining the effects of exposure therapy with female rape victims, which also found improvement in symptomatology. In addition, four studies have examined exposure therapy's efficacy for a variety of other traumas.

d. Summary Studies of exposure therapy have demonstrated the strong data supporting efficacy of exposure treatments for PTSD. Imaginal exposure has generally become a part of all psychotherapies as the therapist frequently brings the patient back to the traumatic event to talk, recall, reconstruct, and reexperience in a safe controlled manner the events and their subsequent consequences. It has been important to recognize that a traumatic event is rarely a single moment in time. Therefore, identifying the traumatic event as it extended over time means exposure can be more complex than it may first appear.

matic event to talk, recall, reconstruct, and reexperience in a safe controlled manner the events and their subsequent consequences. It has been important to recognize that a traumatic event is rarely a single moment in time. Therefore, identifying the traumatic event as it extended over time means exposure can be more complex than it may first appear.

2. Eye-Movement Desensitization/Reprocessing (EMDR)

EMDR, developed by Francine Shapiro in 1995, incorporates elements of imaginal exposure therapy. In this treatment, trauma survivors are asked to recall disturbing elements of the trauma while the therapist moves a finger back and forth in front of the patient's eyes. The resultant saccadic eye movements in conjunction with the disturbing images are hypothesized to result in neural reprocessing of the trauma and symptom resolution. There has been substantial controversy surrounding this treatment, focusing primarily on the theoretical basis regarding the role of eye movements. Research findings have been mixed on its efficacy but have suggested that improvement is more likely due to the exposure therapy elements rather than the eye movements.

3. Systematic Desensitization

a. Description of Treatment Systematic desensitization is a form of exposure therapy developed by Joseph Wolpe in 1958. Based on reciprocal inhibition, it posits that an individual cannot be relaxed and anxious simultaneously. A hierarchy of the patient's fears is developed. In the first part of the therapy, the patient is taught relaxation training. Once proficiency in relaxation is attained, the patient is gradually exposed to the trauma-related items that frighten him or her, starting with the least feared situation object or memory. The patient is instructed to note the onset of anxiety symptoms, and the treatment is paused while the patient initiates relaxation techniques. When the patient has regained a sense of comfort, the exposure resumes. This cycle continues until the patient can tolerate all the stimuli on the fear hierarchy without anxiety.

b. Empirical Studies While there have been six studies of systematic desensitization for the treatment of traumatic stress reactions, however, only the 1989 study by Daniel Brom, Rolf Kleber, and Peter Defares (described earlier) was well controlled.

c. Summary Although several studies have found that systematic desensitization was effective in reducing

trauma-related symptom, the studies suffer methodological problems. Most researchers have moved away from systematic desensitization, preferring exposure therapy. These two approaches have much in common and emphasize the importance of understanding and working with the actual events of the trauma and the cognitive and emotional responses.

B. Cognitive Therapy

1. Description of Treatment

Cognitive therapy was developed in 1976 by Aaron Beck for the treatment of depression and was later applied to the treatment of anxiety. Beck theorized that it is the individual's appraisal or interpretation of an event, rather than the event itself that determines mood states. "Automatic thoughts" are dysfunctional thoughts that interpret events with a negative bias that, in turn, contribute to negative feelings such as anxiety, depression, anger, and shame. In cognitive therapy, patients are taught to identify these automatic thoughts, challenge those that are unhelpful or inaccurate, and replace them with more accurate or beneficial thoughts. For patients with PTSD, it has been postulated that patients see the world as a dangerous place and view themselves as incompetent to navigate it. In order to be successful, treatments for PTSD are believed to need to change these distorted cognitions. Treatment programs are particularly focused on patients' self-concepts and appraisal of safety. A specific form of cognitive therapy, cognitive processing therapy, for sexual assault victims with PTSD has been suggested. This model focuses on correcting dysfunctional cognitions thought to be common in rape victims related to self-esteem, safety, trust, power, and intimacy.

2. Empirical Studies

One well-controlled study found that cognitive therapy, exposure therapy, and the combination of the two were all equally effective but more effective than relaxation therapy for patients who had sustained various traumas. Another study comparing cognitive therapy and systematic desensitization with wait-list controls, found cognitive therapy and systematic desensitization to be equally effective and superior to the wait-list controls. A third study found cognitive therapy to be as effective as exposure therapy in producing improvement relative to pretreatment for survivors of a variety of traumas.

3. Summary

Two controlled studies have demonstrated that cognitive therapy is effective in reducing trauma-related

symptoms. Cognitive therapy focuses on the effects of the traumatic event as it spreads through time and across personality dimensions. In general, the cognitive therapies and the psychodynamic therapies often overlap on their goal to alter appraisals although their techniques differ.

C. Cognitive Processing Therapy

1. Description of Treatment

Cognitive process therapy (CPT) has components of exposure therapy and cognitive therapy. Patricia Resick and Monica Schnicke developed CPT specifically for rape-related PTSD. The exposure element consists of developing and reading a detailed history of the rape. This narrative is used to discover "stuck points," elements of the rape that challenge previously held beliefs or are especially difficult to accept. These "stuck points" are then addressed in the cognitive component. The cognitive component teaches patient skills in examining and challenging distorted cognitions, for example, self-blame, and attempts at "undoing" the event.

2. Empirical Studies

In 1992, Resick and Schnicke reported that cognitive processing therapy was effective in reducing PTSD and related symptoms in 19 female sexual assault survivors compared to a wait-list control group. This study was not randomized.

3. Summary

Cognitive processing therapy has only been used with women who have been sexually assaulted. Because it was designed specifically for this population, it requires modification for use in other settings.

D. Anxiety Management Therapies

In contrast to the other therapies described in this chapter, anxiety management therapies do not aim to change underlying beliefs or structures that maintain PTSD. Rather, their goal is to teach patients to manage their symptoms.

1. Stress Inoculation Training

a. Description/Theory In 1974, Donald Meichenbaum developed stress inoculation training (SIT) as an anxiety management treatment. SIT assists patients in learning to manage anxiety that is conditioned at the time of the trauma and then generalizes to many situations. Dean Kilpatrick, Lois Veronen, and Patricia

Resick modified the program to treat victims of sexual assault. Their program included training in muscle relaxation and breathing, education, guided self-dialogue, and thought stopping.

b. Empirical Studies All four studies of stress inoculation training have used women who have been sexually assaulted as subjects. Two studies had excellent methodology whereas two were less well controlled. As noted earlier in this chapter, Edna Foa has performed some of the most rigorous studies in the field. She and her colleagues have found that nine 90-min sessions of stress inoculation training were effective in reducing PTSD. SIT was also found to be as effective as peer counseling in a study by another group. A study comparing SIT with supportive therapy and assertiveness training, found them all to be equally effective.

c. Summary Although stress inoculation training has been shown to be efficacious in treating women who have been sexually assaulted, it is unclear whether this finding can be generalized to other trauma populations. In general, SIT is often seen as a combination of cognitive, behavioral, and relaxation elements.

2. Biofeedback and Relaxation Training

Biofeedback and relaxation therapy have also been used as techniques for managing anxiety for patients with PTSD. In biofeedback, patients learn to control their physiological responses. They learn to decrease muscle tension by watching their electromyographic (EMG) activity change on a monitor. Only one study has examined biofeedback in a controlled design, comparing it to eye-movement desensitization and reprocessing (EMDR) plus milieu and to relaxation therapy plus milieu. Biofeedback was not found to be effective. EMDR in conjunction with milieu therapy was more effective. Another group used a combination of biofeedback and relaxation training to treat six Vietnam veterans with PTSD. They reported symptom improvement on all measures. Biofeedback was also found to be helpful in reducing muscle tension, nightmares, and flashbacks in another group of Vietnam veterans.

IV. SUMMARY

The psychotherapeutic treatment of PTSD is increasingly studied with rigorous methodological designs. No studies have rigorously evaluated combined psychotherapeutic and medication treatments. Across the psychotherapies, there is a developing consensus on the need to attend to the specifics of the traumatic event. The interpersonal experience over time after the event, the meaning of the traumatic event, distortions of interpersonal and emotional perspective that derive from the experience of the trauma and for therapists to be alert to the countertransference issues in these often profoundly terrorized patients. The complex comorbidity often seen in PTSD also means that multiple therapeutic modalities are often needed in treatment.

within series ABAB experimental design An experimental method applied to single subjects wherein the subject is intermittently exposed to treatment and no-treatment conditions. Differences in behavior observed during the varying conditions form the basis for conclusions about the effectiveness of treatment.

GLOSSARY

Berkson's bias The tendency in clinical research to study clinical populations with compound problems, especially hospitalized populations. The findings from the pertinent study are skewed because of the severity of the study groups.

encopresis Frequent fecal accidents occurring after the age of 5 and not due to an organic condition.

enuresis Frequent urinary accidents occurring after the age of 5 and not due to an organic condition.

incontinence Urinary or fecal incidents that occur in clothing or bedding.

primary care Branch of medicine devoted to prevention and early intervention.

temperament An aspect of a person's behavioral style that is more inherited than learned. Temperamental characteristics involve dispositions toward emotional reactions, mood shifts, and sensitivity to stimulation.

Tourette's syndrome An impulse control disorder involving the habitual emission of vocal sounds and motor movements referred to as tics. The tics sometimes involve obscene gestures or words.

trichotillomania Habitual hair pulling preceded by a mounting urge to pull and accompanied by detectable hair loss.

Behavioral pediatrics is the branch of pediatrics that addresses child behavior problems that populate the intersection between clinical child psychology, child psychiatry, and pediatric health care. Although problems of importance to behavioral pediatrics occur across all domains of medicine, the field upholds the longstanding tradition in pediatric medicine of emphasizing prevention over treatment or rehabilitation. In the words of Stanford Friedman, an early architect of the field of behavioral pediatrics, "curative and rehabilitative orientation (is) always second best to preventing the disease or defect in the first place...". This chapter focuses on the evaluation and treatment of child behavior problems that initially, and often only, present in primary care. We will refer to this as primary care behavioral pediatrics (PCBP). PCBP is an eclectic field but most practitioners are either primary care pediatricians who take a special interest in the management of behavior problems in their practices or pediatric psychologists whose practice includes close collaboration with their clients' primary care physicians.

I. DESCRIPTION OF PCBP TREATMENT

The term psychotherapy may not be appropriate for PCBP; it is grounded in a context of psychopathology or mental illness and is thus inconsistent with the preventive context of PCBP. Many definitions for psychotherapy exist but the most traditional and widely held involve primarily verbally based, processed-oriented treatment the goal of which is remediation of psychopathology or mental illness. In many cases the behavior problems seen in primary care are not indications of child psychopathology or mental illness. Rather they arise out of problematic interactions between children and their environment. For example, confident, experienced parents with abundant social support may not view their 8-week-old child's crying for 2 to 3 hours a day, which is less than one standard deviation above the expected mean for daily duration of crying for children this age, as a problem. However, less confident, experienced, and supported parents may interpret the same amount of crying in their similarly aged child not only as a serious problem but also as indictment of their parenting skills. These less experienced parents, however, might be unconcerned if the crying averaged only 1 to 2 hours a day (slightly less than the expected mean). Thus it would be inappropriate to assume that the crying, the average daily duration of which is above the mean but well within the range of normal, is an indication of psychological disturbance in the child or skill deficiencies in the parents. Providing health education about the extent to which behaviors such as extended crying are part of the normal variations in a child's life is an important part of PCBP practice and one we will discuss in greater detail later in the chapter.

Having emphasized that many behavior problems seen in PCBP are not reflective of psychopathology, it is also important to note that PCBP acknowledges the existence and importance of child psychopathology. The PCBP view, however, is that although the presence of psychopathology is always accompanied by behavior problems, the reverse is not necessarily true, especially for problems initially presenting in PCBP. Nonetheless, at least some of the problems presenting in PCBP are reflective of psychopathology and thus PCBP practitioners must be able to recognize when children have major disorders and be willing to refer those children to specialists. Moreover, a fundamental reason PCBP is viewed as preventive care is based on the belief that persistence of problematic interactions between chil-

dren and their environment increases the likelihood that psychopathology will develop. The care provided for problems presenting in PCBP involves two intersected kinds of intervention, supportive counseling and prescriptive behavioral treatment.

A. Supportive Counseling

The primary goals of supportive counseling in PCBP are to provide emotional support and health education. To be effective, practitioners must be able to communicate care and compassion for parents of children exhibiting problem behaviors and an appreciation for the distress and disharmony those problems cause the family. Additionally, practitioners must have informative and persuasive answers for the parents' questions about the problems and a prime function those answers must serve is demystification. Parents want to know why their child is exhibiting the problematic behaviors and typically the answers they obtain on their own are overly pessimistic. Fortunately, many troubling aspects of childhood are actually normal and expected. For example, extended crying in the first 3 months, although stressful, is normal. Incontinence in children younger than 5, although unpleasant, is normal especially for boys. Limit testing, although exasperating, is common throughout early childhood. Separation anxiety spikes between 11 and 14 months, negativism is common in the second and third year, and thumb sucking is prevalent and harmless up to age 4. There are many other examples. The successful PCBP practitioner is knowledgeable about most or all of these and can communicate that knowledge in a respectful, accepting, and compassionate way.

In some cases supportive counseling is sufficient to address the presenting complaints. PCBP practitioners can reassure parents of a child presenting with behavior problems by informing them that the problems are not unusual at their child's age and are likely to resolve within specified age limits. For example, separation anxiety diminishes after 14 months in most children. However, if the problems persist (or emerge) beyond these age limits, substantially worsen, or begin to cause health concerns, supportive counseling is supplemented by prescriptive behavioral treatment recommendations.

B. Prescriptive Behavioral Treatment

When a child behavior problem presents in PCBP, practitioners place it in its appropriate developmental and prognostic context via supportive counseling (as in-

licated above). If the problem does not involve one of the major psychiatric conditions (e.g., major depression) at the boundary of PCBP, practitioners recommend a series of therapeutic steps to be followed at home (or school) to address the problem. The therapeutic advice typically emphasizes procedure over process and most procedures recommended are derived from the more pragmatic parts of the behavioral sciences, particularly those focused on learning and development. For example, according to Edward Christophersen, another major architect of the field, "Behavioral pediatrics is the application of the principles and procedures of the behavioral sciences to the prevention or resolution of problems encountered in the practice of pediatrics." Prescriptive behavioral treatments are the primary methods PCBP practitioners employ to remedy behavior problems. Treatments that work are valued for their own sake and their importance is not diminished because they are at odds with this or that theory. Efficiency, effectiveness, and acceptance are valued over and above theoretical consistency, precision, and scope. Furthermore, PCBP treatment, although predominantly verbal and thus consistent topographically with traditional child psychotherapy, differs from it in at least two important ways.

First and perhaps most fundamental, parents (or primary caregivers) rather than children are the direct recipients of treatment (i.e., supportive counseling and the recommendations that make up the prescriptive behavioral treatment regimens). Children are, of course, the ultimate recipients of PCBP treatment, regardless of its form and they are often present during its discussion and even participate in its preparation. But the most common vehicle for PCBP treatment is educational and prescriptive advice pertaining to the parent portion of parent-child interactions. Although the comparison is not perfect, it may be helpful to view PCBP treatment as a specialized form of parent training. The critical point, however, is that although child problems are the reason for PCBP treatment, parents are the proximal recipients of the therapeutic advice pertaining to those problems. Thus PCBP treatment is fundamentally different from traditional child psychotherapy wherein the child is the direct recipient of treatment.

Second, because of limitations on time and the emphasis on procedure in pediatric settings, PCBP treatments are often brief and protocol driven. In this respect they differ dramatically from the process-based, time-intensive interventions that characterize traditional child psychotherapy. PCBP treatment, however, is consonant with the increasing emphasis on empirically supported treatment and manualized practice in

contemporary psychotherapy. The therapeutic armamentarium of the PCBP practitioners includes a variety of procedures each with abundant empirical support including (but not limited to) time out, contingency management, home-school notes, simple point systems, and various procedures for simple habits, chronic incontinence, bedtime struggles, and feeding problems.

C. More on the Practitioners

Because of the preventive emphasis in PCBP, clinical expertise in the treatment of major psychiatric problems of childhood is not a prerequisite for practitioners in the field. PCBP therapists, however, must have a strong appreciation for the variations commonly seen in normal child development, which then allows them to distinguish behavior problems that are best viewed as interactional from those that represent psychopathology. For example, hair play, twirling, and pulling in toddlers, although potentially problematic and certainly important enough to address in a PCBP visit, is not necessarily reflective of psychopathology or indicative of true trichotillomania. But compulsive hair pulling of long standing in a 12-year-old girl is a much more serious condition, one typically requiring more intensive care than that provided in PCBP. Thumb sucking in preschoolers is more likely a benign source of self-soothing than a malignant sign of oral fixation or regressive personality disorder. But chronic sucking in a school-aged child can be a serious problem and should, at a minimum, be regarded as a threat to optimal social development. Soiling in young children is much more likely to result from constipation than from psychic mechanisms such as resentment, regression, or anal fixation. Yet soiling in older children unaccompanied by constipation is likely to be the result of potentially serious psychogenic variables and unlikely to respond to a procedure-based PCBP treatment. There are many other examples.

Another important qualification for PCBP therapists is working knowledge of the biologic variables that are functionally related to child behavior problems. Many of the behavior problems managed in PCBP have important biologic dimensions (e.g., enuresis, encopresis, recurrent abdominal pain). To be effective, PCBP practitioners must at a minimum have a rudimentary understanding of variables such as bowel and bladder function, sleep physiology, and pain sensation.

Because the child problems that are appropriate for PCBP are diverse, the field is professionally eclectic. Thus primary care physicians (e.g., pediatricians, family

practitioners) can specialize in behavioral pediatrics just as readily as pediatric, school, and clinical child psychologists or psychiatrists. And there are a growing number of specialized training programs for these various types of professionals. The limited emphasis on psychopathology and the eclectic makeup of the field make the PCBP orientation to child behavior problems a novel, perhaps even unusual, but nonetheless important candidate for an encyclopedia on psychotherapy.

Generally PCBP will favor those whose orientation to practice is guided by science more than art, whose claim to expertise is predicated on empiricism more than clinical or ex cathedra authority, and whose methods are typified more by procedure than process. Thus, there are similarities between therapists in PCBP and those in some branches of psychology (e.g., behavior therapy, applied behavior analysis, pediatric psychology) but not those in others (e.g., psychoanalysis, existentialist psychology, human potential psychology).

II. THEORETICAL BASES

Coverage of all the theoretical bases that underlie PCBP is beyond the scope of this chapter. Because of its inherent pragmatism and largely agnostic stance toward most psychological theories, virtually all of the principles of behavior, learning, and development that could be exploited for therapeutic benefit are potentially part of the theoretical base. Rather than providing shallow coverage of a large number of relevant principles, we will more fully cover four basic assumptions that are pertinent to supportive counseling and central to prescriptive behavioral treatment: (1) individual differences and temperament are real and important; (2) effective use of behavior change language is critical to effective management of behavior problems; (3) effective management of behavior problems requires more emphasis on what children do than on what they say; (4) child learning is governed largely by repetition leading to experiential contrast.

A. Individual Differences and Temperament

As emphasized above, the origin of behavioral problems presenting in PCBP usually involves an interaction between child characteristics and environmental variables. Although psychopathology is possible, it is infrequently present. A more accurate and less stigmatic perspective involves child behavior that is safely within

the wide range of normal variation in development and/or behavioral style but that is outside of, or at odds with, environmental (e.g., parental) expectations. As stated by Stella Chess and Alexander Thomas, pioneering researchers in the area of individual variation, a good fit between an individual and the environment occurs.

when the properties of the environment and its expectations and demands are in accord with an organism's own capacities, motivations, and style of behavior. When this consonance between organism and environment is present, optimal development in a progressive direction is possible. "Poorness of fit" involves discrepancies and dissonances between environmental opportunities and demands and the capacities and characteristics of the organism so that distorted development and maladaptive functioning occur.

In other words, misinterpretation of child skill level (i.e., under or over) and misunderstanding of normal individual differences cause discrepancies between what parents expect of a child and what the child can and does do. These discrepancies, in turn, result in problematic parent-child interactions and, pertinent to this chapter, many of the problems presenting in PCBP. For example, overinterpretation of children's cognitive abilities is widespread (and is discussed later in the section on effective use of behavior change language).

Variations in developmental processes can also contribute to the onset of child behavior problems. For example, variations in the development of sleep architecture can contribute to a range of potential bedtime problems such as infant night waking and sleep terrors in toddlers. Variations in child sensitivity to bladder distension, especially during sleep, can contribute to enuresis. Variations in appetite, especially the decreases that often accompany the natural reduction in growth rate during the second year of life, can lead to difficulties at mealtime. These, and many other examples not mentioned, underscore the theoretical assumption of PCBP that the process of development and its variation clearly influences the behavioral concerns likely to be seen in PCBP.

Elevated parental concern also contributes to child behavior problems and when variations in child behavioral style or temperament conflict with parental lifestyles, elevated concern is very likely. For example, a child with a low activity level may concern active athletic parents, but may not be a concern to less active parents. A toddler who is hungry or sleepy at irregular times may concern parents who are committed to a regimented schedule but may not concern parents in a less

tightly scheduled family. The cluster of temperamental characteristics that is most likely to conflict with preferred lifestyles, especially for new parents, includes irregular biologic rhythms, frequent withdrawal from new stimuli, slow adaptation, frequent negative mood, and high intensity responding. This cluster is believed to occur in approximately 10 to 15% of children and its presence significantly increases the probability of parental concern and correspondingly, the probability of reportable behavior problems. But its presence in some children is of minimal concern to parents and correspondingly, the probability of behavior problems is substantially reduced.

The capacity to recognize and describe how variations in child behavioral style and temperament can conflict with parental expectations and lifestyles is a critical component of supportive counseling. Use of this capacity can help parents understand why some of their attempts at management (e.g., those recommended by family, friends, the media) have failed with their child. It can also provide relief for parents who have been on the receiving end of the widespread tendency to view child behavior problems as reflective of poor parenting and/or child psychopathology. The science of temperament helps explain why some obviously caring and talented parents sometimes have difficult children. These explanations and interpretations are necessary but sometimes insufficient for successful outcomes, however, and interventions that improve the interaction between child temperament, family environment, and parent teaching style are sometimes needed.

These interventions usually involve a combination of modifying the learning environment and teaching the child the behaviors necessary for meeting environmental requirements. For example, parents of an inattentive 4-year-old could be taught to use good eye contact and one-step instructions when teaching the child (a modification of the environment) while the child could be taught to follow the one-step instructions. A child who has tantrums when instructed to change activities (e.g., come to dinner) may have a temperamental difficulty of adapting to transitions. Teaching parents to provide warnings for incipient transitions may help their child cope with the changes and comply with the related commands. But the child would still need to be taught that a tantrum is not an acceptable response to an upsetting situation. There are many other examples that underscore the importance role theory and research on individual differences and temperament play in the practice of PCBP.

B. Effective Use of Behavior Change Language

From the earliest stages of human life, language is such a ubiquitous presence that subtle but powerful aspects of its unfolding development are widely missed or at least largely misunderstood. The result is a high likelihood of mismatches between parental assumptions about child knowledge and what the children actually understand. Fortunately, due to developmentally beneficial processes such as modeling, the mismatches are beneficial in many parent-child interactions. But when the interactions involve parental attempts to change child behavior (e.g., discipline), these mismatches can frustrate parental attempts to teach, thwart child efforts to learn, perpetuate established behavior problems, inaugurate new problems, and deteriorate parent-child relations. There are multiple behavior-relevant aspects of child language development and we will cover the two that emerge most frequently in PCBP, the capacity to conserve and instructional control.

1. Conservation

Although many child researchers have demonstrated the incremental nature of language development, perhaps the first, and if not, certainly the most authoritative, was Jean Piaget. Among his many discoveries was the relatively slow development of the child's ability to meaningfully understand abstractions and abstract relations. Piaget's studies and related theories in this regard are too multifaceted and systemized for a full discussion here, but his concept of conservation is sufficiently general to serve as vehicle for our purposes. Conservation is largely synonymous with abstraction; it involves the capacity to conserve a quality of an object or event and meaningfully apply to another object or event. The capacity to do so when objects or events closely resemble each other emerges early but when they do not, when the objects or events are formally or contextually dissimilar, the capacity to conserve emerges late (averaging between 5 and 7 years) and does not fully develop until the teen years.

Piaget (and other investigators) conducted numerous studies that demonstrated the young child's limited capacity to conserve. For example, when asked to hold a pound of lead and a pound of feathers and then asked which weighed more young children usually said the lead. When in the presence of two containers with identical volume capacities but different forms (e.g., one tall and thin the other short and fat) and asked which held more water young children usually said the tall one.

When shown two similar apples, one cut into fourths and one cut into eighths, and asked which they preferred, young children picked the one with eighths (“because there was more apple”). When shown five quarters in a bunch and five quarters in a row and asked which grouping had more quarters children usually said the row. There are many other examples. Those above generally pertain to children younger than 7 years of age. But there are also related tests that have been conducted with older children and they too underscore the difficulty children have in seeing sameness in the presence of manifest topographical or contextual difference.

One example involves the water level task. Typically the test includes four pictures of containers, holding an identical amount of water, arrayed in a row. There are usually several such rows and in each row the containers are positioned at different angles. The angles are different within rows and identical across rows. In each container a line depicts the level of water within. One row accurately depicts what happens to the water level when the angle of the container changes (i.e., the water level remains the same, parallel to the bottom of the container, regardless of the position of the container). In the other rows water levels are inaccurately depicted (e.g., they change with the angle of the container). Tests of the water level task have revealed that even early teens will sometimes fail to identify the row with the accurately depicted water levels. In conclusion, children—especially younger children—have difficulty seeing sameness in objects or events that have substantially different physical or contextual characteristics.

Conservation is important to PCBP because the effectiveness of behavior change language heavily depends on the child’s capacity to discern similarity in differing behavioral episodes. No two episodes are completely alike and thus, to learn conduct-relevant relations between combinations of episodes, children must be able to conserve aspects that form the basis of the relevancy. For example, the inception of a disciplinary event often includes a parental attempt to forcefully assert similarities between a current and a previous behavioral episode (e.g., “Isn’t that the same thing I warned you about yesterday?” “Didn’t your father tell you not to do that last week?”). There are at least two conservation-based assumptions implicit in parental comments of this kind: (1) the child should have been able to see conduct-relevant sameness in the indicated behavioral episodes; and (2) the child can currently see the sameness because the parent has pointed it out verbally. But if conservation is weakly developed, which is true of most children younger than 7

years, there is a good chance both assumptions are incorrect. For example, if children have a difficult time seeing quantitative sameness between five quarters in a row and five quarters in a bunch, it seems safe to say they would have much more difficulty seeing conduct-relevant sameness between something they have just done and something they did hours or even days ago. Furthermore, the test situations with quarters are simple and uniform with the exception of the differing arrangement of the quarters. Behavioral episodes, however, are often very complex and differ in many ways including time frames, persons present, and physical locations.

Additionally, when conducting tests of conservation capacities in the laboratory, investigators exhibit calmness, acceptance, perhaps even gentleness. As much as possible, investigators attempt to expunge any hint of disappointment, judgment, or possible punishment. Most children respond in kind (e.g., by cooperating, trying their best). But in the prototypical disciplinary event, parents demonstratively exhibit disappointment, judgment, and sometimes anger and the possibility of punishment is always implicit and often very explicit. Many (probably most) children respond emotionally (e.g., by crying, yelling, denying). A large scientific literature shows that high levels of emotional arousal substantially diminish cognitive functioning. While in an intensely emotional interaction with their parents, children are probably functioning cognitively at a level much lower than their chronological age. Thus even children who exhibit a developed capacity to conserve in routine situations may be unable to do so in disciplinary situations.

2. Instructional Control

Many child behavior problems involve children failing to do what they are told to do by their parents and many of these failures occur because parental instructions are unclear and/or too complex. Similar to the discussion on conservation, mismatches between parent expectations and child understanding are the central problem. These mismatches are generally the result of parental overestimates of the clarity of their instructions and/or of their children’s capacity to follow those instructions. Three decades of research on parent–child interactions and on parent training programs has shown strong correlations between vague instructions and delayed development of child instructional control. A representative (but not exhaustive) list of exemplar vague instructions includes those that are question-based (e.g., “Are you going to put that away?”), indirect (e.g.,

“You know you should really be getting ready for school”), veiled (e.g., “Somebody left the door open”), or multistep (e.g., “Go down stairs, pick up your clothes, sort out the dirty ones, put them in a basket, and bring them here”). It is important to note that instructional control is not necessarily achievable through a focus on clarity alone. Everyday exchanges between parents and children necessarily involve diminished clarity and it is ultimately necessary for children to learn to understand and follow instructions that are vague, offhand, imbedded in other grammatical structures (e.g., questions), or communicated through vocal inflection more than through word arrangement. To become proficient at following instructions in their everyday form, however, children must first have abundant practice at following instructions that are in a clear, simple, direct form. Without this preliminary practice, many children are slow to develop optimal instructional control skills and more likely to exhibit problem behavior as a result.

Two related findings from developmental psychology are among the more ironic and counterintuitive aspects of early child language and they are also directly relevant to the language of behavior change (especially for children between 2 and 4 years of age). The first is that children respond to instructions that involve action onset (i.e., “do” or “start” commands) more readily than to instructions that involve action offset (i.e., “don’t” or “stop” commands). The ironic aspect is that parents are much more frequent users of “don’t” or “stop” than of “do” or “start” instructions. The counterintuitive aspect is that telling a child to do something (i.e., other than what they are currently doing) can be a more effective way to halt the activity than actually telling them to stop.

The second finding is that young children often respond more to vocally intensified components within an instruction than to its semantic content. For example, when issuing an instruction such as “whatever you do, don’t drop that cup” a parent may say the last three words much more intensively than the first four, resulting in a simple instruction, ostensible for the child, to drop the cup, inside of a more complex instruction, intended by the parent, to do the exact opposite. The ironic aspect is that attempts to ensure instructional compliance through selectively placed vocal intensity can result in noncompliance with the instructions issued. The counterintuitive aspect is that this noncompliance actually reflects instructional control, albeit with the instructions understood by the child and not the ones intended by the parent.

In conclusion, mismatches between parental assumptions (and expectancies) about child knowledge

and actual child understanding are common, especially in early childhood. These mismatches, reflected in the language used by parents in their interactions with their children, set the occasion for problems especially when the interactions involve parental attempts to modify child behavior. A theoretical assumption of PCBP is that the mismatches play an important part in the inauguration and perpetuation of child behavior problems. A core goal in PCBP is to train parents to use language more effectively, especially when attempting to establish and enforce rules, implement discipline, and manage behavior problems. A major emphasis is placed on use of simple language, but care is taken to explain that use of complex language when the parental goal is not child behavior change is not problematic, that it can be beneficial. For example, modeling new and/or complex language can expedite children’s ability to use and understand it. The purpose of behavior change interactions, however, is to teach children to exhibit appropriate behavior in everyday life (e.g., not to leave the house without asking) not to expand their command of complex language. To enhance effectiveness of behavior change language, especially in the early stages of child training, clear, simple, and direct should be the rule not the exception.

C. Emphasis on Doing

Another theoretical assumption of PCBP rests on a distinction between two types of knowing, knowing how to do and knowing how to say (or to specify verbally what is to be done). Although not the first to draw this distinction, the philosopher Gilbert Ryle most effectively brought it widespread attention with publication of his book, *The Concept of Mind* in 1949. The distinction has been drawn in many other ways since then (e.g., cognitive knowing versus behavioral knowing, knowing a rule versus behaving consistent with the rule, theory versus practice). The distinction is the basis for a theoretical assumption of PCBP that has three fundamental components: (1) knowing how to say does not entail knowing how to do; (2) adult attempts to change child behavior typically emphasize saying much more than doing; (3) the combination of 1 and 2 is an important source of child behavior problems.

For example, during toilet training it is routine to ask 2- and 3-year-old children if they have to go to the bathroom. Accurately answering the question can be difficult for such young children. First they must determine whether the question refers merely to a change in location (i.e., just going into the bathroom) or to an act

of elimination. When (more accurately if) the children ascertain that the question involves elimination, an accurate answer requires that they examine their own bodily responses and determine whether their bowel is full and/or their bladder is distended and therefore that an act of elimination is imminent. If imminence is determined, the children then have to decide whether it is in their best interests to say so. Children in the early stages of toilet training are typically in Pampers or Pull-ups, both of which protect them from discomfort that would otherwise result from wetting or soiling themselves. In the absence of a toilet training program that reprograms the natural contingencies, most young children would typically rather eliminate in the Pampers or Pull-ups than stop what they are doing, go into the bathroom, take off their clothes, sit on the toilet, and attempt elimination there.

Thus the difficulty occasioned by the question “do you have to go to the bathroom?” is potentially problematic in at least five ways. First, the question places emphasis on an answer about toileting and not on a toileting action. In other words it calls for children to say, not to do. Second, the developmental limitations of 2- and 3-year-old children, coupled with the contingencies that typically prevail in interactions involving toileting, dramatically decrease the chances of an affirmative answer even when elimination is imminent. Third, nonaffirmative answers in such situations (e.g., child says “no” and has an accident shortly thereafter) set the occasion for punishment (or at least unpleasant parent–child interactions) because such answers make it seem as if the child has misbehaved (e.g., by being dishonest, stubborn, or stupid). Fourth, as a result of punishing exchanges during or following toileting episodes, toileting situations and behavior can acquire aversive properties. Fifth, young children will tend to avoid such situations and behavior in the future, resulting in delayed development of toileting skills.

A focus on doing instead of saying at the beginning of parent–child interactions involving toileting can obviate these problems and expedite training. For example, when timing (i.e., time elapsed since last act of elimination) or child responses (e.g., shifting weight from foot to foot) suggest elimination is imminent, rather than making an inquiry about toileting urge, parents should instead issue a toileting instruction requiring that their child make an attempt to eliminate in the toilet, guide them as they do so, and praise performance and any success achieved. This method removes the focus on saying and places it on forms of doing that are central to toileting. Additionally, by focusing on toileting instructions, this method con-

tributes not just to development of toileting skills, but also to development of instruction control skills in general. Because it is easier for children to follow simple instructions (such as those that accompany successful toilet training programs) than to answer complex questions (such as those about toileting need), a focus on instructions (rather than inquiry) reduces the potential for contention between child and parent during the process.

From a slightly different perspective, the scientific literature on toileting supports the instruction-based approach by showing that children generally do not acquire the ability to succeed with an inquiry-based approach (i.e., respond accurately to questions about whether they have to go and independently conduct the act if they do) until late in their third or early in their fourth year. But the inquiry-based approach is widely used with much younger children resulting in many toileting problems that are ultimately brought to PCBP.

A focus on doing more than saying is also important for other reasons. For example, in many domains of children’s lives their ability to say what they should do is learned before their ability to do it. That is, children can often readily say what they are supposed to do (or what they should have done) but lack the actual skill necessary for accomplishing the task. For example, they can easily say they should share their toys and yet not have the slightest inclination to do so because they lack the social and emotional skills that are essential for proficient sharing. Unfortunately, many adults assume that if children can say they should share it means they actually know how. For these adults, the children’s subsequent failure to share is much more likely to be interpreted as evidence of a flawed character than of a skill deficit.

That a disparity between saying and doing exists and differential emphasis is more productively placed on doing is no surprise, at least where adults are concerned. Tell-tale examples are legion in everyday life. For example, all golfers know they should keep their head down during the golf swing but many (most) routinely lift their head up. Or more generally, lovers say they should look before they leap, readers say a book should not be judged by its cover, and fools say they should not rush in. Yet lovers often leap, readers frequently judge by the cover, and fools typically rush in all because their knowledge involves a facility for saying far more than it does a capacity for doing what has been said. Many proverbs, aphorisms, and epigrams make similar points and underscore the importance of doing over saying (e.g., “put your money where your mouth is”). The importance of doing over saying also suffuses the marketplace. As an example, the January

2001 issue of *Wired Magazine* included a symposium on marketing in the new millennium in which David Kelley, a prominent participant, said, "If you listen to the customers, they can't tell you anything. You have to *watch* the customer to really learn something. That's how you get at what they think and feel."

The surprise is actually how little this disparity is recognized where children with behavior problems are concerned and how minimally it is incorporated into attempts to modify those problems. As indicated above, children can often readily say what they should or should not do (e.g., not suck their thumb, pick on smaller children, take things without asking) but their ability to exhibit the requisite behaviors often lags far behind their ability to enunciate them. The related mistaken assumptions about what children know results in at least three sources of child behavior problems and corresponding difficulties. The first involves parental teaching efforts undermined by overemphasis on saying and underemphasis on doing, resulting in delayed child learning of behavioral skills (e.g., instructional control) critical to successful home and school life. The second involves the frequency of punitive discipline used with behavior problem children whose ability to say what they are supposed to do greatly exceeds their ability to do it. The third involves a widespread cultural tendency to interpret child behavior problems as a reflection of psychopathology rather than skills deficits. A fundamental assumption of PCBP is that the strength of these sources of problems and complications is substantially reduced when teaching focuses more on child doing than on child saying.

D. Repetition Followed by Experiential Contrast

The final theoretical assumption underlying PCBP that we will discuss involves how children derive meaning from the teeming multitude of events that compose their day-to-day life, how they learn to exhibit appropriate and inappropriate behavior, or more generally, how they learn. A century of research on learning with major contributions by eminent scientists such as John Watson, Edward Thorndike, B.F. Skinner, Albert Bandura, and Sydney Bijou shows that child learning largely results from the emergence of functional relations between what children do, what happened before they did it, and the change or contrast in experience generated by what they have done. The second theoretical assumption underlying PCBP we discussed dealt with antecedents or events occurring before children do things.

Antecedents (e.g., instructions, rules) that compose a major portion of child teaching (e.g., by parents) were discussed, and the importance of salience, clarity, and simplicity as well as an emphasis on doing was stressed. The final theoretical assumption involves how children make adaptive (i.e., preferred by parents) connections between these types of antecedent events and what they subsequently do. Specifically, the assumption is that the connections result from repetition of behavior that follows the antecedent events and the changes or contrast in child experience that follows the behavior.

In very general terms, there are four classes or categories of experiential events that establish learning-based connections, two that make repetition of behavior more likely and two that make it less likely. The two classes that make behavior more likely are (1) contact with experientially pleasant or preferred events and (2) avoidance of, or escape from, experientially unpleasant or nonpreferred events. The two classes that make behavior less likely are (1) contact with experientially unpleasant or nonpreferred events and (2) disconnection from, or loss of contact with, pleasant or preferred events. An important corollary of the final assumption is that the number of repetitions necessary for children to make meaningful connections is governed by the amount of the experiential contrast that follows what they do. The more contrast, the fewer repetitions necessary for learning a meaningful relationship between a behavior, its antecedents, and its experiential consequences.

For example, flame or fire is a very salient (and attractive) antecedent event (e.g., the primary purpose of most fireplaces is for viewing fire, not for heating homes) but also very dangerous for children. Very young children who initially encounter fire are typically unaware of its dangers but are enthralled with its beauty and if unsupervised, they will often try to touch it. As a result a very important lesson (i.e., meaningful connection) is instantly learned. The learning results from the presence of fire (antecedent event), behavior that brings the child into contact with fire (touching), and the experiential (unpleasant, nonpreferred) consequences of that contact (being burned). These experiential consequences involve so much contrast (i.e., temperature of the body versus flame) that an instance of one-trial learning generating caution around fire occurs and it typically lasts a lifetime (i.e., the child will be unlikely to deliberately place his or her hand in open flame again). This is not to say that children who have been burned will not be burned again, but as the saying goes "once burned, twice shy." If the temperature of fire were lower, if it were much closer to skin temperature (e.g.,

102°F), many repetitions (and probably some supplemental aversive—disciplinary—consequences) would be necessary to establish a level of caution similar to that generated from flame.

The power of learning resulting from such extraordinary levels of experiential contrast is revealed by some parents who, after being unsuccessful in using other methods to teach their toddlers to avoid breakable household objects, achieve temporary success warning them that the objects are hot. A child with some experience of being burned and who has learned a connection between that experience and the antecedent event of hearing a parent say “hot” will often avoid, albeit temporarily, objects so described.

Critical to this discussion of learning is the logical necessity of incorporating the obverse of the primary point made above. That is, if behavior followed by high experiential contrast requires few repetitions to result in the learning of meaningful connections, responses followed by low experiential contrast will usually require many repetitions to result in a similar amount of learning. Numerous everyday examples corroborate this second point.

For example, many parents report high rate use of tactics such as nagging, reminding, warning, and threatening when attempting to teach their problem children appropriate behavior. Each of these tactics is a class of topographically similar antecedent events and in most teaching situations the events are repeated multiple times before a parent takes any further action, if indeed any action is taken at all. The reason for the repetition is that the children (who have been repetitiously nagged, reminded, warned, or threatened) have presumably not responded to the parent (i.e., they ignored their parent). Each instance of these parental tactics (e.g., each warning) sets the occasion for a learning trial in which the child actually learns to continue ignoring the parent. This unwanted and unfortunate result occurs for two reasons related to the theoretical assumption we are discussing here. First, the ignoring typically fails to generate the type (unpleasant) and the amount of experiential contrast necessary to reduce the likelihood of ignoring in the future. Second, the ignoring generates a consequential event of the type (avoidance of unpleasant or nonpreferred activity—i.e., whatever the parent wants the child to do or not do) that makes ignoring more likely to be repeated in the future.

Another type of learning trial that strengthens the learning of ignoring parents even further often accompanies the first type. In this second type of trial parents ignore or respond minimally when children actually do

what they are told. That is, the tendency to ignore the parent, established by frequent parental warnings with no followup, is made even more likely when the child complies with the parent and still receives no followup. More generally, the learning of inappropriate behavior (e.g., ignoring as described above) is often accompanied by learning trials in which appropriate alternatives (e.g., compliance) are not followed by the type (pleasant, preferred) or the amount of experiential contrast necessary to increase the likelihood of the alternatives. In conclusion, many child behavior problems result from a confluence of learning trials where inappropriate behavior receives more of an experiential payoff for the child than its appropriate alternatives.

Making matters even worse is the devolution in parent teaching tactics that can result from these problematic teaching and learning processes. Many parents, frustrated by the extent to which their instructions and rules are ignored, resort to highly punitive consequences, especially yelling and sometimes even spanking. These consequences produce high levels of experiential contrast and thus readily instigate learning, but their potential benefits are outweighed by several potential risks. For example, children habituate to yelling and spanking quickly so more is gradually needed, an escalatory process that can lead to abusive child treatment. Additionally, frequent use of punishing tactics often creates so much distress for child, parent, and family that the quality of the family environment is usually diminished as a result. The effects of highly punitive tactics on child behavior are also reductive and so they are less likely to teach new skills than they are to increase avoidance and escape. Lastly, the tactics can cause unwanted side effects (e.g., fear, retaliation) that can worsen the parent–child relationship even further. For these reasons, the use of highly punitive consequences are neither recommended nor endorsed in PCBP.

1. The Experience of Nothing

For most disciplinary purposes, an alternative approach to discipline, derived from the fourth theoretical assumption of PCBP (i.e., repetition with contrast) as well other fundamental aspects of human life, is employed instead. Specifically, the approach involves the strategic use of the experience of nothing. Events in which very little stimulation occurs involve the type of experience (unpleasant, nonpreferred) that reduces the probability of behavior that produces it. Faced with the extended experience of nothing, children (and indeed most humans) prefer events that produce something, even if those events involve unpleasantness. Said

slightly differently, most children ultimately prefer negative over nothing. Unfortunately, from a theoretical perspective nothing is hard to define and from an empirical perspective it can be difficult to document. But fortunately, from a procedural perspective experiences involving nothing, not much, or very little can be programmatically arranged, as we will discuss below.

a) Sensory Deprivation The importance of nothing as an experience is predicted on humans as sentient beings whose senses must be stimulated in order to maintain perceptual integrity and ultimately life itself. If one or more sensory modalities are cut off (e.g., through blindness or deafness) the acuity of those that remain increases substantially. It is as if a requisite amount of stimulation is necessary for humans to maintain perceptual health. An illuminating example of the power of the experience of nothing involves enclosure within sensory deprivation chambers. In the chambers persons lie in water the temperature of which is identical to that of the body. There is no light or sound and there is nothing to taste or smell. In other words, in sensory deprivation chambers the stimuli available for differential perception are held to a profound and potentially life-threatening minimum. In the short term, enclosure in the chambers has been associated with such experiences as exhilaration, relaxation, and awareness enhancement. In the long term, however, enclosure in the chambers has been associated with such experiences as hallucination, hyperventilation, and panic. Extended stays (e.g., more than an hour) are thought to be dangerous especially for novices. The point of this discussion is not to review sensory deprivation but rather to use a brief description of it to illuminate a correlate of the fourth theoretical assumption of PCBP. Specifically, programmed (i.e., planned contingent use of) consequences generating the experience of nothing powerfully reduce the likelihood of behaviors that produce those consequences.

We used the deprivation chamber example to reveal a very important dimension of the experience of nothing, the experiences where very little external stimulation occurs. Another equally important dimension is the experience of not being able to do anything about it (e.g., being powerless to provoke a reaction in a parent). In other words, situations in which there is nothing going on and nothing one can do about it are aversive for humans and particularly for children. One feature of the deprivation chamber that makes it tolerable is that the person within can readily terminate the experience and produce some external stimulation. Re-

moving this feature, however, makes the experience highly aversive, one that few persons would willingly seek. There are many other examples that, although less exotic than the deprivation chamber, can be just as reflective of the influence the experience of nothing can have on learning and behavior, for example, parents on the telephone and the use of time out.

b) Parents on the Telephone The influence the experience of nothing can have on learning is often in evidence when young children are alone with a parent who takes an extended telephone call. Escalated child misbehavior and demonstrative child upset are two common results and both can puzzle parents. Viewed from the perspective of our discussion of nothing, however, there is little mystery here. The most treasured source of external stimulation for young children is usually the parent and during telephone calls the parent is mostly psychologically (and physically) unavailable; that is, they provide their child little or nothing. In the unlikely event that children behave appropriately during the call, for example, they sit on the couch and look at picture books, the likely consequence for them will be an extension of the call. When children are behaving appropriately there is no compelling reason for a parent to terminate an activity and attend to them. The unfortunate result for the children, however, is an extended experience of nothing, at least as far as the parent as a source of stimulation is concerned. In other words, appropriate child behavior occurring while a parent is on the telephone usually produces nothing for the child. Extended telephone calls in the presence of a young child, however, are not neutral from a learning perspective. They are learning trials in which appropriate behavior is followed by experiential consequences (i.e., nothing) that are of the type (unpleasant, nonpreferred) that make the behavior less likely to occur in the future.

Making matters worse is that inappropriate child behavior, especially of a highly escalated sort, can and often does terminate parental telephone calls. When this happens, parents are likely to express frustration or anger and possibly even impose some discipline. Despite this quite logical parental approach to the problem, child misbehavior during telephone calls often subsequently increases rather than decreases. Although counterintuitive, from a PCBP perspective this outcome is readily explained. Although the parental response to the child appears to involve unpleasant consequences, these consequences are something (experiential) and from the typical child's perspective as we have argued,

something is better than nothing. Through misbehavior the child is, in effect, able to neutralize both of the dimensions of the experience of nothing that make it aversive. The first (nothing going on) is neutralized as soon as the parent interacts with the child because something begins to happen. The second (nothing the child can do about it) is neutralized by the instrumental quality of the misbehavior (i.e., it causes the parent to respond). More generally and from the perspective of the fourth theoretical assumption of PCBP, attempts to discipline child misbehavior that occurs in the context of nothing (as we have discussed it here) are more likely to increase than decrease the misbehavior. The reason is that when the disciplinary consequences occur, the context of nothing transforms them into the type (preferred) that make the behavior that generated them more likely in the future.

c) Time Out Another example of the role the experience of nothing can play in a child's life is a very common disciplinary procedure called time out. Time out, an abbreviation for Time Out From Positive Reinforcement, established in basic science experiments years ago, has become the most used method for disciplining children in this country, with the possible exception of verbal reprimands. A disclaimer, frequently heard in PCBP, is that time out has been tried and it did not work. The implicit assumption is that what was done in the name of time out closely resembles the procedure developed in the laboratory long ago. Unfortunately, close resemblance is the rare exception rather than the rule. In the laboratory, time out conditions involve what we have been referring to as the experience of nothing. Specifically the subject could not make contact with events that would be reinforcing, rewarding, stimulating, or interesting. In other words for laboratory subjects, a time out meant there was nothing going on, and for a specific period of time, there was nothing they could do about it. This laboratory experience, however, differs dramatically from the typical experience called time out in homes and schools across the country.

During the typical time out children are taken to a specific location, usually a chair, lectured briefly on the nature of their offense, and told they must sit quietly for a certain amount of time. A timer is often placed in the child's visual and/or auditory range so that the youngster can keep track of time passing. Verbal components such as warnings, rationales, and commands are frequently directed at the child. Children in time out are also often allowed to bring favored objects (e.g., teddy bear, book) with them. The location of the time

out is often near rich sources of external stimulation such as the television or a picture window. So in terms of the first dimension of the experience of nothing, specifically nothing going on, most time outs often fail.

Also detrimental to the process is the ease with which children can do something about their situation, thereby neutralizing the intended effects of the time out experience. For example, simply calling out, crying out, or coming out of time out (without permission) are very successful means of fully engaging the attention of parents and thereby undermining the effects of time out. Other types of inappropriate behaviors (e.g., profanity, disrobing) also typically engage parental attention. The attention thus engaged is usually negative but, because it is delivered when the child is in time out, resulting in a temporary escape (the instant attention is delivered, time out functionally ends) it is more likely to increase rather than decrease the inappropriate behavior. In other words, negative attention is something and for children in time out, something is usually better than nothing.

Not surprisingly, helping parents to strategically apply the experience of nothing (e.g., time out, planned ignoring) as a disciplinary alternative to raising their hands or voices is an important part of PCBP. Much of this assistance involves helping them eliminate sources of social stimulation (e.g., warnings, criticisms, expressions of parental anger) that often occur while children are in time out. Perhaps even more important is assisting them to see that the experience of nothing is relative phenomenon. If little external stimulation is available for a child (e.g., they are bored because nothing is happening) time out, even when done well, produces little experiential contrast. Needed is an experience, resulting from an act of discipline, that is unpleasant or nonpreferred and that stands out starkly from what was happening before the discipline was imposed. Yelling or spanking can serve this purpose but we have already discussed the problems associated with their use. Time out is much more subtle but it can serve the purpose very well if three conditions are met: (1) sources of social stimulation are eliminated during the time out (as above); (2) the child's inappropriate attempts to terminate time out are ignored outright; and (3) the child's life was generally interesting and fun before time out was imposed. In other words, time out must be devoid of social interaction and must occur in a context called time in.

d) The Role of Time In As indicated, in order for time out to have desired effects, it must represent a change in the experience of the child and if nothing was going on before the time out occurred, and the

child is then put in a situation with nothing going on, not much contrast and thus not much learning occurs. Actually, this principle applies to virtually any form of discipline. For example, if parents usually talk to their children with stern voices and then use a stern verbal reprimand for discipline, the reprimand produces little contrast and thus little possibility of learning. However, if parents usually talk to their children in soothing, affectionate, or emotionally positive ways and then use a stern verbal reprimand, the stark contrast between the typical parent-child interaction and the stern one increases the probability of children learning an important connection between what they have done and the parents' reaction to it. In honor of this principle, PCBP therapists are unlikely to recommend any form of discipline without first recommending ways for parents to increase the positive aspects of their child's daily life. Said slightly differently, PCBP practitioners routinely recommend procedures to increase time in, the functional opposite of time out, wherein multiple sources of preferred external stimulation (e.g., physical affection, parental participation in child activities,) are made available to children as well as a variety of minimally effortful methods accessing those sources.

In conclusion, a large part of PCBP involves provision of procedural advice generally based on developmental and behavioral science and specifically on the four theoretical assumptions we described above. That is, this advice almost always involves some combination of (1) consideration and explanation of child behavioral style; (2) more effective use of behavior change language; (3) a focus on doing; and (4) the arrangement of teaching circumstances that result in the type and amount of experiential contrast necessary to produce children's learning of appropriate behavior.

III. APPLICATIONS AND EXCLUSIONS

Some children resist most, and most children resist some, key aspects of the socialization and education processes in this culture and a vast number and array of child behavior problems is the result. For example, nutritional and maturational health is predicated on food preferences that include the major food groups and yet some children, whose behavioral style may include slow adaptability and approach to new experience, resist parental attempts to introduce new tastes and textures into the daily diet. Adaptive child performance during the day is dependent on receipt of adequate sleep at night, yet children with slow adaptability or irregularity

in sleep cycles may resist parental efforts to establish a reasonable bedtime. Most parents, preschools, and many day care programs require full toilet training during the third year of life, yet many children resist parental training efforts. Success in most life situations requires a reasonable amount of instructional control yet many children resist following important adult instructions. There are many other examples and they generally emerge in situations in which the requirement for adherence to family, school, or societal standards or requirements is not well matched with aspects of the child's behavioral style and/or learning history.

There are also a large number of child problems pertinent to PCBP that do not involve child resistance as much as they do child inability to emit, maintain, reduce, or cease important behavior. Although many of these problems are clinically unremarkable and resolve with time and routine parental efforts, some do not and require professional assistance for complete resolution. Furthermore, some of these problems resemble or, if unresolved, can lead to more serious conditions and thus they require some level of professional assessment prior to intervention. For example, simple tics and other child habits involving repetitive but nonadaptive behavior are common yet difficult for children to stop and highly resistant to routine parental efforts to help. In addition, tics may be an early sign of serious clinical conditions (e.g., Tourette's syndrome). Urinary and/or fecal incontinence is common, even in school-age children, yet without professional help incontinence can become a threat to physical and psychological health. School problems involving excesses or deficits of various behaviors critical to school performance (e.g., attention, activity) are common, stubborn, and absent effective intervention, can lead to serious problems later (e.g., school failure). There are many other examples and they generally emerge in situations requiring inhibition of potentially maladaptive behavior and increased exhibition of adaptive behavior.

The PCBP perspective on types of problems described above is that most are more productively viewed as a skill or performance deficit than as psychopathologies. Nonetheless, the problems are usually serious enough to warrant a professional opinion and sufficiently complex enough to require professional assistance for resolution. Psychopathology, however, is rarely the appropriate interpretive context for the assessment or the assistance warranted by these problems. As indicated, the problems emerge as a function of the friction between child style, preference, and/or skill level and the requirements inherent in socialization and education processes.

This “otherwise normal” perspective, unfortunately, is at odds with the vast majority of psychology and psychiatric literature on child behavior problems, which is focused almost entirely on detection of psychopathology with minimal regard for detection of child health. In fact, very few clinical assessment instruments are even designed to detect behavioral health. Behavior assessment instruments used in clinical research and practice on child behavior ask questions about symptoms or behavior problems and the typical intent is to determine whether a given child has significantly more than children of a similar age in the group used to norm the instrument. In other words, the *de facto* definition of child behavioral health within clinical child psychology and psychiatry is a composite of symptoms and problems that are below a threshold established for psychopathology, not a composite of healthful behaviors.

Perhaps the best way to view the PCBP approach to behavior problems is as early intervention. By providing parents and families with supportive counseling and prescriptive recommendations sufficient to improve interactions between children and their learning environment, PCBP aims to facilitate adaptive child development and behavior and thus prevent more severe problems in the future. For example, inadequate sleep leads to behavioral deterioration during the day and PCBP advice on how much sleep is needed and how to produce it can prevent these problems. Incontinence poses a number of risks to child health and development and PCBP advice on when and how to start toilet training can eliminate them. Resistance to adult instructions places children at risk for perpetuated conflict with adults. PCBP advice on instructional control can reduce child noncompliance with adult authority. The list of other examples is very long. They typically involve mild to moderate child behavior problems, most of which are responsive to changes in practices by parents (or teachers). Although some of the problems may meet diagnostic criteria for clinical conditions (e.g., enuresis, encopresis, simple phobias) the problems are usually in their early stages and are much more responsive to changes in teaching or training practices than problems that have been chronic for years. Thus even though PCBP provides treatment, the context of care is still characterized as preventive rather than curative or rehabilitative.

In conclusion, PCBP focuses on mild to moderate behavior problems exhibited by children who initially present in primary care. The context of care is one of prevention (preservation of health) much more than it is treatment (restoration of health) or rehabilitation (minimization of illness). Adopting this context, how-

ever, does not mean that PCBP denies the possibility of psychopathology or mental illness in children. Rather, the position taken is that children are deemed psychologically well until proven otherwise. Forms of such proof include resistance to PCBP treatment, an initial severe presentation, or incontrovertible assessment-based evidence; if any of these occur, cases are referred to appropriate specialists. PCBP, however, is an appropriate form of care for the vast array and number of child behavior problems presenting initially, and often only, in primary care settings.

IV. EMPIRICAL STUDIES

As emphasized, an important portion of PCBP involves educating parents about childhood and what to expect socially, emotionally, and behaviorally from their children. Thus virtually all child and developmental research is potentially relevant to PCBP. Three categories of this research are particularly relevant, however, the first two because they supply some justification for the well child focus of PCBP and the third because it reveals the size of the empirically supported armamentarium of the PCBP practitioner. The first category involves research on child temperament and individual differences, the second involves research assessing whether mild to moderate child behavior problems necessarily involve psychopathology, and the third involves research on PCBP appropriate treatments (pragmatic, procedure-based, outcome oriented, and time-limited) developed for various mild to moderate child behavior problems.

A. Temperament and Individual Differences

The expanding role of temperament or behavioral style in the professional approach to child behavioral problems is due in no small measure to the work of Stella Chess and Alexander Thomas and their colleagues working on the New York Longitudinal Study. This landmark research identified nine characteristics of temperament: activity level, rhythmicity (regularity of physiologic functions such as sleep, hunger, etc.), adaptability, intensity, mood, approach-withdrawal (to new stimuli), persistence, distractibility, and sensory threshold. There is, however, variation in the opinions of other researchers on the number and nature of the dimensions that compose variations in temperament, with more recent views favoring fewer dimensions.

These differences of opinion notwithstanding, there is consensus that dimensions of temperament do exist, play a significant role in behavioral expression, and are relatively stable over time.

Two other potent influences have contributed to the expanding role of temperament in the theoretical assumptions of PCBP. The first influence involves neonatal assessment of temperament, most notably with the instrument developed by T. Berry Brazelton. Related studies show that long before environmental influences could produce major changes in behavioral responses, substantial differences in behavioral expression exist in newborn children. The second influence involves assessment of temperament across early and later childhood, authoritatively (but not solely) documented in the papers and books authored by William Carey. The evolution of temperament from theory and basic science (e.g., Chess, Thomas) to routine assessment in a hospital setting (e.g., Brazelton) to routine assessment in a private pediatric practice setting (e.g., Carey) has contributed greatly to its current important role in PCBP practice.

B. Testing for Psychopathology

The second category of research is unfortunately small for reasons we have discussed briefly. For example, most of the research conducted on child behavior problems involves attempts to detect psychopathology and failure to do so usually means a failed experiment. As another example, children who do not exhibit psychopathology are much less likely to interest professionals (e.g., clinical child psychologists and psychiatrists) whose careers are focused on the study of it than children who do. Thus essentially healthy children are rarely the focus of clinical research.

There is, however, a small group of child studies whose group data were more reflective of clinical normality than psychopathology, despite presenting problems often interpreted as evidence of an underlying disorder. Examples include studies on children exhibiting problems such as enuresis, encopresis, chronic hair pulling, and thumb sucking. Note that these types of problems are very likely to present in primary care and thus are directly pertinent to this chapter. In these studies, the majority of children studied did not exhibit a sufficient number of clinical symptoms other than the target problem (e.g., enuresis) to justify a label of psychopathology. Rather, with the exception of the presenting problems, the groups appeared to be appropriately located within a spectrum of normality. There were extreme cases within the groups, but they were in a small minority.

Unfortunately for the empirical base of PCBP, however, the extreme case is much more likely to be the source of data for published papers than the routine case. This publication practice, sometimes referred to as selection bias (e.g., Berkson's bias), is typical not just of clinical psychology and psychiatry but also of clinical medicine. A long line of research shows that in any field of clinical science, extreme cases (multiple presenting problems) are more likely to be used for research and teaching than otherwise normal cases (one presenting problem). From the standpoint of professional education, this bias makes sense; the extreme case or the textbook case, as it were, provides a richer source of teaching material than the routine case. Yet the institutionalized practice of basing professional teaching mostly on extreme cases has its limitations. For example, the practice can result in the overinterpretation of routine cases, especially in clinical settings. Additionally, it probably diminishes incentives to study routine cases.

There are three important implications for PCBP to draw from the extant research on child behavior problems. First, a small but growing body of directly relevant research, as well as a long line of indirect study (e.g., on selection bias) supports our assumption that the initial evaluation and treatment of children with mild to moderate behavior problems is appropriate for PCBP. Second, it is incumbent upon PCBP practitioners to ably distinguish between routine and severe cases in order to make appropriate referrals. Third, the historical mainstream emphasis on the search for psychopathology in children with behavior problems and the resulting differential emphasis on extreme cases is a research opportunity for PCBP (e.g., research exploring the spectrum of normality in populations of children with bona fide psychological and behavioral problems is needed).

C. Evaluation of Treatments

The growing research on hair pulling in children is a good bridge from tests of psychopathology to research on treatment of behavioral problems presenting in PCBP. Reviews of the literature on chronic hair pulling or trichotillomania have shown that there is a spectrum of severity and that in many individuals, especially young children (i.e., younger than 10), hair pulling is a relatively simple habit (albeit with potentially serious consequences) similar in function and situational presentation to other simple habits such as thumb sucking. This point is not intended to downplay the seriousness of classic cases of trichotillomania where those afflicted experience frequent powerful urges to pull their own

hair, psychological satisfaction when they do so, and cosmetically significant hair loss. Although effective therapy exists for such cases, its dependence on specialized knowledge and its inherent complexity places it well beyond the bounds of PCBP. Such cases are at the pathologic end of a spectrum of severity in which mild and moderate cases also exist. In fact, as research on trichotillomania evolves, mild and moderate cases may ultimately be classified in other ways, leaving only the more serious cases in the diagnostic category. Regardless, the children in the mild and moderate portions of the spectrum are indeed pulling their own hair and many present with serious hair loss. In support of the position we have taken, multiple published papers have described many cases of child hair pulling that resolved with treatments suitable for use in PCBP. Our case illustration (described below) will describe one of these cases. We used hair pulling for the case illustration because it, perhaps more than any other child problems appropriate for initial evaluation and treatment in PCBP, is believed by most clinicians to be reflective of psychopathology and in need of specialty care. Below we will briefly discuss some of these other problems with particular attention paid to the success of PCBP appropriate treatments that have been used with them.

1. Risky Infant Behavior

Crawling, cruising, and early walking infants explore their worlds with enthusiasm and tenacity. Although essential to healthy development, these explorations often lead to danger (e.g., electrical outlets, fireplaces, swallowable nonedible objects). Informed parents can minimize risks to their infants by “childproofing” their home, but no home is risk free. The parental task remaining after risks have been reduced involves actually teaching children to avoid the dangerous objects and situations that remain. Typical tactics include redirection, stop commands, warnings, threats, and even mild corporal punishment (e.g., slight slap on the hand). Despite use of these tactics, risky infant behavior often continues and sometimes even increases. From the theoretical perspectives of PCBP, this perpetuation of risky behavior is readily explained. Infants explore mostly when they are otherwise not engaged and most of their exploratory behavior produces little adult attention. When the behavior becomes risky, however, adult attention is quickly engaged, redirection and/or mild discipline is employed, and experiential contrast is produced for the infant. But because adult attention is such a powerful incentive for infants, and because the contrast it produces in these instances typically occurs

in a context involving little or no social stimulation for infants, it can strengthen rather than weaken the infants’ risky tendencies.

An important study, derived from this interpretation, was conducted with teenage mothers who had been reported for abusing their 1-year-old children. In the study, the mothers were taught to use language more effectively (e.g., eliminate threats, reasoning), focus on doing rather than on abstract personality traits (e.g., “you are so stubborn”), establish “time in” (e.g., by increasing physical affection, using more pleasing voice tones, more play times), and to use a brief time out (i.e., a few moments in a playpen) when their child engaged in risky behavior. Risky infant behavior dropped to near zero levels and mother–child interactions improved dramatically. Although some special training was necessary for these mothers, this approach is readily taught to older, more experienced mothers who bring their concerns to primary care.

2. Bedtime Problems

One of the most common presenting problems in PCBP involves resistance to bedtime (e.g., some combination of crying out, calling out, and coming out from the bedroom after bedtime). Several aspects of behavioral style may contribute to this difficulty. Children who are persistent and slow to adapt may resist and prolong the bedtime routine. Children with a low rhythmicity of relevant biologic processes may develop an erratic sleep schedule and not be tired at bedtime. Regardless of origin, bedtime resistance often generates experiential contrast of the type (e.g., contact with the parents) that perpetuates problem behavior.

Several PCBP appropriate treatments have been shown to be effective at curtailing resistance and establishing reasonable bedtimes. They achieve their success by modifying parental responses to achieve a more effective use of language, a focus on doing, an increased child experiential payoff for compliance, and a decreased experiential payoff for resistance. The bluntest form of PCBP treatment for bedtime problems involves ignoring the children altogether after they have gone to bed and extending appreciation for the night thus spent in the morning when they get up. This procedure is controversial because it can produce severe “bursts” of crying, especially in persistent children with slow adaptability to change and these bursts can be very difficult to manage even for confident, experienced parents. A more modulated version of this approach involves graduated ignoring (e.g., ignoring for 5 minutes the first night, 10 the second, and so on). An apparently equally effective

(as indicated by comparative published research) less controversial technique involves establishing pleasant bedtime routines that occur when children comply with bedtime procedures and suspending the procedures when they do not.

A final technique was the subject of a recent scientific report and it is a classic demonstration of PCBP treatment as an early intervention. The technique is called the bedtime pass and it involves providing children with a pass, constructed by the parents, for use as an exchange for one trip out of the bedroom after bedtime. During the trip the children are allowed to make one request of their parents that can be satisfied readily with an action (e.g., request to use the bathroom, have a drink, obtain a hug). Once the action is satisfied, the children surrender the pass and return to bed. The recent report showed the program was highly effective with children who were routinely disruptive at and after bedtime. Additionally, the pass was deemed more acceptable than ignoring or the family bed by groups of pediatricians and parents.

3. Routine Oppositional Behavior in Younger Children (1 to 7 years)

Oppositional behavior in younger children is common. Instructional control is not an inherent trait; it is a learned skill and although children whose behavioral style is marked by easy adaptability, positive mood, and low intensity may learn it with minimal effort on the part of parents or teachers, other children learn it much more slowly. Relevant to the PCBP view, there is a very large literature, including numerous scientific papers and books that derive their message from those papers, on how to teach instructional control skills to younger children. The fundamental method emphasized in this literature involves the tactics we have discussed here. Specifically these include effective use of language, heightened focus on what the children do, increased time in, and imposition of experiential consequences that increase the likelihood of appropriate behavior and decrease the likelihood of inappropriate behavior. Detailed examples of this kind of child training are provided in a selection of books in our recommended reading section.

4. Routine Oppositional Behavior in Older Children (7 to 12 years)

As the social environment of children expands, the potential for direct parental control contracts. Said differently, as children's important social relationships increasingly develop outside their home and family, social influences that compete with parental influence mount

and the possibilities for opposition to parental authority increase. As with younger children some of the opposition occurs in the home (e.g., chores undone) but increasingly with age some occurs outside the home (e.g., poor grades, school rules broken, curfew violations). Multiple studies have shown that effectively managing routine opposition in these older children involves the general tactics used with younger children (e.g., effective use of language). The critical difference involves the composition of the experiential consequences used to increase and decrease behaviors of concern. Whereas various forms of time out are usually sufficient for younger children, tactics such as contingent access to family and home resources (television, telephone, bike, etc.) and contingent permission to leave the home are needed, in addition to time out, for success with older children.

For example, an early (1972) study demonstrated that a simple home point system, where points earned or lost contingent upon appropriate and inappropriate behavior were used to "purchase" special privileges, dramatically improved the behavior problems of a group of misbehaving older children. Since then, many studies using similar tactics, although often in a less elaborate form (e.g., without a point system), have been used to successfully reduce opposition to parental authority in older children. Directly pertinent to this chapter is the fact that these methods can be prescribed readily in PCBP sessions.

5. Nocturnal Enuresis

Nocturnal enuresis involves nighttime urinary accidents that occur in children over the age of 5 who do not have a causal organic condition. The National Health Examination Survey estimated that as many as 25% of first-grade boys and 15% of first-grade girls were enuretic and not surprisingly, given its high prevalence, enuresis is one of the most frequent presenting problems in PCBP. Pertinent to this chapter is a voluminous body of scientific evidence showing the effectiveness of the urine alarm, a treatment for enuresis that is entirely consistent with the theoretical assumptions of PCBP and well suited to its practice. The alarm displaces the ineffective use of language (threats, reasoning, etc.) that often accompanies enuresis before it is seen professionally. Bedwetting children cannot be talked, threatened, or reasoned into continence. If they could, enuresis would be much more rare. The alarm is connected to a moisture-sensitive switching system and as little as one drop of urine completes the connection and turns it on. The alarm emits an unpleasant stimulus but the child

can easily turn it off and thus continence-based learning occurs on two fronts. First, accidents produce the alarm (i.e., unpleasant experiential consequence) which reduces their likelihood. Second, turning off the alarm produces pleasant (or at least preferred) experiential consequences (escape from the alarm) that increase the likelihood of waking after or during the accidents. Initially the latency between the onset of urination and the alarm is large but it reduces over time until escape from the alarm segues into avoidance of it altogether (i.e., the latency ultimately decreases to the point where accidents do not occur and the alarm does not go off). This explanation of how the alarm works is accurate but highly simplified. The fundamental point is that the alarm can be used readily in PCBP and it works. The alarm has not just been shown to be effective; it has been shown to be more effective, in terms of continence achieved and relapse avoided, than any other treatment used for enuresis including all other behavioral approaches and a variety of medications.

6. Habit Disorders

Habitual repetitive behaviors are common in young children. For example, between 25% and 50% of children younger than 4 exhibit habitual thumb sucking. Smaller, but substantial, percentages of children exhibit other habitual behaviors such as head banging, body rocking, nose picking, fingernail biting, or hair pulling. These habits are typically benign in young children and the PCBP service offered is usually supportive counseling. But perpetuated (beyond specified age norms) or singularly intense practice of the habits places children at risk and in need of prescriptive behavioral pediatric treatment. A large collection of studies document the effectiveness of treatments, based on assumptions of PCBP (e.g., time in, simplified instruction, targeted consequences), for a broad range of problematic habits in young children (see case illustration below).

Effective treatment of habit problems in older children usually involves more complex approaches and more active participation of the child than treatment for young children. The most outstanding example of such treatment is habit reversal, a habit treatment package based on the assumptions underlying PCBP, suitable for use in PCBP, and more empirically supported for treatment of a broad range of habits (from tics to tantrums) than any other approach described in the literature. In its conventional form, habit reversal is a multicomponent procedure that includes relaxation training, self-monitoring, situations (where habits are likely to occur) review, awareness training, review of

consequences (of the habit), social support, and competing response exercises. Although the number of components in habit reversal may make it seem impractical for some PCBP practitioners, especially those whose sessions are short (e.g., pediatricians), streamlined versions have been shown to be just as effective as the full package. For example, a recently published study showed that an abbreviated version of habit reversal, including only brief relaxation and competing response exercises, eliminated habitual mouth biting in a 16-year-old boy. The biting was a long time habit that occurred almost “unconsciously” especially when the boy was nervous or bored. Treatment was delivered in one session and results were produced almost immediately. This study (and many others like it) supplies the empirical basis for our conviction that habit reversal is a valuable part of the PCBP armamentarium.

7. Other Problems

The examples above represent only a small sample of empirically supported treatments for problems presenting in PCBP. Successes with similar treatments (i.e., PCBP appropriate) have been documented for many problems not mentioned, including difficulties with feeding, encopresis, recurrent abdominal pain, other “learned illnesses,” early onset anxiety, simple phobias, other mild anxiety problems, attentional problems, and school problems. Collectively the breadth of the problems, and the extent of the evidence showing their successful treatment, supplies a major part of the empirical basis for the rapidly expanding view that PCBP is a highly appropriate and important approach to mild and moderate child behavior problems.

V. CASE ILLUSTRATION

A 3-year-old girl was seen for chronic hair pulling of 1 year's duration. The hair pulling had resulted in abnormal hair loss on the crown of her head (approximately a 13 × 8 cm patch). The hair pulling occurred mostly during sedentary activities or during the onset to sleep. She did not exhibit other significant behavior problems and was described by her parents as happy, compliant, and highly intelligent. The parents had tried several procedures to stop the hair pulling with no success. These included scolding, reasoning, hats, edible rewards for not pulling, and spanking.

The treatment for hair pulling involved three components: (1) increased nurturing (i.e., time in) was provided by asking each parent to increase physical touching

by 50 touches per day and to play with their daughter at least 10 minutes per day, providing frequent praise and avoiding questions, commands, or criticisms. In addition, the usual bedtime routine was extended by 15 minutes. (2) The child was placed in time out for 3 minutes contingent on observed hair pulling. (3) Response prevention was used to help the child limit her hair pulling. The child agreed to select a pair of loose fitting cotton socks (hand socks) to be placed over her hands if she was observed pulling her hair while in time out. She also wore the hand socks to bed at night. Three days per week one parent observed the child for the presence or absence of hair pulling during 5 high-risk 1-hour time intervals. The percentage of intervals during which hair pulling occurred was recorded for each day.

A within-series withdrawal of treatment (ABAB) experimental design was used to assess the effects of treatment. This design involves periods of no treatment baseline (A) and periods of treatment (B). Experimental effects are determined based on differences between the A and B periods. For example, high levels of the target behavior during the baseline (A) periods contrasted with low levels during the treatment (B) periods are strong evidence that the treatment works (reduces the target behavior). During the initial baseline period in this case, hair pulling occurred in 76% percent of the observation intervals (see Figure 1). During the first treatment period, hair pulling reduced to 22% of intervals. During the second baseline period, hair pulling resumed at the original baseline levels and during the second treatment period it reduced to zero levels, where it stayed. The use of hand socks at bedtime was stopped after 2 months, but the parents continued the use of increased time in. Six months after the study, hair pulling was still at zero levels, and at a 2-year follow-up the child had a full head of hair, approximately 14 inches in length.

This case is a classic demonstration of PCBP, for at least three reasons. First, it involves a behavior problem, chronic hair pulling, that it is routinely viewed as evidence of psychopathology. The evaluation and treatment used here, however, negate this view. The pulling was not accompanied by other problem behavior, responded readily to direct treatment, and did not recur in another form during or after treatment. In other words, the pulling appeared to be a simple habit disorder presenting in an otherwise normal child and an appropriate context of care for such problems is PCBP. Second, the clinical approach involved both forms of PCBP, supportive counseling (e.g., the pulling was placed in its appropriate developmental and prognostic context) and prescriptive treatment. Third, the prescriptive treatment was based on

the theoretical assumptions of PCBP. The parents' verbal interactions with their daughter regarding pulling were reduced to a highly simplified and quantitative minimum. The focus of their interactions was directed away from what their child thought, felt, and said about pulling and onto pulling itself (i.e., doing). For example, their repeated attempts to obtain an explanation for the pulling from their daughter or to reason with her about it were terminated. They imposed consequences (time out) for pulling that involved the type of experiential contrast (unpleasant, nonpreferred) that would reduce its likelihood in the future. Lastly, in order to increase the amount of contrast produced by time out, the parents employed various methods to increase the experientially pleasant aspects of their daughter's life (i.e., to increase time in).

VI. SUMMARY

There is a vast number and array of child behavior problems that, although not necessarily representative of true psychopathology, do pose psychological risks for the children who exhibit them and for their families. Almost all of these problems are initially seen in primary care settings and, absent a deterioration sufficiently serious to warrant specialty care, the majority are seen only in primary care. To remedy the problems early and obviate the risks they pose, we propose they be evaluated and treated within pediatric primary care itself via a special branch called primary care behavioral pediatrics. The principal types of therapies used in PCBP are supportive counseling and prescriptive behavioral treatment. Supportive counseling involves placing presenting problems in their appropriate developmental and prognostic context and prescriptive behavioral treatment involves the provision of procedure-based interventions for their remediation. PCBP is a multidisciplinary specialty but its practice is largely confined to psychologists and physicians. Limitations on time and in training, however, may reduce the physician's ability to deliver more complex procedures or to modify treatment in accord with unexpected responses. But because the physician is very likely the first professional to whom behavior problems are reported and because there often are medical considerations in the evaluation of behavior problems, the position of this chapter is that a partnership between physician and psychologist is optimal for practice. A representative sample of problems appropriate for PCBP includes risky infant behavior, oppositional behavior in younger and older children, bedtime problems, incontinence, and various habit disorders. It is important to stress that PCBP is not

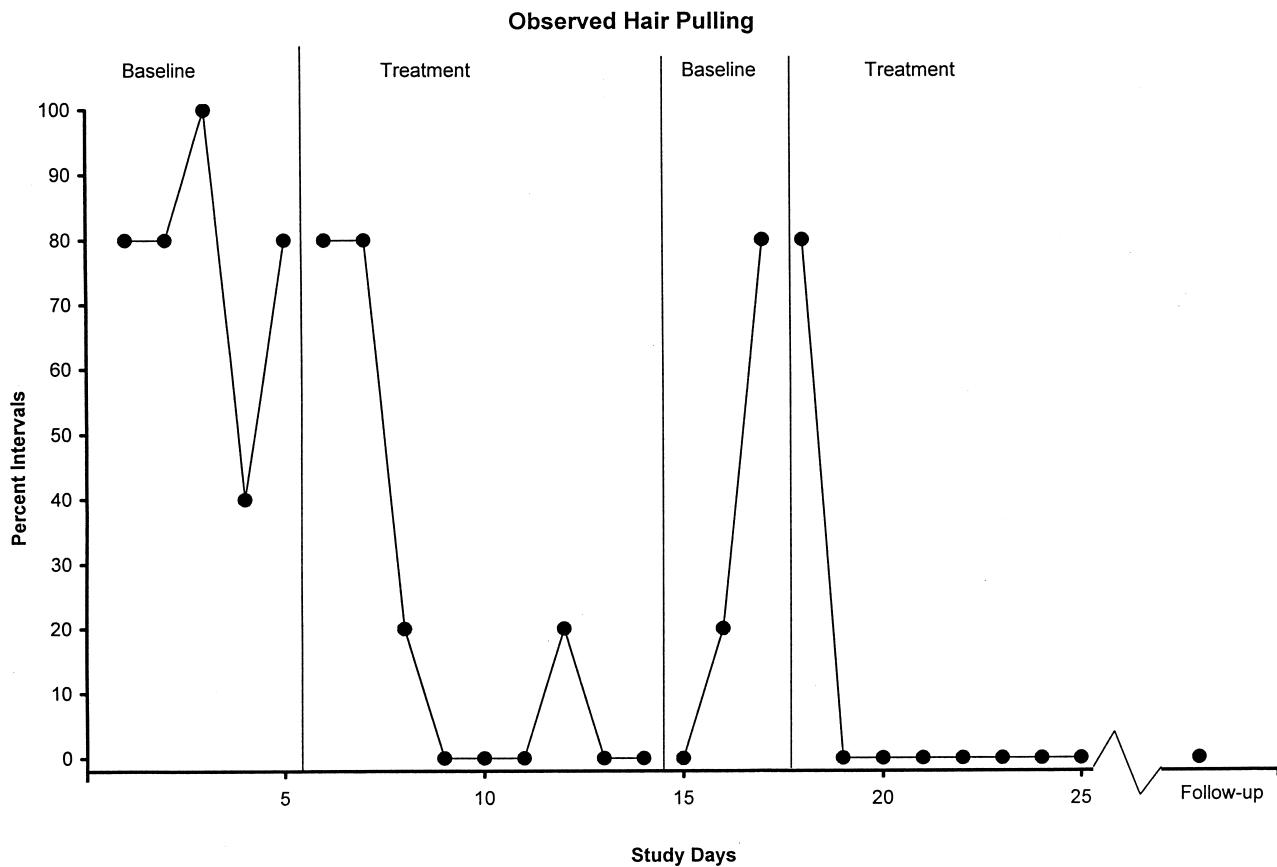

FIGURE 1 This figure shows the effects of treatment on hair pulling. The data points represent the percentage of intervals where hair pulling occurred. During baseline periods treatment was not administered. Reprinted with permission from *Pediatrics* 91, 944. Copyright 1993, the American Academy of Pediatrics.

a universal approach for behavior problems in childhood. It is rather best viewed as the optimal domain for early intervention. Serious diagnostic conditions such as major depression, suicidal behavior, or delinquency represent boundary conditions for PCBP and should be referred for specialty care as soon as they are identified. Additionally, referral is recommended when presenting problems prove resistant to supportive counseling and prescriptive treatment. Behavioral pediatrics is thus proposed as a supplement to and not a substitute for existing care systems.

to be aware of muscle tension and to release quickly that tension. One common system of progressive relaxation involves tensing and releasing various muscle groups until a deeply relaxed state can be accomplished through simply recalling the feeling of relaxed muscles. Progressive relaxation is used with a variety of populations to alleviate a range of complaints including anxiety, depression, and psychophysiological disorders.

GLOSSARY

autonomic nervous system The part of the nervous system that controls involuntary actions of the smooth muscles, heart, and glands. Consists of sympathetic and parasympathetic portions.

psychophysiological Pertaining to the branch of psychology that is concerned with the biological bases of psychological processes.

sympathetic nervous system The part of the autonomic nervous system that inhibits or opposes the effects of the parasympathetic nervous system, as in reducing digestive secretions, speeding up the heart, and contracting blood vessels.

systematic desensitization A behavior therapy technique that is used to reduce or eliminate anxiety. Deep muscle relaxation is paired with imagined scenes or actual anxiety-provoking situations that increase in intensity.

Progressive relaxation represents a group of therapeutic techniques that seek to reduce one of the physiological manifestations of anxiety by teaching a person

I. DESCRIPTION OF TREATMENT

A. The Basic Procedure

Progressive relaxation training should take place in a quiet, dimly lit room with little chance of disruption. The client is seated in a chair that completely supports the body, thus enabling tension and relaxation of all required muscle groups. The client is encouraged to wear loose-fitting clothing to prevent the distraction of uncomfortable attire.

Progressive relaxation training involves teaching the client to tense and relax a series of 16 muscle groups: (a) dominant hand and forearm; (b) dominant biceps; (c) nondominant hand and forearm; (d) nondominant biceps; (e) forehead; (f) upper cheeks and nose; (g) lower cheeks and jaws; (h) neck and throat; (i) chest, shoulders, and upper back; (j) abdominal or stomach region; (k) dominant thigh; (l) dominant calf; (m) dominant foot; (n) nondominant thigh; (o) nondominant calf; and (p) nondominant foot. To begin, the client is

encouraged to focus on the first muscle group and to tense the muscles in that group for a period of 5 to 7 sec. Then the client is instructed to relax the muscle group for 30 to 40 sec. During both tension and relaxation, the therapist helps focus the attention of the client on the muscular experience. Comments such as, "Notice what it is like to have tension/relaxation in these muscles" are useful. The tense-relax sequence then is repeated with the same muscle group, with an increase in relaxation time to 45 to 60 sec. The client is required to attain full muscle relaxation with each muscle group before progressing to the next group. The therapist asks the client to signal complete relaxation by raising a finger of the right hand before continuing to the next muscle group. If the client does not report total relaxation in the specified muscle group, the tense-relax procedure is repeated. To avoid muscle fatigue or pain, repetition should not exceed four or five times.

With the application of the tense-relax sequence to the chest, shoulders, and upper back, breathing cues are added to the instructions. The therapist begins including mild suggestions about breathing into the script (e.g., "Notice your slow and regular breathing"). In addition, the client now is instructed to take a deep breath and hold it during the tension phase and to release the breath during the relaxation phase of each subsequent muscle group.

Upon completion of the entire sequence, the therapist reviews the targeted muscle groups and encourages the client to continue to relax. Then, the client's overall level of relaxation is assessed. Once again, the therapist asks the client to signal when a state of complete relaxation throughout the body has been achieved. If the client does not signal complete relaxation, then the client is asked to signal tension in a muscle group as the therapist lists the possible groups. On the identification of tension, the tense-relax sequence is repeated. The assessment phase is continued until complete relaxation is obtained or until the therapist decides to terminate the training. Prior to concluding the training, the client is allowed to experience complete relaxation for a few moments. At this time, the therapist makes comments that aid the client in remaining focused on the feeling of relaxation. After a few minutes, the therapist may begin the termination process.

The therapist guides the client out of the relaxed state by asking the client to begin moving muscle groups. For example, the therapist may count backwards from 1 to 4, informing the client to move legs and feet at 4, arms and hands at 3, head and neck at 2, and to open the eyes at 1. The client is encouraged to continue feeling re-

laxed and calm. In addition, the client is prepared for the possibility that he or she may feel dizzy or disoriented on emergence from the state of deep relaxation.

Relaxation is a skill that cannot be perfected without practice. Therefore, the client should be encouraged to practice twice a day for 15 to 20 min. The therapist helps the client identify appropriate times and places to practice progressive relaxation. For best results, the client is asked to practice on a comfortable chair or bed when there is no time pressure and little chance of disruption.

B. Variations on the Basic Procedure

Once the client is able to completely relax the 16 muscle groups, the therapist condenses the progressive relaxation procedure to decrease the amount of time needed to reach a fully relaxed state. Frequently, the initial 16 muscle groups are decreased to 7 muscle groups including: (a) dominant arm; (b) nondominant arm; (c) facial muscles; (d) neck and throat; (e) chest, shoulders, upper back, and abdomen; (f) dominant thigh, calf, and foot; and (g) nondominant thigh, calf, and foot. The procedure can be further reduced to include 4 muscle groups in the tense-relax sequence: (a) arms, hands, and biceps; (b) face and neck; (c) chest, shoulders, back, and abdomen; and (d) thighs, calves, and feet. The client must master each variation both in session and during home practice before progressing to the next version.

Following competence in relaxation through the tense-relax sequence, the client is introduced to relaxation through recall, or muscle relaxation achieved through memory of the relaxed state, without the initial tension. The therapist encourages the client to think about a particular muscle group and then relax by remembering how to release those muscles. After focusing on the relaxed muscle for 35 to 45 sec, the therapist asks the client to signal if the muscle group in question is relaxed. Similar to the basic procedure, the client should achieve complete relaxation in a muscle group prior to proceeding to the next group. Also, the therapist may repeat a muscle group if needed. This new approach is incorporated into the home practice sessions.

When the client becomes proficient at relaxation through recall, the therapist transitions the client into relaxing the entire body by counting from 1 to 10. The therapist first introduces this technique when the client already is in a relaxed state. After relaxing each muscle group through recall, the therapist instructs the client to notice all the muscles in the body continuing to relax as the therapist counts to 10. Once the client has

practiced this approach at home several times, the therapist works with the client toward reaching a relaxed state solely by counting from 1 to 10. Again, the client must practice this skill.

C. Applied Relaxation

The goal of progressive relaxation training is for the client to learn an effective way to reduce muscle tension in daily life. Therefore, the client needs to learn to transfer these skills from the twice-daily practice sessions to routine situations throughout the day. The process of using relaxation skills in specific stressful situations is called “applied relaxation.” Applied relaxation training as described by psychologist Douglas Bernstein and colleagues, consists of four components. First, the client learns to monitor tension in the body and notice when the body begins to move away from a relaxed state. Second, the client becomes adept at implementing relaxation responses subsequent to the detection of tension. Next, frequent practice is recommended to improve the skill of the client at deploying relaxation strategies. Last, the client learns several different approaches for reclaiming a relaxed state to optimize the chance of success in a variety of anxiety-provoking situations.

II. THEORETICAL BASES

Several conceptual explanations have been theorized to account for the ability of progressive relaxation to reduce anxiety. Edmund Jacobson’s work in the first half of the 20th century represented the first significant attempt to investigate this relationship. In his early studies, Jacobson observed that the subjective state of anxiety was accompanied by a contraction of muscle fibers. In subsequent investigations, he observed that thoughts of physical activity elicited corresponding electrical activity in the expected muscle group. Similarly, absence of thought was associated with negligible electrical activity in the musculature. Using the earlier information, Jacobson theorized that prolonged stress resulted in chronic tension. This chronic tension caused excessive strain on the musculature and a sustained increase in activity in the central nervous system that contributed to a variety of pathological conditions. In Jacobson’s view, deep relaxation of the muscles would decrease activity in the central nervous system thus preventing and ameliorating psychological and/or physical distress. In 1938,

he developed the tense–release procedure he named progressive relaxation and used it to treat anxious people. By 1962, the therapy was an intensive experience involving 15 muscle groups and extending over 50 hour-long sessions of training.

Around 1950, the inclusion of an abbreviated form of progressive relaxation in a successful treatment for anxiety called systematic desensitization precipitated another wave of empirical scrutiny. Systematic desensitization is a treatment approach that entails imagined or actual contact with the feared stimuli in stages progressing from least stressful to most distressing. At each stage, an individual is encouraged to experience the stimuli until a reduction of anxiety occurs, thus lessening the learned fear. The subjective experience of anxiety is thought to have cognitive, behavioral, and physiological components. When a person experiences anxious arousal, increased activity in all of the components contributes to the amplification and length of the anxious state. Psychologist Joseph Wolpe theorized that muscle relaxation was physiologically incompatible with the experience of anxiety. Therefore, relaxation intervenes in this process by reducing physiological arousal. As such, the presentation of a feared stimulus coupled with a physiological state incompatible with fear could eventually eliminate the conditioned anxiety response.

Additional research has supported this theory. The physiologist Ernst Gellhorn developed the most thorough explanation of the mechanisms by which progressive relaxation affects the autonomic nervous system. Gellhorn theorized that relaxed muscles correspond to a decrease in activity in the autonomic nervous system caused by the lack of feedback information from the skeletal muscles. The physiological aspects of anxiety are activated by the part of the brain that stimulates the sympathetic nervous system, or the reticular system. Gellhorn noticed that a large proportion of the nerve input into the reticular system came from fibers in the skeletal muscles. As such, progressive relaxation reduces autonomic arousal (e.g., decreased heart rate and blood pressure) by reducing input to the reticular system and therefore, the sympathetic nervous system. In addition, nerve fibers also connect the reticular system to the cortex: the area of the brain associated with the feeling of nervousness and increased vigilance. Thus, progressive relaxation may also dampen alertness and cognitive activity. Indeed, the research of psychologist F. J. McGuigan revealed that all thought is associated with muscular activity. Hence, reduction of muscular activity can result in a lessening of cognitive activity.

III. APPLICATIONS AND EXCLUSIONS

A. Applications

Progressive relaxation was developed to reduce tension in clients who have chronic anxiety problems; thus early applications were predominately limited to this population. However, in recent years the range has greatly broadened to include a variety of people who suffer from an extended scope of problems including insomnia, hypertension, tension headache, explosive anger, chronic pain, and depression. In addition, progressive relaxation occasionally is used to aid the therapeutic process. For example, relaxation training may enable a client to discuss a particularly distressing topic. On the other hand, research suggests that progressive relaxation works best when the central difficulty is tension. Progressive relaxation is appropriate for both adults and children, and there is a manual that includes suggested amendments in procedures for children with special needs.

In their 2001 manual, Bernstein and colleagues recommend a pretraining inventory to assess the appropriateness of a client for progressive relaxation training. First, any biological bases for the presenting problem should be ruled out. Second, the therapist should assess the possible risks of relaxation for that client. For example, a client may have an injury that is aggravated by repeated tensing and releasing of a muscle group. Next, if possible, the client should discontinue the use of any muscle-relaxing drugs as they may interfere with the client learning how to control tension and relaxation. Finally, the therapist should consider whether progressive relaxation training is likely to alleviate the client's complaint.

B. Exclusions

There are a few reasons why some clients may not benefit from training in progressive relaxation. However, adjusting some basic procedures can accommodate the limitations of most clients. For example, if a person has an injury that prevents tensing a muscle group, the therapist may instruct only to relax that muscle group thus forgoing the tension phase. Similarly, clients with breathing difficulties (e.g., chronic congestion due to smoking or allergies) may need to sit upright for the training to prevent coughing. Other exclusionary factors are more serious. For example, individuals who lack muscle control will, obviously, not

benefit from this intervention. Second, a minority of individuals experience "relaxation-induced anxiety" that may prevent them from gaining any benefit from relaxation training. Relaxation-induced anxiety refers to a variety of symptoms including fear of losing control, increased tension, and increased indications of anxiety that appear to be triggered by relaxation. Third, relaxation approaches are ineffective when skill deficiencies rather than anxiety appear to be the problem. For example, highly test-anxious college students are helped more by instruction in test-taking skills than by relaxation methods. Finally, there are many disorders for which progressive relaxation has been found to be inappropriate (e.g., muscle pain disorder, excessive gastric acid output, tinnitus).

IV. EMPIRICAL STUDIES

Progressive relaxation has been applied to a large variety of physical and psychological complaints. This section reviews the research on those classes of disorders most frequently investigated in connection with relaxation methods. As the original progressive relaxation procedure was designed to counteract anxiety, the majority of the research falls within this topic area. In addition, a considerable amount of research has investigated progressive relaxation as a component in the treatment of depression. Finally, progressive relaxation also is used to help treat psychophysiological disorders such as headache, hypertension, insomnia, and chronic pain.

A. Anxiety Disorders

Progressive relaxation training is an element present in the treatment of almost all anxiety disorders including generalized anxiety disorder, panic disorder, specific phobias, and posttraumatic stress disorder. Progressive relaxation training is often used as an essential component in a more comprehensive treatment package targeting physical, behavioral, and cognitive aspects of anxiety. For example, although progressive relaxation reduces anxiety, the most successful treatment for generalized anxiety disorder is a multicomponent package that includes cognitive, behavioral, and physiological aspects. The empirical literature reveals that individuals with anxiety treated with a treatment package tend to report significantly less anxiety than people given a placebo, drug treatment, nondirective counseling, or no treatment. Similarly, in the treatment of panic disorder, progressive relaxation alleviates panic to a greater extent

than no treatment. However, the therapies with the most empirical support are multicomponent composed of exposure to panic triggers, cognitive therapy, deep breathing, and progressive relaxation.

In the treatment of specific phobias, repeated exposure to the feared stimuli is essential. Contact with the feared object or situation is introduced in stages through systematic desensitization. At each stage, exposure is encouraged until a reduction of anxiety occurs, thus lessening the learned fear. Progressive relaxation has been used for decades as part of systematic desensitization to facilitate the fear reduction process. Indeed, in a few studies, the addition of a relaxation component to exposure has increased the effectiveness thereby demonstrating its validity as a necessary component of treatment.

Research on the treatment of posttraumatic stress disorder reveals that progressive relaxation alone is not a viable treatment. However, the treatment packages that have empirical support all include a relaxation module. In each therapy program, progressive relaxation is used to create a mood state that resists anxiety in a systematic desensitization, flooding, or stress inoculation procedure.

B. Depression

Applying progressive relaxation procedures to depression emerged from the observation that anxiety symptoms often occur along with depression. Moreover, depression can be exacerbated by stress. A few research studies have demonstrated the superior effectiveness of progressive relaxation alone to no treatment in adolescents and adults with mild to moderate depression and in women with postpartum depression. More frequently, research supports the inclusion of a relaxation component in a comprehensive treatment package for depression. One such treatment program has garnered an extensive amount of research endorsement. The Coping with Depression Course was designed by psychologist Peter Lewinsohn and colleagues to aid in the treatment of depressed adults and adolescents. In clinical trials, it has proven to significantly reduce depression scores and the rate of diagnoses in comparison to a wait-list control condition. Moreover, the empirical literature suggests that results are maintained over time. In addition to progressive relaxation training, the Coping with Depression Course is composed of several treatment components including cognitive therapy, social skills training, pleasant events scheduling, self-monitoring, and training in personal goal achievement in a group setting.

C. Behavioral Medicine

In recent years, progressive relaxation increasingly is used to alleviate the effects of stress-related and psychophysiological disorders such as headache, hypertension, insomnia, and chronic pain. Progressive relaxation training is an effective treatment for both tension and migraine headaches. Recent investigations demonstrated that in the treatment of tension headache, relaxation training is more effective at reducing the strength and frequency of headaches than headache monitoring, false biofeedback, medication placebo, and attention placebo. In addition, gains in treating tension headache through progressive relaxation tend to be long-term improvements. Progressive relaxation in combination with thermal biofeedback appears to be a successful treatment for migraines, proving more beneficial than headache monitoring and medication placebo. Component treatments that include progressive relaxation (or applied relaxation) and cognitive therapy also reduce and weaken migraine headaches more than headache monitoring, and at times, placebo conditions.

Early research on the effects of progressive relaxation on hypertension yielded promising results, leading research reviews at that time to conclude that relaxation training was effective in lowering blood pressure. Unfortunately, many of the positive results of these investigations have not been replicated. In fact, few studies continue to support the benefits of progressive relaxation over blood pressure monitoring and placebo. Currently, more attention is being paid to comprehensive treatment packages that include relaxation as a component along with stress management skills and healthy lifestyle behavior training. However, further research should be done to determine whether progressive relaxation is a useful component in the treatment of hypertension.

Insomnia is probably the most common behavioral medicine complaint that progressive relaxation has been applied to treat. Progressive relaxation is considered to be an effective treatment for insomnia. However, combination treatment packages that also include stimulus control and sleep restriction techniques tend to be more effective than relaxation training alone.

Similarly, multicomponent treatments for chronic pain have proven to be more effective than relaxation training alone. The more effective treatment packages for chronic pain are cognitive behavioral in orientation and composed of goal setting, increased activity and/or exercise, pain education, and medication management. These comprehensive treatments generate more

favorable results than no-treatment control, standard physical rehabilitation, and attention placebo conditions. However, the overall effectiveness of progressive relaxation training on the treatment of chronic pain is unclear as the majority of research is based on lower back and joint pain and pain experienced as a result of rheumatoid arthritis.

V. CASE ILLUSTRATION

“Tom” was a 42-year-old male living alone subsequent to a recent divorce. Tom had no history of previous psychiatric treatment, although he did report a serious head trauma when he was a teenager. At the time of referral for depression, Tom was self-employed as a painter and also performed routine maintenance on several houses. Tom presented for treatment on the recommendation of his parents who were concerned about his lingering depression. In the initial interview, Tom stated that he was apprehensive about therapy and was willing to attend only because it relieved his parents’ fears. Throughout the session Tom sat rigidly upright and gripped tightly the arms of the chair.

As Tom began to trust the therapist in subsequent assessment sessions, he confided that he had been depressed since his divorce 1 year ago. In addition, he had recently experienced suicidal thoughts in the form of visions of himself jumping off the roof of a house that he was painting. He reported that that he did not want to die, but was terrified that he would “lose control” and jump. He stated that this fear caused him a great deal of anxiety resulting in difficulty sleeping and an inability to concentrate on his work. These initial sessions were extremely difficult for Tom as he maintained his high level of muscle tension and stated that it was anxiety provoking to confide his fears to another person.

As a result of the assessment, the therapist concluded that Tom would benefit from cognitive-behavioral therapy for his depression. However, his high level of anxiety surrounding the therapeutic process was a significant barrier to this process. Therefore, the therapist introduced progressive relaxation training as a coping skill to be used during therapy and at his work. The therapist predicted that after mastering progressive relaxation, Tom would be able to discuss his concerns with less distress and be able to examine more readily his thoughts and behaviors.

Progressive relaxation training followed Bernstein and colleagues’ 2001 manual for this purpose. The first four sessions focused on tensing and relaxing 16 major muscle groups. Tom was able to signal deep relaxation during

the second training session. The therapist asked Tom to practice the training on his own at least twice a day. Tom reported practicing three times the first week, but increased his practice sessions in the following weeks as he became more familiar with the procedure. In the next two sessions, the therapist concentrated on tensing and relaxing 7 major muscle groups. Tom continued to report deep relaxation during the training sessions. He also appeared visibly more relaxed. He stopped gripping the arms of his chair during session and presented a more relaxed posture. Tom reported that he was less anxious at work and his suicidal thoughts had decreased. In the next few sessions, the therapist continued the tense-and-release training with four muscle groups. Finally, Tom was able to progress to relaxation with recall training and relaxation with counting training. Tom was instructed to continue to practice at least once daily during the continuation of therapy.

Following the progressive relaxation training, Tom obtained slightly lower scores on measures of depression and greatly reduced scores on measures of anxiety. More important, his fears of committing suicide disappeared. Tom was able to discuss his thoughts surrounding his divorce with less distress. He reported continuing the therapeutic process both for his parents and for himself.

VI. SUMMARY

Progressive relaxation refers to a closely related group of procedures designed to reduce muscle tension, one of the physiological symptoms of anxiety. The described technique involves repeated tensing and releasing of a series of muscle groups. The tense-relax process increases awareness of muscle tension and how to alleviate that tension. After a client achieves deep relaxation with the original procedure, the amount of muscle groups is systematically reduced. Once the client attains a state of deep relaxation using the tense-release system, the client then is introduced to a less intensive way to relax. For example, counting from 1 to 10 as the client relaxes the body is often used to encourage relaxation. In this way, the client learns to reach a relaxed state with less investment of time and energy. Learning the basic progressive relaxation skills enables the client to then utilize the skills in stressful situations in daily life. Progressive relaxation may be used with both adults and children and is easily adapted for individuals with special needs. However, relaxation training is not appropriate for people who cannot control their skeletal musculature. Progressive relaxation frequently is used to treat anxiety

disorders, depression, and several psychophysiological complaints. Progressive relaxation is most effective when included in a multicomponent treatment package.

GLOSSARY

diagnostic evaluation report The vehicle for communicating interpretations of test data that illuminates the underlying personality structure, object-relations paradigms, sources of psychological distress, and the framework for understanding defense constellations, as well as providing treatment recommendations and consultation to the referring therapist.

early memories test Procedures to elicit early childhood memories work from the basic assumption that early childhood memories are retrospective narrative creations that reveal aspects of psychological functioning rather than objective truths about the person's life. Narratives are analyzed using a variety of content and structural scoring systems to assess object-relations themes, character styles, depression, and behavioral disorders.

personality assessment Utilizing various instruments, diagnosticians are able to synthesize an understanding of individual's cognitive style, emotional attitudes, and aptitudes, as well as primary defenses and conflicts.

projective techniques A broad array of assessment procedures utilizing ambiguous stimuli and opaque instructions to conceal the nature of the task and the personality struc-

tures being assessed. Ambiguity presses the individual to organize responses in terms of personal motivations, perceptions, attitudes, ideas, emotions, problem-solving strategies and core dynamic conflicts.

Rorschach inkblot method Hermann Rorschach's perceptual/projective test consisting of 10 standardized inkblots of varying color and form that are administered to the participant one at a time with the request to describe, "What the inkblot might be." From the free associations and the inquiry of the determinants making up a percept, the examiner applies one of several standardized scoring systems to develop hypotheses relevant to personality traits, perceptual and problem-solving styles, prototypic modes of interpersonal relating, degree of thought, mood, and impulse disturbance. Systems for analysis vary from a-theoretical empirical approaches to psychoanalytically derived systems.

thematic apperception test Conceived by Henry A. Murray as a narrative projective device, the TAT consists of 20 scenic pictorials from which participants are instructed to create narratives about the scenes and human representations. Through the participant's imaginative elaborations, the psychological examiner makes inferences about themes most important in the participant's life. From these themes, psychological datum such as the participant's needs and "press," prototypic relationship paradigms, object relations, and understanding of social causality can be ascertained.

word association methods A series of assessment methods utilizing stimulus words or phrases to elicit immediate associations. Thematic analysis and comparison of participant's responses to normative data allows for discerning complexes and defenses.

I. PROJECTIVE TECHNIQUES AND PSYCHOANALYSIS

The demand for assessment techniques that probe beyond the patient's conscious defenses and resistances could only have developed from clinical and theoretical systems that endeavored to comprehend the obscure layers of personality functioning, and to explore the interplay of conflicts and fantasies in the creation of symptoms. Inherent in the psychoanalytic model is the assumption that superficial layers of personality structure are readily available to consciousness, but to comprehend unconscious motivations, fantasies and complexes require the specialized techniques of free association, dream interpretation, and the analysis of the transference. Projective techniques are the logical application of psychoanalytic theory to assess underlying structures.

Assessment methods specifically designed to tap into hidden complexes and conflicts has a rich history involving luminaries and revolutionaries from the psychoanalytic movement. Carl Jung developed the first projective test with the Word Association Task to uncover hidden complexes and conflicts as an aspect of psychoanalytic investigations. Since Jung's test, numerous sentence completion tasks have sprung from the essential theory that irregularities in response style and repetitive patterns of themes reveal underlying conflicts that the patient would not readily reveal through traditional interview methods. Alfred Adler crafted a technique for analyzing early childhood recollections as a projective test that reveals the individual "lifestyle" and major life themes including self-schemas. Although somewhat outside the mainstream of psychoanalytic discourse, Adler's test is widely used by practitioners of the individual psychology movement. Martin Mayman, an analyst from the Menninger Foundation, drew on modern ego psychology and object-relations theory to develop a highly versatile assessment technique by inquiring into specific early childhood memories. Another class of projective test relies on complex pictures depicting people involved in various interactions to which the participant is pressed to create stories that are then analyzed for structure and content. Tests such as the Thematic Apperception Test rely on the participant's apperception of relationships to project their beliefs and emotional reactions in their stories.

Herman Rorschach, one of the first presidents of the Swiss Psychoanalytic Society, is best known for developing the now-famous inkblot method bearing his name. Rorschach believed his method did not uncover

layers of unconscious processes. Rather, he thought of it as an experimental, atheoretical method for assessing personality styles based on the perceptual organization of patient's responses. In his 1921 monograph he made patently clear that the test could not be used to tap into the contents of the subconscious. Thus from its inception, the Rorschach Inkblot Method was considered a perceptual task based on objective scoring criteria of how participants organize the inkblots into images. In this way specific contents were less important than what portions and features of the blot were utilized in the development of the percept. It is now widely acknowledged that Rorschach underestimated the full application of his technique in its ability to reveal aspects of the individual's representational world of self and others. In the last four decades analysts and nonanalytic diagnosticians have broadened the scope of the method from essentially two angles. From an atheoretical stance of a perceptual task, diagnosticians and researchers have developed empirically validated structural variables by correlating them with behaviors and personality constructs. Working from psychoanalytic theory, David Rapaport, Roy Schafer, Steven Applebaum, Sidney Blatt, and Paul Lerner have not only articulated psychoanalytic test theory, they have brought their learning from projective testing to deepen and extend psychoanalysis as a science. Still other analysts have developed specialized psychoanalytic analog scales to assess intrapsychic phenomena such as primitive defenses, object representations, and interpersonal phenomena such as dependency.

Projective techniques encompass a number of methods for measuring personality constructs that makes an all-inclusive definition impossible. Nonetheless, they share some common features and purposes. First, their purpose is to gain insight into the individual personality as a system, rather than assessing one facet or a series of disconnected features. Most tests of this nature rely to some degree on ambiguous stimuli and opaque directions as catalysts for creating data. These tests pressure the examinee to draw on inner resources to respond to visual and verbal stimuli. This forces the examinee to utilize perception, apperception, associative processes, and memory to create responses to the examiner's questions: the more ambiguous the stimuli, the greater freedom to form idiosyncratic responses that reveal aspects of individual personality. A second feature of projective tests is the nature of data analysis—like the examinee's multitude of possible interpretations of the stimulus—the diagnostician interprets data from empirically derived scoring methods, to

more “experiential” analysis that emanates from a well-organized theory of personality.

II. PROJECTIVE TECHNIQUES FOR DIAGNOSTICS AND TREATMENT PLANNING

Testing is generally undertaken to answer questions about puzzling diagnostic possibilities, to determine the presence and form of a personality disorders, and to provide consultation to therapists prior to, or during the course of psychotherapy. The standard method for answering these questions is to select a series of tests that have the greatest potential for answering the referral questions. A second consideration when compiling a battery of tests includes choosing measures that are differentially sensitive to unique manifestations of personality. For example, it is widely held that the TAT and Rorschach tap different levels of “implicit” personality functioning, and that findings from various tests, including self-report measures, provide the opportunity to observe the patient functioning under different circumstances. This data is then integrated into the formulation of the patient’s character organization and the understanding of symptoms and defense configurations (Rapaport, Gill, and Schafer wrote the classic text on this topic).

A review of the diagnostic validity of projective tests in assessing symptoms, diagnoses, and prediction of outcomes would require volumes to complete. Rather than a specific review, the following is a brief sample of how projective testing is used in treatment planning and prediction in psychoanalytic treatments.

Early developments in theory-based psychological assessment can be traced to David Rapaport’s efforts to interpret projective test responses using psychoanalytic theory of motivation, drives, and defensive structure. The fruits of such a major undertaking were best described by Martin Mayman:

Rorschach inferences were transposed to a wholly new level of comprehension as Rapaport made a place for them in his psychoanalytic ego psychology and elevated psychological test findings from mundane, descriptive, pragmatically useful statements to a level of interpretation that achieved an incredible heuristic sweep.

Although Rapaport’s approach was a considerable advance, a broadening of its scope was necessary to capture the experience and influence of the testing sit-

uation and its relation to transference paradigms as they are revealed in the testing situation. Roy Schafer, psychoanalyst and expert diagnostician, wrote the classic treatise on how the testing situation stimulates the expression of underlying dynamic configurations. For Schafer, the constraints of the patient role in being tested is an anxiety-arousing situation that stimulates and exacerbates defensive and transference reactions that can be scrutinized and integrated into the understanding of the patient. This approach brought the prediction of potentially disruptive and useful transference configurations into the scope of diagnostic testing.

Schafer and others were successful in shifting the focus from testing solely to determine analyzability to an approach that emphasizes the assessment of problems that interfere with the establishment of a therapeutic alliance to discover potential therapeutic levers, as well as predicting potential therapeutic stalemates and transference enactments that may not be readily discernible in the course of a standard diagnostic evaluation. The ability to employ new models for predicting transference enactments has become critical, as more patients were referred to treatment with severe character pathology and vulnerability to psychosis and suicide. Such patients create special challenges for therapists and hospital staff because premature terminations, turbulent transference-countertransference struggles and negative therapeutic reactions are more the rule than the exception. Predicting transference enactments are best done through a careful assessment of object relations prior to beginning psychotherapy because the capacity for interpersonal relations depends largely on an individual’s internal array of object representations.

The strength of object relations theory when applied to psychological assessment is that it provides an understanding of the complex interactions among self and object representations, defenses, pathological formations, and ego strengths that make up the entire personality. The clinical utility of testing improved dramatically when diagnosticians shifted from more traditional focus on ego structures and impulse-defense configurations framed in abstract terms, to a middle language, grounded in a patient’s phenomenology that create meaningful clinical generalizations about a patient. Diagnosticians who craft test reports in this middle language create a textured picture of a patient’s character style, their modes of relating and vulnerabilities that alert the therapist to potential pitfalls that may emerge months later during an intensifying transference.

Test data from Rorschach, TAT, and Early Memories protocols are particularly well suited to these newer

modes of data analysis. Psychoanalytic Rorschach scales have been crafted to examine features of self and object representations, generally along a developmental continuum from pathological to healthier and more mature modes of object representation. Two such scales are Sidney Blatt's Concept of the Object scale and Jeffery Urist's Mutuality of Autonomy scale. The former assesses the developmental level of object representations using a variety of projective tests including the Rorschach and the TAT. Utilizing structural variables, Blatt and his colleagues have studied the developmental progression of object representations along more cognitive lines by integrating the theories of Piaget and Werner into the system.

The Mutuality of Autonomy scale was developed for the Rorschach to assess the degree of differentiation of object representations, focusing primarily on the developmental progression of separation individuation from engulfing, fused relations, to highly differentiated self-other representations. Studies have demonstrated that the scale can be reliably scored, has a high degree of construct validity with behavioral ratings, and has been utilized in treatment outcome studies.

Drew Westen's Social Causality and Object Relations scale has been applied to TAT and Early Memories data, as well as interview and psychotherapy process data. Westen's scale assesses both cognitive and affective features of patient's understanding of interpersonal relations and the underlying structures of object representations and the affective quality of those representations. The scale successfully differentiates diagnostic groups and predicts behavioral outcomes such as early termination from treatment. A growing body research attests to its construct and convergent validity.

Early childhood memories have also been utilized to understand crucial aspects of personality functioning. Because of their reconstructive nature, early memories allow patients to express critical life themes in a camouflaged and unconscious way, while revealing their inner object relations, character structure, and prototypic transference enactments. Inner object-relation constellations intrude into the structure and content of early memories, just as they occur repetitively in important interpersonal relationships. This is precisely what makes early memories so revealing of the private inner world, allowing therapists to make informed decisions about therapeutic stance, and timing of interventions in order to facilitate a viable therapeutic alliance. A vast array of studies assessed early memories in treatment planning, determining character organization, and assessing potential transference paradigms.

III. EMPIRICAL EVIDENCE AND THE SCIENTIFIC STATUS OF PROJECTIVES

The fate of projective testing is continuously in question because heated disagreements over the scientific status of projective techniques, most notably the Rorschach Inkblot Method, are consistently engaged in scholarly journals. This article cannot address the scope of this debate but provides some evidence of the utility and empirical validity of the projective techniques, using the Rorschach as the prototype. A brief review is undertaken to examine the accuracy of Rorschach in assessing select disorders, in predicting treatment outcome, and in assessing change during and after intensive psychodynamic treatment.

Research has demonstrated the validity of some, but certainly not all Rorschach indexes in accurate diagnosis. When appropriately formulated, the Rorschach has demonstrated high degrees of validity in measuring specific personality constructs such as interpersonal dependency, ego strength, defense mechanisms, and quality of object relations. In terms of differential diagnosis, specific patterns of Rorschach responses have been correlated with independent diagnosis of schizophrenia; major mood disorders; and antisocial, narcissistic, and borderline personality disorders. Perhaps one of the most important uses of the test is in predicting dangerous behavior during treatment. The Rorschach when appropriately scored and formulated can predict with approximately 75% accuracy which patients will make a lethal suicide attempt within 60 days of the administration of the testing. The Rorschach has also demonstrated that scoring indexes can predict similar levels of accurate prediction of patients who will make a near lethal suicide attempt within 60 days of administration of the test.

Traditional applications of projective testing include their use in clinical settings to predict who will most likely benefit from certain forms of psychological treatment. Anecdotal evidence is far more abundant than scientifically sound studies that support the empirical validation of projective testing in predicting treatment outcome. This is in part due to the fact that most researchers in the field conduct exploratory studies rather than replicating others work. As a result research is not cumulative, making it difficult to summarize the general effectiveness of specific measures in predicting specific outcomes. One stunning exception is the myriad studies of Bruno Klopfer's Rorschach Prognostic

Rating scale (RPRS). In a sophisticated statistical and conceptual analysis, Meyer and Handler analyzed the results of 20 separate studies assessing the validity of the RPRS in predicting treatment outcome. This meta-analysis (involving 752 participants) revealed that the RPRS was highly predictive of subsequent therapy outcome. To examine its predictive power the authors compared the RPRS to other predictor-criterion pairs from various fields including medicine and education. They found the RPRS was a better predictor of psychotherapy outcome than the SAT and GRE scores are at predicting subsequent grade point average. The RPRS as a predictor of psychotherapy outcome was also superior to electrocardiogram stress tests in predicting subsequent cardiac disease. For an enlightening view of how psychological testing compares to medical diagnostic testing, readers will profit from Meyer and colleagues' latest work appearing in the *American Psychologist*.

Steven Applebaum produced two clinically based studies that directly compared inferences based on projective test data to inferences based on traditional interview data. In a small sample of 13 cases, Applebaum found test-based inferences were more accurate than inferences based on interview data. Psychological test-based inferences were most accurate in assessing ego strength, quality of interpersonal relationships, core conflicts, patterns of defense, and transference paradigms. In a second study, 26 additional cases were added to the original 13 to compare interview-based predictions to test-based ones. When psychiatrists and psychological testers disagreed on the predictions, most often testers made correct predictions about the patient's ego strengths, core conflicts, transference paradigms, defense configurations, and the degree of psychological mindedness. The results suggest that projective test data, in the hands of well-trained diagnosticians can be used for making predictions about treatment planning and outcome that is superior to that of clinicians who have clinical data from interviews.

One facet of assessment that has received relatively little attention is the application of projective tests in assessing changes in intrapsychic functioning as an aspect of psychotherapy outcome research. Given that psychoanalytic treatment endeavors to effect structural change, it is remarkable that few researchers have used sensitive measures such as the Rorschach to monitor change. Nonetheless, there are examples of how the Rorschach has been utilized in this manner. Irving Weiner and John Exner, for example, assessed 88 patients prior to starting exploratory dynamic therapy, then retested them on three occasions including at ter-

mination. A second group of 88 patients undergoing brief nondynamic psychotherapy were also assessed throughout the course of treatment and at termination. The researchers chose 27 Rorschach variables indicative of patient's ability to manage stress, perceive reality in conventional modes, modulate affective experience, adaptively utilize ideation, be self-reflective, and represent interpersonal relationships.

Results indicated that 24 of the 27 variables were significantly improved for patients in the long-term dynamic therapy, demonstrating progressive improvements at each testing through termination. Short-term patients also made significant improvement but to a lesser extent than patients in psychodynamic treatments. In a similar study Exner and a colleague replicated the first study with 70 patients, 35 in long-term treatment and 35 in brief therapy. The researchers added a fourth testing after termination. They found similar results with one major exception—improvements for patients in long-term treatments were more likely to be sustained, whereas short-term patients did not sustain improvements at follow-up.

In one of the most in-depth and extensive studies of intrapsychic change (involving 90 psychiatric inpatients with serious disturbances. Sidney Blatt and Richard Ford examined the nature of intrapsychic and behavioral change across all patients, while simultaneously assessing differential change in two distinct groups. At 1 year into treatment, the researchers found that the patients as a whole had made significant improvement in externally validated real-world behaviors such as social behavior and symptom expression (assessed from hospital case records). In terms of structural change measured by the Rorschach, they found statistically significant decreases in the degree of thought disorder, with the clearest improvements in the most serious forms of thought disorder frequently found among patients with psychotic disorders. Patients also demonstrated a greater capacity to engage adaptive fantasy and demonstrated a significant improvement in the quality of object representations, both in terms of decrease in their expectations of malevolent interactions and their ability to represent objects as separate and more autonomous.

Blatt and Ford then assessed the possibility that psychodynamic treatment might affect patterns of intrapsychic functioning in different ways depending on the patient's character structure. Blatt and his research group at Yale University had earlier distilled two essential developmental trajectories corresponding to two global character styles, the anaclitic and introjective.

The anaclitic character's actions are organized around defending against vulnerabilities to disruptions in need-gratifying interpersonal relationships. Anaclitic patients are highly dependent people who often experience somatic symptoms and seek solace and care from others including physicians and therapists. By contrast, the introjective character is focused primarily on issues of self-definition, autonomous identity, and self-esteem. Introjective characters often eschew dependent longings for fear they will disrupt efforts to secure autonomy and clarity of identity.

When patients were divided along anaclitic and introjective lines, interesting results emerged. For patients primarily concerned with maintaining need-gratifying relationships, changes were noted in moving from experiencing relationships as malevolent, controlling and fused, to more benign and differentiated. This structural change corresponded to the anaclitic patients' improved social competence and motivation for treatment. For patients with introjective character organizations, the greatest change occurred in decreased thought disorder on the Rorschach, with a corresponding improvement in clinician's assessment of symptoms—most notably, introjective patients demonstrated significant decreases in psychotic symptoms with corresponding improvement in affect modulation. Blatt and Ford's findings support decades of clinical case reports demonstrating that structural change occurs in specific arenas of functioning most related to the patient's psychopathology. An equally, if not more important finding is the fact that psychiatric patients with severe disturbances appear to benefit from intensive psychodynamic treatment. Finally, they demonstrate the way in which projective techniques can be sensitive to subtle changes in patients' intrapsychic processes and can be quantified to study treatment outcome for large groups of patients.

IV. SUMMARY

This article reported on the evidence for specific uses of projective tests in developing an accurate portrait of a patient's personality—their frailties and strengths. The diagnostic facet of projective testing can be integrated into treatment recommendations for specific patients to

help the therapist develop a working model of the patient's functioning and to help predict potential transference developments. The scientific status of projective testing was considered in light of recent comparisons between the Rorschach in predicting treatment outcome and the ability of medical diagnostic tests in predicting the development of disorders such as cardiac disease. Finally, the use of projective testing to monitor intrapsychic change illuminates the current and potential uses of projective testing in measuring treatment outcome.

GLOSSARY

abstinence The refrain of the therapist/analyst from gratifying the patient's wishes.

adaptational perspective The perspective that addresses the patient's attempts to adjust and compromise with external reality.

clarification A technical intervention on the analyst's part asking the patient to consider the unconscious intentions of the patient's communications.

confrontation The technical intervention on the part of the analyst in which the analyst brings to the patient's awareness some aspects of feelings, thoughts, or context of which the patient has been unaware.

countertransference The experience of transference by analysts and therapists.

free association The technical instruction from the analyst for the patient to say anything that comes to mind, and to suspend the usual effort to think clearly and coherently and to pass judgement on the appropriateness of the idea.

freely hovering attention A mode of functioning and listening on the part of the analyst in which the analyst is sensitive to symbolic metaphorical communications, and listens in a creative, imaginative frame of mind, attempting to discern the underlying unconscious intentions of the patient's communication.

freely hovering role responsiveness The manner in which the analyst participates in the psychoanalysis, allowing himself or herself to experience the transference, as well as countertransference, forces at play in the relationship.

historical perspective The perspective of psychoanalytic thought that emphasizes the influence of past history on present behavior.

interpretation A technical intervention in which the analyst attempts to assist the patient to understand exactly how and why he thinks, feels, and behaves as he does.

neutrality The stance which the analyst/therapist takes in which he or she does not express personal preferences to the patient and does not ally himself or herself with important dimensions of the patient's conflict.

psychodynamic perspective The emphasis in psychoanalytic theory demonstrating conflict and compromise among various psychological structures to create new behaviors, symptoms, and psychological structures, such as wishes and fantasies.

structural perspective A psychoanalytic view that describes the components of the mind, emphasizing the specific functions and tasks of these components.

topographical perspective A psychoanalytic perspective that emphasizes there are two qualities of mental activity, conscious and unconscious.

transference The tendency to unwittingly construct and create, through an active but unconscious process, the pattern

of imagined and real past relationships with an important person.

I. THE TALKING CURE

Psychoanalysis and psychoanalytic psychotherapy are often referred to as the talking cures. That term emphasizes that psychoanalysts help patients by talking with them and that a conversation is central to what heals the patient. However, although the term *talking cure* captures something very special about psychoanalysis, it is misleading. It fails to stress that at the core of what heals is the relationship between the analyst and the patient, and that their conversation is the way the aspects of that relationship are formed and expressed.

A. Basic Assumptions

An examination of the basic assumptions underlying psychoanalysis and psychoanalytic therapy will further clarify what has just been emphasized. In the past various groups of analysts have come together in more or less official schools, groupings that emphasize somewhat different theoretical perspectives. Today, there is an emphasis on harmonizing those groups, and finding the common ground in the basic assumptions they share. In a recent article, Donna Kline and Stephen Sonnenberg suggested that four basic assumptions were useful in describing contemporary psychoanalysis. These are (1) that the analyst is experienced by the patient as having characteristics of important people from the patient's past, (2) that the patient's actions in and outside the analysis repeat patterns from the patient's past, (3) that some mental activity of all people takes place outside of consciousness, and (4) that people have a wish to understand themselves, to know, and that what is known can lead to changes in the way they think, feel, and act.

It is very important that the analyst is experienced as having characteristics of people from the past. The technical term for this is *transference*, and because it occurs in the relationship between the patient and the analyst, that relationship becomes a living experiment in which the influence of the patient's past on the patient's present life can be explored.

Past patterns are repeated in the present that provide another component of the transference, again making possible an exploration of the effect of the past on the present.

The idea that some portion of mental activity takes place outside consciousness is also of vital importance

in psychoanalysis. Certainly, it is that idea which was central when Freud invented psychoanalysis as a method of personal inquiry and healing: Freud reasoned that when an unconscious idea became conscious it could be examined, and if it was unreasonable, placed in a new perspective. For example, consider a person has a powerful unconscious wish to put a business competitor out of business and fails at his own business out of unconscious guilt over that unconscious wish. When the wish becomes conscious the individual in question can thoughtfully decide to abandon the idea/wish, or perhaps to follow through and develop a business plan that is acceptable and does not cause him second thoughts.

The desire to know is an assumption of psychoanalysis that has not always been sufficiently emphasized. If one pauses and gives serious thought to this matter, one must marvel at the human capacity to question and seek answers. Indeed, were it not for that capacity, one might realize there would be no field of psychoanalysis, no discipline that has at its purpose the illumination of the mysteries of what goes on in the human mind.

A corollary of this assumption is that the wish to know allows the patient and the analyst to come together in an alliance, sometimes called a working alliance, sometimes called a therapeutic alliance. It is certainly the case that a journey of deep self-inquiry will have many rough spots, many difficult times, and it is because the patient and the analyst are joined in a mutual commitment to knowing, to learning, that they can form a relationship in which they examine together often emotionally painful aspects of the patient's life. Put another way, it is the mutual wish to know that binds the patient and the analyst together in a relationship in which they both tolerate the frustration and sometimes painful challenge of the analytic journey.

II. ANALYSIS AS A DRAMA

Another useful metaphor in understanding the technique of psychoanalysis and psychoanalytic psychotherapy is that of a dramatic performance. In the treatment relationship the patient is asked to write a play about his life, and to act many of the roles in that play in his relationship with the analyst. For her part, the analyst is asked to give herself over to the playwright patient and psychologically assume various roles assigned by the patient in the course of their analytic relationship. This vivid process is described by

psychoanalysts when they use the technical terms transference and countertransference.

A. The Transference

This term has already been introduced. The reason to discuss this term further in this section is to emphasize that it is the analyst's responsibility to teach the patient that the creation of the transference—the pattern of past relationships with an important figure—derives from the patient. Most often, the patient “creates” the transference out of an active, though unconscious, aspect of repeating a past experience. At times, this has been thought of as part of the wish to correct the past, but this is not a necessary part of the concept of transference. Rather, the pattern of interpersonal relationships laid down by early experience in our biopsychosocial world may give us few options of choice unless we become aware of our patterns of behavior. When the analyst helps the patient understand consciously this old pattern that is awakened (and is creating a drama driven by past experiences rather than present ones), the analyst helps the patient understand his contribution to the present conflict and for the life he lives.

Analysts are trained to both experience and observe the drama the patient constructs in words in the analytic consulting room. The analyst imagines herself in the world the patient creates, places herself in her imagination in the roles the patient describes for those with whom he interacts, and recognizes how in subtle ways similar patterns are created by the patient in the interactions with the analyst or therapist. The products of those reflections by the analyst are the various ideas the analyst conveys to the patient.

To illustrate this point, imagine a patient who feels helpless in all situations with authority figures. The patient will regard the analyst/therapist as an authority figure. The analyst will feel that role assigned to her, and that feeling will help the analyst understand the helplessness the patient feels.

B. The Countertransference

Psychoanalysis is neither an intellectual exercise nor a spectator sport. In the analytic relationship both the analyst and the patient experience the patient's life in an active, vivid way. In that spirit, psychoanalysts have stated that in their professional relationships with their patients they are participant observers, not simply outside observers. Therefore, analysts and therapists also

experience transference—called countertransference—to the patient when the patient reminds the analyst of an important figure from the past. The analyst's awareness and attention to countertransference permits the analyst/therapist to have a fuller appreciation of the drama of the patient's life. The analyst does not act on the countertransference but rather uses her awareness of these feelings as further information to inform the understanding of the patient's world.

C. Abstinence and Neutrality: The Design of the Therapeutic Encounter

The analyst is restrained in interaction with the patient to words designed to help the patient learn about himself. In that spirit, the analyst strives to create an environment in which the patient feels safe to experience a part of the drama of his life and be able to observe it in this subtle form. This requires that the patient not be burdened with worry about the realities of the analyst's life, values, or ideas about living. The analyst maintains neutrality, does not express personal preferences to the patient, and provides limited information about his or her own life. A corollary of this is that the analyst maintains anonymity, thereby protecting the patient from knowledge of the analyst's personal style and values. The term abstinence refers to the fact that the analyst avoids gratifying the patient's wishes, whatever those might be—praise or punishment—direction or to be left alone. The analyst's task is to understand and to convey the patterns of interpersonal relating that emerge and reflect the past experience of the patient. This occurs in part because the analyst does not praise or punish or in general fulfill the unspoken wishes of the patient. When the patient's wishes remain unfulfilled, they are felt as obstacles by the patient and become available for examination. The concept of abstinence shares a common border with the concepts of neutrality and anonymity. As a group, these aspects of the analyst's behavior might usefully be seen as the way the analyst provides the context in which the patient can both experience and examine the interpersonal drama of his life and its past origins.

III. CORE TECHNICAL CONCEPTS

Four technical concepts of psychoanalysis and psychoanalytic psychotherapy are important to therapeutic process: free association, the metaphors in the

patient's words, freely hovering attention as a mode of analytic listening, and freely hovering role responsiveness as a mode of establishing the countertransference during analytic listening.

A. Free Association

Psychoanalysts have observed that when people think and say what comes to mind their thoughts reveal a layering. On the topmost layer is rational thought, the kind of thinking that takes place when one performs an intellectual task or has a conversation about a particular topic. However, buried in that conscious rational verbal exchange and thinking are the hints of a parallel layer of thought that occurs simultaneously, outside conscious awareness. In this form of thinking, different rules apply. For example, many different things may be represented by a single symbol, a process sometimes described as condensation, sometimes described as symbolization. We see this same logic in other areas—such as a rebus in which a clock with wings represents “time flies,” or when one recalls a vacation at the beach in childhood as a way to remember an entire year of one's life that may include many important but not yet recalled events.

Thus, when the psychoanalyst or psychodynamic psychotherapist listens to her patient, she first instructs the patient to say anything that comes to mind, to suspend the usual effort to think clearly and make sense. When the patient is able to do that, and it is not easy, the unconscious layer of thinking is more apparent, symbols are more apparent, and the analyst can hear somewhat more directly what goes on in the patient's mind outside usual awareness. In fact, this process of free association is always relative and only really becomes free as the patient resolves the conflicts that are the source of his or her pain.

B. The Focus on Metaphor

This core technical concept dovetails with free association. The psychoanalyst believes he or she can best help the patient if the analyst can equip the patient to examine his thoughts, recognize the clues to what is unconscious, examine the unconscious layer of mental activity, and determine how such thinking influences current behavior. Therefore, it is essential for the analyst to listen for the symbolic meaning in what the patient says.

For example, let us imagine that just as thoughts of dogs outside of conscious awareness may represent all four-legged animals, all similarly considered children

who want love and praise may represent all adults who feel starved for love and praise. Let us also suppose that the patient in treatment is one such adult. When asked to free associate the patient may return repeatedly, in many forms, to the subject of children who need love and praise. Suppose also that the patient is a pediatrician who gives lectures to parents about the need of children for parental love and praise. Eventually, through noting when and in what context these associations occur, the patient's hints and verbal symbols about children and their need for parental love may be understood as the patient talking about his own need for love and praise when speaking of the children.

The analysis of dreams is a part of psychoanalysis and psychoanalytic psychotherapy. Dreams have been called the royal road to the unconscious, and certainly they often occupy an important place in a clinical psychoanalytic treatment. Dreams are used in the same way as free associations—a source of material to free associate to, as the patient and analyst/therapist listen for the unconscious concerns of the present and the forgotten links to the past. The analyst listens to the patient describe a dream in a search for symbols and for metaphor to educate the patient and facilitate an understanding of the meaning of the thoughts and the way of thinking, and an appreciation of all the mental activity which is outside conscious awareness.

C. Freely Hovering Attention as a Mode of Analytic Listening

As the analyst/therapist listens to the patient's free associations, he or she listens for the patient's unconscious mental activity. In this listening, the analyst is sensitive to the symbolic communications of the patient. This is not a process that is easy, nor ever automatic, no matter how well an analyst/therapist knows the patient. The analyst listens in a creative, imaginative frame of mind, in which layering of meaning and symbols become vivid experiences for the analyst. The analyst has as background the many previous topics that have been discussed by the patient and the context of these and of the present and past life of the patient.

For example, as the patient describes a needy child, the freely hovering analyst may note that a mental image of such a child has come to mind, and that image may change in the analyst's mind's eye into an imaginary mental image of the patient as a young child. The analyst/therapist continues to listen, now no longer freely hovering, but rather reasoning that perhaps the image is related to a subtle communication from the

patient—how the patient phrased something or the empathy in the patient's associations. The analyst then wonders if he or she should ask the patient if he is talking about himself. If the patient responds in the affirmative, a piece of analytic information has been generated, and the patient has shared an experience of making the unconscious conscious.

D. Freely Hovering Role Responsiveness

Much that the analyst learns about the patient comes from being a participant observer in the analytic relationship. Imagine, then, that along with imagining the patient as a needy child, the analyst began to recognize the patient's subtle but demanding requests that the analyst praise him. That request by the patient and experience by the analyst could come in relatively hidden ways. For example, the pediatrician patient, despite having other alternatives, may ask his analyst to change the times of several hours because he must attend several national professional meetings, at which he has been asked to speak about the emotional needs of children. He may say to the analyst that he is available to meet at times he knows are not the usual working hours. For her part, the analyst may sense with great force the patient's request/demand for special treatment, as part of the recognition of what an outstanding pediatrician he is. The analyst practicing abstinence, neutrality, and anonymity, and using a freely hovering role responsiveness that has thus identified an unconscious meaning in this request, will be able to convey to the patient the particular meaning of the patient's associations and actions within the analytic relationship and wonder if the patient is alert to these feelings and wishes. With appropriate analytic inquiry on the part of the analyst, and a willingness to explore his desires on the patient's part, further insight will be gained by the patient of what he originally thought was only a "practical" request.

IV. CORE INTERVENTIONS

A critical part of an understanding of the technique of psychoanalysis and psychoanalytic psychotherapy includes how the therapist speaks to the patient. While the psychoanalyst listens to the wishes and feelings of the patient that are both conscious and out of awareness in order to have a deep understanding of the patient as another human being, the setting of that listening is specifically restrained. In addition, the ways

of speaking to the patient are designed to effect change in specific ways. In sum, the analyst tries to speak in a way that enhances the patient's awareness of his own unconscious processes, and more generally of how his mind works, so that the patient can learn to practice effective introspection on his own. There are three technical ways the analyst speaks to the patient that are designed to enhance the capacity for insight: confrontation, clarification, and interpretation.

A. Confrontation

At times in psychoanalysis, the analyst confronts the patient with information or observations. The term confrontation in this context does not mean a hostile exchange between analyst and patient, but bringing to the patient's awareness some aspect of feelings, thoughts, or context that the patient is not aware of. In keeping with the notion of the therapeutic alliance, the analyst attempts at all times to create a safe atmosphere in which the analysis will take place. This will be described in more detail later. Nevertheless, it is often the case that the analyst points out, in a kind way, that the expectations or ideas of the patient are quite different from what the patient realizes them to be.

For example, returning to our dedicated pediatrician, suppose he asked his analyst to see him on Saturdays, which she normally took off, and when she refused, said he was going to quit his analysis because she obviously did not care about him. In that instance, the analyst would appropriately point out to the patient that he was assuming that she could see him on Saturday and simply chose not to, and that on the basis of that unproven assumption was ready to stop a much needed treatment. This example, by the way, is common; there are many similar instances in which individuals desperately needing psychological help quit treatment without realizing that their actions are being guided by one of the problems for which they are seeking treatment. Thus, the analyst must be prepared to vigorously confront the patient, when necessary.

B. Clarification

There are other times when the analyst must ask the patient to clarify what he has said, or speak to the patient in a way that offers clarification from the analyst's viewpoint. Again, returning to our pediatrician, he might ask his analyst to give up her day off in a way so subtle that he unconsciously hopes she will not recognize that the request comes from him. Unconsciously,

he desires her to feel spontaneously that she should offer to see him on Saturday. Consciously, he may be aware of none of this; not even that he has made an actual request of this kind. Here is a situation in which the patient requires clarification, rather than confrontation. The clarification may involve the analyst asking the patient to consider, in a thoughtful way, what he has said and to wonder if there may have been a subtle request, or a veiled threat if the wished-for offer was not spontaneously forthcoming from the analyst. Alternatively, the clarification may involve the analyst making such an observation to the patient.

C. Interpretation

Often interpretation is seen by analysts as the crown jewel of the methods available to help patients think more effectively about themselves. Interpretation involves telling patients in a convincing way that there is an unconscious process at work in their thinking and, in a complete interpretation, explaining exactly why and how that unconscious process works. In the example we are using, it might involve the analyst telling her patient that he requested sessions on her day off because he wanted to know that she loved and admired him, and that this was a strong desire of his for certain specific reasons that she would elaborate related to specific childhood experiences and needs which she would describe in detail. It is the addition of the developmental explanation of the feelings, wishes, and hopes that makes an interpretation a linking the past with the present in a convincing manner.

Interpretations are designed to help the patient understand exactly how and why he thinks, feels, and behaves as he does, but it is incorrect to think that they are more important than confrontations and clarifications. These three methods of communication are used throughout an analysis, and it is the judicious use of all three modes of communication that is an important skill of the clinical psychoanalyst.

V. PSYCHOANALYTIC PERSPECTIVES ON THE MIND

Psychoanalysis works by enhancing the patient's ability to examine the workings of his mind, especially workings that were previously unconscious. Put another way, psychoanalysis is a method of making the unconscious conscious or what is out of awareness available for the patient to consider and include in decisions and choices. However, there are several per-

spectives that psychoanalysts use in observing their patients, organizing their ideas about their patients, and which they try to convey to their patients in the belief that these perspectives will help them practice effective introspection during psychoanalysis and afterward on their own. These perspectives include the topographic, the structural, the historical, the psychodynamic, and the adaptational. These are, in effect, the smaller units into which the working of the mind can be divided. By understanding these, the patient has additional tools for introspection.

A. The Topographic Perspective

The topographic perspective emphasizes that there are two qualities of mental activity—conscious and unconscious. Much mental activity, increasingly supported by neurosciences of brain function, takes place outside conscious awareness. Forces pushing thoughts out of awareness appear to be always at work.

B. The Structural Perspective

The structural perspective describes the components of the mind, each of which has specific functions and performs certain tasks. Of course, these components do not really exist but rather are a way to group conceptually certain types of thinking and cognitive processes. For example, Freud described three components, or “structures” in the mind—the ego, the id, and the superego. Roughly, the first is where we do most of our thinking, the second where we do our wishing, and the third where our conscience and goals reside. Knowledge about these systems helps the clinician think more clearly about the patient. In addition, when understood in the specifics of one's life, it can help the patient think more clearly about himself.

Returning to our pediatrician, it is obvious that at the time he is asking his analyst to give up her Saturdays, there are desires (that we consider part of the id) that are very powerful, and ways of thinking (ego functions) that may allow him to implement his desire without it coming into full awareness. The knowledge that he has a mind that performs these different functions simultaneously can be helpful to this analytic patient.

C. The Historical Perspective

The historical perspective focuses on the aspects of mental function that show the influence of past history on present behavior and our attempts to resolve our conflicts and choices. This perspective, also, can be

very helpful for the patient as one of the tools of introspection. It is essential that the analyst teach the patient to appreciate the ongoing nature of transference, and that transference takes place not only within the analysis, but in life outside the treatment setting. When the patient understands the ubiquitous nature of transference and the influence of the past and its important interpersonal relations, he has a perspective that will consistently enhance self-analysis.

D. The Psychodynamic Perspective

The psychodynamic perspective involves an appreciation of the conflicts we experience in our mental life and their path to compromise. From the psychoanalytic view, this means the way the different psychic agencies (structures) clash throughout mental life, and as a result, how much mental activity remains outside conscious awareness. For example, the dynamic perspective traces the evolution and alteration of a wish, a desire, or a hope from childhood and adulthood into being kept unconscious, molded by the ego into a compromise, and subjected to the judgment of the conscience. Returning for a moment to our pediatrician—the patient, thinking dynamically, recognizes his wish to be loved and his anger when love is not available. He recognizes his wish to threaten the person who does not bestow the love he wants, his compromise of lecturing on the need for love by others (young children), and that such lecturing brings him a loved feeling. In addition, he has come to realize that this process was previously outside awareness because such ignorance was more comfortable than knowing. With a new awareness of this complex set of feelings, thoughts, motives, and actions related to problems going back to childhood, the pediatrician may feel empowered to give up the wishes of childhood. The pediatrician recognizes that his previous frustration is replaced with a mature awareness that the disappointments of childhood no longer have the powerful impact they had when he was dependent on his parents for everything at the age of five.

E. The Adaptational Perspective

The adaptational perspective emphasizes how our feelings, thoughts, and behaviors are an adaptation, an adjustment and compromise with what was possible. This is important to the patient because it puts in context the patient's psychological strengths, his assets, and the reality of the world of the past and the present. Indeed, whatever compromises have been made throughout a person's development, part of the reason

for them is that they have certain adaptational advantages. To avoid throwing out the baby with the bath water, it is crucial for the patient to have an enduring appreciation of how he came to be, what he was before psychoanalysis, and how he can and should retain the best of himself throughout the process. This includes an appreciation of the strengths of his personality structure, and the useful ways he has learned to use his thoughts and his feelings.

VI. HOW DO PSYCHOANALYSIS AND PSYCHOANALYTIC PSYCHOTHERAPY WORK?

Much has been written about the therapeutic action of these treatments. The goals of treatments include resolution of symptoms but, even more important, an enhanced maturity and ability to introspect and analyze one's mental conflicts on one's own after treatment. An enhanced maturity is indicated by more intimate, responsible, committed relationships. A more effective capacity to engage in self-analysis provides the patient with a tool for the future. Life is not static; human development involves ever new challenges. An effectively psychoanalyzed individual has developed the autonomous capacity to engage in productive self-reflection. What has occurred during a psychoanalysis, as a result of the techniques described, that promotes such personal maturation and self-reflection? These broad goals are reached through the patients obtaining:

1. A working understanding of his history, his psychodynamics, and his adaptational skills.
2. A mind now much more aware of itself than before. His unconscious mental processes are much more accessible to consciousness and, therefore, much more manageable.
3. A set of new and rearranged psychic structures, including an autonomous self-analytic, self-observing function, and a conscience that is both reasonable and appropriate.

VII. THE THERAPEUTIC ACTION OF PSYCHOANALYSIS AND PSYCHOANALYTIC PSYCHOTHERAPY

We have already established that analysis works because it is a relationship in which there is a process of

examination, and that, during that process of examination, the patient changes in many ways. Analysts use the term working through to describe this. The process often takes several years. However, more recently, brief forms of psychodynamic psychotherapy have been introduced that are more focused, often to a single conflict-defense pattern, and rely much more on the patient's ability to carry on significant work after the treatment. For psychoanalysis, many analysts believe that at the start the patient needs to experience the examination as open ended. In this way, the patient is less able to use a special end point as a safe harbor, a place to which he can travel with the belief that once there he will be spared the difficult task of profound introspection. When the open ended treatment is not available, the therapist's and analyst's work must be even more alert to the patient's defensive choice of endings of the treatment or a protective definition of successful outcome.

The relationship with a psychoanalyst and a psychoanalytic therapist is unique in the modern world. Where else in adult life does someone listen to another person with such attention and concern? Such an environment provides the patient with what has been called a corrective emotional experience, an experience of being understood, accepted, held in a safe place, protected by someone with whom the patient can actually share his pain, his worries, his fears. This last activity is known as the analyst's containing function. Good parents of young children perform such a function. It is rarely available outside very close, loving relationships in adult life. Indeed, because most patients who seek analysis have trouble forming such close, loving relationships, the uniqueness to the patient of the analytic situation is evident.

Many analysts believe that the provision of such a safe and understanding environment provides the patient with such a new experience that the memories of the analyst's many functions and interactions can become the organizing psychological force behind the creation of a new psychic structure in the patient. As

such, it can be an important, new idea in the patient's mind about what is possible in a human relationship. This new structure in turn permits the patient to develop a new structure of his self, a part of his mind in which his sense of himself is different than it was before. This new self is capable of the many psychological changes and behaviors described in this article because of psychoanalytic treatment. This self structure exists in a new and stable equilibrium, capable of loving itself and others, and working hard to do a good job in a wide range of life activities. In this new structure there are also new and old memories of others, memories that are now also stable, enduring, and either pleasing or relatively tolerable to the patient.

GLOSSARY

analyze To make conscious and to describe the structure, relationships, meanings, significance, and origins of mental phenomena, especially emotional representations.

associations Experiences that come to mind, including memories and fantasies, that link emotionally to the topic under discussion. That topic may be a symptom or a pathological character trait.

cognitive A word for conscious thinking.

cognitive-behavioral therapy The use of conscious focus and will to overcome mental symptoms. The focus is on behavior and conscious thinking.

compromise formation A term used to refer to the result of conflicting forces. The compromise result may be a symptom or personality trait. A compromise formation may also

be nonpathological. The difference is whether or not the compromise is adaptive to both the outer world and inner wishes and fears.

conflict The experience of opposed emotional forces causing anxiety and generating symptoms and pathological personality traits.

implicit memory Memory of aspects of experience inherent in, but not obviously part of, the content of events. Usually nonverbal and unconscious.

induction phase of psychoanalysis The first phase of psychoanalysis in which patients are engaging with the treatment process and emotional aspects of their own history start to emerge. The transference relationship to the analyst begins. The focus is on interpretation of resistances to the treatment process and to the transference.

mental representations The content and organization of mental experience. The term refers especially to self and object representations. Psychoanalysis is particularly interested in affect representations.

mental structure The relatively stable and lasting organizations of mental contents and functions.

middle phase of psychoanalytic treatment The phase of treatment when the patient's unconscious dynamic psychology unfolds in consciousness, the transference intensifies and focuses in a transference neurosis, and when interpretation of unconscious conflict and the working through of better compromises is occurring.

neurocognitive rehabilitation A method of teaching education techniques for learning to patients with neurological difficulties in learning.

neurotic A level of intensity of mental illness in which reality testing and emotional control are present.

parameters Noninterpretive techniques in psychoanalysis.

personality Characteristic attitudes and behavioral reaction patterns based on temperament and experience.

personality defenses Personality traits that are used to protect the conscious mind from painful mental experiences.

procedural memory The memory of processes that organize events. A type of implicit memory. Usually unconscious.

procedural rules The rules of organization and use of mental experience.

psychoanalysis A talking treatment method for eliciting and understanding the psychology of unconscious emotional experiences and representations. The method reveals the unconscious structures that organize emotional experience. The word also refers to a theory of human emotional development.

psychoanalytic psychotherapy A talking treatment method of less intensity than psychoanalysis. Usually conducted with the patient sitting up and facing the analyst, the treatment occurs one or two times a week. The goals are less ambitious. The objectives are more limited and focused. The treatment involves many different interventions, not just interpretation of conflict.

psychoanalytic treatment An intensive talking treatment method to understand the emotional conflicts in mental symptoms and personality. The patient lies on a couch with the analyst behind and is seen four or five times per week. The focus of treatment is especially on the emotional relationship with the analyst.

psychopharmacological treatment The use of medications to affect mental illness.

symbolization The representation of mental experience, particularly affect experience, that involve one image or element to refer to and express emotional meaning.

temperament Inborn reaction propensities composed of stimulus sensitivity, latency time, intensity of response, and dominant affect elicited.

termination phase The last phase of psychoanalysis. The transference neurosis resolves. Shifts in personality function and symptom improvement are consolidated. The psychoanalytic process itself is internalized.

transference The transfer of feelings about childhood relationships onto the experience of the relationship with the analyst.

unconscious Mental experiences, particularly emotional experiences, of which a person is not aware.

working through The process of applying insights from psychoanalysis to many different areas and to the working out of new compromise formations.

servations and treatment for emotional illness. Psychoanalysis and psychoanalytic therapy are talking treatments in which a person's psychology is explored in order to help the person master emotional conflicts. These conflicts are manifested in mental symptoms, in troubled relationships with others, in work, in love inhibitions and disruptions, in unhappiness, and in poor self-esteem. Through a detailed description of what troubles a person, and all the associations this brings to mind, the elaborate complexity of how the person's mind functions is brought to consciousness.

Psychoanalysis is based on the concept of unconscious mental representations that are built up from childhood. These mental representations of self and others include intense and conflicted emotions. The conflicted emotions involve wishes, associated fears, and attitudes that organize compromises among them. These representations are influenced both by temperament and experience. The representations are linked by association mainly of affect. They are mediated by and encompass the various groups of mental functions. They can be made conscious in an affect-stimulating relationship and changed if they can then be consciously observed and thereby better synthesized in more adaptive ways. The psychoanalyst achieves this goal by becoming the focus of and then analyzing the patient's projections of mental representations and attitudes.

Mental representations and attitudes include conflicted emotions. Emotional conflicts involve simultaneous wishes and fears. An example is envious hatred of, and longing feelings of love for, the same person, or the same type of relationship. The compromise might be avoiding love and having unhappy, longing feelings. If a compromise of distant love is rigid and fixed, the patient's love life will be lonely, sad, and unrequited. Psychoanalysis, tries to understand the conflict and its defensive avoidance so thoroughly that the patient can understand and achieve a new and better compromise that involves an intimate relationship.

The idea that we are not aware of all our feelings, of all the conflicts in our feelings, of the ways we defend against them, and the ways we compromise those feelings in our minds and in our everyday lives, or the rules that organize those compromises, was first thoroughly researched and systematized by Sigmund Freud. He discovered the rules of organization of emotional life in the late 19th century when the physical sciences were beginning to discover the rules of organization of physical matter. Freud's initial training was in physical science and neurology and he brought that intellectual

I. INTRODUCTION

Psychoanalysis is a theory and a method for understanding the development and functions of human psychology, especially the emotions. Psychoanalysis is a theory of human emotional development based on ob-

approach to his study of human psychology and the unconscious.

II. GOALS AND OBJECTIVES OF PSYCHOANALYTIC TREATMENT

The goal of psychoanalysis is the relief of mental symptoms and life stalemates through understanding the contributing conflicted emotional forces involved. The objective is a shift in the compromises of those forces so that symptoms ease, psychological development renews, and life growth progresses. The specific objectives will depend on the particular categories of symptoms and behaviors in each case.

III. INDICATIONS AND CONTRAINDICATIONS

The indications for psychoanalysis are quite broad. Although classically limited to neurotic symptoms and personality disorders, the modern practitioner may attempt this method with a much broader spectrum of patients, either alone or in combination with other treatments.

The majority of patients in psychoanalysis have neurotic symptoms and neurotic personality disorders. Psychoanalysis is particularly indicated for personality disorders because the illness affects almost all areas of interpersonal functioning and requires a model relationship to use as an example. The doctor–patient relationship in the psychoanalytic setting becomes that model.

Central to the treatment is the analysis of symptoms and of personality defenses. Symptoms are repetitive mental experiences the patient finds unpleasant. Personality defenses are attitudes the person experiences as part of themselves, justified and valuable, which are used to protect the person, but at a price. Both symptoms and maladaptive personality traits are stable, psychological structures that encode conflicted feelings and responses from years of emotional feelings. These structures are associated with the memories they originated with and are partly in response to. They therefore encode the developmental history of the emotional life. Their structures involve the symbolization of emotional conflicts in symptoms and in attitudes.

Patients with neurotic symptoms and personality problems have their cognitive and emotional control functions intact. They are therefore able to understand and use a psychological treatment to gain conscious in-

sight into the emotional forces at work in their problems. They have the capacity to apply this information to many different related areas. With insight, they can construct new compromises for the warring emotional forces so that the symptoms and personality traits that are the pathological compromises can change.

However, sicker patients are more and more being treated by this method in conjunction with medications, other treatments, and nonpsychoanalytic technique mixed with psychoanalytic technique. These parameters of treatment are aimed at strengthening cognitive and emotional control functions damaged by severe psychiatric illness. The sickest patients alter their view of reality to fit their conflicted emotional states. These patients cannot function well in psychoanalysis, and may even get worse, unless medications and other parameters of treatment are used. Such combinations can be highly successful.

The major contraindications for psychoanalytic treatment are, therefore, patients who have severe cognitive–integrative function disorders, patients who have extreme emotional control disorders, and patients whose reality testing is gone or severely limited. Of particular concern are those with emotional discontrol problems because they respond to intense emotion with disruptive actions or worsening emotional states. This is a problem in psychoanalysis because the technique is specifically geared to increase available affect for neurotic level patients, especially in the relationship with the therapist.

Relative contraindications are those patients who are not psychologically minded, or cannot use metaphor and meaning to generalize and apply to specific symptoms and concrete behavioral actions. Sometimes these functions can be rehabilitated or taught anew, making a psychological treatment possible.

IV. METHOD

The method of psychoanalysis has two components, the setting and the technique. The setting is an intensive psychotherapeutic setting where the patient is seen four or five times per week. The frequency of sessions is to achieve a persistence in focusing on pathological symptoms and actions and an intensity in the relationship to the analyst. This intensity is usually required for the conscious experience and analysis of unconscious emotional conflicts. The treatment lasts for a number of years, so that the deepest intensity and the deepest possible resolution of emotional conflict can be achieved.

The patient lies down on a couch with the analyst seated behind so that ordinary social interaction can recede and the patient's inner world of long-standing self and object relationships and attitudes can emerge. The frightening aggressive and loving fantasies that are organized in symptoms and personality attitudes can then be analyzed, and their earliest manifestations recovered in memory.

The method needs privacy and confidentiality. Because people are talking about their most intimate fears, wishes, and memories, the treatment cannot work unless the privacy of the analytic setting, and utmost confidentiality about any records of the treatment, is maintained. Breaches of this privacy and confidentiality barrier, whether casual or systematic, destroy the possibility of the treatment.

V. TECHNIQUE

The main technique of psychoanalysis is free association, in which the patient says whatever comes to mind about the symptoms and attitudes. Because associations are organized especially by affect-linked relationships, entering a free association pattern will reveal affect-organized self and object relationships. These patterns have a long developmental history beginning in early childhood. The free association method leads back to these early memories.

The free association method slowly discovers not only the content of thoughts, memories, and fantasies, and not only their historical antecedents in memory, but also their organizing procedural rules. Those procedural rules are crucial aspects of personality attitudes and form the basis of the experience of one's self and other people. The organizational rules of these emotional patterns may be stored in a special memory capacity that cognitive science calls procedural memory, a type of implicit memory. Psychoanalysis enters the procedural memory bank through the free association method.

By saying what comes to mind in free association, new historical information and/or new, previously unconscious, emotional attitudes to the life historical information become conscious. Crucial to this emerging story are the unconscious fantasies organizing attitudes and life history. Dreams and conscious fantasies are clues to this more unconscious material. More emotional and less factual dreams and fantasies show the surface of emotional conflicts, their historical associations, their present triggers, and their personality defenses more clearly. This allows for a more complete

understanding of the life history, the emotional history, and their relationship. The influences on the development of the personality slowly become clear. Because of the intimacy of the setting, the intensity of the affect experiences, the pointing to resistances against associations and against the unfolding of affect experiences, the patient reexperiences the full force of affect associations, their memories, and their organizations.

The patient then has an emotional reaction to the listener. In this case, the listener is a psychoanalyst who can describe these reactions to the treatment and to the person of the analyst. These reactions are called transference reactions because they are transferred from formative relationship experiences in the past. When the analyst describes them in detail, the analyst is said to be analyzing the transference.

The transference is a crucial aspect of psychoanalytic technique because it gives the analyst a firsthand view of core emotional reactions in the patient. There is no other way to experience the specificity and the complexity of those emotional reactions because, being unconscious and composed of affect, the patient may not at first have descriptions in conscious language. The transference is the reason that the setting involves the supine position, frequent sessions, interpretation of resistance, and relative abstinence of the analyst. All of these techniques are to foster and catalyze an intense transference reaction that will reveal the deeper layers of personality.

The transference is different than the same old attitudes played out with other people in the patient's life for two reasons. The first reason is that the transference is usually clearer in its content and functions than interactions with people in the patient's present relationships because the associated conflicts become conscious. The second reason is that the conflicts are described in words. Language helps with new syntheses by reorganizing feelings into concepts. Logical sequence, cause and effect, and reality can now enter the new synthesis.

The technique of analyzing the transference allows for the slow emergence and better elaboration of the unconscious, and for understanding and integrating the new material that emerges. It is this emergence from the unconscious and from the past that allows more adaptive compromises in the present. This is what leads to more adaptive real-life relationships and to more emotional satisfaction. The unrealistic wishes, unrealistic fears, and resulting poorly adaptive compromises can now change. The more mature compromises form when patients are better able to see the unrealistic and impossible to satisfy nature of the previous conflicts

and unhappy compromises. New compromises also form because the fears lessen and therefore more of the previously unacceptable wishes can find their expression in new reaction patterns and new attitudes that are both more generous and more realistic. This does involve giving up some of the intensity and unrealistic focus of these wishes but because it also involves giving up uncomfortable, unrealistic fears, new compromises can form that can achieve greater emotional and real-life satisfaction.

Interpretation is another crucial technique. Interpretation is the description by the analyst of what is unconscious, what the conflicts are, what the compromises are, and how they are linked to symptoms and attitudes. Interpretation describes the emotional link between the past and the present. Particularly important is the interpretation of transference, of resistance to transference, and of free association.

VI. INDUCTION PHASE

The treatment can be divided for discussion into three overlapping phases. The first is the induction phase, during which patients are becoming comfortable with the treatment process, and are telling their life history and present illness or unhappy state. Engagement with the treatment process and emotional aspects of their own history start to deepen. The real attributes of the analyst fade from view and patient's fears and wishes about other people begin to be focused on the analyst. In order for this phase to progress and be completed successfully, the analyst must pay attention to, and descriptively analyze, resistances to the analytic process and to treatment. Resistances use personality defenses and therefore are a leading edge of the personality neurosis of the patient. Because this personality neurosis is a primary focus of the psychoanalytic treatment, the resistances elicited by the induction phase form the crucial beginning to the treatment.

VII. MIDDLE PHASE

The middle phase of treatment is when the emotional history starts to progressively unfold. The transference intensifies, consolidates, and focuses intensely on the psychoanalyst. This focusing of the transference on the analyst, and the intense involvement the patient has with that transference, is called the transference neurosis. The transference neurosis provides crucial

data about the subtleties of conflicts and compromises basic to the person. The transference neurosis allows the analyst as well as the patient to experience these attitudes, to thereby better understand their contents and their organizations, and to better reconstruct both their origins and present functions.

When the transference neurosis is established, the analyst and the patient are witness to the patient's full range of unique, emotional, personality reactions in a setting where they can be consciously experienced and their elements, conflicts, and troublesome compromise manifestations understood and analyzed.

A defense is an unconscious mechanism that protects the conscious mind from unconscious, conflicted emotional experience. Symptoms express defenses. Aspects of personality function are defensive. Conflicted emotional experience would be even more disruptive and painful than the defense in symptoms or personality. As defenses are analyzed and unraveled, as their functions become more known and more conscious, the underlying, conflicted emotional experiences they protect against emerge more clearly. Because this process is gradual, because each step of uncovering is preceded by a new and more satisfying organization of compromise, the patient can tolerate the uncovering of the deeper layers. A patient's tolerance is one of the factors requiring a long and intense treatment. The analysis of defense and of underlying conflicts allows for the better resolution of unhappy, symptom-generating, and maladaptive attitudes. The conscious mind, seeing the structure and functions more clearly in the course of analysis, and seeing their first origins in childhood, is better able to bring an adult perspective to bear, shifting mental problems in the direction of reality and emotional adaptation in the direction of new, more adaptive, and more satisfying compromises.

The application of insights about emotional conflict applied over and over again to different situations and manifestations, so that new compromises can be applied in all areas of mental life, is called the process of working through. The middle phase of psychoanalysis involves many intense periods of working through as each aspect of conflict is understood, and the insights gained are applied.

Analysis of the transference neurosis and personality defense, and the working through of conflict form together the major and defining aspects of the work of the middle phase. Both the analysis of the transference neurosis and the working through process require constant analysis of resistance defenses against the work. This analysis of resistance and defense is what opens

up the character defenses in order to work them through to better compromises.

VIII. TERMINATION PHASE

The termination phase is the last phase and is also an intense period of the treatment. New data emerge making the life history and emotional history more complete, more understandable, and more useful. New compromises are applied to a range of life situations. Significant shifts in personality functioning and associated symptoms are consolidated. Conclusions to emotional stories and the transference neurosis are arrived at.

Crucial to this phase is the understanding of the full impact of the transference neurosis. In this phase, the analyst once again, as in the beginning, emerges more into the reality experience of the patient. The analyst is now seen more clearly as a person very separate from the projected attitudes and fantasies of the patient. This results in further conviction about the neurosis for the patient and further consolidation of the new, healthier compromises of personality conflict. During this phase, there is an internalizing of the psychoanalytic process itself, so that patients can continue understanding their mental life on their own. Patients are able to do some free association for themselves and to understand the central themes of their personality, dramatized in their fantasies and dreams. They can therefore figure out their new unhappy feelings and the reality triggers causing them, and plan to meet those reality challenges in ways that will be as satisfying as possible.

IX. CASE ILLUSTRATION

A 40-year-old man is in the perilous phase of fighting with his wife in a second marriage after a painful divorce ended his first. He is intensely unhappy and while he blames his second wife, as he did the first, it is he who is unhappy and it is he who cannot help but notice that the fight is the same one that ended his first marriage. He does not want the second one to end.

In consultation with a psychoanalyst, it is apparent in the first session that the same fight has gotten him into trouble at work and has retarded his career. The fight has something to do with who is in control. In analysis, this issue immediately affects his attitude to the analyst and he struggles over every issue, from time to money to the exact wording of interpretations by the analyst. Associations lead to a relationship with his

mother in which there was a struggle over dominance. The relationship was filled with anger, recrimination, and humiliation. Years are spent untangling what seems to have been his mother, what seems to have been him, what seems to have been each one's reaction to the other, and how all this is played out now. He gradually comes to see that not every difference of opinion is a contemptuous judgment, not every variation is an attempt to humiliate, and not every suggestion is an attempt to control. He also comes to see that he is exactly like the mother he accuses. His personality gradually mellows, he becomes more flexible, and his career and marriage improve dramatically. Of added benefit is the great improvement in his relationship with his children, a benefit he had not expected because he never noticed it was also infected by his core issues. The transference to the analyst is quite stormy for the first few years and he berates and threatens the analyst with quitting treatment. Much careful confrontation, together with great tact and patience were required so that the analytic relationship could be useful to the patient.

X. TRAINING OF PRACTITIONERS

Becoming a psychoanalyst requires many years of training. The usual background for such a person is advanced training in one of the mental health fields and then psychoanalytic training. In the United States, for many years physician psychiatrists dominated the field. In the past 20 years, Ph.D. psychologists have increasingly sought psychoanalytic training. More recently, clinical social workers and others have sought this training. Psychoanalytic training involves 4 to 5 years of classroom work, supervision of patients treated by the student, and a personal psychoanalysis. This intense course of study is necessary to learn the theory, practice the technique, and get enough self-analysis so that personality attitudes of the analyst do not interfere with the work. Another crucial advantage of personal psychoanalysis for the analyst is the ability to use emotional reactions to the patient as information about the patient, rather than only about the analyst. In this way, when one's own personality is well enough known, the analysts themselves can become, and can tolerate becoming, the vehicle of treatment. After many years of training and practice, psychoanalysts may undertake a formal certification process by the American Psychoanalytic Association if they are a graduate of the one of the institutes that comprise that association. On successful

completion, the analyst may call himself or herself a certified psychoanalyst.

XI. PSYCHOANALYTIC PSYCHOTHERAPY

Psychoanalytic psychotherapy is a modified form of psychoanalysis. Its goals are similar in that it tries to achieve relief from mental suffering through a careful understanding of mental functions and contents. Although the goal is the same, the objectives, setting, and technique vary. The objectives are more focused and limited, the setting is once or twice a week with the patient sitting up, and the technique may be very much more active on the part of the therapist.

The indications are generally the same as for psychoanalysis but because the sitting position and active interventions of the therapist often prevent an intense emotional regression, this type of therapy may be better suited to sicker patients whose integrative mental functions cannot yet tolerate a full analysis. In addition, the method may be used when very specific, time-limited objectives are needed by the patient and no personality reconstruction is necessary for those objectives. Some examples of this situation are difficulty in mourning a lost one, panic attacks or social anxiety as isolated symptoms in an otherwise high-functioning person, difficulty adapting to a difficult spouse or boss, or help in understanding a troubled relationship with a child. This kind of therapy is often used in conjunction with medication. Examples are the treatment of depression, panic attacks, or social anxiety situations. The combination is a potent one. The duration of such treatments are weeks to months to a few years. In some situations, generally because of constraints of time or money on the patient's part, such therapy can stretch on for years with the goal of providing a modified psychoanalysis for the treatment of long-standing personality disorders.

The technique generally involves both interpretation of dynamic conflict and support of defenses and of self-esteem. The usual goal is to repair, not reconstruct. However, for those whom the technique is being used as a modified psychoanalysis, interpretation, reconstruction, uncovering, and the intensification of transference and its interpretation are important techniques just as they are in psychoanalysis.

The training of practitioners is difficult for the patient consumer to ascertain because there are few programs specifically teaching dynamic psychotherapy. Psychiatrists may learn dynamic psychotherapy in their residen-

cies. Those who are psychoanalytically trained at psychoanalytic institutes after residency training at least are well grounded in the theory and technique of psychoanalysis, which is then applied to psychodynamic psychotherapy. Psychologists and social workers may get specific training in dynamic psychotherapy during the course of their degree programs. Some get further training in the few psychotherapy training programs that exist or go on for full psychoanalytic training themselves.

XII. COMBINATIONS WITH OTHER TREATMENTS

Psychodynamic psychotherapy and psychoanalysis are sometimes used with other treatments. The combination with medication for the treatment of depression is a very powerful combination because the psychopharmacological treatment treats the physical manifestations and the talking treatment treats the psychological manifestations. This combination is powerful because depression usually involves both components. Each component may catalyze or trigger the other component. A single uncombined treatment may or may not affect the other arm of the illness. Treating them both at the same time achieves a more rapid and more complete relief for more people. Although there is as yet little research proof of this, it is the overwhelming majority opinion among clinicians at this time.

Another combination that is growing in use is couples treatment combined with psychoanalysis or psychodynamic psychotherapy. The marital therapist can observe behavior that might otherwise go unreported in the individual treatments. Similarly, patients can gain insight into aspects of their own conflict that are counterproductive in their relationships. This may help in the more rapid uncovering of psychological conflict and in the more complete working through of its resolutions.

Another combination that is sometimes used is the combination with cognitive-behavioral therapy, which is highly focused on target symptoms such as phobias, panic, social anxiety, and obsessive-compulsive disorder. The combination with psychodynamic psychotherapy and psychoanalysis is especially helpful in two situations. The first is when a rapid resolution of symptoms is mandatory for the comfort of the patient and the progress of the psychodynamic treatment. The other is when the psychodynamic treatment has been going on for a long time without resolution of symptoms because the patient needs hand-on help in the working through and application process.

Another combination growing in importance is concomitant neurocognitive rehabilitation in patients who have severe learning disabilities, especially when those learning disabilities make it hard for them to integrate and apply a psychologically based treatment. Neurocognitive rehabilitation also helps the patient with academic work and with employment problems. Information from the neurocognitive psychologist to the psychoanalyst or psychotherapist can help the therapist understand better what the cognitive problems with the patient are so that the talking treatment can be better targeted, better framed, and more understandable.

XIII. RESEARCH

Research about psychoanalysis has a long history. Outcome studies of efficacy include Wallerstiene's small but intimately detailed study of 42 patients in psychoanalysis, Weber and Bachack's much larger study of outcome at the Columbia University Center for Psychoanalytic Training and Research, the Menninger psychotherapy research project for many years under the directorship of Otto Kernberg, and the largest study to date done by Joan Earle and colleagues at the New York Psychoanalytic Institute. These many studies tend to demonstrate certain conclusions. The first is that the longer and more intense the treatment, the better the result tends to be. The next is that even if patients fail to develop a full psychoanalytic process, and are instead in treatments with major psychotherapy parameters, the outcome in approximately 80% is excellent. What is left to be proved is whether the psychoanalytic process itself, rigidly defined if that is possible, is crucial to the beneficial outcome. My own reading of the data is that psychoanalytic psychotherapy aspects are crucial and the strict psychoanalytic process may or may not be crucial. One would expect this to vary not only because of the difficulty in standardizing psychoanalytic process but also because patients' needs vary according to illness.

Psychodynamic psychotherapy research has been advanced in a major way by Barbara Milrod and Fred Busch, who succeeded in manualizing a psychodynamic method of treating panic disorder and in show-

ing the success of this method. Peter Fonagy and others who are psychoanalytic child researchers have succeeded in showing the excellent outcome of psychoanalytic treatments of children.

In conclusion, research over many years supports the general efficacy of psychoanalysis and psychoanalytic psychotherapy. The current challenges in research are to demonstrate the efficacy of the process, of various applications to different illnesses, of the efficacy of combination treatments, and of the relative efficacy against other treatments.

XIV. SUMMARY

A method is said to be psychoanalytic if it has certain crucial elements of treatment. The elements are the analysis of resistance and defense in the making conscious of unconscious conflicts and their compromises, the use of transference as a vehicle to understanding, some effort to reconstruct past patterns as they influence present functioning, and frequent sessions so that an intensity of treatment is achieved that can reveal these patterns. The goal is the progressive unfolding of personality psychology.

explores how any given couple acts, thinks, and feels, but also the meaning each partner attaches to these experiences. Such exploration is undertaken with the aims of reducing conflict and enhancing intimacy. In this approach, the therapist balances views of what is universally true about intimate relationships with respect for the uniqueness of every partnership between two people.

GLOSSARY

countertransference The way the patient interacts with the therapist which induces feelings in the therapist towards the patient.

intrapsychic defenses Mental strategies developed to contain, and in some instances keep from consciousness, unacceptable wishes and impulses.

object relationships The internalized concepts of self and other that carry with it expectations, sources, type of gratification, and considerations of value.

temperament The biologically-oriented predisposition of a child towards particular ways of behaving, perceiving, and processing information and interactions.

transference The ubiquitous component of all human relations which in psychotherapy refers to how the patients experience the therapist.

Psychodynamic couples treatment involves interventions that incorporate concepts of mental functioning based on psychoanalytic theories. It is an approach that

I. THEORETICAL MODEL

Psychodynamic couples therapists believe that adult behaviors and perceptions in intimate relationships are patterned on the interactions, and the associated feelings and fantasies, of important childhood connections with others, usually most powerfully with parents and siblings. Even under the most favorable circumstances, human development inevitably contains conflict and ambivalence as children struggle with such opposing needs and feelings as closeness and separation, love and hatred, and guilt over forbidden sexual or aggressive wishes. The mental strategies that develop to contain unacceptable wishes and impulses are called intrapsychic defenses, and their many variations and complexities are discussed in psychoanalytic literature. Some defenses are more adaptive than others. Those that allow people to recognize their feelings and take constructive action, for example, work better than those that involve the denial of feelings or self-destructive behaviors. Each

person develops a unique repertoire of compromises between the expression of potentially dangerous (psychologically or otherwise) wishes or impulses and the efforts to contain them with intrapsychic defenses.

Because intrapsychic defenses develop in childhood, they contain irrational conclusions based on childhood reasoning. For example, young children imagine causal associations between unrelated events that occur at the same time. If a 4-year-old girl gets angry at her mother for bringing home a baby brother and then the baby gets seriously ill, the little girl might conclude that her angry feelings and wishes harmed the baby. Because seeing such a bad wish come true is frightening and guilt-provoking, the little girl may then develop intrapsychic defenses to contain her anger, which in turn may cause her to behave in a more inhibited manner. This resolution may persist as the little girl matures without her giving any conscious thought to its origins.

Intrapsychic defenses are well established by adulthood. They operate automatically and mostly unconsciously, but these defenses, and the impulses and wishes they protect against, can in part be indirectly observed through repetitive patterns of behavior and feelings in relationships. Exploration through psychodynamic couples therapy examines these patterns and the associated beliefs and fantasies that the patient uses to explain his or her interpersonal world. So, for example, the woman described earlier might return to the experience of her brother's illness if she seeks to understand in therapy why, when her husband's criticisms make her angry, she silently withdraws (her defense) rather than assert her opposing viewpoints (her aggressive wish).

Psychodynamic exploration also clarifies positive and negative internalized concepts of the self and of others, which are referred to as object relationships. For example, a boy who feels loved and cared for by his mother may have internal images of himself as handsome and appealing, and of his mother as protective and nurturing. By contrast, a little boy who feels his mother takes minimal interest in him and his well-being may have images of himself as unlovable and unworthy, and of his mother as remote and uncaring.

Although this example suggests that these images are created by a simple process, this is not at all the case. Children and parents bring to their interactions unique ways of behaving and experiencing the world, and there is also the matter of the fit between them. A father who is athletic and adventurous may perceive his highly active and mischievous son as great fun, whereas this same little boy could be perceived as a

problem child to a quiet and studious father whose primary mode of expressing himself is through conversation. Children create images of themselves that incorporate how they believe they are seen in eyes of people who are important to them. This is affected by the child's temperament as well. So, for example, an easygoing child may both elicit more positive responses and reach more optimistic conclusions than a child with an irritable temperament. Subjective truths are as important as objective facts, and they help explain how two siblings can emerge from the same family with very different perceptions of childhood.

Children depend on their adult caretakers for nurturance, but because they are relatively helpless, they also fear being harmed by them. Young children cope with this contradiction by keeping the good and bad images of their caretakers separate. An example is their fascination with fairy tales that depict the good and bad images of mothers as fairies and witches. These contradictory images are integrated as the child grows and develops greater autonomy and more mature cognitive and emotional capacities. Integration allows for a more realistic view of others so that a range of negative feelings can be tolerated while still maintaining a predominantly positive image of an important person. Children can best accomplish this integration when they feel safe and loved.

Adults enter relationships using these mental structures constructed in childhood. We bring to our search for intimate partners our deepest hopes and fears and our preconceived ideas about how relationships work. We then think and act in ways that encourage a repetition of these expectations or perhaps seem to be an antidote to them. The attraction of one person to another is in large measure based on finding a fit for childhood constructs. When this fit results in the repetition of patterns that lead to excessive conflict, disappointment, or detachment, it can produce the suffering that is often the presenting complaint of a couple seeking treatment.

One of the central ways the psychodynamic therapist learns about the internal constructs a patient uses to guide relationships is by focusing on transference and countertransference. In individual therapy, transference refers to how the patient experiences the therapist. It is partly a response to the real qualities of the therapist and partly the unprovoked projection of expectations onto the therapist that are based on the internal constructs discussed earlier. For example, a man may anticipate that his therapist is going to be incompetent and judgmental because he perceived his father

in that way. He may then doubt the therapist's opinions or perceive them as criticism. The degree of tact, respect, and reassurance the therapist manifests will to some extent enhance or discourage the patient's tendency to perceive the therapist in this manner.

The way the patient interacts with the therapist induces feelings in the latter known as countertransference, which are partly a response to the real qualities and interpersonal behaviors of the patient and partly a manifestation of the therapist's emotional reactions based on internal constructs from his own past. Psychodynamic therapists are trained to examine their countertransference feelings in such a way that they can use them constructively to help patients. For example, rather than respond to a patient's disdain by being offended or arguing to the contrary, the therapist seeks to understand what he can learn about how the patient approaches relationships. By examining the patient's transference feelings and the therapist's countertransference feelings, the therapist gains critical information about a patient's wishes, intrapsychic defenses, and object relationships. The therapist can then use this information to help the patient reconsider childhood assumptions and develop more adaptive adult strategies.

Most psychodynamically trained therapists learned their skills conducting individual therapy, which is by far the most commonly practiced form of psychodynamic treatment. However, with a shift in perspective, these same psychodynamic principles can be applied to couples interventions.

Transference is not a phenomenon unique to the process of therapy. Rather it is a ubiquitous component of human relationships. Each member of the couple is enacting models of the self and others that only partly correspond to the partner's reality. Thus, in effect, each member of the couple both projects expectations onto the partner (transference) and responds to the partner's projected expectations (countertransference). Negative transference and countertransference feelings can interact with one another in a vicious circle, each setting off the other in a spiral that can cause considerable pain and despair. A man who experienced his mother as inept and now reacts to his wife in the same way can easily elicit the wife's preexisting insecurities about her own abilities. The wife might respond by avoiding tasks in the marriage that could provoke her husband's criticism, which in turn confirms the husband's belief in his wife's ineptitude. Recognizing and exploring these cycles creates possibilities for profound change by allowing the couple to form more realistic and empathic views of one another, by separating the present relation-

ship from past experience, and by creating clearer boundaries between what each person thinks and feels.

Psychodynamic couples therapy moves along much more rapidly than individual psychodynamic treatment. This is primarily because individual therapy brings together two strangers—the patient and the therapist—who develop a relationship over time. When a husband tells his individual therapist about a fight with his wife, the therapist hears only half the story. He does not know how the wife actually behaved, or how she perceived her husband's actions. In fact the individual therapist can best understand the whole story of how the patient relates to others from the experience of how the patient relates to him. Here the therapist is the partner in the relationship, and he knows how he felt and behaved in the interaction. He is learning firsthand about the patient's approach to others by observing and responding to the patient's transference and the therapist's countertransference. This takes time and unfolds with the development of the patient-therapist relationship.

By contrast, in couples therapy the couple brings an already existing intense relationship into the therapeutic process. By directly observing, for example, the hundreds of verbal and nonverbal exchanges that occur in only a few minutes of a couple's typical argument, the therapist begins to see how the wishes, disappointments, inhibitions, and preconceived ideas each member of the couple brings to the relationship play out between them.

The presence of three people in the session also greatly increases the complexity of what the therapist must attend to, including the interactions of the members of the couple with each other and the interaction of each of them with the therapist. This requires the therapist's intense and constant concentration because even a momentary lapse can result in a loss of crucial information. There is also a greater need to control what happens in the room lest the couple simply repeat destructive interactions or pull the therapist into their conflicts without achieving any therapeutic goals. This requires the therapist to make rapid decisions about interventions using less information than that upon which individual therapy interventions are usually based. Some dynamic therapists feel ill at ease with these requirements, whereas others find couples therapy lively and engaging, a remarkable opportunity to have a profound effect on the well-being of others in a relatively brief period of time.

Although Sigmund Freud laid the groundwork for the psychodynamic approach, many subsequent psychoanalytic clinicians and theorists have contributed

substantial modifications to the original theories. Others have made an attempt to integrate these theories with new discoveries about the biology of the brain and the development of the mind. The skilled therapist uses a range of interventions within an overall framework based on psychodynamic principles and tailored to the particular couple's needs. So, for example, the therapist might employ behavioral interventions to improve a couple's skills in the areas of communication and negotiation, or he might refer a member of the couple who weeps throughout the session for an assessment of whether she would benefit from antidepressant medication. There is no single technique that provides an answer to every issue that arises. Skilled couples therapists know when to augment their primary approach with other strategies that are either more effective or more efficient but that do not undermine the framework of the overall treatment.

The psychodynamic therapist is interested both in what is universal and what is unique about people. She understands that just as no two people are the same, so it is that no two couples are the same. It follows that there are no simple formulas, instructions, or remedies for how couples should live their lives. Although the therapist uses her own emotional responses as a tool for understanding a couple's experiences, she has deep respect for the fact that her perspective is also unique to her own past and she avoids imposing her personal solutions on the couple. The psychodynamic therapist respects the couple's autonomy. With the exception of life-endangering situations, the therapist understands that only the couple can reach conclusions about the viability of their relationship, and that they are the ones who must live with the consequences of a decision to stay together or separate. The psychodynamic therapist also believes that all theories are only approximations of the truth, and that the couple's truth is more important than the therapist's theories. She is humbled by the knowledge that beneath every layer of truth is yet another layer. Each member of a couple selects what to reveal, and, however great a couple's willingness to be open, some truths will remain unconscious and therefore unavailable. An awareness of the enormous complexity of people and the irrational forces that influence them contributes to the depth and flexibility of the psychodynamic approach.

Because in most states anyone can hang up a shingle claiming to be a couples therapist, even with no training at all, complaints about the simple-mindedness and lack of success of couples treatment are commonplace, and such experience often leads to a jaundiced view of all couples treatment. Moreover, books and workshops

abound that offer to teach couples how to have a more fulfilling relationship. Although these offerings may present meaningful opportunities for self-improvement, they are to be distinguished from psychodynamic couples therapy, which avoids one-size-fits-all solutions and involves a highly individualized assessment and treatment plan.

II. PRESENTING COMPLAINT

Sometimes a couple will present following an event that crystallizes a long-standing pattern of difficulties. Among the most dramatic of these precipitants are the revelation of an affair or an uncharacteristic act of physical violence. Couples may present because one member has given the other an ultimatum—for example, to marry or break up, to have a baby or divorce. Prenuptial agreements are sometimes experienced as ultimatums as well. Meeting with divorce lawyers prior to marriage may be economically sound, but it is a painful way to begin a marriage. Disappointment in the partner based on the perception of being emotionally and sometimes physically abandoned at a critical time of need, such as during job loss, infertility treatment, or an episode of serious illness may be the presenting complaint. Chronic feelings of anger are prominent in almost all these situations, and a reduction of sexual interest is common.

III. ASSESSMENT

Assessment begins with an evaluation of the presenting complaint. In obtaining this information, the therapist needs to convey the following complex set of concepts: that no two members of a couple see a story in the same way; that the therapist is more interested in subjective truth than objective fact; that the therapist listens for the purpose of understanding and not assigning blame; that the difference between the two stories that emerge will be useful to the therapeutic process; and that each member of the couple has the final say about his or her feelings or intentions. The therapist is in effect making an important intervention by creating an environment in which it is relatively safe to look at areas of disagreement and in the process clarify how each member of the couple may be projecting feelings or motivations onto the partner that create inaccurate perceptions of who the partner is. In the process, members of the couple can learn to separate past perceptions (e.g., "My father never took an interest in what I had to say.") and present reality (e.g., "I pres-

ent my opinions in such an angry way that my partner finds it difficult to listen sympathetically.”).

Elucidation of the presenting complaint leads naturally to inquiring about other areas essential for the therapist's understanding. These include the story of the relationship; the factors that attracted them; the history of their difficulties; their sexual functioning; the birth or adoption of children; the presence of any serious physical or mental illness in either of the partners or a child; and prior experience with individual or couples therapy. The couple's relationship then needs to be put into the context of each partner's family dynamics and, unless the couple is uncomfortable with discussing it, an understanding of previous important couples relationships. Religious and cultural factors also need to be taken into account. For example, the marriage of a Japanese-born businessman to a musician of Irish extraction raised in the Midwest presents enormous complexity with regard to the differences in assumptions, patterns of communication, and expectations each brings to the relationship.

The assessment allows the therapist to begin to answer the following questions: Why is the couple presenting now? What has drawn them together or kept them apart? What is each member of the couple seeking from therapy? To what extent are their goals compatible? How does this relationship repeat patterns each partner learned in childhood? How does the couple function at their best and at their worst? To what extent is their anger and disappointment with one another balanced by a reserve of good feelings? What skills does each partner possess in communicating, negotiating, and empathizing with the other?

Maladaptive patterns of behavior are often passed from one generation to another. For example, a man who becomes verbally abusive or physically violent with his wife will often have experienced similar abuse as a child, and in turn risks raising a new generation of children who engage in such behavior. This man's maladaptive patterns are accompanied by painful internal constructs of a victimized, revenge-seeking self in relationship to undeserving and untrustworthy others. The roles of victim and perpetrator are intertwined.

One essential area of assessment that is often overlooked in couples treatment is the presence of major untreated psychiatric illness, most often depression, manic-depressive illness, anxiety disorders, and addictive disorders (e.g., alcohol, drugs, gambling). Each can place enormous stress on a relationship. For example, the irritability and pessimism of depression, the aggressive behavior seen in mania, the need for constant reassurance induced by anxiety disorders, and the loss of impulse control associated with addiction are each

associated with interpersonal difficulties that can have a severe negative impact on how the couple functions. Personality disorders may also be present, and the therapist needs to assess what aspects can be addressed in the couples treatment and what difficulties are best handled by referral for individual therapy.

Consider a young woman who marries a middle-aged divorced man with two preadolescent sons from a previous marriage. Things go relatively smoothly until she gets pregnant, gives birth to a healthy baby girl, but then develops a severe episode of postpartum depression. She becomes withdrawn and irritable and expresses increasing annoyance with her stepsons. They feel rejected and displaced by the new baby, and become progressively more angry and defiant. This in turn reminds the new mom of her unhappy childhood experiences following her own parents' divorce and the subsequent emotionally distant relationship she developed with her father's new wife. She is frightened at finding herself in the position of becoming the evil stepmother. Although there are many psychodynamic issues for the couples therapist to explore, it is essential to consider the contribution that this woman's untreated depression is making to the deteriorating family situation and her inability to repair it.

The therapist also needs to appreciate what she is not likely to hear about in couples sessions: secrets that one partner wishes to keep from the other (e.g., an extramarital affair); hidden agendas (e.g., a plan to hide financial assets in the event of a divorce); full disclosure of each partner's feelings toward the other; and the type of intimate self-revelation that is the focus of individual psychodynamic treatment. Meeting with each member of the couple alone has the advantage of providing some additional information, and the potential disadvantage of burdening the therapist with secrets that the couple may not be prepared to confront. Whether or not the therapist elects to meet with each partner separately, she remains humbly aware that there are deep unconscious forces at work, that these will remain in place throughout the therapy, and that there is much that the therapist and even the members of the couple cannot understand.

Obtaining information from a couple stirs up strong feelings that need to be addressed, and thus the assessment process is also the beginning of the treatment.

IV. TREATMENT PLAN

Many couples enter therapy reluctantly, believing this admission of failure to solve problems on their own is the first step to separation or divorce. Not uncommonly,

one partner has pressured the other to come to the initial session. A couple in angry conflict may fear that this form of passion is the only force that binds them. Often each partner puts the responsibility for problems on the other, and there is an almost universal desire to effect a change in one's partner rather than in oneself. Other common themes at the beginning of treatment include the wish to be understood without having to put feelings or requests into words, and the belief that one's own inner despair could be quelled by a more responsive partner.

The initial phase of couples treatment is the creation of a safe therapeutic environment in which discussion of painful issues does not cause further harm. This involves setting limits to destructive behaviors such as name-calling, shouting, interrupting, and other forms of angry interaction that serve no useful purpose. In their place, the therapist helps the couple use such strategies as identifying specific issues (e.g., "So you feel rejected when he comes home late every night."); adhering to the topic rather than engaging in global warfare (e.g., "Let's stay focused on the arguments you're having about the kids' bedtime rather than all the past failures to discipline them."); achieving useful goals (e.g., "Do you think that calling him a whining wimp will get you what you want?"); not invoking absent third parties (e.g., "Since your mother isn't here to concur that your wife is neglectful, let's focus on your own opinions."); and distinguishing past grievances from future hopes (e.g., "You're both bitter about the past, but perhaps there's enough good feeling between you to work on handling things differently from here on.").

The presence of physical violence is in a category of its own because it is unsafe to conduct couples treatment in this situation without setting very clear limits to what is acceptable behavior. The therapist's failure to do so can result in an escalation of violence. Consider the case of a lawyer who enters therapy after neighbors called the police in response to his wife's cries for help during a physical altercation. The husband accedes to his wife's demand to see a couples therapist because he is fearful that further police action could result in his being disbarred, but he believes his actions were amply justified by his wife's provocations. Both members of the couple act as if the husband has two different personalities: the good and caring one, and the out-of-control one. The therapist must indicate his belief that there is no provocation that justifies violence, that the threat of disbarment reflects a societal judgment that physically abusing a spouse is unacceptable under any circumstance, and that the husband has a single personality

whose good and caring side must take responsibility for his angry and destructive side. It is essential as well to work with the wife on removing herself and her children from the situation (e.g., keeping clothes in the car, having a place to go to) when she observes the warning signs of impending violence. Exploring the feelings and barriers that might prevent her from taking such protective measures must be part of this process.

All sophisticated couples therapists use strategies for creating a safe environment regardless of theoretical orientation. When the psychodynamic couples therapist employs them, she maintains awareness of the powerful but unidentified intrapsychic forces each member of the couple brings to the joint creation of their repetitive pattern of painful and seemingly self-defeating behaviors. She knows that in childhood when each member of the couple developed the strategies they now use, these approaches were a way of coping with distressing feelings and creating some sense of safety. She has respect for the role of these strategies in maintaining each partner's emotional well-being, and is careful not to make matters worse.

The therapist's approach is then guided by her understanding of how much is at stake in making any changes. This is true whether she makes behavioral suggestions (e.g., "Let's work on how you'll carve out a time of the day to talk to one another without interruptions."); or addresses the underlying psychological problems (e.g., "I guess when your father died and left you alone to deal with your alcoholic mother, it felt like you should just learn to manage on your own and not have to depend on anyone.").

The goals of couples therapy depend on the motivation, capacities, and focus of the couple. They include such diverse possibilities as reducing conflict; improving communication; enhancing empathy and support; promoting trust; creating more effective teamwork; enhancing the depth of relatedness in such areas as self-revelation and sexual intimacy; using humor and pleasurable activities more effectively; improving relationships with extended family; and initiating appropriate treatment for coexisting psychiatric disorders. Because fewer conventional structures are in place and because discrimination exists, gay and lesbian couples, and sometimes interracial couples, may need to make a more conscious effort to integrate themselves into one another's families and work lives.

Although it raises cost and reimbursement issues, longer couples sessions are often more effective than shorter ones because they allow for greater closure of the topic under discussion. This reduces the likelihood

that the couple will leave the office with feelings that they cannot successfully manage between sessions. The amount of time a couple needs to work on a particular goal can vary enormously from a few sessions to a lengthy treatment. Also, couples may be ready to focus on different issues at different times, and it is best to be open to the possibility of couples returning following an initial course of therapy. Decisions about how much collaboration to have with individual therapists, if present, and distinguishing between goals best met in couples therapy rather than individual therapy, are also important components of the treatment plan.

V. EMPIRICAL STUDIES

There is a substantial number of studies examining the outcome of a variety of models of marital therapy. However, most do not meet the current research standards for demonstrating the effectiveness of a treatment (e.g., random assignment, a control group comparison, use of questionnaires that have been shown to be reliable and valid, detailed protocols for administering and observing the intervention), and few of the studies test the outcomes of psychodynamic couples therapy. On the positive side, the direction of the findings taken as a whole suggests that marital therapy is effective and is more likely than individual therapy to solve marital problems.

VI. CONCLUSIONS

Psychodynamic couples therapy uses in-depth models of psychological functioning both within and

between people to enhance intimacy and reduce conflict and suffering. This treatment works best when it takes advantage of the entire array of interventions known to improve couples functioning. This includes the diagnosis and treatment of psychiatric disorders present in either member of the couple and the use of cognitive and behavioral strategies as necessary to improve communication and interpersonal skills. The skilled psychodynamic couples therapist does not offer simple formulas, but rather assists each couple in finding solutions that are responsive to their unique needs and hopes.

GLOSSARY

countertransference Broadly defined, the emotional and behavioral response of the therapist stimulated by the therapeutic encounter.

group cohesion (cohesiveness) A property of the group in which the members are committed to the aims and work of the group, and from the satisfaction of being a member. Moreover, the properties of the group influence the members, creating a reciprocal experience in which individuals influence the group and the group influences the individual. The influences may be “positive” or “negative.” This is akin to “the therapeutic alliance” in dyadic therapy.

identification An unconscious process in which the participant (patient) takes on parts or aspects of another. By taking on aspects of another, the individual changes by altering perceptions, behaviors, or affects.

norms Unwritten “rules,” either conscious or unconscious, which evolve during the therapeutic process that regulate members’ “behaviors.” The behaviors may be either what is expected or what is sanctioned.

partial hospital A treatment setting that patients attend for portions of a day, evening, or night. Partial hospitals represent an alternative to full hospitalization.

personality disorder A constellation of inflexible and maladaptive personality traits that result in significant functional impairment or subjective distress.

posttraumatic stress disorder (PTSD) A set of symptoms that develop after a person sees, is involved in, or hears of an “extreme traumatic stressor.” The symptoms must last more than 1 month. People reexperience the event in dreams or daily events. They attempt to avoid any stimulus that will reawaken the event. They may respond with numbness or hyperarousal.

psychosis The term is not precise, but is taken to mean grossly impaired in reality testing. It may be considered synonymous with major impairment of social and personal functioning.

repetition compulsion A person’s tendency to repeat intrapsychic conflicts that have resulted from past traumatic experiences.

resistance Patients’ difficulties in effectively collaborating in their therapy (They are late, forget to pay bills, miss sessions, unable to verbally participate). The source of these phenomena are thought to be unconscious.

transference A set of expectations, beliefs, or emotional responses displaced from prior experiences (often parents) to individuals in the present (often a therapist).

I. DESCRIPTION OF TREATMENT

Psychodynamic group psychotherapy is a treatment modality in which a specified number of individuals, who have been appropriately interviewed and prepared for the treatment, gather together at a regular day and time for treatment of their psychological problems. The groups may be of predetermined or indeterminate duration. They may have a fixed membership or be open to additional individuals, as space permits. Members,

through examination of their in-group behaviors, learn about unconscious processes arising from prior experiences that distort present relationships with peers, authority, or with their relationship to the whole group (transferences). They become familiar with resistances and defenses against the emergence of unconscious processes, through manifestations in their relationships, slips (of the tongue), dreams, and fantasies as they emerge in the group process. Examination of the in-group process and dynamics are a primary, but not exclusive, focus of attention in members gaining insight into both conscious and unconscious aspects of themselves as they strive to understand and change their psychological problems.

A. Planning a Psychodynamic Psychotherapy Group

An essential element in the conduct of psychodynamic group psychotherapy is careful planning. Clinicians must determine the potential for finding sufficient individuals (6 to 10) who would benefit from and are willing to enter group treatment. They need to carefully plan for the space and time commitment involved in conducting this therapeutic modality, and they need to properly prepare members for participating in the group. A private practice setting differs from one in a clinic in which administrative and systems issues require particular attention.

The group format should be specified. One option is an ongoing, open-ended group, in which, as individuals leave, they are replaced. Another option is a time-limited group, which is usually defined as a predetermined number of sessions. Generally, time-limited groups are closed for new admissions once they begin.

In composing treatment groups, consideration of ethnicity, age, gender, education, diagnosis, or degree of patients' psychological (functional) impairment should be taken into account. Groups may be heterogeneous as to these elements, but too great a disparity across these various dimensions would likely interfere with effective group treatment. Although each individual is unique, a degree of commonality along one or more of these dimensions is important in order to provide for linkages and identification(s) among members.

Time-limited groups are often composed for a specific commonality (eating disorders, bereavement, reactions to a medical illness, victims of a disaster, including post-traumatic stress disorder) with the expectation that the commonality will enable the members to more readily identify with one another and facilitate sharing.

B. Therapeutic Factors

The therapeutic elements in group treatment arise from interactions among the members and with the leader. In addition, the image individuals develop of the group contributes to treatment outcome. The working theory posits that individuals will repeat their dysfunctional ways of experiencing and interacting (repetition compulsion) in the group setting, thereby providing a window into the person's conscious and unconscious emotional and cognitive processes. Individuals will experience the leader or other members as they have important individuals in their past (transference).

Insight into a person's unconscious emotional life as exemplified through their transferences has been the traditional cornerstone of the therapeutic action of dynamic group treatment. However, insight alone has never been sufficient explanation for a positive treatment effect. The value of the therapeutic relationship has always been appreciated as important, but only recently has it been differentiated from "nonspecific" or supportive categories. Cognitive elements, such as sharing of information or learning about an illness, have also been seen as useful.

Irvin Yalom, in 1975, working primarily in a framework of interpersonal relationships, listed 12 "therapeutic factors" that he believed were central to the mutative action of group psychotherapy. A cornerstone of this perspective was the potential for mutative impact from others' feedback as problematic transactions emerged in the course of the interaction. Yalom also emphasized group cohesion as a necessary, but insufficient, group element in effecting change. Group cohesion broadly defined as the commitment of the members to the aims and the work of the group, is a property of the entire group. Interpersonal influence (feedback) was most effective when a group was cohesive.

In 1997, Roy MacKenzie regrouped and modified Yalom's factors into four categories. The factors included in Yalom's formulation are indicated in bold:

1. *Supportive*: a sense of belonging to the group, which includes acceptance, **altruism**, **hope**, and **universality** (we are all human). **Group cohesion** is subsumed in this category.
2. *Self-revelation*: self-disclosure and **catharsis**. This included cognitive and affective dimensions.
3. *Learning*: **education**, guidance, **modeling**, and **vicarious learning** (observing how others interact and seeing similar aspects in one's self).
4. *Psychological work*: **interpersonal learning** and insight.

Psychological work is conceptualized as individuals' examine and learn about wishes, fears, hopes, and motivations that emerge in the manner they interact with others. Such work optimally takes place when the person feels supported, understood, and has revealed significant emotional aspects of her- or himself.

C. Recruiting and Preparing Members

Prior to recruiting members, clinicians need to attend to the composition and to an appropriate framework for the group. To form a group with the potential for achieving cohesion and a working atmosphere, the membership should not be too diverse along the dimensions of age, culture, socioeconomic background, or psychological awareness. Members should have a similar degree of psychological awareness as expressed in recognition of their inner emotional motivations or in their contributions to dysfunctional relationships. An individual might be excluded from a particular group, for example, on the basis of profession (a university professor with blue-collar workers), or age (a 65-year-old person with individuals in their twenties). Some exclusionary criteria based on traditional stereotypes are not valid if other aspects of the individual are basis for commonality (persons of color, if they have a similar occupation or common interests with others). However, using the theory of group process and dynamics described in the succeeding sections, modified psychodynamic groups can be formed with persons with persistent mentally illness or those with personality disorders who have significant deficits or absence of self-reflective capacities.

Fees for the sessions should be predetermined. Availability of appropriate space where members can sit in a circle with an unobstructed view of one another is necessary. In private practice settings adequate space may only be available in a waiting room, and under such circumstances, the clinician needs to assure privacy. Generally, groups are held in the evening after working hours. In the planning, clinicians must be aware of the extra time that is involved for administrative tasks (i.e., record keeping, patient contacts, or completing insurance forms). In clinics, arranging for a group requires collaboration with various levels of the administrative structure to assure collaboration with the clinician's needs in conducting a group in contrast to conducting dyadic treatment.

Any individual suitable for dynamically oriented psychotherapy is a prospective candidate for group

treatment. However, most persons seeking psychotherapy request individual treatment. Thus, clinicians find it necessary to recruit and conduct careful preparatory interviews to determine an individual's motivation and psychological capacities to participate in group therapy. Clinicians also provide information regarding the treatment format.

Members may be recruited from the therapist's own practice. This has an advantage of both parties knowing each other and having worked together. Often therapists have insufficient prospects to begin or maintain an adequate group census. Other practitioners, or the clinician's usual referral sources, should be informed of the planning for a group to obtain additional candidates. In clinic settings, collaboration with persons in charge of admissions (intake), conferences reviewing patients' treatment, or in managing transfer from one clinician to another (often in the context of a therapist departing the clinic) provide additional referrals. Educational presentations serve to inform others of this treatment modality, as do flyers announcing the formation of a group. This latter method, however, seldom produces many referrals, but functions to remind others of the presence of a group that is seeking members.

Criteria for selecting individuals who would benefit from group treatment are linked to the therapist's goals for the group. Three basic criteria are: (1) an individual's motivation to work on his or her problems, (2) an ability to trust and share inner feelings, and (3) a capacity to examine one's inner states of mind and bodily responses.

General exclusionary criteria include persons (1) who show great reluctance or do not wish to join, (2) have mental retardation, (3) in a relational crises (i.e., divorce, death, loss of job), (4) in acute emotional reaction (i.e., a major depression or a psychosis), or (5) certain persons with certain personality characteristics (i.e., antisocial tendencies, limited frustration tolerance, or inability to maintain confidentiality). An additional consideration is individuals' life circumstances that prevent them from regular attendance (i.e., businesspersons, entertainers, or professional athletes who travel). None of these criteria are absolutes. Persons in crises may become good candidates when they recover. Insufficient data exist to define who should be excluded, because the attributes of the therapist and the characteristics of the specific group membership may be such that a particular individual may benefit from a particular group.

Candidates should be individually interviewed to determine their suitability for group treatment. The tasks of preparatory interviews as outlined by J. Scott Rutan and Walter Stone, include:

1. Obtaining a history and gaining a preliminary understanding of the person's problem(s).
2. Forming a relationship with the patient.
3. Setting treatment goals.
4. Providing information about the group.
5. Exploring initial anxieties about joining the group.
6. Gaining acceptance of the group agreement.

Interviews are not solely focused on determining a clinical diagnosis. They are conducted to learn, also, about an individual's prior role functioning in groups. Participation in the family, school, work, church, and recreational activities are almost universal group experiences. Therapists should inquire if individuals assumed leader or follower roles? Do they keep to task or have conflict with authority? Are they active or passive? Do they speak up or are they listeners? Can they keep secrets? The history and examination of role behavior alerts clinicians and patients to aspects of future group behaviors. Such an interview focus helps patients more clearly specify treatment goals. Furthermore, clinicians' interest in trying to understand the nature of their patients' problems in the various settings increases the likelihood of individuals negotiating the initial anxiety of entering and successfully remaining in the group.

Patients' treatment goals should be as specific as possible. These are usually formulated in interpersonal terms such as, "I need to understand why I become so angry at x," or "I seem to always get into relationships in which I am taken advantage of"; or "I cannot maintain a loving relationship with a man (woman)."

Information should be provided about the group. Usually this includes where the group meets, the time and duration of the sessions, gender composition, and if it will be an open or closed group. For ongoing groups, goals may be stated, "The group will provide members an opportunity to examine relationships both inside and outside the meetings." An additional explanation might include that a person's relational problem will emerge in the interactions among members and with the leader, and in this respect the group will be a microcosm of one's extra-group world. Learning about oneself in the group can be used in one's daily life.

Prospective members are informed that the group will be composed of persons who have no known prior relationships with each other. This leads into exploration of patients' initial anxieties about entering a group and further discussion of their ways of managing those feelings. Preparation serves to help patients work with their feelings and also provides an additional indi-

cation of the therapist's interest in the patient, further strengthening their alliance.

The group agreement (contract) is a central element in the preparation process and serves as a structure for the treatment. The elements include agreement to

1. Be present each week on time and remain throughout the entire meeting.
2. Work actively on the problems that brought you to the group, remain in the group until those problems are resolved, and provide sufficient time to say goodbye.
3. Put feelings into words, not actions.
4. Use the relationships in the group therapeutically, not socially.
5. Be responsible for your fee.
6. Protect the names and identities of your fellow members (confidentiality).

Each element can never be entirely fulfilled. Yet the agreement provides a structure and an indication of what behaviors are useful in the pursuit of treatment. The agreement alludes to patient safety, both physical and emotional. Proscribed actions include physical behavior and verbal attacks that are also considered actions. The ambiguous instruction to use groups therapeutically, not socially, leads to a discussion of extra-group contacts among members. They are asked to discuss in the group all salient contacts between them that take place outside of the meeting, as a means of learning more about themselves.

Fee arrangements should be explicit. The author distributes statements in the group at the initial meeting of each month for payment by the end of the month. If problems arise about payments, they should be discussed openly in the group. (This proves to be a very difficult assignment because money is not readily discussed in the American culture.) Groups cannot function without confidentiality, and it must be emphasized to the members. Members are not prohibited from speaking with others about the meeting, but they are instructed to do so in a fashion that no one can be identified. Members are reminded that confidentiality cannot be guaranteed, and each person is responsible to protect the information that is shared.

Failures to abide by the agreement provide opportunities to examine the reason and meaning of the particular behavior. It is easy to ignore members' slight tardiness or their delinquency in paying fees. Therapists need to overcome their own resistance to addressing such "violations" and help members to do the same.

The group agreement is incomplete without also informing members of the therapist's obligations. Therapists need to tell members about how they will use information gathered outside of the sessions, and how they will participate in the meetings. The former includes information from diagnostic or regularly scheduled (individual, family) therapeutic sessions, phone calls, chance meetings, or contact with other therapists. Moreover, patients should be told what information will be provided to insurance companies or of its use by the therapist in her or his professional capacity (i.e. writings or lectures). Finally, the therapist explains that he or she will try to help members understand themselves in their interactions in the group and in their lives. The members set the agenda. The therapist will intervene when a comment might be helpful.

D. The Therapist's Role

The clinician has the major initial responsibility for creating a group atmosphere that can be therapeutically useful to the members. The clinician must maintain a balance between understanding individuals, subgroups, and the whole group and be able to utilize that understanding for members' benefit.

Leaders need to initially establish boundaries between the group and the outside world, among members, and between themselves and the members. The concept of boundaries includes the time, place, and duration of the meetings (when do the session begin and end; where and when do we meet). The agreement is the first step in this process, because it defines aspects of the relationships among the members, and members with the therapist and with the group. For example, an external boundary is represented by selecting or excluding participants or by the emphasis on confidentiality. An internal boundary is exemplified by the element in the agreement to put feelings into words and not into action.

Clinicians help members begin to relate to one another in the here and now of the group. Yvonne Agazarian, in 1997, emphasized this process by pointing out similarities among pairs or subgroups. Such linking reduces members' sense of alienation. The therapist may identify a common group theme, which generally includes an assumption that silent members are participating, although they are not speaking. Moreover, not everyone has to be in agreement, because some members may favor a certain notion and others may "fight it," but all are reacting to it.

Therapists also have a responsibility in monitoring and, if necessary, helping members' contain or express

their emotions, whichever is salient. Expression of intense emotions is inevitable. When feelings threaten to disrupt, rather than advance, therapy, the clinician must step in to prevent injury to an individual or to the group. Judgment is necessary in this task, and no rules are possible other than the general principle that safety is paramount.

The therapist also monitors and, when appropriate, comments on the unfolding group process, with the goal of alerting members to particular behaviors or interactions (confrontations) or of understanding unconscious elements in the transactions (insight). Many narratives seem only to describe events outside the meeting. However, they may be (displaced) communications or metaphors for unexpressed relationships or emotions within the group. Explaining these two levels (internal or external to the group) may lead to patients' insight into aspects of themselves.

Traditional theory elevates "insight" to a privileged place in helping patients. Insight may refer to understanding in the here and now of the meeting, to relationships in one's daily life or in the past. Interpretations provide insight into the transferences with linkages between "behavior" or feelings in the group, examples from the patient's current life, and from the patient's past. Interpretations illustrate the repetitious quality of patients' responses and their propensity to transport the past into the present. In the group, multiple opportunities for transferences are available with others representing parents, siblings, teachers, or other emotionally significant persons in the patient's life. The treatment setting opens transferences to examination and to understanding (insight). With insight the person can change.

Advances in theory have focused on the function of the relationships and interactions as significant in helping patients change their experience of others—this is often labeled a "corrective emotional experience," which means that people in the present respond differently than those in the past who have injured or traumatized a particular individual. A significant element in the therapist's task is to monitor the group atmosphere and try to form a setting in which such experiences can take place. The "relational experience" in itself is understood as mutative. Therapists, through their predictability, dependability, and reliability, contribute to the mutative impact of the treatment.

The focus of the therapist's activities is conceptualized by J. Scott Rutan and Walter Stone as encompassing two dimensions: role and focus:

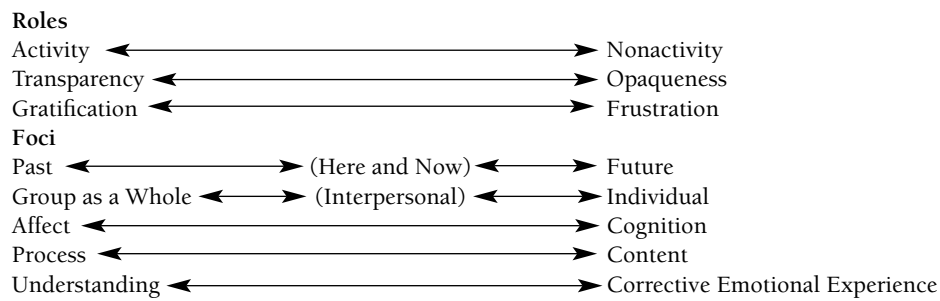

FIGURE 1 Roles and foci for the group therapist. Reproduced with permission from Rutan and Stone (2001). *Psychodynamic Group Psychotherapy*, 3rd ed. New York: Guilford Press.

1. Role

Role function addresses the leader's manner of engaging in the treatment. Each of the three dimensions is on a continuum. Clinicians may show considerable variation where they would be classified along theoretical or clinical places on a continuum. For instance, some clinicians might be active and gratifying during the initial meetings as a way of containing anxiety and creating a warm and accepting group atmosphere. Other clinicians might choose to remain inactive and opaque. They would view their position of nongratification of the "typical" leader role as creating anxiety that would help the members expose prior maladaptive relational patterns (transferences). It is unlikely that any therapist who rigidly adheres to one or another position on these continua would be therapeutically effective.

2. Focus

Leadership foci describe clinicians' stance regarding which aspects of the leadership will command their attention. No single dimension is the sole focus, nor is a single point along the continuum. For example, initially, individuals may not feel safe examining in-group feelings, and they resort to discussing events outside the meeting. The therapist may sense that such discussions promotes cohesion and identifications among members. At a later time, the therapists, hearing a similar discussion, may suggest that the discussion is a metaphor for transactions in the here and now of the group. Nevertheless, no matter which focus leaders choose, unanticipated responses are inevitable because many levels of individual and group experiences are simultaneously touched on. A comment to an individual about his or her behavior in the current transactions may reverberate to members' current life, their past, or imagined future.

E. The Group Process

Viewed from a perspective of a living organism, groups, somewhat akin to individuals, traverse developmental stages. These stages are not fixed or invariant but are subject to the capacities of the membership and the ability of the leader.

Like embarking on any enterprise, individuals enter a group needing to determine the nature of the task and of the emotional relations with peers and the therapist. The task in a psychodynamic group is to learn about and alter dysfunctional relationships and one's inner emotional responses. The therapist usually minimizes ordinary instructions in how to achieve these goals and leads by following—that is the clinician does not introduce topics or provide agendas but follows the members' lead and attempts to understand and convey understandings in a usable manner. This strategy of removing the "ordinary" expectable instructions creates a setting in which transferences, resistances, and unconscious processes are more available for examination.

The basic outline of group development was proposed by Warren Bennis and Herbert Shepard in 1956. An assumption of group developmental schema is that many of these processes are not conscious, yet they significantly affect an individual's emotions and behaviors. Knowledge of these processes serves to inform clinicians of influential elements that are outside of ordinary awareness.

1. The Formative Phase

On entering a group, members have two tasks—to determine how the group can be used to achieve their personal goals and to determine what is emotionally safe. With the leader providing only a bare outline of how to proceed, members naturally employ their usual

strategies to obtain answers on how to proceed. Under the pressure evoked by meeting and having to reveal shameful or guilty aspects of themselves to unknown others, patients utilize previously learned strategies to manage the stressful situation. In the main, such strategies are unconsciously determined, having been arrived at during childhood, but are no longer adaptive. This process is termed *regression*. In this anxiety-laden context, members may cautiously reveal aspects of themselves while simultaneously assessing their emotional safety. Moreover, they invariably have an eye on the leader to determine if their behavior meets with approval, a reaction that suggests “childlike” dependency.

Members, through their interactions, unconsciously develop “rules” (norms) that will protect themselves from being emotionally injured. Norms serve as powerful restraints on the members, but simultaneously they function to protect members from overstimulation and intense discomfort. As these unconscious norms become established they partially replace the therapist, because they serve as rules. Under these circumstances the leader no longer has the same salience for dependency.

Members can benefit from this stage by studying how they respond to new situations. They can learn about their emotional adaptations (defenses) at an interpersonal and internal (unconscious) level, both in relation to authority and to peers. They may feel better because they have shared some of their problems (catharsis), discovered that they are not alone (universality), and they have been respectfully listened to. These represent relational elements inherent to group treatment.

2. The Reactive Phase

Similar to the manner in which children interpret rules rigidly, initial group norms often are experienced (unconsciously) as tyrannical, constricting, and impersonal. In response, clients begin to free themselves and assert their individuality. They may begin to argue or fight, and members’ commitment to the group is tested. At times the group may feel on the verge of disintegration because of the tension. The process unfolds as if participants are saying, “I am an individual with my own feelings and responses, and I will not be controlled by the group.” Thus the members’ task is to find ways of remaining an individual in the group and simultaneously forgo a portion of their individuality. This is a difficult period because the process evokes powerful feelings, which may, for some, seem foreign and aversive. Members may threaten or actually drop out. During this phase, the therapist may lose confidence and may seriously question the value of the enterprise.

In most instances the group and the members survive, discovering that they can manage intense feelings they had not handled previously. They learn to recognize differences, and they learn about the use of their own and others “power.”

3. The Mature Phase

This phase is characterized by clients being able to engage in deeply emotional interchanges and self-expression, with others recognizing the significance of what is being transacted and not interfering with the discourse. Members learn to explore their relationships, including their manner of handling conflict and affection within the group, and apply the new knowledge to their lives outside in a more mature and productive fashion. Not only do participants explore their interactions with others, they examine the personal meanings, as it may be contributing to both their life in the present and in the past. This is not a search for “absolute truth,” but an attempt to examine patterns of behavior and feelings that have created ways of experiencing and interacting that continue from childhood into the present. The ongoing process allows members to experience their repetitious ways of handling relationships and to explore new ways of relating.

The therapist is no longer the only expert, as members learn that they can powerfully and effectively interact with others. This provides a sense of personal competence and efficacy, which is not present in dyadic therapy.

4. The Termination Phase

In ongoing groups clients enter and depart. Optimally, individuals do not leave abruptly. Rather, they provide sufficient time to say goodbye to others with whom they have formed meaningful relationships. Members usually have the opportunity to see others depart, and they familiarize themselves with a variety of responses to leaving. Their own departure, however, is much more personal. Often, under the stress, the departing person regresses to former behaviors. This provides an opportunity for “one more” chance to learn about oneself. No participant leaves entirely “cured.” Group membership provides real relationships as well as transference experiences.

Termination is not easy, as members experience envy, resentment, sadness, and pleasure. Memories of other meaningful losses (separations or deaths) are stimulated. Some may try to convince the departing patient that he or she is not ready to leave, so that they will not have to face the departure. Others push to condense the termination period and diminish their associated affects.

Therapists are not immune to similar emotions. As they do with all phases of treatment, clinicians need to monitor their own emotional states (countertransferences [see later]) to help the group and the departing member experience, to the best of their ability, their departure.

F. Treatment Factors That Affect the Process

1. Cotherapy

Some groups are led by two therapists, which provides clinicians opportunities to share the therapeutic responsibility and to observe and learn from one another in direct action. Cotherapy is often used in training settings. The format requires that the clinicians spend time addressing the process and exploring their areas of agreement and difference.

For patients, the format provides two authority figures, often experienced as parents, with one being experienced as father and the other as mother. It creates an environment similar to a family, with members' associations to the positives and negatives of their family. They can observe how differences and inevitable conflict are managed by the therapists, which may serve as a corrective emotional experience to what was experienced in the family of origin.

Drawbacks to the model are the deemed inefficiency (two persons working where one may do) and the extra time involved in the clinicians addressing their relationship as the process unfolds. Assets of the model include its use in training, an opportunity to work directly with another colleague, and to hear differing perspectives about the conduct of treatment.

2. Combined Therapy

Some patients simultaneously participate in both individual and group treatment. Individual treatment may be either with the group therapist or another clinician. The advantages of such formats are that patients can address emergent problems in private, where there is more individual time for exploration than is available in the group. When the same clinician is therapist in both formats, patterns in the group can be linked to behaviors in the individual treatment, even if the patient does not observe them. Moreover, problems emerging in the dyadic treatment may be brought to the group for further elucidation. This is usually a responsibility of the patient, and not of the therapist.

Almost without exception, patients reveal in the group that they are participating in combined therapy.

This information is examined like any other process element. Other members' common responses are of envy and wishes for special relationships. Opposite concerns suggest that the patient is more ill and requires extra treatment. Many clinicians endorse combined therapy as a very powerful treatment approach.

G. Certain Difficulties in the Treatment Process

1. Countertransference

In the modern therapeutic era, therapists' emotional responses in the treatment situation are examined as potential information about the therapeutic process. These responses may be in the form of the clinician's emotional states or behaviors that may be conscious or unconscious. Historically, countertransference was seen as an impediment to treatment due to the therapist's unconscious responses. Currently, therapists examine their emotional responses, fantasies, dreams, and interactions as sources of information about themselves and their patients. This expanded notion of countertransference separates clinicians' responses into those that can be useful in understanding either the individuals or the process from behaviors that may interfere with the treatment.

In group treatment therapists may respond to experiences from their past as stimulated by an individual, subgroups or the group-as-a-whole process. Mistakes and misunderstandings are inevitable. They may arise from a "reasonable" response to the emotions in the present or from the clinician's past. Interventions that are well intentioned may be heard, understood, or experienced by members in unintended or aversive fashion. Remaining alert to these possibilities enables the clinician to detect processes that may have been derailed.

2. Group Safety

For any treatment modality to function effectively, participants must have confidence in the safety of the situation. The agreement establishes a basic element—no physical contact. Patients who are unable to control themselves may not be able to continue in the group and may be asked to leave temporarily or permanently. In addition to physical actions, patients may threaten others verbally—an action that on a continuing basis is not compatible with group treatment.

3. Extra-Group Contacts

Members almost universally have contact with one another outside the treatment setting. This may naturally occur in the waiting room before the meeting or

when leaving together at the end of a session. Ordinarily, this is not problematic. Not infrequently, though, patients will attempt to manage feelings emerging in the group by meeting with others. Sexual liaisons take place rarely. All salient contacts need to be openly discussed in the therapy, where patients can learn about themselves (see group agreement). Persistence of any emotionally laden extra-group contacts sets up destructive subgroups (i.e., there are secrets) and may be incompatible with an effectively functioning group.

4. Excessive Premature Terminations or Dropouts

Patients leave the group prior to completing treatment for a variety of reasons. Within the first 12 weeks, in almost every new group one or two members are likely to stop treatment, sometimes without notification. Reasons for dropping out may include fears that hearing others emotions may be harmful, or life changes interfere with regular attendance (these changes are sometimes unconsciously “arranged” because of emotional responses).

To provide stability, replacements should be added to the group. If an excessive number of patients drop out, the viability of the group may be in doubt. Most groups do not function effectively with four or less members.

H. Other Populations

Groups described in this section are conducted with basic psychodynamic principles. Characteristically, patients have limitations in their ability to examine unconscious processes. This limitation does not obviate the unconscious processes that contribute to group dynamics. In these circumstances, treatment focuses more extensively on support, stabilization, and reintegration that in part arises from the supportive elements intrinsic to group dynamics. Examination of unconscious processes is limited, concordant with patients’ limited capacities. Such groups represent the application of psychodynamics in an expanded range of setting and populations.

Psychodynamically informed groups have been shown to be useful in inpatient or in partial (day) hospitals. In these settings, patients may meet daily in dynamically oriented groups as an intrinsic element in a broader range of therapeutic activities. The increased meeting frequency serves as support and enables individuals to expose deeper layers of their personality. The results of this treatment have been encouraging for difficult patients who do not respond to more usual outpatient therapy.

Groups for victims of a common trauma or for individuals experiencing grief have been found to be effective in relieving individuals of the resultant acute and sometimes chronic symptoms. Such groups are generally time limited, and the dynamic theory often focuses on the termination issue, which may more specifically reexpose the experience of loss or death.

Psychodynamically informed groups benefit persons with chronic mental illness. Patients with diagnosis of schizophrenia, bipolar disorder, other persistent major illness, or severe personality disorders represent the greatest number of individuals in this category. These individuals are generally not seen as amenable to “insight,” but they can benefit significantly from the slower developing, attenuated relationships. As described by Walter Stone in 1996, groups form in which some individuals attend regularly (core members) and others intermittently (peripheral members). Over time the group develops a workable degree of cohesion, and patients gradually develop trusting relationships. Members of these groups often do not thoroughly examine intragroup relationships and thus have limited potential for insight into their here-and-now transactions. Rather members achieve their benefits primarily through supportive, self-revelation and learning factors.

II. THEORETICAL BASES

Psychodynamic group psychotherapy arises from two theoretical bases: social psychology and psychoanalytic theory.

A. Social Psychology

Social psychology addresses the interaction between the social environment and the individual. Kurt Lewin, who developed field theory, conceives of a group not as a sum of its parts, instead groups form as a system that arises from interacting individuals. In turn, the system affects members’ behavior and feelings. Groups have goals, roles, norms, boundaries, and develop cohesion, and evolve over time.

Psychodynamic groups have goals of improved individual functioning. Roles define the functions necessary to accomplish the task. The schema suggested by Roy MacKenzie posits four group roles: task, social, divergent, and cautionary. The task role, primarily cognitive, helps define what has to be done to accomplish goals. The social role attends to members’ feelings. The divergent role challenges authority and questions normative

views. The cautionary role hides feelings and thoughts. These roles are omnipresent and represent group, not solely individual, functions. Potentially any person could fill each role.

Norms are the conscious and unconscious rules of behavior that influence and regulate the members and the nature of the interactions (i.e., conscious: we should all be on time; unconscious: we will not express anger here). External boundaries define the time, place, and proper information to bring to the group (i.e., one is to tell about oneself). Internal boundaries also define aspects of relationships among members (i.e., feelings are verbalized, not acted on or levels of communication: conscious/unconscious).

Over time, groups will “develop,” as initially described by Warren Bennis and Herbert Shepard. As members resolve conflicts concerning authority and intimacy, roles become distributed and flexible; norms change, and exchanges are freer in the service of achieving goals of individual development and maturation. This is a sociopsychological process seen as somewhat akin to individual psychological development.

B. Psychoanalytic Theory

Sigmund Freud was the founder of psychoanalytic theory of the human personality. Basic theoretical tenets include individuals' behavior is influenced by unconscious processes, (which may be glimpsed through dreams and “mistakes,” like slips of the tongue); individuals are in conflict with efforts to satisfy their instincts (aggressive or erotic), and their own or societal standards. Symptoms are a result of such conflicts. Individuals will transfer their childhood instinctual lives, often expressed as wishes and hopes, to persons in their current life (transference). They will be resistant to directly examining or acknowledging aspects of themselves (resistance) because of perceived danger associated with past childhood experiences or from their own internal prohibitions. They will repeatedly try to master these early conflicts (repetition compulsion) that will emerge in their present relationships. Psychoanalytic/dynamic theory attempts to help individuals understand the meaning of their behaviors or emotions, thereby freeing the person from unconscious forces.

Modifications of original Freudian theory have placed greater emphasis on wishes for relationships, rather than as gratifications of instincts. Moreover, more attention has been directed toward the role of culture in determining one's behavior.

Patients will exhibit repetitious patterns of behavior directed toward the therapist, peers, or to their image of the “group.” The group then becomes a microcosm of their behavior in the external world, with allies, enemies, saviors, or as objects (others or the whole group) of affection or hate (transferences). Members learn about their unconscious motivations or wishes for relationships through their interactions (transferences) that emerge through their repetitious behaviors and emotional responses. This new knowledge will then be available for members to make changes as they are made conscious and examined in the group interactions.

III. EMPIRICAL STUDIES

Treatment efficacy of group psychotherapy has been explored for more than four decades. This has been a most problematic area of research because of the multiple elements contributing to treatment outcome. Nevertheless, meta-analytic reviews of group therapy have shown that group treatment is more effective than no treatment and has equivalent efficacy with individual therapy. These findings, however, need to be appreciated as generalizations, because most of the studies have been with cognitive behavioral treatments. Those with psychodynamic orientation have been limited by a lack of specificity along general demographic dimensions, including age, gender, diagnostic description of the patient populations, and duration of treatment.

Moreover, efficacy studies of group psychotherapy have emphasized individual patient outcome and underemphasize group outcome, that is some groups (therapist–client composition) appear to be more efficacious than others. Insufficient emphasis has been placed on assessing the contribution to outcome of leader behaviors, member-to-member interactions, or the group as a whole setting. In 1999, The National Advisory Mental Health Council's Clinical Treatment and Services research workgroup, concerned with fundamental flaws in present research designs, proposed much broader guidelines in hopes of learning more about the subtle factors of relationship and personality in the therapeutic venture.

Nevertheless, certain consistent findings have emerged that inform group therapy outcome. Patients are generally reluctant to enter into group treatment. Individuals assigned to group treatment are less likely to appear for their initial group meeting than persons assigned to individual treatment. Persons of lower social class and of color are more likely to drop out.

Groups that have a greater number of dropouts are less likely to have good outcomes than those with more stable membership. Individuals who successfully complete their group treatment are likely to credit their benefit to peer interactions, rather than their interactions with the therapist.

Studies of homogeneous populations have been few. Recently, however, reports of patients with borderline personality treated in partial hospital settings have shown improvement as reported by Canadian researchers, Anthony Joyce, Mary McCallum, and William Piper in 1999 and by the Norwegian research team including Theresa Wilberg, Sigmund Karterud, Oyrind Urnes, and colleagues in 1998. Individuals in these studies were treated with a variety of group formats daily in a partial hospital for 16 to 18 weeks. The major emphasis was psychodynamically oriented group treatment. The Wilberg *et al.* study included a 30-month continued outpatient group treatment. Those participating in the continuing treatment had better outcomes than those who did not. The methodology did not include random assignment and therefore requires replication. These studies represent a focus on more homogeneous populations with methodologies that include direct verification of therapists' behavior, thereby controlling for some of the variability.

Despite the overall limitations, research into the efficacy and the process variables that may contribute to the outcome of psychodynamic group psychotherapy remains promising.

IV. SUMMARY

Psychodynamic group psychotherapy is a treatment modality in which a small group of individuals (6–10) meet at a regularly scheduled time and place to address and seek to improve their emotional functioning. The theoretical bases for the treatment derive from social psychology and from psychoanalytic theory. Groups require careful preparation that includes setting goals for the group, recruiting, and preparing prospective members.

Therapists are responsible for creating a structure that facilitates open-ended discussion in which individuals can freely express themselves and examine the un-

folding relationships among them, with the leader, and with the image of the group. In the therapeutic process members will, through repetition compulsion, recreate difficulties that brought them to therapy. Through the relationships and interpretations, participants will learn about their emotional responses and dysfunctional behaviors. The group provides a setting in which they may experiment with new behaviors before attempting them outside. Through the repeated opportunities to see, understand, and alter their behaviors and feelings, patients will mature and gain the capacity for greater intimacy and satisfying relationships and societal roles.

GLOSSARY

- aphonia** Loss of voice.
- breathiness** Audible flow of air during phonation.
- dysphonia** Abnormal voice quality, heard as hoarseness, breathiness, or harshness.
- conversion aphonia** Voice loss in the absence of physical factors.
- conversion dysphonia** Voice disorder characterized by hoarseness, breathiness, or harshness that appears in the absence of physical factors.
- harshness** Phonation that has sudden onsets of phonation along with pitch and intensity abnormalities.
- hoarseness** Aperiodic vibration pattern of phonation, breathiness, pitch breaks, low pitch, and episodes of aphonia.
- hyperfunctional** Excessive function due to behavioral misuse or abuse.
- laryngeal massage** Therapeutic technique used to relax the musculature surrounding the larynx.
- muscle tension dysphonia** Voice disorder caused by excess muscle tension in the larynx.
- mutational falsetto** Voice disorder associated with a high-pitched phonation without structural abnormalities.
- phonation** Vibrations of the vocal folds creating voice.
- puberphonia** Voice of an adolescent.
- psychogenic** Referring to a voice that has psychological origins.

The human voice conveys a wide range of emotions, feelings, attitudes, and affections. It is a dynamic, complex mechanism that is central to verbal communication and is so individualized that for all practical purposes, no two voices are alike. A person's voice may be aesthetically displeasing or may convey a particular personality or emotional state. It is possible to hear a tremulous voice when a person faces fear or danger, an aphonic or dysphonic voice when someone endures extreme emotional stress, or an abnormal vocal pitch in which a man may sound like a woman or a woman like a child. Thus, the human voice has an extremely wide range of pitch, loudness, flexibility, and qualities, but the boundaries between normal and abnormal are not clearly defined. In 1990, Arnold Aronson defined a voice disorder as one that differs in terms of pitch, loudness, quality, or flexibility from the voices of other individuals of similar age, gender, and/or cultural group. However, there is no universal agreement of when either a normal or an abnormal voice exists.

There are a number of reasons why a person's voice might sound abnormal. Some voice problems can result from behavioral or hyperfunctional misuse of the vocal mechanism, abnormal medical and physical conditions, and psychological stress. Given the focus of this book, this article is limited to a discussion of the symptoms and treatments for three types of psychologically based voice disorders. These include (a) conversion reactions resulting in aphonia and dysphonia, (b) mutational falsetto or puberphonia, and (c) muscle tension

dysphonia. These voice problems are commonly referred to as “psychogenic” voice problems because the disorder emerges from abnormal psychological factors in the presence of a physically normal voice.

I. DESCRIPTION OF TREATMENT

Before the treatment for these three psychogenic voice disorders is described, it is necessary to discuss some general features of patients with these types of voice disorders. In light of the strong connection between emotions and vocal behaviors, it is not surprising that emotional conflicts and stress change the way the voice sounds and functions. In 2000, Daniel Boone and Stephen McFarlane noted that increased emotionality or stress will cause significant perceptual changes in the voice because people will: (a) produce shorter and more shallow breathing patterns, and (b) increase the tension of the vocal folds and neck musculature, creating an elevation of the larynx in the neck. The vocal symptoms resulting from these physiological changes can range from complete aphonia to varying degrees of dysphonia characterized by hoarseness, breathiness, and abnormally high-pitched phonation.

Because emotions and vocal performance are so closely related, effective therapy for psychogenic voice disorders requires attention to the entire profile of the person rather than the simple remediation of the vocal symptoms. Therefore, most voice therapy involves a multidisciplinary team approach. Key team members include a speech-language pathologist, an otolaryngologist, a neurologist, and/or a psychologist. The speech-language pathologist and otolaryngologist are the primary members of the team and work collaboratively to rule out the presence of organic laryngeal disease, systemic illnesses, and any form of vocal fold movement disorder. A neurologist is called on to evaluate the voice disorder from a neurological perspective while a psychologist may provide important follow-up support to voice therapy when it is apparent that the voice problem is an expression of significant psychological difficulties.

One of the hallmark features of all psychogenic voice disorders is that the voice sounds abnormal yet the person doesn't have any form of organic laryngeal pathology or disease. In other words, the voice appears normal on visual inspection but is perceptually different from other normal voices. In most cases, the cause of the disorder can be traced to some form of life stress or to personality disorder. Interestingly, normal movement of the vocal

folds usually occurs during a variety of vegetative laryngeal maneuvers such as quiet breathing, coughing, throat clearing, and laughing. Disordered vocal symptoms appear once the verbal communication is initiated.

The following is a description of voice therapy for conversion reactions, mutational falsetto, and muscle tension dysphonia.

A. Conversion Reactions: Aphonic and Dysphonic Voices

People who suddenly display hoarseness or lose the ability to phonate are thought to be suffering from a conversion reaction. These patients believe their voice problem is due to a physical or medically related disorder when, in fact, the problem is related to behavioral repositioning of their larynx due to unresolved interpersonal conflicts. They are unaware that they have translated an emotionally based communication problem into a physical voice problem. Typically, the voice symptoms are triggered by colds, flu, or a short period of laryngitis. Consequently, the person believes the vocal symptoms are a result of an upper respiratory infection rather than an unresolved emotional conflict that is related to communicating feelings toward others. The client's voice is characterized by aphonia, high-pitched squeaks, or varying degrees of hoarseness.

Treatment for this type of voice disorder involves the cooperation of the otolaryngologist and the speech-language pathologist. A patient needs to be reassured by both professionals that the larynx appears and functions normally. In 1995, Moya Andrews pointed out that it is important for the speech-language pathologist to build a positive relationship with the patient to help the patient discuss the main source of emotional conflict and stress. This should set the stage for having the patient accept the notion that the vocal condition is due to some type of emotional conflict. Once this issue is discussed, the speech-language pathologist explains to the patient how emotional stress and tension can interfere with the voluntary control of the voice. Next, the clinician should attempt to elicit a better-sounding voice pressing in, up, or down on the larynx while the patient sustains a vowel sound. Laryngeal massage, which involves using the fingers in a circular motion to reduce tension in the neck musculature around the larynx, is attempted also to help restore normal voicing. It is common to have the patient produce a significantly improved sounding voice during a cough, while clearing the throat, laughing, and shouting. If the voice improves dramatically during these involuntary forms of

phonation, the problem is clearly a conversion reaction. A clinician can facilitate a normal sounding voice through the use of these vegetative vocal gestures. For example, the clinician can have the patient cough but then say a sustained vowel sound immediately after the cough. By extending the vocal sound of the cough into a sustained vowel gives the patient an auditory image of a normal sounding voice and also shows the patient that a normal sounding voice is possible. Therapy continues with having the patient recite the days of the week, counting, or simple oral reading. Gradually, the person should be asked to maintain the voice during a conversation with the clinician. If this occurs, then the patient can be encouraged to talk about the underlying emotional stress or conflicts that precipitated the aphonic or dysphonic voice. Follow-up therapy sessions might be needed to ensure that a normal sounding voice is maintained. In those cases in which the patient is unable to maintain voicing, referral to a psychologist or psychiatrist is recommended.

B. Mutational Falsetto (Puberphonia)

The second major type of psychogenic voice disorder is mutational falsetto, which is sometimes called puberphonia. This voice disorder is most commonly found in young adolescents, but it can also occur in adults. The main vocal symptom of this disorder is an abnormally high-pitched voice for either the male or female even though the voice has undergone its normal postpuberty changes. In other words, the patient has a mature larynx but for some psychosocial reason rejects the normal, lower-pitched voice. Typically, the mutational falsetto voice patient exhibits an elevated larynx, tightly stretched vocal folds creating a thin vibratory mass, and a shallow breathing pattern.

In 1995, Andrews pointed out that treatment of this disorder begins with medical confirmation that laryngeal maturation has occurred and that a laryngeal web or other structural deviations in the larynx have been ruled out. If there are no concerns about the physical condition of the larynx, the clinician can elicit a lower-pitched voice in the following ways. First, the clinician can use laryngeal massage to decrease extrinsic and intrinsic laryngeal muscle tension, adjust head position, and attempt to pull the larynx down to a lower neck position. Gradually, the fingers move down to the thyroid cartilage and thyroid notch where the larynx is gently moved into a lowered position. Some patients will resist the lowering of the larynx, but a clinician

should be persistent and apply considerable force in pulling the larynx down to a more typical resting posture. Massage helps loosen tense musculature and stretches the laryngeal musculature, which contributes to a relaxed vocal mechanism. At the time the clinician is pulling the larynx down, the patient is instructed to cough, sustain a prolonged vowel sound, or repeatedly produce an abrupt onset of phonation. The patient also will produce a lower-pitched voice if a deeper breath is taken prior to phonation. In 1990, Aronson noted that the shift from a high- to a low-pitched voice will be sudden when the voice is produced forcefully and aggressively.

Once a lower-pitched voice is achieved, the clinician should have the patient habituate the lower pitch sound through repeated vowel productions using an abrupt or sudden onset of phonation. Eventually, the lower-pitched voice will become more consistent as the patient moves from vowel productions to words, and then phrases to spontaneous conversation. The speech-language pathologist will encourage the patient to use the lower-pitched voice because it is the most desirable and acceptable voice. Usually, only a few therapy sessions are sufficient to achieve a consistent, normal-sounding voice. At times, the patient rejects the lower-pitched voice because of the difficulty accepting the new vocal image. In those cases, it may be necessary to refer the patient for psychotherapy. Usually, patients return to therapy once they have accepted and become accustomed to the idea of the lower-pitch voice.

C. Muscle Tension Dysphonia

This type of voice disorder was first described by Murry Morrison, Hamish Nichol, and Linda Rammage in 1986. It is usually seen in young to middle-age adults who have difficulty coping with stress or use their voice in stressful situations. There is palpable muscle tension around the larynx, and during phonation, the suprahyoid musculature becomes tight. One of the main features of the disorder is that during indirect laryngoscopic exam, there is a visible space between the vocal folds in the posterior portion of the vocal folds during phonation. This posterior gap in the vocal folds contributes to the perception of a breathy voice and, to some degree, a harsh voice quality. Patients with muscle tension dysphonia usually complain that their voice is weak, lacks appropriate loudness, and tires easily.

Treatment for this type of psychogenic voice disorder typically involves laryngeal massage and a technique

called “yawn-sigh.” The yawn-sigh technique involves having a patient pretend to yawn, which creates an open vocal tract and helps the neck musculature to relax so that a lowered laryngeal position is obtained. When the patient exhales after the yawn, the patient is encouraged to create a gentle and brief phonation (i.e., a sigh) at the end of the yawn. Repeated practice of this technique may facilitate an improved voice quality. However, if this technique is ineffective in producing a better-sounding voice, a clinician will want to perform laryngeal massage and manual repositioning of the larynx, combined with simple vocalizations as done with conversion reactions and mutational falsetto patients. As stated earlier, the patient is asked to produce a sustained vowel sound while the laryngeal massage is taking place. A clearer voice quality and slightly lower pitch indicate that excessive muscle tension around the larynx is subsiding and/or the larynx is pulled down or the thyroid cartilage is gently squeezed. Once a better voice is achieved, the patient should practice using the voice in gradually more complex speech contexts. Patients can be taught how to massage their larynx and move it into a lowered position. In addition, the clinician explains the connection between emotional stress and its impact on increasing muscle tension levels in the neck as well as the direct effect muscle tension has on changing voice quality.

II. THEORETICAL BASES

In 2000, Boone and McFarlane stated that the most accurate theory that explains the mechanics of phonation is the myoelastic-aerodynamic theory of phonation developed in the late 1960s. The basic notions of this theory are that intrinsic vocal fold muscle contractions create elastic movements of the vocal folds, which interact with aerodynamic components. Specifically, airflow expelled from the lungs generates air pressure (aerodynamics) below the vocal folds as exhalation for speech begins. At the same time this aerodynamic process is initiated, there is simultaneous adduction of the vocal folds through contractions of the vocal fold adductor musculature. The vocal folds vibrate in response to the airflow passing between the vocal folds, separating the folds. The elasticity of the vocal fold mass brings the folds back toward the midline, and the vibratory process is repeated. The pitch of the voice and the flexibility of vocal fold movement are directly dependent on the mass, length, and internal tension of the vocal fold musculature.

In addition, the contribution of the epithelial covering and underlying lamina propria of the vocal folds (i.e., mucosa) cannot be ignored as an important component to vocal fold vibrations. Complex movements of the vocal fold cover create a mucosal wave that moves laterally across the superior surface of the each vocal fold at typical conversational pitch and loudness levels. Any type of voice disorder can be explained in terms of disruptions in any one or more components of the myoelastic-aerodynamic theory of voice production and alterations in mucosal wave activity. As stated earlier, changes in the internal position and tension levels of the larynx as well as changes in the airflow and air pressure characteristics of phonation can lead to abnormal voice qualities in psychogenic voice disorders.

III. EMPIRICAL STUDIES

Research confirming the effectiveness of the therapy approaches for psychogenic voice disorders are lacking. Perhaps the major reason for this is that most clinicians are able to achieve a normal or close-to-normal sounding voice within one or two therapy sessions. Moreover, clinicians may not have a sufficient number of these types of cases to warrant publication of the results of their clinical treatment. Our clinical results show that approximately 90% of the psychogenic patients we treat exit our clinics with normal-sounding voices. Relapse can occur but one or two treatment session(s) is usually sufficient to have the patient's voice return to normal.

The studies that are available indirectly address the effectiveness of the techniques used to treat psychogenic voice disorders. As discussed in the treatment section, laryngeal massage and repositioning of the larynx are used with all three psychogenic voice disorders described in this article. In 1993, Nelson Roy and Herbert Leeper showed that laryngeal massage was effective in improving the voices of 17 patients with voice problems that had no organic involvement.

In another study in 1998, Louis Luguna, Charles Healey, Debra Hope described the successful remediation of a patient with a voice disorder secondary to social phobia. At the outset of therapy, the patient was diagnosed with muscle tension dysphonia. The patient's voice was characterized by a combination of dysphonia, vocal tremors, and occasional spasmodic closure of the vocal folds. Treatment was successful in reducing the abnormal vocal symptoms and social phobia.

IV. SUMMARY

Psychogenic voice disorders represent a small portion of patients with voice disorders that a speech-language pathologist treats. However, the large majority of patients are capable of achieving a normal-sounding voice in a treatment session or two. This is possible because the voice disorder is not related to any organic involvement. Elevated levels of muscle tension in and around the larynx, a heightened posture of the larynx, and poor respiratory support for phonation can result in a voice problem ranging from complete aphonia to varying degrees of dysphonia. High-pitched, tense voices are always seen within the subgroup of the population with voice disorders. Treatment for psychogenic voice disorders involves convincing the patient that the problem is related to a functional misuse of the larynx. Through laryngeal massage and manual repositioning of the larynx while the patient produces simple vocalizations such as sustained vowels, coughing, or clearing the throat, a normal voice can quickly be established. Treatment for these types of voice disorders is effective when proper

diagnosis and management are provided by a speech-language pathologist.

- c. *Selective serotonin reuptake inhibitors*—medications that promote greater synaptic availability of the neurotransmitter serotonin.
 3. *Hypnotics*—different classes of compounds (e.g., benzodiazepines) used to induce sleep.
 4. *Mood stabilizers*—multiple types of medications that reduce or prevent mood lability and associated symptoms in affective disorders (e.g., bipolar disorder).
 5. *Antipsychotics*—different classes of medications that target many types of malfunctioning neurotransmitter systems such as the dopamine system and relieve and prevent symptoms of psychoses.
- sequential treatment* The addition of psychotropic medication to psychotherapeutic treatment or psychotherapy to pharmacotherapy when a monotherapy is unsuccessful in alleviating symptoms of a patient's mental disorder.
- split treatment* The primary treatment of a patient by a psychotherapist in collaboration most often with a psychiatrist who is responsible for the management of medication.

GLOSSARY

combined treatment The simultaneous prescription of psychotherapy and pharmacotherapy in the treatment of a patient's mental illness.

integrative treatment The provision of pharmacotherapy and psychotherapy by the same clinician.

psychopharmacology The treatment of mental illness with classes of medications that include the following

1. *Anxiolytics*—compounds that possess antianxiety effects to relieve emotional tension.
2. *Antidepressants*—agents from a number of different classes used primarily to relieve depression although often useful in treating other symptoms.
 - a. *Monoamine oxidase inhibitors*—medications that inhibit the degradation of monoamine oxidase in the brain thereby elevating levels of available biogenic amines.
 - b. *Tricyclic antidepressants*—compounds that increase the availability of multiple neurotransmitters, (e.g., norepinephrine) in the brain.

I. DESCRIPTION OF TREATMENT

Throughout the last 10 years, managed behavioral health care has demanded an increasing accountability of mental health professionals to demonstrate both effectiveness and cost effectiveness in the treatments they provide. Because cost containment is the primary objective of managed care systems, the delivery of least expensive treatments has been paramount. This demand has resulted in a significant shift in the treatment models of patients or clients with mental illness toward therapies

that are less costly and time intensive. However, the use of combined treatment, that is the employment of both psychotherapy and medication in the treatment of mental disorders, has been a preoccupation of modern psychiatry for more than 40 years and is becoming standard for many mental disorders and psychological problems. In the case of the physician mental health professional, managed care has, in general, preferred a model wherein psychotherapy is provided by a nonphysician mental health provider, and the physician, usually a psychiatrist, becomes responsible for the initiation and ongoing management of pharmacotherapy. For nonphysician mental health professionals, they have become increasingly obligated to adhere to guidelines that mandate a specific treatment for a specific disorder that frequently requires the use of medication. This type of treatment has been referred to most often as split or collaborative treatment. Managed care has undoubtedly refocused professional attention on collaborative care.

Although there is sparse data to support either the effectiveness or cost effectiveness of split treatment in naturalistic settings, nevertheless it has become a common practice. There are however a small number of studies that have suggested the possibility of reduced costs when medication and psychotherapy are provided by the psychiatrist under the auspices of a managed care arrangement.

The use of medication with psychotherapy is limited by neither the type of disorder nor the theoretical model of psychotherapy employed. Indeed in the case of interpersonal psychotherapy (IPT) medication issues where appropriate are routinely presented as a significant component in the treatment process from the start. Part of the appeal of this type of psychotherapy is the direct attempt to provide treatment in a situation that closely resembles the traditional nonpsychiatric doctor-patient relationship thereby reducing the stigma often associated with the need for mental health services. Similarly, the integration of psychotherapy and medication, when indicated, often characterizes cognitive-behavioral as well as psychoanalytically oriented psychotherapies.

II. THEORETICAL BASES

The prominence of a biologically based psychiatry within the last 40 years was in no small part facilitated by the substantial development of new compounds to treat mental disorders. Initially there was resistance to the introduction in psychotherapy of psychotropic med-

ications. Some expressed concern that psychotropics irreparably altered the treatment relationship and dampened symptoms to such a degree that patients were no longer motivated to undergo psychotherapy. Others claimed that the introduction of medication encouraged a passive, dependent stance and perhaps the potential for magical thinking and symptom substitution. Still others claimed a lowering of the patient's self-esteem as a result of viewing himself or herself as being more ill and requiring some external agent to function. Some therapists feared that using medication raised unnecessary fears in patients that they were somehow less interesting to treat.

On the other hand, there may be benefits of employing medication within the psychotherapeutic relationship. These include:

- Patient self-esteem may be enhanced through symptom reduction.
- Greater safety and therefore increased expression of emotions by patients.
- Greater patient accessibility to psychotherapy through enhanced cognition, verbalization, and abreaction.
- Improvement in autonomous ego functions such as thought, attention, concentration, and memory permitting greater ego strength for verbal treatment.
- Reduction of stigma in help seeking through a positive placebo effect.
- Evocation of feelings and fantasies about receiving medication and the accompanying side effects that provide useful insights about the patient's personality and psychological state.
- Creation of an avenue to explore countertransference feelings around medication side effects or dose changes.
- Provision of a transitional connection between patient and therapist at times of unanticipated interruptions in treatment.
- Demonstration of patient conflicts about success when medication provides improvement.

Conversely, patient compliance or adherence to prescribed medication is a daunting problem for all physicians regardless of specialty. Some studies have found that nearly one-half of all patients prescribed a medication do not follow the prescription. Very often adding psychotherapy to a medication-based treatment program brings significant improvement in this problem because it establishes a format to explore noncompliance issues. In this respect, it is important to remember that effective treatment with pharmacological agents

requires a solid therapeutic alliance as is the case when psychotherapy alone is provided. Helpful psychiatric treatment is based on correct diagnosis, however making a correct psychiatric diagnosis without a productive doctor–patient relationship does not assure that patients will take their medications.

Regardless of theoretical persuasion, therapists know that the prescription of medication has significance for each patient in psychotherapy. If the psychological meaning of taking medication can be understood, it can provide a useful resource for the psychotherapist. This is true for either a treatment plan in which a psychiatrist is both prescribing medication and providing psychotherapy or in those instances when a physician is directing the pharmacotherapy and a nonphysician mental health professional is responsible for the psychotherapeutic component.

Medications may have positive and negative meanings for patients. For some, the prescription of medication is a positive reflection that the professional or professionals are interested in and acknowledge the patient's emotional pain and discomfort. Other patients may feel that the introduction of medication into a psychotherapy can be a reflection of the therapist's disinterest or discomfort with the patient's plight. For most patients, medication is viewed as a trustworthy and effective intervention, yet for the suspicious patient medication may be experienced as toxic, hurtful, and an attempt on the part of the physician to control the patient. Similarly, although most patients view medications as relatively safe interventions, others attribute psychological significance to even the most benign side effects. Because for many psychotropics, improvement in symptoms does not occur for 2 to 3 weeks or longer, some patients view the gradual onset of action as a sign that the psychiatrist is inept and or uncaring and that the nonphysician collaborator is not to be trusted because of the questionable referral. For those who have difficulty following the medication regimen, the psychotherapist is obligated to explore the possible reasons. Is it a matter of the patient's denial, incompetency, lack of motivation, the presence of an recognized comorbid disorder, or might this nonadherence be a true reflection of a poor therapeutic alliance? Regardless of diagnosis, for some with a mental disorder, poor adherence may be a representation of an unstable, inconsistent, or chaotic lifestyle.

Despite the substantial scientific evidence demonstrating (alone and in combination) the efficacy of psychopharmacology and psychotherapy for many disorders, cognitive neuroscience does not offer a unified theory explicating the precise mechanisms about the in-

teractions between the two types of treatment. Medications, by and large, are conceptualized in terms of their ability to enhance the capacity of the biological system to respond, experience, and integrate information. Psychotherapies address these issues as well, but fundamentally they are concerned with meaning. Different psychotherapies, of course, utilize different approaches at discovering and modifying the meaningfulness of certain events, feelings, conflicts, wishes, and fears. There is a growing knowledge, for example, about the neurobiology of psychotherapy that has described on the molecular and structural levels how learning and memory may bring about change in psychotherapy. Integrated neuroscience promises that someday what we call the mind will be explained from a biological point of view, at this point in time however, the clinician must juggle two conceptual approaches to understanding human behavior in illness and in health.

III. CLINICAL CHALLENGES IN USING PSYCHOTHERAPY AND PHARMACOTHERAPY

When a psychiatrist is providing both psychotherapy and pharmacotherapy there are some specific challenges to the delivery of effective combined treatment. These include:

- *The adoption of an overview to the patient that encompasses and integrates both biological and psychosocial domains.* This may require the clinician to adopt a more directive and educational manner of relating when discussing medication concerns, and perhaps, in the case of a psychoanalytically oriented psychotherapist, becoming more active than usual in this portion of the visit.
- *The establishment of a system for addressing medication issues with the patient.* The clinician may decide to raise medication issues at the start or very end of the session. In the former case, medication concerns are sure to be covered, and important and helpful material about the therapist–patient relationship may be introduced and explored throughout the entire visit. However, some therapists object to the physician setting the initial agenda for the meeting and favor permitting the patient to begin each session with whatever is most pressing. Others feel that by electing to discuss medication at the very end of a meeting, there is the possibility of premature closure of a significant discussion. Regardless of which approach is selected, it is vital to establish consis-

tency. Deviation from the traditional approach is often helpful in identifying potential countertransference events. For example, when a medication discussion is introduced by the clinician atypically in the middle of a session, it is often an indicator of some discomfort.

- *The development of a systematic format for addressing side effects, requests for changes in medication dose and type, and requests for discontinuation of pharmacotherapy.* In the first case, complaints about side effects may be an important manifestation of patient resistance to psychotherapy. If in the middle of a well-established insight-oriented psychotherapy, the psychiatrist considers raising the possibility of medication, this may be an indication of increasing frustration with the patient's lack of progress.

- *Acquiring a particular sensitivity to termination issues.* It is not uncommon for patients in some types of therapies to experience a recurrence of symptoms at the end stage of treatment. The clinician should not assume that such events require additional or reintroduction of medication. Invariably, this phenomenon is a reflection of the patient's conflicts about the end of the therapeutic relationship and requires appropriate exploration.

Professionals working in collaborative or split treatments face quite different challenges. These treatment relationships may consist of a nonphysician mental health professional and a psychiatrist, a primary care physician and a psychotherapist, and a psychoanalyst or psychiatrist and psychopharmacologist to name but a few formats. The practice of collaborative treatment is by no means rare and two-thirds of practicing psychiatrists have reported prescribing medication for patients in psychotherapy with other professionals. However, the greatest challenge in providing quality collaborative care is assuring adequate communication. This includes communication between the patient and each of the professionals but especially between the psychotherapist and physician.

The amount of time that is required to establish an effective relationship between two providers in a split treatment is by no means insubstantial. However failure to delineate many aspects of the collaborative relationship at the outset is undoubtedly the primary reason for poor patient outcome. First, cooperative treatment implies equal respect for the responsibilities and contributions of each provider. There is no place for ideological or professional tensions in the provision of effective split treatment. Second, the patient must be educated about the unique aspects of entering this type of treatment relationship. These include consent for the professionals to communicate frequently about the patient's progress,

difficulties, and medication side effects. Confidentiality is defined differently in this type of treatment relationship, and patients must be aware that information from either professional will be discussed routinely and particularly at times of change or crisis in the treatment.

Informed consent in collaborative treatment should outline clearly the benefits and risks of each type of treatment component as well as explore the patient's expectations of the combined treatment. Organizational guidelines in the field of psychiatry suggest that there should be documentation of each party's responsibilities and that this information has been conveyed to the patient. This includes the need for periodic assessment of the treatment process. It is helpful to prepare a document that explains responsibility in times of emergencies, need for hospitalization, vacation coverage, and a method and frequency of collaboration that is not limited to times of crisis. In this regard, many professionals have begun to rely on electronic mail or fax to keep their collaborators up-to-date. Others prefer face-to-face meetings or telephone conversations.

Consistent communication between the treating professionals serves other purposes beyond legal concerns. Because transference is universal regardless of treatment modality, the introduction of a second professional may often provide some unique challenges. Depending on a patient's psychological problems, a three-person system may activate significant unresolved conflicts and unexpressed expectations about the treatment team. On the other hand, the propensity for splitting is high in some types of patients especially those with particular personality disorders. Idealization of the physician because he or she prescribes medication whereas the psychotherapist does not is common. Similarly, some patients experience a quick medication visit as being reflective of the disinterest of the physician, and the therapist is then held in much higher regard. Negative comments about either professional may serve as important indicators of the patient's problems and characterological style and require that their psychological importance be understood and explored with them within the treatment. Under no circumstances, except in cases of ethical misconduct or malpractice, should either professional collude with the patient to criticize another collaborator. Persistent negativity about one provider should be discussed within the collaborative relationship to decide how best to address this issue.

As noted previously, the suggestion to seek a pharmacological consultation invariably raises relevant patient concerns about the meaning of the current treatment relationship as well as the prognosis. How consideration

for medication consultation is introduced has great influence on the patient's ability to follow through with the recommendation. The nonphysician professional should be clear for the reasons for referral. Is it a request for a second opinion about the patient's problems and suitability for psychotherapeutic treatment alone, a request for assistance in controlling disruptive symptoms, or even concern about the potential for an unmerited lawsuit.

IV. APPLICATIONS AND EXCLUSIONS

As will be reviewed shortly, the empirical evidence for employing combined treatment is growing. This is true across the spectrum of mental disorders from the most disabling to those disorders that are often associated with higher levels of functioning and coping. There appear to be no patient populations for which combined treatment is contraindicated although the usual culturally based reservations about psychotherapy or the taking of medication are always relevant. Beyond cultural considerations, the nonphysician professional must be aware that for some patients, medication is not an acceptable form of treatment and that a significant number of patients depending on their disorder will not respond to medication regardless of the type and duration of treatment.

There may be some clinical indications when combined treatment by a psychiatrist may be advantageous although there is no scientific evidence to support these assumptions. These might include those patients with highly complex medical conditions; cluster B personality disorders that have a history of significant self-harm and have experienced the need for frequent hospitalizations; and for those individuals with severe anorexia nervosa who require intensive medical care. Some, but not all, noncompliant patients with severe Axis I disorders such as schizophrenia and bipolar disorder may be candidates for this type of care as well.

V. EMPIRICAL STUDIES

A. Mood Disorders

With respect to combined treatment, unipolar nonpsychotic depression or major depression has been the most extensively studied disorder. Recent randomized controlled studies have provided the best evidence of the efficacy of psychotherapy and pharmacotherapy

in the treatment of mood disorders. In a study of approximately 200 elderly patients with recurrent nonpsychotic major depression, interpersonal psychotherapy (IPT) in combination with a tricyclic antidepressant was found to be more effective than either medication or psychotherapy alone. More specifically, those receiving the combined treatment has a recurrence of 20% compared to 43% in those patients with medication alone, and 64% of those treated exclusively with psychotherapy. Those patients receiving only placebo in a typical medication clinic program had a recurrence rate of 90%.

The largest meta-analysis of approximately 600 subjects with nonpsychotic unipolar depression has established that combined psychotherapy and pharmacotherapy was more effective than psychotherapy alone. This study examined patients treated with either cognitive-behavior therapy (CBT) or IPT and compared them to those who were treated with IPT and medication. Combined treatment produced better outcome and also shorter time to recovery. However in patients with less severe depression, psychotherapy alone was equivalent to combined treatment.

A very recent study, the largest randomized controlled trial to date, demonstrated that medication and psychotherapy is clearly superior to either monotherapy. This study of nearly 700 patients found that psychotherapy and a newer antidepressant (nefazadone) provided greater relief than either treatment intervention by itself. This study used a manualized cognitive behavioral treatment called cognitive behavioral analysis system of psychotherapy (CBASP). Study participants receiving integrative treatment had an 85% response rate compared to 55% of those taking medication alone and 52% of participants being treated with psychotherapy alone.

European researchers were able to demonstrate the cost effectiveness of adding psychodynamic psychotherapy in outpatients with depression being treated pharmacologically. The addition of the psychotherapy resulted in fewer hospital days at the end of treatment as well as at 1-year follow-up. In addition to lower direct costs from hospitalization, combined treatment was also associated with less indirect costs for sick days.

As many as 40% of adolescents with chronic depression fail to respond to an initial trial with either a selective serotonin reuptake inhibitor (SSRI) or psychotherapy. Some of these so called treatment-resistant teenagers may have comorbid disorders such as attention-deficit-hyperactivity disorder (ADHD), bipolar disorder, and/or substance abuse. However, in adolescents

with only chronic depression, as many as 70% of these patients will respond when both medication and psychotherapy are provided.

In what order should medication or psychotherapy be added to either ongoing monotherapy is an important treatment issue. Sequential therapy refers to this clinical decision as to when to augment psychotherapy with medication or when to add psychotherapy to a pharmacotherapy. In the treatment of recurrent major depression it was found that in women who did not fully recover with IPT, the addition of an antidepressant was more effective than treating participants from the outset with combined treatment. Although this study was not a randomized controlled one, it did examine participants from a single patient population treated at one center. This treatment sequence may have particular appeal to women who are against taking medication during pregnancy or lactation.

The data from combined treatment in patients with dysthymia is inconclusive, but this is not the case in the treatment of bipolar disorder. Patients with bipolar and schizoaffective disorders are treated more effectively when they receive family therapy with medication as opposed to psychotherapy alone. Those in combined treatment had fewer relapses and hospitalizations, and researchers were able to demonstrate that family members viewed their affected relatives in a much more positive light.

B. Schizophrenia

There is a wealth of studies going back more than 20 years that has demonstrated the efficacy and effectiveness of treating schizophrenia with psychotherapy and medication. Contrary to some views, families and patients affected by this disorder value psychotherapy greatly. Early studies have demonstrated that patients living in families characterized as having high expressed emotion are more vulnerable to relapses. Such families are characterized by intense affect, frequent criticism, and intrusiveness which have been associated with noncompliance. One randomized controlled study of first-episode patients found only a 10% hospital readmission rate with participants who received both family therapy and medication. This figure compared to a 75% readmission rate in those patients who received no treatment. In addition to family therapy, individual psychotherapy has shown substantial promise. A recent 3-year randomized controlled trial of patients with schizophrenia who received medication and a type of individual treatment called personal therapy that addressed stress management, education about ill-

ness, and interpersonal relationship issues was found to be superior to medication and supportive measures. It also promoted enhanced social adjustment throughout the entire study period.

Patients in a British study whose illness did not respond to medication were helped with the addition of 9 months of CBT. Improvement persisted after the completion of formal therapy that was not the case for those patients receiving medication and a nonspecific befriending relationship. This study also noted that rational discussion of hallucinations and delusions when included as a formal component of the psychotherapy accounted for 50% less symptomatology. Another randomized controlled study of patients treated with 20 individual sessions of CBT showed significant improvement compared to groups who either received only medication or supportive psychotherapy plus medication.

Two other studies have demonstrated that CBT is helpful in the treatment of patients with schizophrenia. Treatment refractory patients started on an atypical antipsychotic medication and provided with CBT and social skills training showed greater improvement than a comparison group treated with supportive psychotherapy and medication. Another randomized controlled trial where CBT and medication were compared to medication plus routine care demonstrated nearly four times the improvement in the former group.

C. Anxiety Disorders

Compared to schizophrenia and affective disorders, there are considerably fewer studies of integrative and combined treatment in panic, generalized anxiety, and obsessive-compulsive disorders. In the case of panic disorder, a recent randomized controlled trial of approximately 300 patients receiving CBT and the tricyclic antidepressant imipramine demonstrated greater improvement at the end of the maintenance phase of treatment than those patients with panic disorder who were treated with either monotherapy. One report examined combined treatment of panic disorder with clomipramine and 15 sessions of brief psychodynamic psychotherapy. Patients who received both components showed greater improvement 9 months after the discontinuation of medication compared to those who were treated only with clomipramine. The efficacy of psychodynamic psychotherapy as a monotherapy in the treatment of panic disorder is currently under study, and preliminary reports are very promising.

In the 1980s there were numerous publications that supported the superiority of tricyclic antidepressants and behavioral therapy in combination for the treat-

ment of panic disorder and agoraphobia with single interventions. However, there is considerable controversy regarding the advantage of using combined treatment compared to medication or psychotherapy alone in large part due to the high rate of relapse after medication is discontinued. The integrative treatment of social and specific phobias may be more helpful than is the case with panic disorder. It appears that the same may also be true for combined treatment of generalized anxiety disorder with CBT and medication. However the literature is very limited in this area. The clinician must remember that the vast majority of early studies in combined treatment of anxiety disorders employed older tricyclic antidepressants that often cause considerably more side effects than newer-generation medications. Therefore, studies using selective serotonin reuptake inhibitors may clarify the usefulness of these agents with psychotherapy.

Some practice guidelines support the use of medication and behavioral therapy in treating obsessive-compulsive disorder. Clinical consensus is that exposure and response prevention psychotherapy coupled with selective serotonin reuptake inhibitors is the treatment of choice. The superiority of behavioral therapy over medication alone is well established, but there are few substantive studies of combined treatments.

D. Substance Abuse

There are a number of reports that have noted the superiority of combined treatment with the opiate dependent. A randomized controlled trial assigned 84 opiate-dependent patients to either 4 months of counseling and supplemental drug counselling or counseling with supportive-expressive psychotherapy. At 6 months after treatment, those participants receiving the psychodynamic psychotherapy could be maintained on lower doses of methadone and also were less likely to test positive for cocaine. Another randomized controlled study of the same population found that those provided with psychiatric and vocational counseling services as well as family therapy were less likely to be hospitalized, experience job instability, and to be on welfare than patients who were assigned to medication or medication and counseling groups.

With regards to the treatment of alcoholism, two medications have been used traditionally and are FDA approved: disulfiram and naltrexone. The effectiveness of psychotherapy has been studied in a multisite effort called Project MATCH (Matching Alcoholism Treatment to Client Heterogeneity). This study of more than 1,700 patients, compared three forms of manualized treatment

(CBT, motivational enhancement therapy, and 12-step facilitation) and found that all three treatments were effective in treating alcohol dependence with the last proving the most effective at 3-year follow-up.

E. Eating Disorders

At present there is only one randomized control trial addressing the treatment of women with bulimia nervosa. This study of 120 participants examined groups that were treated with CBT, supportive dynamic psychotherapy, and medication. Results indicated that CBT plus antidepressants was more effective than the psychotherapy by itself. Also patients given either CBT or supportive psychotherapy with medication experienced less depression and binge eating. The medication component of the study permitted the prescription of new-generation antidepressants if an older medication was unhelpful. This sequential treatment provided only modest improvement compared to the effectiveness of the CBT or supportive treatment.

F. Personality Disorders

There exists one randomized controlled trial of combined treatment for personality disorders, and therefore many clinicians follow consensus treatment guidelines. In this recent study of patients with borderline personality disorder treated with psychoanalytic psychotherapy and medication compared to patients receiving only standard care without psychotherapy, the former group showed decreased suicidal attempts, self-mutilating behavior, number and duration of hospital admissions, and the use of other psychiatric services. This group also demonstrated symptomatic improvement in anxiety, depression, and general symptom distress. There were also gains in interpersonal functioning and social adjustment.

The use of medications in the psychotherapeutic treatment of borderline personality disorder has been associated with a decreased treatment drop-out rate and fewer severely disruptive regressions. Some have cited a positive effect of medication in decreasing intense feelings of aloneness, a common characteristic of many patients with borderline personality disorder. Many clinicians use split treatment arrangements that augment the psychotherapy with medication for reducing target symptoms of aggression, impulsivity, affective lability, and behavioral dyscontrol.

From the review of the literature it is clear that many questions must be answered about the combined use of psychotherapy and pharmacotherapy. Which disorders

are best treated with an integrative approach? What are the indications for sequential treatment, that is, when should treatment begin with psychotherapy and then be followed by the introduction of medication? For which patients and when in the treatment should psychotherapy be added to a pharmacological approach? Which psychotherapies are more advantageous for which disorders in a combined treatment? For which disorders is split treatment cost effective? Many mental health professionals work under significant fiscal pressure to be accountable to payors for the services they provide. Some of these constraints are not based on scientific support and require substantial investigation.

VI. CASE ILLUSTRATION

Ms. Jensen is a 27-year-old unmarried accountant who was referred by a recently relocated family physician to a social worker for assistance in managing the patient's depression and anxiety. According to her physician, the patient has not responded within the last 6 months to any of the various medications he has prescribed. She has a long-standing history of depressive episodes beginning as grade schooler and a well-established pattern of self-defeating behavior since her high school days. The patient has been difficult for the physician as she frequently calls for appointments because of a multiplicity of symptoms and complaints. He is unable to ascertain any significant illness in his patient, and all diagnostic tests have proven normal. Because the psychotherapist has not worked previously with the referring doctor, she recommends that they meet to discuss the patient before an evaluation for treatment is started. The doctor puts off the therapist saying he is pressed for time in his new practice and would prefer to send a summary of the patient's history. The social worker, not willing to disappoint a new referral source, agrees reluctantly to see Ms. Jensen.

The patient tells the therapist that her doctor seemed disinterested in her and stated that she was instructed to visit with a mental health professional for counseling. She describes her physician as very controlling and insisting that she take medication. The history indicated that the patient grew up in a household where both her mother and father were very demanding and rigid, always insisting that there was only one way to view life. This had major consequences for the patient particularly in her adolescence.

Ms. Jensen acknowledged that she had stopped taking the medications prescribed for her because of side effects despite the fact that her doctor had reassured her that they would pass after the first week of treatment. She felt

he had been dishonest because some side effects, like her sexual dysfunction, did not improve. The patient was effusive in her praise for the psychotherapist who clearly was interested in her plight and gave her sufficient time to talk. This was not the case with her family doctor whom she experienced as somewhat rigid.

At the completion of the assessment, the social worker summarized her thoughts about the possible ways in which to proceed. She mentioned that the patient should discuss her side effects with her physician and that perhaps there might be another medication that would be less problematic for her. She instructed Ms. Jensen to return to her primary care doctor and share with him that psychotherapy would be helpful as well and that therapist was available to meet with this patient on a regular basis.

After trying to contact the referring physician without success, 4 days later the psychotherapist received a discouraging phone call from Ms. Jensen's doctor who felt he was undercut in his treatment decisions because the patient refused to take any of the medications he wished to prescribe and had nothing but glowing words about her interaction with the therapist. According to the physician, Ms. Jensen explained that she was instructed to tell him that psychotherapy was indicated and not medication treatment.

A. Discussion

This vignette illustrates the complications that can arise in a collaborative treatment when the expectations of both collaborators are never fully presented. First, even prior to the referral, the meaning of medication to this patient was never appreciated. She experienced her physician much like her parents who insisted they were correct at all times and that everything she did should conform to their wishes. In addition, there was a failure to explore side effects that resulted from the medication. This referral was made after the physician became frustrated with the patient and began to experience her as a difficult or problem patient. However, the psychotherapist should not have agreed to evaluate this patient because the necessary guidelines for the referral were never clear. Because the respective roles of the professionals were not delineated, the patient began even within the diagnostic sessions to polarize her treatment relationships with her physician and therapist. She also misconstrued what was recommended by the mental health professional, but this remained unclear because the physician had not returned the consultant's call in a timely manner. In short, this collaborative effort was doomed from the first.

It would have been helpful if the professionals had agreed to meet in person as this was their initial referral experience. At the very least, an in-depth phone conversation should have detailed the physician's concerns and expectations about the referral, and the social worker could also explain her requirements to evaluate and treat the referred patient. If treatment were indicated, the physician would be aware of the central need for communication and in what form and how frequently it should occur. There was no opportunity to discuss any of the groundwork either clinical or legal for this type of treatment relationship, and it was apparent from the outset that the physician did not respect or value the potential assistance from the mental health professional.

VII. SUMMARY

Integrated and combined treatment is the provision of both psychotherapy and pharmacotherapy to a patient. In the case of the former, therapy is most often administered by a psychiatrist. Combined, split, or collaborative treatment is administered jointly by a psychiatrist, other physician, or nurse practitioner with another mental health professional psychotherapist. Although collaborative or split treatment lacks scientific support for its effectiveness or cost effectiveness, it nevertheless is widely used. Mental health care financing has undoubtedly played a major role in the acceptance of split treatment. The psychiatrist who treats the patient with medication and psychotherapy must be hypervigilant to the meaning of medication for each patient and how it is reflected in the treatment relationship. Those clinicians working in collaborative treatment relationships must above all develop concise and consistent plans for professional communication about their patient's experiences if the treatment is to succeed.

Last, despite early efficacy initiatives, the clinician is in the best position to discover the benefits and challenges of treating clients or patients with multiple approaches. For the near future, the naturalistic setting is likely to provide the exciting findings and suggest new areas of inquiry. Mental health professionals will undoubtedly become more sophisticated in their ability to provide integrative and combined treatment.

GLOSSARY

culturation The process by which a person learns, integrates and assumes the characteristics of a culture different from the person's original culture.

culture The sum total of human social organization, socialization, and learning.

ethnic group A group of people who share cultural norms and values and who identify with each other as a reference group different from other groups.

multiculturalism A branch of psychology that is based on the theoretical orientation that cultures are determining factors in the practice of psychology.

race A sociopolitical concept that describes a group of people who predominantly interbreed with one another and, therefore, share certain salient physical characteristics.

I. THE RISE OF MULTICULTURALISM

The field of psychology has evolved over time to include the dimension of race/cultural diversity as an area of professional competency. The American Psychological

Association, the American Psychiatric Association, and the National Council of Schools of Professional Psychology have included guidelines for cultural competencies in their written policies for practice and training. It was not always so. A recent survey of the PsycLit files showed a total of 19,418 references under the key term "cross-cultural." For the period between 1872 and 1950 there were 14 references cited, and most of these were rooted in anthropological origins. Then starting in the 1950s and 1960s the number of citations jumped to 863, and the numbers have continued to climb since then. This "burst" of interest coincides with the social reform movements during these periods, that is, the Civil Rights movement in the 1950s and 1960s and the women's and gay rights movements of the 1970s onwards. Clearly psychology as a field has responded to the forces of social change in the larger society.

There is no scientific evidence to support the existence of racial subgroups in the *homo sapiens sapiens* species. Physical anthropologists and geneticists have argued the point for over a century. Both definitions and typographies of racial groups have been difficult to establish. The reasons have to do with the distribution of genes in the human gene pool. No genes of significance are found in any human subgroup that are not found in all others. It seems certain that, after much scientific analysis, there are no human races, and yet the concept has had enormous social, economic, and political impact.

Since the beginning days of psychotherapy, problems have persisted when the client is an ethnic minority and

FIGURE 1 2000 population in thousands (U.S. Census Bureau).

the therapist is White. Eurocentric practitioners were prone to constructing improper judgments in diagnosis and treatment. For many years many minority clients were either misdiagnosed or treated with medications and hospitalizations in greater numbers than White clients with similar diagnoses. Many minority clients were denied psychotherapy because it was believed that they were either not verbally skilled or not intellectually capable of achieving insight into their psychological problems. Other studies have shown that minority clients do not present themselves for treatment as often, or drop out of treatment earlier than White clients. In many situations minority clients have been subjected to racial bigotry. Such bigotry is rarely intentional. Most therapists have been unaware of harboring racist attitudes and beliefs. Overall, the experiences of many ethnic minorities has been that psychotherapy has served as a means for furthering and promoting the “status quo” of the dominant White society. The prevailing dilemma is, despite the good intentions in the professional community, psychotherapy with ethnic minorities has frequently failed.

Efforts to solve the problem of ethnocentric psychology practices have been organized under the general category of the “multiculturalism” movement in psychiatry and psychology. Other terms have been used previously. “Cross-cultural,” “culture centered,” “inter-cultural,” “transcultural,” and “culturally sensitive” have also been used as terms to define the struggle to expand the awareness and skills of practitioners working with clients from different cultural backgrounds.

The multicultural approach grows out of the debates in anthropology, which saw the concept of “races” give way to the concept of “cultures.” From a “race” perspective it is clear that not all human groups are equal to each other and that some groups are subject to domina-

tion, extermination, and exploitation by other groups. When people are grouped in terms of “cultures,” the possibility emerges for equality and relativism. That is, each group can be seen as equally valuable and equally deserving of respect and dignity as any other group. Proponents of multiculturalism have been acutely aware that the population “complexion” of the United States is rapidly changing. The changing demographics, with increasing numbers of non-White groups leads away from previous “assimilationists” thinking toward “cultural pluralism.” (Figure 1 shows recent ethnic group figures for the 2000 census. Figures 2 and 3 are projections based on the 1990 census.)

The emphasis remains on ethnic minority clients, but the concept has also been extended to include many circumstances that place a person in a “minority position” in society. Clients who may be disadvantaged by their social position include persons from low socioeconomic backgrounds, women, gays and lesbians, disabled and elderly persons, certain religious groups, and immigrant/refugee clients. In other words, the multiculturalism movement potentially encompasses any clients who are not White, middle class, heterosexual, and mainstream in their social rank and values.

Multiculturalism addresses the failures of psychology to adequately treat diverse peoples, by positing that the cause of failure is the failure to fully realize existence of determining cultural factors. When client populations are viewed from a perspective of cultural/social determinism, a necessary set of questions arises. How does culture affect identity formation and pertinent social roles? What are the cultural factors that influence mental disorders? Are there culturally different norms for healthy or developmentally appropriate behavior? How does culture affect interpersonal behavior? Especially, how does culture influence the client–therapist relationship? How does

FIGURE 2 2020 projected population in thousands (U.S. Census Bureau).

culture affect help-seeking behavior? What are the implications for treatment and assessment?

Extending “culture” to include “diversity” means extending the concepts to include any significant social or environmental determinants that distinguish between dominant versus subordinate people. This means extending the same questions to incorporate variables, such as gender, age, socioeconomic status, and sexual orientation, and so on. How does a history of experiencing social oppression, discrimination, racism, sexism, and homophobia affect mental health and the development of healthy functioning? Again, what are the implications for assessment and treatment?
