PSYCHOTHERAPY

Editors-in-Chief

Michel Hersen

Pacific University, Forest Grove, Oregon

Michel Hersen, Ph.D., ABPP, is Professor and Dean, School of Professional Psychology, Pacific University, Forest Grove, Oregon. Dr. Hersen is a graduate of State University of New York at Buffalo, and completed his post-doctoral training at the West Haven VA (Yale University School of Medicine Program).

Dr. Hersen is past president of the Association for Advancement of Behavior Therapy. He has co-authored and co-edited 133 books, and has published 223 scientific journal articles. Dr. Hersen is also co-editor of several psychological journals, including *Behavior Modification*, *Aggression and Violent Behavior: A Review Journal*, *Clinical Psychology Review*, *Journal of Anxiety Disorders*, *Journal of Family Violence*, *Journal of Clinical Geropsychology*, and *Journal of Developmental and Physical Disabilities*. He is editor-in-chief of a new journal entitled *Clinical Case Studies*, which is devoted to description of clients and patients treated with psychotherapy. He is co-editor of the recently published 11-volume work entitled: *Comprehensive Clinical Psychology*.

Dr. Hersen has been the recipient of numerous grants from the National Institute of Mental Health, the Department of Education, the National Institute of Disabilities and Rehabilitation Research, and the March of Dimes Birth Defects Foundation. He is a diplomate of the American Board of Professional Psychology, Fellow of the American Psychological Association, Distinguished Practitioner and Member of the National Academy of Practice in Psychology, and recipient of the Distinguished Career Achievement Award in 1996 from the American Board of Medical Psychotherapists and Psychodiagnosticians. He has had full-time and part-time private practices.

William Sledge

Yale University, New Haven, Connecticut

William H. Sledge, M.D., is Professor of Psychiatry at Yale University School of Medicine, and is the Medical Director of the Psychiatric Services at Yale-New Haven Hospital. Dr. Sledge is a graduate of Baylor College of Medicine and the Western New England Institute for Psychoanalysis. He completed his residency training in psychiatry at Yale University, Department of Psychiatry.

Dr. Sledge has been a faculty member at Yale University School of Medicine for 25 years. He has written about psychotherapy and psychoanalysis and is a mental health services and health services investigator. In addition, he provides psychiatric consultation to the aviation industry and investigates the neurobiological basis of the thought disorder of schizophrenia.

Dr. Sledge has had a long, distinguished career as an educator, and has functioned as an administrator of a variety of medical educational programs at Yale. In addition to his medical duties, he has been Master of one of the Yale undergraduate residential colleges, Calhoun College, for seven years, and is the chair of the Council of Masters.

Dr. Sledge has been active in the American Psychoanalytic Association and the American Psychiatric Association, primarily in the areas addressing education and psychotherapy. He is former chair of the American Psychiatric Association Committee on the Practice of Psychotherapy and a member of the Commission on the Practice of Psychotherapy by Psychiatrists. He is a member of the Group for Advancement of Psychiatry Committee on Therapy.

Associate Editors

Alan M. Gross

University of Mississippi, Oxford, Mississippi

Alan M. Gross, Ph.D., is Professor of Psychology and Director of Clinical Training at the University of Mississippi. He is the former editor of the *Behavior Therapist* journal, and recently served as associate editor for the *Journal of Clinical Child Psychology*. He currently serves on the editorial boards of several scientific journals, including *Behavior Therapy*, *Journal of Clinical Child and Adolescent Psychology*, *Behavior Modification*, *Journal of Family Violence*, and *Aggression and Violent Behavior*.

Professor Gross has published numerous articles and book chapters in the area of self-management, behavior problems in children, and sexual aggression.

Jerald Kay

Wright State University School of Medicine, Dayton, Ohio

Jerald Kay, M.D., is Professor and Chair in the Department of Psychiatry at Wright State University School of Medicine, Dayton, Ohio. He is a Fellow of the American College of Psychiatrists and of the American Psychiatric Association (APA). Currently he is the chair of the APA Commission on the Practice of Psychotherapy by Psychiatrists. He is the founding editor of the *Journal of Psychotherapy Practice and Research* and associate editor of the *American Journal of Psychotherapy*.

Dr. Kay is the editor of 8 books and has published extensively on the topics of medical and psychiatric education, medical ethics, child psychiatry, psychoanalysis, psychotherapy, and psychosocial aspects of AIDS and of cardiac transplantation. He was designated as a 1994 Exemplary Psychiatrist by the National Alliance for the Mentally Ill and is the recipient of the 2001 APA-NIMH Seymore Vestermark Award for contributions to psychiatric education.

Bruce Rounsaville

Yale University School of Medicine, New Haven, Connecticut
and

U.S. Veterans Administration, West Haven, Connecticut

Bruce Rounsaville, M.D., is Professor of Psychiatry at the Yale University School of Medicine and director of the U.S. Veterans Administration New England Mental Illness Research Education and Clinical Center. Since he joined the Yale faculty in 1977, Dr. Rounsaville has focused his clinical research career on the diagnosis and treatment of patients with alcohol and drug dependence. Using modern methods for psychiatric diagnosis, Dr. Rounsaville was among the first to call attention to the high rates of dual diagnosis in drug abusers. As a member of the Work Group to Revise DSM-III, Dr. Rounsaville was a leader in adopting the drug dependence syndrome concept into the DSM-III-R and DSM-IV Substance Use Disorders criteria.

Dr. Rounsaville has been a strong advocate for adopting psychotherapies shown to be effective in rigorous clinical trials. Dr. Rounsaville has also played a key role in clinical trials on the efficacy of a number of important treatments, including outpatient clonidine/naltrexone for opioid detoxification, naltrexone for treatment of alcohol dependence, cognitive-behavioral treatment for cocaine dependence, and disulfiram treatment for alcoholic cocaine abusers. He has contributed extensively to the psychiatric treatment research literature in over 200 journal articles and 4 books.

Warren W. Tryon

Fordham University, Bronx, New York

Warren W. Tryon, Ph.D., ABPP, is Professor of Psychology and Director of Clinical Training at Fordham University, Bronx, New York. He is a fellow of Division 12 (Clinical Psychology) of the American Psychological Association, a fellow of the American Association of Applied and Preventive Psychology,

and a founder of the Assembly of Behavior Analysis and Therapy. He is a diplomate in Clinical Psychology—American Board of Professional Psychology (ABPP). He is listed in the National Register of Health Service Providers in Psychology and is a licensed psychologist in New York State.

Dr. Tryon has published over 130 articles, has authored 1 book, and edited 2 others. He has presented over 115 papers at professional meetings. Dr. Tryon is on the editorial board of *Behavior Modification* and has served as reviewer for over 30 journals and publishers. Seventy doctoral students have completed their dissertations under his direction.

Preface

When we began this project, it would have been beyond our most radical beliefs to think that we would be seeing a nation fraught with intense worry, anxiety, acute stress disorder, post-traumatic stress disorder, grief, and depression less than three years later. So now, as we put our finishing touches on this work, and following the terrorist incursions, we regrettably have been forced to see the graphic proof of the inherent value of psychotherapy. The critical contributions and the value of the psychotherapeutic arts have never been clearer to us than in the aftermath of the terrorist strikes. We say this with much humility, in that we would have preferred to continue to talk about the sometimes small theoretical differences in various psychotherapeutic applications, in what now seem to be needless polemics between such psychotherapeutic camps. Nonetheless, the original intent (which continues today in spite of world events) was to present a compilation of both the science and art of psychotherapy.

Psychotherapy has been a vital treatment in health care since development of the great innovative and technical approaches embodied by psychoanalysis and behaviorism at the beginning of the 20th century. In the course of its development, many questions have been raised about this treatment: What is psychotherapy? How does it work? Which forms are cost effective? Who can do it? How does it fit into a comprehensive approach to health care? What is its scientific basis? How does theory drive treatment? What is the role of complementary treatments such as pharmacotherapy in combination with psychotherapy?

The *Encyclopedia of Psychotherapy* strives to answer the aforementioned questions. It is a comprehensive reference to extant knowledge in the field and written in clear expository language so that it will be of value to professional and lay persons alike. Within its pages, this encyclopedia addresses over 200 topics by experts

in psychotherapy. Topics were selected in order to give broad coverage of the field (albeit not exhaustive) so as to encompass the most contemporary schools and approaches that have clearly defined techniques, some form of systematic study, and measurement of outcomes. Eclectic and integrative approaches have also been considered. Additional topics that transcend all schools, such as the impact of culture and the importance of the therapeutic relationship, have also been included as well as discussion of the treatment for some specific disorders.

Psychotherapy is an extremely complicated process that is difficult to fully capture even in a work of large scope, such as this encyclopedia. The interplay between scientific confirmation of particular strategies and the actual implementation of a given therapeutic technique is not always isomorphic. Also, how theory drives practice and ultimately the empirical confirmation of such practice, is not always clear cut. Moreover, how cultural, financial, legislative, and forensic issues act in confluence further complicate the intricacies of what we refer to as psychotherapy. However, it is these very intricacies and complexities which make psychotherapy such an interesting field to examine. In many ways, this work may raise more questions than it does provide answers, and that, perhaps, is the way it should be.

The *Encyclopedia of Psychotherapy* is designed to serve the needs of a multi-faceted audience. As a reference work, we see it being used by students and professionals from counseling and clinical psychology, psychiatry, psychiatric nursing, and social work. Certainly, other disciplines will make reference to it as well. But the encyclopedia will also be of use to interested lay individuals seeking information about this burgeoning field. Topics are arranged alphabetically. As appropriate, a good many of the entries have case

descriptions to illustrate the specifics of theory and technique. The topics addressed span clinical, theoretical, cultural, historical, and administrative and policy issues, as well as the matters of schools and specific patient conditions. Most importantly, a comprehensive user friendly Index is provided.

Early on it was apparent that a project of this magnitude would require associate editors and an advisory board to ensure broad coverage of issues and topics. The inclusion of these colleagues has added immeasurably to the fruition of this work. The associate editors (Alan M. Gross, Ph.D., Jerald Kay, M.D., Bruce J. Rounsaville, M.D., Warren W. Tryon, Ph.D.) were chosen in order to represent the cross-fertilization between the medical and the psychological, adult and child, theoretical and pragmatic, research and practice, and behavioral and non-behavioral. Similarly, the 18 advisory board members (both M.D.s and Ph.D.s) were selected because of their broad range of interests and expertise in all aspects of the psychotherapeutic endeavor.

The iterative process began with a large list of topics selected by the two editors-in-chief, which was then refined by the associate editors and the advisory board members. Excellent suggestions for authors were made and the solicitation process began. When received by Academic Press, each entry was evaluated by an appropriate associate editor, revised to the editor's specifications, and then sent on to one of the two editors-in-chief

for approval and/or further modification. All entries were reviewed on the basis of accuracy, completeness, clarity, brevity, and the absence of polemics. The resulting *Encyclopedia of Psychotherapy* is a product of complete collaboration between the two editors-in-chief, and hence the order of editorship is alphabetical.

We are grateful to the many individuals who helped make the *Encyclopedia of Psychotherapy* possible. Thank you to the four associate editors who performed in an exemplary fashion. Thank you also to our 18 members of the advisory board for their wise counsel and excellent suggestions. Thanks also to our contributors who took time out from their busy schedules to become part of our project, sharing their expertise as well as articulating their views on where this field stands. We thank Alex Duncan, Angelina Marchand, and Angelina Basile for their research efforts. We appreciate Carole Londeree's technical assistance. We thank all at Academic Press who were involved in the production effort, especially the acquisitions editor, George Zimmar, and the coordinator of the *Encyclopedia*, Anya Kozorez, for helping us to conceptualize this work and overcome obstacles to see it through to publication.

We dedicate this work to our colleagues who work on a daily basis to relieve the suffering of their clients.

GLOSSARY

cognitive fusion The act of perceiving private experiences such as thoughts and feelings from the perspective structured by the private event itself rather than the perspective of an observer of that event as a process. Reducing fusion is a key target of meditation, mindfulness, and deliteralization interventions in ACT.

cultural change agenda The culturally sanctioned model most clients bring into therapy holds that the goal is to gain control of and eliminate negative personal content. This agenda for changing from an unhealthy person with “issues” to a healthy person without “issues” has the paradoxical effect of increasing suffering.

literality The capacity of representational thought and language to take on literal meaning and for the derived stimulus functions of referents to dominate over other sources of behavior. An example is “anticipatory panic attacks,” which result from simply imagining being in a panic associated situation, such as a mall or elevator, and then taking those thoughts literally.

relational frame theory (RFT) A post-Skinnerian account of the structural and functional properties of human language and thought that is based in contextual behaviorism. RFT views language and thought as relational behavior that is controlled by learning factors.

Acceptance and commitment therapy (ACT) is a contextually based cognitive behavioral treatment. The ACT model holds that culturally supported attempts to control and eliminate unpleasant private experiences (i.e., negative emotions, thoughts, memories) result in personal suffering, behavior disorders, and a lack of vital and purposeful living. ACT attempts to teach clients to accept, rather than control or eliminate, private experiences that are not amenable to first order change. Acceptance is accomplished through teaching the client to see these private experiences as conditioned verbal responses, rather than literal truth. ACT emphasizes that the client approach, rather than avoid, valued life goals, even though pursuing such goals may stimulate “uncomfortable” private experiences.

I. THEORETICAL BASES OF ACT

Acceptance and commitment therapy is unique among the cognitive behavioral therapies in that it is theoretically derived from relational frame theory (RFT). RFT is a post-Skinnerian behavior analytic account of the functional properties of human language and thought, developed by Steven Hayes and other behavior analytic researchers around the world. Hayes and colleagues conducted two decades of basic research to validate the core principles of RFT before introducing the ACT therapy model. As we shall see, many ACT interventions are based in RFT principles and are designed to influence the contextual and functional characteristics

of language and thought. There are several principles of RFT that are directly relevant to both the development of human suffering and psychopathology, as well as clinical interventions.

First, it is not functionally useful to separate the functions of human language and thought from the contextual field in which the human organism operates. These processes are learned, reinforced, and reciprocally governed in the same fashion as any other learned human behavior. In RFT, language and thought are a special form of relational behaviors that enable the human organism to relate events bidirectionally and in combination, whereas direct experience is only unidirectional. For example, learning that a ball is called "ball" enables the human to look for and orient toward the ball when later hearing "ball." This simple process is apparently absent in nonhumans, but occurs in human infants by about 14 months.

A second critical RFT principle is that the context or "field" of language and thought involves both externally and internally generated verbal relations. The external context is the verbal community, consisting of verbally transmitted cultural practices (i.e., the language called "English" is what you will speak), social influence and consequence (i.e., you need to justify with the correct set of words why you hit someone, otherwise you get punished), and interpersonal influence (i.e., if you don't give a good reason why you hit Johnny, you will get a spanking). The development of a culturally compliant human organism is dependent on this process. The main vehicle of cultural transmission is the process of language acquisition and refinement. Eventually, language is experienced covertly in the form of thinking. The internal context is the relationship between the thought and the thinker. Humans have the ability to "receive" thoughts, weigh their merits (using other thoughts) and produce an action justified in terms of the second set of thoughts. The complexity of this constantly evolving set of relationships, combined with a constant reciprocal interaction with the verbal community, requires that humans engage in hundreds of thousands of language and thought transactions daily, much of them beneath the level of conscious awareness. The result is that humans become so dependent on these symbolic processes that they cease to recognize them for what they are: arbitrarily derived relations between verbal stimuli. When this occurs, the dominance of language and thought can become so excessive that the organism ceases to adapt to the demands of the environment and, instead, is controlled by symbolic representations of the envi-

ronment. In ACT, this is referred to as the hegemony of language.

A third key principle of RFT is that there are distinct functional properties of language and thought that explain not only the tremendous evolutionary advantage of human thought, but also its "dark side." The bidirectionality of human language enables humans to produce pain simply by remembering past pain or anticipating it in the future. For that reason, humans cannot regulate their psychological discomfort by escaping aversive situations, and instead begin to attempt to avoid or modify emotions. Thus, emotional avoidance is built into human language. Many unique forms of human behavior (e.g., humans are the only species known to commit suicide), seem to be a side effect of this process.

Relational behavior in turn enables rule-governed behavior: the generation of verbal formula to use in guiding human action. Unlike contingency governed actions, which are shaped systematically through direct trial and error (e.g., learning to ride a bicycle), rule-governed behaviors are developed through the verbal specification of contingencies, rather than through direct contact with them. This form of learning greatly expands the potential for learning important rules without having to make direct contact with the contingencies specified by those rules.

There are many different types of rule-governed classes that have clinical significance. Augmentation involves a rule that changes motivation, typically by relating some immediate situation with a verbally constructed set of future contingencies. For example, a young college student might be highly motivated to study by having images of getting a high-paying job several years hence (i.e., a motivative augmental). Getting an "A" on an important exam is reinforcing because of the augmenting effect of the future contingencies. The consequence is the persistence of studying behavior. Pliance is a more basic form of rule-governed behavior. "Plys" are rules that influence the person to behave in culturally sanctioned ways. Telling a crying child, "Be a good boy now and stop crying," is in effect saying to please the parents by stopping the act of crying. The child may stop crying, even though significant physical discomfort is present. Tracking is another common form of rule following that involves establishing a relationship between a rule and a set of nonarbitrary contingencies. A track might involve responding to a weather report that calls for record cold temperatures by securing a heavier coat, because past history has established a relationship between the

temperature outside and the type of clothing that produces warmth.

Because of the general utility of rules, a pervasive consequence for rule-governed behavior is sense making. It appears that humans are highly motivated to organize derived relations within an overarching framework that helps them “make sense” of these relationships. Independent of whether the relationships are factually correct, humans will create this type of conceptual order. In ACT, this is referred to as the “context of reason giving.”

The ACT account of human pathology applies RFT principles to the larger rule-governed context of human behavior. First, RFT research has established that, for all their evolutionary utility, rule-governed behaviors are extremely resistant to the mitigating effects of direct experience. At the same time, these change-resistant features are hidden in the very structure of language and thought. A brief clinical example will highlight how basic RFT principles directly convert into clinical dysfunction:

A woman who was sexually abused as a child reports persistent problems with extreme fearfulness when engaging in any kind of intimate behavior with a new boyfriend. She reports having the same kinds of experiences she remembers having when she was being sexually victimized (based on a “frame of coordination” between the two events). She reports being unable to trust her male friend even though there is evidence that he is different than her abusive father (a “transformation of functions” through that frame of coordination). She has been taught that the key to a fulfilling life is to form a positive intimate relationship, and has continued dating so as not to disappoint her mother (pliance). She is frustrated and angry with herself because she believes she is “defective” due to her childhood abuse history. The proof of this is healthy people are able to trust others in intimate relationships and she cannot (sense making). She has decided to stop dating because she believes her fear, mistrust, and disappointment will just get worse (augmentation). She wonders what she ever did to deserve being abused.

When a person encounters negative personal content such as in the sexual abuse vignette, culturally transmitted, verbally based responses are activated that determine both the outcome to be achieved and the processes needed to achieve it. Basic social programming suggests that “health” is measured by the absence of negative psychological content. In western culture, psychopathology and suffering are viewed as

deviations from a natural state of psychological health. When confronted with negative personal experience, the socially sanctioned response is directly analogous to the process used to handle challenges in the external world. Specifically, first one identifies the cause of the problem, then employs strategies designed to eliminate the cause and, through the causal chain, the problem itself.

In contrast, the ACT approach holds that suffering and dysfunction arise from following these culturally sanctioned, but ineffective, rules for coping with distressing experiences. Paradoxically, the use of control and elimination strategies leads to greater suffering and an apparent loss of control of the symptoms to be eliminated. In ACT, this is termed the “rule of mental events.” Specifically, the less one is willing to have a problematic private experience, the more one gets of it. There is significant research to support this core feature of human experience. For example, the thought suppression literature demonstrates that suppression and control strategies produce an upsurge in unwanted thoughts, and increased distress. Ironically, the strategies that have produced so much success for the human species in the external world are the cause of suffering and psychopathology when applied to events “between the ears.” The reasonable, normal, sensible things people do to address suffering in fact generates suffering. In ACT, this is referred to as the problem of unhealthy normality. Clients do not present for treatment because they are “broken,” but because they are trapped in an unworkable culturally supported change agenda.

The cultural change agenda is supported by basic rule-governed behaviors that normally are not within the awareness of the client. In ACT, these core dysfunctional responses are described in the FEAR model of suffering:

Fusion: This is the tendency of humans to merge with the content of their private experiences, leading to the problem of literality. Literality means that the distinction has been lost between symbolic activity and the event that acts as its referent. In the example above, the woman is fusing historically learned physical and emotional symptoms (from the original trauma) with a conceptually similar current event (intimate relations with her boyfriend) and attributing her reactions to the current event. She has fused the emotional and physical properties of a distant event with a minimally similar current event. Hence, her verbal formulation suggests she has trust issues, whereas the core issue is her fusion with historically conditioned responses.

Evaluation: This is the tendency of humans to categorize and attribute qualities to referents, as though they are primary properties of the referents. An example of major evaluative themes in psychopathology and human suffering are “good-bad,” “right-wrong,” or “fair-unfair.” Through the process of fusion, evaluations become inseparable from the events they are intended to qualify. In the example above, the woman states she is defective, as if defective was a primary property at the level of being. In truth, she is a woman who is having the self-evaluative thought called, “I am defective.” She indicates that healthy people do not have these issues, a form of good-bad attribution. She wonders what she did to deserve the abuse, essentially imbuing life with some independent property of fairness.

Avoidance: Due to the impact of bidirectionality and rule-governed behavior, humans are inclined to avoid the situational or representational “triggers” for unpleasant consequences. Paradoxically, this type of experiential avoidance may stimulate feared or unwanted private experiences such as thoughts, feelings, memories, or bodily sensations. There is a significant empirical literature demonstrating the unhealthy effects of experiential avoidance, even in nonpsychiatric samples. It is implicated as a primary mechanism in numerous mental and chemical dependency disorders. Experiential avoidance is almost always predicated on the mistaken belief that, by avoiding participation in challenging life events, one will not have to experience the uncomfortable private experiences associated with participation. In the example above, the woman indicates she has decided to stop dating, rather than experience continued fear, mistrust, and relationship failure. Paradoxically, it is precisely by withdrawing from the “field of play” that her childhood trauma exerts its maximum negative influence over her life. Each day spent not participating lends credence to her notion that she is “defective,” elevates her anticipatory fear response about accidentally meeting a soul mate, and deprives her of the opportunity to practice being intimate while being afraid.

Reason Giving: This is the tendency to present reasons that explain the cause of particular forms of private experience and/or behavior. In essence, the cultural context of language and thought teaches humans to give socially sanctioned reasons for behavior, especially behavior that is out of the perceived cultural norm. The most common reason-giving strategy is a two-step process: First, describe a set of historical influences that hypothetically explain a predisposing pri-

vate experience such as a negative thought, feeling, memory, or physical sensation: Second, describe the predisposing private experience as a cause of the resulting behavior. In the example above, the woman presents her problem as being linked historically to her sexual abuse. The sexual abuse is used to explain her fear experiences during intimacy. She then justifies her lack of intimacy behavior by setting her private experiences in opposition to the desired outcome (i.e., one cannot be intimate while being afraid; fear causes the loss of intimacy). In the end, she has “justified” why intimacy is impossible and why she is entitled to cease efforts in that area.

Reason giving is a pervasive issue in human dysfunction for many reasons, but two are worth noting. First, not only do humans have extremely limited access to the vast multitude of influences that shape their learning history, but also there is no convincing evidence that private events “cause” behavior. The client’s story is an arbitrary set of internally consistent, culturally shaped and sanctioned reasons that probably bears little resemblance to a complete historical analysis. Second, most forms of therapy are rooted in the verbal community and consequently a premium is placed on giving “good” reasons for being distressed and dysfunctional. Not only is the abused woman giving an inaccurate account of her learning history (focusing on the sexual abuse and ignoring a multitude of other learning factors), proposing an unlikely cause–effect relationship (her fear “causes” her to stop being intimate), but very likely will have this “story” tacitly endorsed by the therapist.

II. DESCRIPTION OF ACT TREATMENT

ACT seeks to accomplish several major results. The first is to help the client use direct experience, instead of rule following, to discover more effective responses to the challenges of being alive. The second is to discover that control and elimination strategies are the cause of suffering, not the cure for suffering. The third is to realize that acceptance and willingness are viable alternatives to struggle, control, and elimination. The fourth is to understand that acceptance is made possible by learning to detach from the rule-governing effects of language and thought. The fifth is to realize that the basic, unchanging self as consciousness is a place from which acceptance and committed action can occur. The final result is the understanding that

the road to vitality, purpose, and meaning is a journey consisting of choosing valued actions that are performed in the service of valued life ends. In ACT, the response to the life-limiting effects of FEAR is:

*Accept
Choose
Take action*

To many clients, the notion of turning around and embracing feared memories, hidden insecurities, perceived shortcomings, and negative personal history is frightening. The grip of self-limiting, rule-governed responses is so complete that clients cannot even see the system they are trapped in. Most clients know they are suffering, but are completely immersed in the private logic of their verbal conditioning. To attack this basic problem, ACT tries to engender a healthy skepticism about the role of language and thought in managing negative personal content. Ironically, therapy is an enterprise that occurs within the context of the verbal community. To attempt to undermine dysfunctional rule-governed behaviors through the use of verbal concepts such as “belief,” “understanding,” and “insight” is analogous to fighting a small fire with a can of gasoline. The ACT therapist must use words, images, metaphors, and experiential exercises in ways that undermine the client’s confidence in the utility of language and thought. This must occur without ACT concepts being coopted into the client’s system of “understanding.” It is not unusual for an ACT therapist to say such things as, “If this makes sense, then that’s not it” or “Don’t believe a word I’m saying.” By attacking the hegemony of language and thought through the nonliteral use of verbal concepts, the therapist is fighting fire with fire. The trick is to avoid being burned.

ACT can be separated into basic thematic components that often occur in a somewhat predictable sequence. However, it is important to understand that the relative prominence of different themes drives both the focus and strategies of therapy. It is frequently unnecessary to expose a client to all the stages of ACT. Some clients already have applied experience with acceptance and mindfulness strategies and may readily employ them when supplied with the proper framework. However, the same client might struggle mightily with committed, valued actions. With this type of client, more focus would be placed on values clarification, distinguishing life processes from life outcomes and so forth. For present purposes, we shall describe the core themes as “stages,” because there is a sort of logic to how

human suffering unfolds and, consequently, to how ACT might unfold.

A. First Thematic Stage: Creative Hopelessness

The goal of creative hopelessness is to help the client determine that the cultural change agenda is unworkable. The change agenda the client typically brings into therapy is to determine the cause of suffering and then to eliminate the cause, so the problem will dissipate. This typically converts into a cause and effect statement: “If I had more confidence in myself, I wouldn’t be so anxious in new social situations.” The goal of therapy is to provide me with more confidence, so my anxiety will go away. The notion of “workability” is central to ACT. Generally, clients have tried these commonsense change strategies repeatedly, even in the face of repeated disconfirming experience (the more you try to get confidence, the less confident you are). The client’s rule following has all but eliminated the corrective effects of direct experience. The client tries the same strategies over and over again, even though direct experience suggests these strategies are doomed to fail. In ACT, the therapist is likely to ask, “Which are you going to believe here? Your mind or your experience?” Often, the clinical goal of this stage is simply to get the client to stop using strategies that are not workable. At the same time, the therapist is attempting to create a readiness to see the problem in a larger context.

B. Second Thematic Stage: Control Is the Problem, Not the Solution

In this thematic module, the client is exposed to the unworkable, paradoxical nature of control and elimination strategies and their natural offshoot, experiential avoidance. The client is exposed via metaphor, story, and experiential exercise to an essential feature of control and elimination strategies: The more one attempts to control undesirable content, the more undesirable content occurs. The rule of mental events, described earlier, is a cornerstone of this stage. In this stage, the negative effects of experiential avoidance are drawn out for the client. Generally, this involves determining what situations and/or experiences the client is avoiding in the service of controlling negative experiences. Next, the client will evaluate whether the avoidance is “paying off” in terms of promoting positive psychological events or reducing

negative ones. For example, the sexually abused woman might be asked to gauge whether avoiding dating has increased or decreased her sense of mistrust of men, increased or decreased her sense of relationship failure, and so on. Generally, the concept of “willingness” will be introduced, as an alternative to control, elimination, and avoidance. Willingness is the choice to have unpleasant private content at the level of awareness, but without evaluation or struggle. Often, clients will be asked to maintain a “willingness-suffering-workability” diary that lets them collect data on the relationship between levels of willingness, intensity of suffering, and perceived workability of their lives.

C. Third Thematic Stage: Defusing Cognitive Fusion

The Latin root of fusion means to “pour together.” As discussed earlier, clients suffer when they pour together direct experience, representations of direct experience, thoughts, feelings, and so forth. They become lost in the maze of private events, such that it becomes difficult to separate what is real from what is being represented. The goal of this stage is to help the client detach from the literal meaning of private experiences and instead to see private experiences as separate from the basic self. This goal is critical because it is very difficult for clients to accept the most provocative, negative forms of private experience without the ability to see private experiences from the perspective of an observer. ACT employs a wide variety of “deliteralization” strategies in this stage. Deliteralization strategies generally seek to reveal the functional and/or representational properties of language, stripped of their concealment in the system of language. This allows the client to see thoughts as thoughts, feelings as feelings, reasons as reasons, evaluations as evaluations, and so forth. The result is that the client is able to defuse fusion. This might involve showing how easily behavior can be programmed through simple, obvious augmentation strategies. Alternatively, the client might be asked to produce multiple, different autobiographies or to say the word “milk” over and over again until the word “goes away” and a guttural, chopping sound is all that is experienced. Throughout this stage, clients are exposed to the FEAR algorithm, as it is expressed through cognitive fusion. A host of metaphors, stories, and experiential exercises are typically employed to attack the literal attachment to cognition, emotion, memory, and other private representations of experience.

D. Fourth Thematic Stage: Self as Content, Self as Context

Acceptance is most likely to occur when there is an unassailable point from which to observe and make room for distressing private content. Similar to various forms of meditation, ACT seeks to help the client locate a sense of self that is larger than the experience of the products of brain behavior. This is done in the service of making willingness and various forms of acceptance less emotionally hazardous for the client. In ACT, there are three types of self: (1) Self as conceptualized content is analogous to a “self concept.” It is the verbally evaluated summary statement of characteristics and attributes (i.e., I have always hated fighting). This form of self is quite rigid and is frequently a problem in therapy. Many clients will vigorously defend their “self concept,” as if their life depended on it, even when the content of the self-concept is negative; (2) Self as ongoing process reflects the ability to report current mood states, thoughts, verbal analyses, and other products of direct experience. This form of self is necessary for psychological health. It is the vehicle for experiencing what is to be experienced in the “here and now.” Avoidance of this form of self tends to produce the most basic and severe forms of psychopathology; (3) Self as context is the most basic sense of self that is possible. It is awareness and consciousness itself. There are no limits or boundaries to basic consciousness. It contains everything within it. It is immutable and, unlike other forms of self, never changes in character. It is the context in which all private events take on reference. Whatever their form or content, the client’s struggles are acted out on the stage of consciousness itself. Yet, the integrity of consciousness is not at issue. If accessed, this space puts the client in a position where private experiences can be observed, without struggle. In ACT, this is referred to as the “you that you call you.” Learning to make contact with this form of self is a skill that can be learned with practice. Consequently, ACT employs a wide diversity of mindfulness, awareness, and meditation exercises to develop this connection.

E. Fifth Thematic Stage: Willingness as a Chosen Action

Given the conditioned, rule-governed nature of private experience, little direct control can be exerted over the instantaneous reactions triggered by various stimulus events. In a previously described stage of ACT, willingness is used to describe a nonjudgmental

awareness of disturbing private content. However, there is a more basic form of willingness that is central to ACT. Willingness the action is the choice to enter into valued life activities, with certain knowledge that feared, private responses will be stimulated. These “monsters” generally are associated with the control, elimination, and avoidance behaviors that have previously trapped the client. This form of willingness is a qualitative act, driven by choice, rather than by persuasion or reason.

Choice is a core concept in ACT. It is an action taken with reasons, but not for reasons. It is a form of volunteerism, or voting with one’s feet. This is the resting potential of any client; the ability to transcend learning, history, and logic and simply take an action that can produce vitality, meaning, and purpose. A variety of ACT exercises teach the client that willingness is both a chosen action and almost invariably involves making room for feared experiences. Choosing willingness is made more difficult when cognitive fusion is extreme and the sense of self as context is weak. Thus, willingness and choice generally become therapeutic foci when cognitive defusion and self-identification strategies have had some degree of success. In the sexual abuse example, the willingness question might be, “Would you be willing to continue dating in the service of your dreams of developing intimacy, knowing that you will have to make room for mistrust, conditioned fear responses, and self critical thoughts?”

F. Sixth Thematic Stage: Values, Goals, and Committed Action

Although ACT is heavily focused on dismantling ineffective rule-governed behaviors, this process is important only to the extent that it results in the client living a more vital, purposeful life. This can only be achieved through committed actions that are in pursuit of valued life outcomes. Often clients have lost sight of their dreams, because of the pernicious effects of control and avoidance behaviors. They have slipped into a haze where it is difficult to imagine a life much different from the one they are living. ACT attempts to “jump start” the process of committed action by helping the client define core life values, associated goals and develop specific committed actions. A basic ACT intervention is called, “What do you want your life to stand for?” This involves having the client imagine that he or she has died and is listening to eulogies from different significant others at the funeral. The question to be answered

is, “What do you want to be remembered for, by those you leave behind?”

There are many nuances involved in developing committed action. One is helping the client differentiate between values as process rather than values as outcomes. To this end, ACT employs a variety of exercises that emphasize committed action as a journey, rather than a destination. A basic ACT principle is, “Goals are the process by which the process becomes the goal.” Vitality is produced by seeking, rather than by reaching valued outcomes. Further, some values cannot be “achieved,” only enacted on a continuing chosen basis. An example is the value of being a loving spouse. One never “reaches” love; there is always more love to experience. Similarly, a loving act often occurs when the feeling of love is missing. A second issue is that, in the name of seeking vitality, the client may have to jettison a well-practiced story that rationalizes why vitality and meaning are impossible to attain. Frequently, this story involves traumatic personal history and the need to remain dysfunctional to prove that a transgression occurred. The client may have to let go of the sense of trauma, shame, and blame in order to pursue vitality. In ACT, this form of forgiveness is construed to mean, “Giving oneself the grace that came before the transgression.” A common ACT question is, “Who would be made right, or who would have to be let off the hook of blame, if you committed yourself to living a valued life?”

III. EMPIRICAL STUDIES OF ACT

ACT is a relative newcomer to the family of cognitive-behavioral treatments and therefore does not have a highly developed empirical literature at this point. However, the initial empirical results have been positive. There have been two controlled studies looking at the relative efficacy of ACT and cognitive therapy with depressed patients. In one controlled study, ACT produced significantly greater reductions in depression than cognitive therapy. A second controlled study with depressed patients showed the two treatments to have equal efficacy. However, analysis of depressive thinking process measures suggested that ACT had a significantly greater impact in reducing the believability of depressive thoughts. A recent study examined the effect of providing a psychoeducational intervention or ACT with a randomly assigned group of hospitalized patients with schizophrenia. The interventions were designed to target the disturbing effects of visual and auditory hallucinations. Results were intriguing: ACT

patients reported a greater self-reported frequency of hallucinations, but rated the hallucinations as less distressing than the psychoeducational intervention patients. In contrast, the patients undergoing psychoeducational treatment reported significantly fewer hallucinations, but significantly more distress associated with the hallucinations. ACT interventions have also been shown to have a significant effect with such diverse problems as chronic pain, occupational stress, and high medical utilization.

ACT is one of the few cognitive-behavioral treatments to undergo a field-based clinical effectiveness study. Strosahl and colleagues developed an ACT training package for a group of masters' level therapists in an outpatient HMO mental health system. Compared with a control group of therapists who did not receive the training, ACT therapists produced greater clinical benefits as reported by patients, had less referrals for psychiatric medicines, and were more likely to complete cases earlier with the mutual consent of the client. In an uncontrolled clinical effectiveness study, Strosahl found that chronically depressed personality-disordered patients treated in the ACT model reported significant reductions in depression and an increased rate of achieving important personal goals. There are several large clinical trials underway examining the effectiveness of ACT with severe drug addiction, tobacco cessation, and social phobia. Hopefully, results of these and future studies will help delineate the clinical effectiveness of ACT, as well as describe the process mechanisms that underpin the treatment.

IV. SUMMARY

Acceptance and commitment therapy is one of the new generation of cognitive and behavioral therapies that utilizes acceptance and mindfulness strategies, in addition to first-order change strategies. The emphasis on acceptance strategies may be attributed to the growing recognition that first-order change is not always possible, or even desirable. There are many aspects of human experience that cannot be directly altered through psychotherapy or any other type of change effort. As we have discussed, the human nervous system works by addition, not by sub-

traction. Rule-governed responses never really disappear, they are simply placed in a different relational frame under the dominance of new rule-governed behaviors. When ACT is successful, clients understand that there is no need to shun undesirable personal history, temperament, spontaneous emotions, thoughts, and so forth. These are unique and healthy human qualities. Indeed, the human organism is perfectly made to experience each of these qualities, and therein lies the potential for vitality, purpose, and meaning.

GLOSSARY

cultural competence The belief that treatment providers should recognize and respect other cultural groups and be able to effectively work with them in a clinical setting.

special populations People with special treatment needs related to age, gender, ethnic background, or health status that are underserved by alcohol and drug treatment resources.

I. INTRODUCTION

The origin of the term “special population” can be attributed to several U.S. government agencies involved in health and human services in the mid-1970s. The term is reserved for groups whose need for substance abuse treatment programs has been underserved. The purpose was to identify subgroups in order to help with planning and evaluating the national treatment system for alcohol and drug problems. The goal was to provide funding for specialty programs, or to ensure that mainstream programs were structured to provide appropriate treatment services. Special population groups are most often defined in terms of age, race/eth-

nicity, gender, and health status. This article focuses on the treatment of addictive behavior in racial/ethnic minorities and women. These groups present unique treatment issues such as pregnancy and culture-specific beliefs and attitudes regarding substance use. In addition members of minority groups report higher rates of substance abuse problems than do whites, and the number of women entering treatment for substance abuse problems has increased in the past two decades.

II. RACIAL/ETHNIC MINORITIES

A. Description of Treatment

Ethnic and racial diversity is increasing in the United States, and according to the 1991–1993 National Household Survey on Drug Abuse members of various ethnic minorities report higher rates of substance use and related problems than do Whites. Although a need for treatment services exists, special populations often encounter barriers to obtaining treatment for alcohol and drug problems. The Office for Substance Abuse Prevention includes the following common barriers to treatment:

- **Cultural barriers:** Many programs lack staff who share the cultural background of those being treated. In addition, staff may lack sensitivity and/or training regarding the cultural beliefs and practices of their clientele. Language barriers also may exist.

- *Funding*: Many members of minority groups lack insurance or personal funds to pay for treatment.
- *Availability*: Waiting lists are common at affordable programs.
- *Child care*: Often not available at treatment sites. Some people may fear losing custody of their children if they seek treatment for an alcohol or drug problem.

These factors make it less likely that minorities will enter mainstream treatment programs. Of those who do enter treatment, the outcome data are mixed with some studies showing minority patients to have treatment outcomes equal to those for Whites, and other studies showing that minority patients have poorer outcomes and are less likely to complete treatment.

The high rates of substance use problems among many ethnic and racial minorities, combined with the barriers encountered by these individuals in mainstream treatment programs, raise the issue of whether or not to develop culturally sensitive treatment programs. Typically, these programs employ staff from varied cultural backgrounds and/or provide training to staff members in cultural issues. Culturally sensitive treatment programs may improve access to treatment for some individuals, but there are few scientific studies that examine or support their ability to produce improved outcomes. Therefore, the benefits of such programs are not yet thoroughly understood. Moreover, there is often considerable heterogeneity within specific ethnic or racial groups. Major sources of such heterogeneity include

- *Subgroups within a major ethnic group*: For example, there are approximately 300 different American Indian tribes. Many of these have their own unique culture and have developed specific norms regarding substance use, help-seeking behavior, and healing. Similarly, Hispanics who are Cuban American, Central American, Puerto Rican, and Mexican American have different attitudes toward substance use and treatment for substance-related problems.
- *Personal characteristics*: Members of the same minority group vary on several dimensions that have implications for treatment outcome. Included here are socioeconomic status, education level, and employment status.
- *Acculturation*: Members of the same minority group may differ in terms of their acculturation or assimilation to the majority culture.

It is unlikely that a single treatment approach could be developed that would suffice in addressing such

variability. Alternatively, it would not be realistic nor cost effective to develop separate programs for each distinct subgroup. This is not to say that the development and cross-cultural validation of such programs be discontinued. However, while these programs are being developed and evaluated, it seems reasonable to utilize existing approaches that have been demonstrated to have relative efficacy with other populations of substance abusers. Such treatment approaches include, but are not limited to, brief motivational interventions, cognitive-behavioral approaches, behavioral couples therapy, and the community reinforcement plus vouchers approach.

1. Brief Motivational Interventions

Brief interventions (e.g., motivational enhancement therapy, guided self-change) have been shown to be as effective as long-term inpatient treatment for alcohol problems. Core elements of these interventions include objective feedback regarding the nature and severity of the problem, acceptance of personal responsibility for change, providing a menu of change strategies, and an empathic therapist style.

2. Cognitive-Behavioral Approaches

A set of strategies including social skills training, behavioral self-control training, relapse prevention, and cognitive therapy. Core elements often include assertiveness training, coping with high-risk alcohol and drug use situations, managing urges and cravings, managing thoughts about drinking and drug use, problem-solving training, drink and drug refusal skills, and managing negative thinking and negative moods.

3. Behavioral Couples Therapy

This approach aims to improve communication and conflict resolution skills to help achieve and maintain abstinence. It assumes that family members can reward abstinence and that alcohol and drug abusers with healthier relationships have a lower risk of relapse. According to Timothy O'Farrell and William Fals-Stewart a core element of this approach is the daily sobriety contract in which the patient expresses his or her intention not to drink or use drugs on a given day, and the spouse provides support for efforts to remain abstinent.

4. Community Reinforcement Plus Vouchers Approach

This approach includes a number of skills-training components similar to those mentioned earlier. It also includes prompt reinforcement for drug abstinence by

using vouchers. The points accumulated can be spent for anything that contributes to furthering the patient's treatment goals. All purchases are made by the treatment staff.

Given the absence of research on the application of these and other treatment approaches for ethnic minorities, how should one proceed in tailoring existing treatment approaches to culturally diverse groups? The following steps have been proposed by clinicians and researchers alike. First, mainstream substance abuse treatment programs can ensure a degree of cultural sensitivity by hiring minority staff and/or providing training to increase the cultural responsiveness of staff members. Although there is limited evidence to support the overall treatment effectiveness of culturally sensitive therapists (CSTs), there is somewhat more evidence to support the role of CSTs in engaging and retaining minorities in treatment. Second, it would be important to identify the unique cultural aspects of a particular group, including those that may be affecting the person's recovery. For example, a client whose culture teaches her to be passive may feel it is wrong to express her feelings, even though such feelings may be a reason for continued substance use. Third, existing treatment approaches can be modified to include culturally relevant material. Comas-Diaz and Duncan included a cultural component in an assertiveness training program for low-income Puerto Rican women. In addition to standard assertiveness training, the women identified cultural factors prohibiting the development and expression of assertive behavior. They also identified potential conflicts that might arise as a result of their assertiveness and were taught strategies for managing these conflicts.

Although most writers call for culturally relevant treatment, there are few models that operationally define how clinicians and researchers should proceed. Clearly, there is a need for the systematic development and evaluation of such treatment programs. However, while waiting for such programs to be developed, ongoing efforts should be made to adapt existing, empirically supported treatments to specific cultural groups and to enhance the cultural competence of therapists in mainstream treatment programs.

B. Theoretical Bases

Theoretical models of substance abuse among ethnic minorities are lacking. Reasons for substance abuse are more common and are typically based on one or more key characteristics of a given cultural group. Despite

the lack of theoretical development in this area, many accounts of substance abuse within a specific cultural group may be explained by existing models of addictive behavior. For example, a popular cognitive-behavioral model of addictive behavior is the stress-coping model. This model views substance use as a coping response to life stress that can function to reduce negative affect or increase positive affect. *Stress* refers to the problems or tensions that people encounter throughout life, and *coping* refers to the behavioral or cognitive responses that people use to manage stress. Although the nature of the stress may vary across cultures (e.g., PTSD among Southeast Asians), the underlying mechanism—that alcohol and drugs reduce stress—may generalize from culture to culture.

High rates of substance abuse in some ethnic minorities have been attributed to relatively greater experiences of stress. Major sources of stress include

- *Environmental stressors*: Several major stressors include substandard housing, overcrowding, and unsafe living conditions.
- *Social stressors*: Factors included here are poverty, greater exposure and access to drugs, discrimination, and unemployment.
- *Personal stressors*: A few examples include depression, helplessness, and low self-esteem.

In addition to increased stress, ethnic minorities may lack the personal and social resources necessary to support effective coping responses. In the absence of good coping skills individuals may use alcohol and other drugs to cope with stress. The view that substance abuse is a dysfunctional coping response to stress led to the development of psychosocial interventions focused on strengthening an individual's coping skills. With regard to substance abuse treatment for minorities, the objective for coping skills interventions is to incorporate culturally relevant content when addressing the stressors unique to specific cultural groups.

Acculturation theory has also been linked to substance abuse in ethnic minority groups. Briefly, this theory refers to the three phases of contact, conflict, and adaptation through which members of both minority and majority cultures move, before assimilation is achieved. The ability to align equally with values, attitudes, and behaviors of both the minority and majority culture is called "bicultural competence." With regard to substance use, a person with a monocultural orientation is likely to experience more stress than a person with a bicultural orientation, and therefore is more

likely to use alcohol and other drugs to cope with the stress. In this way, acculturation theory is similar to the stress and coping model described earlier.

C. Treatment Outcome

The focus in research has been on demographic and descriptive characteristics of substance abuse problems among various cultural groups. Well-conducted treatment outcome studies are lacking, so it is unknown whether outcomes would be improved if treatment programs were more sensitive to cultural issues. Controlled trials are needed in which the effectiveness of existing treatments for substance abuse problems are compared with treatments specifically designed, or modified, for a given cultural group. The main question to be addressed is whether culturally relevant treatment approaches increase accessibility, retention, and outcome in ethnic minority populations.

III. WOMEN

A. Description of Treatment

In 1991, The National Institute of Mental Health Epidemiologic Catchment Area Study (ECA) reported that substance abuse was the second most common psychiatric disorder among all female respondents. In addition, the number of women entering treatment for substance abuse problems has increased by approximately 10% since the late 1980s. Despite this increase, Yaffee and colleagues assert that the special needs of women remain unmet by the majority of mainstream treatment programs. In fact, it has been argued that mainstream treatment programs may be seen as a barrier to women seeking treatment for substance abuse problems. For example, the lack of on-site child care services may limit access to treatment for many women.

In the past two decades, funding has increased to aid the development of treatment programs specifically designed for substance-abusing women. These women-oriented treatment programs are characterized by an emphasis on understanding the importance of gender roles in society and how these roles may contribute to the development and maintenance of substance abuse problems in women. Important components of women-oriented treatment programs include the following: treatment for other problems (e.g., domestic violence, depression); child care services; parenting and family-oriented services; comprehensive medical services in-

cluding nutrition, hygiene, prenatal and postpartum care; vocational rehabilitation; legal assistance; transportation assistance; and access to female treatment providers. A consistent difference between women-oriented programs and mixed-gender programs is the provision of services associated with pregnancy and parenting.

Common treatment approaches for women include cognitive-behavioral coping skills interventions, brief motivational interventions, family therapy, pharmacotherapy, and self-help groups. Within each of these approaches, women's issues are addressed by the inclusion of one or more of the women-oriented treatment components mentioned earlier.

1. Cognitive-Behavioral Approaches

Women with alcohol problems exhibit poorer skills for coping with stressors than do women without alcohol problems. Alcohol may be used as a primary coping behavior for these women. This treatment approach teaches skills for coping with high-risk alcohol and drug use situations and also provides other life management skills (e.g., problem-solving, communication, assertiveness, and other skills).

2. Brief Interventions

These interventions provide information, feedback, advice, and support and are known to be effective in addressing substance abuse problems. When the goal is drinking reduction, brief interventions for problem drinking have been shown to be more effective among women than among men.

3. Family Therapy

Strategic-structural family therapy and behavioral family therapy are the two most frequently used models of family therapy for the treatment of substance-dependent women. Family therapy is seen as beneficial because family members often play a significant role in the etiology and maintenance of problematic patterns of substance use among women. For example, a woman's drinking pattern is often influenced by her male partner's pattern of drinking. Therefore, it may be helpful to include both individuals in treatment.

4. Pharmacotherapy

Compared to men, women report more psychiatric problems and are more likely to drink to relieve negative affect. In this regard, medications may be used as adjuncts to psychosocial treatment for substance use and psychiatric disorders. Disulfiram (Antabuse) has a

long history of use as deterrent medication. When taken with alcohol it produces nausea, vomiting, dizziness, difficulty breathing, headache, flushing, and rapid heartbeat. Disulfiram is administered orally on a daily basis, and the client cannot drink for 4 to 7 days following discontinuation of the medication. This delay often provides the individual with time to reconsider the decision to begin drinking. Naltrexone (Revia) is an orally administered opioid antagonist that more recently has been found to be effective for the treatment of alcohol problems. It has been found to decrease craving for alcohol and to produce lower relapse rates when added to psychosocial treatment for alcoholism. Antidepressants and other psychotropic medications may be used to help treat a range of psychiatric symptoms that serve to maintain the substance use disorder.

5. Self-Help Groups

In addition to Alcoholics Anonymous, Women for Sobriety is a mutual-help organization designed to meet the specific needs of women. The program consists of 13 statements, primarily focused on improving self-worth and reducing shame and guilt often reported by its members. Self-help groups can be very useful treatment approaches because they provide an excellent opportunity for women to develop new social roles and relationships and to construct a non-substance-abusing support network.

The treatment approaches just summarized are only a few examples of the wide range of treatment options available. Because a large number of substance-abusing women have multiple problems, there is a need to provide broad and comprehensive services for women. For example, a cognitive-behavioral treatment program for women with alcohol problems may be combined with pharmacotherapy to address strong cravings for alcohol or symptoms of depression. In addition, existing treatment approaches may be further modified to address the individual needs of each female patient (e.g., prenatal care).

B. Theoretical Bases

Most of the work regarding substance abuse in women is largely atheoretical. However, social relationships have been reported to play a greater role in the psychological development of women as compared with men. In this regard, interventions that focus on the development of new relationships or that strengthen the woman's social support network are viewed as beneficial. However, most women-oriented

treatment programs generally include a range of services and develop treatment plans in which specific services are matched to the needs of the individual patient.

C. Treatment Outcome

When examining outcome data from mixed-gender programs, studies to date have found few differences in treatment outcome for men and women. In contrast, research investigating the effectiveness of women-oriented treatment programs has produced mixed findings. Some studies demonstrate better outcomes for women in women-oriented programs compared with women treated in mainstream programs, and others report no differences. A study by Dahlgren and Willander compared women in a women-oriented program ($n = 100$) with female patients in a mainstream program ($n = 100$). At the 2-year follow-up, patients in the women-oriented treatment program had better outcomes both in terms of alcohol consumption and social adjustment as measured by employment status and family relationships.

With regard to the effectiveness of specific interventions for women, research has demonstrated that drinking reduction interventions appear to be beneficial for women who are less physically dependent on alcohol. Several studies have demonstrated that women problem drinkers were more successful than men in attaining moderate drinking. Cognitive-behavioral interventions, in which patients are matched on the basis of personality characteristics and level of motivation, have shown benefit with female substance abusers. Brief interventions that incorporate motivational interviewing strategies have also been effective in reducing alcohol consumption for problem-drinking women. Finally, some studies have indicated that women benefit from self-help groups, such as Alcoholics Anonymous and Women for Sobriety. It is thought that women do well in these groups because they become more involved in the social support network offered by this type of treatment.

Although it appears that women do benefit from treatment, well-conducted treatment outcome studies are lacking, so it is unknown whether outcomes would be improved if treatment programs were more sensitive to gender issues. Nevertheless, one advantage of women-only treatment programs may be their ability to attract women who would not otherwise have sought treatment from a mainstream program. For example, a study by Copeland and Hall found that clients enrolled in a women's treatment program were more likely to be lesbian, or have suffered childhood sexual abuse than women enrolled in other programs. Therefore, the

availability of women-oriented programs and services may contribute to reducing barriers to treatment for some women.

IV. SUMMARY

In 1990, an Institute of Medicine report suggested that caution must be exercised when defining a given person only in terms of his or her gender or racial/ethnic group membership; individuals within both of these special populations vary on other important dimensions that have implications for treatment entry and outcome (e.g., socioeconomic level, education). Moreover, the heterogeneity among persons with substance abuse problems suggests that it may be difficult to identify the key characteristic to use in determining a treatment referral. For example, an individual can be a member of more than one special population group (e.g., a married, black female with depression). In this case, how does the clinician decide which special program best meets the need of this client? At present, the answer is not clear. However, Copeland and Hall and others have reported that special programs may be more likely to attract individuals who would not otherwise seek treatment.

split treatment The practices of separating treatment functions into different domains. Most often this treatment is used in long-term hospital settings to address the split between administrative and therapeutic functions.

GLOSSARY

adjunctive therapy Two or more therapies used in an integrative fashion to treat an individual with mental illness.

conjoint therapy Therapy consisting of two distinct treatment models: (1) The treatment of two or more related individuals in the same setting, for example, couples treated in a group therapy or family therapy groups and (2) treatment used interchangeably with *adjunctive therapy*. In this chapter, the second meaning always applies.

integrative treatment Treatment that attempts to theoretically reconcile different therapeutic approaches into a single therapeutic approach, for example, psychodynamic and behavioral. May also be used interchangeably with *adjunctive therapy*.

psychopharmacotherapy The use of medication to treat mental illness. This therapy is performed primarily by a psychiatrist but may also be practiced by primary care physicians, physician assistants, and advanced nurse practitioners.

sociotherapy The consideration of the patient's entire social milieu as an agent of therapeutic treatment. This treatment is most often practiced in a hospital setting but may also be used in residential settings of all types, including group homes and specialized treatment facilities (e.g., substance abuse programs or other psychiatric rehabilitative settings).

I. ADJUNCTIVE/CONJOINT THERAPY

In today's psychological treatment setting, it is common to find two or more treatments being used together by different health care providers to treat the same patient. In fact, with today's emphasis on outcome and results rather than on the process orientation that dominated the treatment environment until the last several decades, it is more common than not to find adjunctive therapy as the dominant treatment intervention. Although the varieties of adjunctive therapeutic interventions are too numerous to catalog, they may be broken down into several common combinations. By far the most common form of this treatment today is the use of psychopharmacotherapy and individual psychotherapy. In addition, individual therapies are often used adjunctively with group therapy and/or family therapy.

As treatment has become more focused and refined, specialized programs are increasingly being used to treat individuals with similar disorders. Consequently, 12-step substance abuse groups are used with individual substance abuse counseling, and dialectical behavioral therapy (DBT) training groups are used adjunctively

with individual DBT treatment and diagnostically focused groups. For example, anxiety disorder groups or obsessive-compulsive groups are used adjunctively with cognitive-behavioral therapy. Each type of adjunctive therapy may involve slightly or even radically different theoretical biases on the part of individual therapists. A substance abuse counselor running a 12-step group will be informed by a different theoretical orientation than a psychodynamic psychotherapist. The DBT therapist may operate from a different orientation than a psychopharmacotherapist. Yet, with adjunctive therapy, the often varying viewpoints of the treaters are not only made to work together but also often produce results that are superior to either treatment alone. Regardless of the type of adjunctive therapy, a common set of issues arise whenever conjoint treatment occurs.

Whenever more than one therapist is involved in the treatment of the same patient, the issues that always give structure to the treatment are the following: (1) *Treatment hierarchy*: Most typically this involves the identification of a primary therapist. (2) *Role definition*: The function of each therapist needs to be clearly defined, his or her primary domain delineated, and there must be a clear understanding of when each therapist would intervene and when a referral would be made to another therapist. (3) *Theoretical clarity*: Each therapist must understand the theoretical perspective of not only his or her own treatment modality but also that of all others involved in the treatment of the patient. It is also imperative for each therapist to understand areas of potential conflict between theoretical orientations and areas where the treatments should be complementary. (4) *Boundaries*: The boundaries or parameters for each therapy need to be defined clearly for the patient, but each therapist should also understand the boundary definitions of all the therapists involved in an adjunctive therapy. (5) *Goals*: Goals, or expected treatment outcome, should be explicitly defined, for each therapist may have a different contribution to make to the outcome. (6) *Communication*: Clear guidelines are needed for communication between therapists that define when to communicate and how much to communicate. These six areas provide the structure for any type of adjunctive therapy regardless of what combination is being used. Because psychopharmacotherapy individual psychotherapy is currently the most common type of adjunctive therapy, I will use it as a model to explicate each of these areas.

A. Treatment Hierarchy

The treatment hierarchy in adjunctive therapy is perhaps the most straightforward, and because it involves power, it is also the most difficult area for therapists to address. There is a twofold need to identify a primary or principal therapist in any adjunctive therapy: the need of the patient to know who is in charge of the treatment and coordinating it and the need of the therapists involved to know who is responsible for the coordination and integration of care.

Typically, the patient identifies the principal therapist as the one he or she first contacts when initiating treatment. If a patient sees an individual therapist for several sessions and the decision is made to seek a psychopharmacotherapy consultation, the patient will invariably regard the individual therapist as the principal therapist. The patient is likely to orient toward the individual therapist in seeking to identify who the psychopharmacotherapist is and later in processing recommendations made by the psychopharmacotherapist. The converse is just as often true when the psychopharmacotherapist is seen initially in consultation. When the need arises for adjunctive therapy with a referral to an individual therapist, the patient is likely to regard the psychopharmacotherapist as the principal therapist. This hierarchical structure implicitly involves power because the patient will regard the principal therapist as being the arbitrator for decisions regarding treatment and, in fact, as the person who is "in charge" of the treatment. For example, if the need arises for hospitalization, the patient will look to the principal therapist for a recommendation. In this case, if the individual therapist is a nonphysician and the psychopharmacotherapist is a physician, the patient may look to the individual therapist for guidance, even though the physician is the therapist with the power to hospitalize.

It is crucial that the treaters understand this hierarchy because these power issues relate directly to the therapist's professional identity. Each discipline that defines the therapist's professional identity comes with explicit and implicit skill sets that define expertise and power. The physician therapist may feel that he or she alone should have the power to make decisions regarding hospitalization or medication changes. The psychologist therapist treating an individual, who is in couple's treatment together with a social worker, may have difficulty with the social worker colleague recommending psychological testing. These discipline-specific sets of expertise and power need to be understood and should

be somewhat fluid to allow for successful adjunctive therapy. Although it is true that the physician alone has the power to prescribe a medication, the patient may not take the medication or comply with the physician's recommendation without the support and validation of the primary therapist, who might be a social worker. If the treatment hierarchy is understood, it reduces the potential for confusion on the patient's part and lessens threats to the professional identity of the therapists involved in the treatment.

The principal therapist can change during the course of a treatment but must make this change explicit and coordinate it. One of the therapists involved in the treatment may leave the area, necessitating a replacement, a therapist may have irreconcilable differences with a patient, or one of several therapeutic components of an adjunctive therapy may reach a termination point. The principal therapist would coordinate addressing and resolving all of these issues.

B. Role Definition

Adjunctive therapy involves two or more therapists intervening in different ways and often in different domains with the same patient. The roles of the therapists may vary widely, and their areas of intervention may overlap to varying degrees. The role of each therapist needs to be clearly defined. Well-delineated roles aid all the therapists involved and diminish the potential for patient noncompliance, acting out, or resistance to treatment. Using individual therapy/psychopharmacotherapy as a model adjunctive treatment illustrates both the difficulties and the need for role definition.

The individual therapist's role is focused on the psychological domain of the individual and is confined to effecting change in psychological processes. The psychopharmacotherapist's role is focused on the biological domain of the individual and is confined to using medications to effect physiological changes and lead to symptom relief, maintenance of a given state (e.g., euthymic mood), or relapse prevention. This oversimplification diminishes the role of both the treaters and the effectiveness of the adjunctive therapy. At the far border of role definition, it is clear that the individual therapist will not be making recommendations about specific medications and the psychopharmacotherapist will not be making recommendations about interventions that need to be made in individual therapy. At the near border of role definition, there may be great overlap. The patient will complain to the individual thera-

pist about increasing dysphoria and may want to deal with it as an individual therapy issue. On another occasion, the patient will seek the psychopharmacotherapist's help with a medication that aids in improving his or her relationship with female co-workers. In these instances, the therapist must be able to recognize the limits of his or her role and be comfortable directing the patient to the other therapist. Between the two borders of the roles there is the need for each therapist to move in and out of the other's domain. Although psychopharmacotherapy may seem to be easily confined to the biological realm, in practice this is rarely the case. Taking a medication can have powerful psychological meaning for the patient and will need to be discussed and dealt with by the individual therapist as well as by the psychopharmacotherapist. On the other hand, socially phobic patients whose symptoms are relieved by medication may have to redefine themselves and examine how the change in a set of behaviors necessitated by the symptom that is now gone will affect their personal identity. Clearly, this is the role of the individual therapist.

Some issues clearly involve both roles and need to be addressed by both therapists. Insomnia is an example. In a patient with a mood disorder, insomnia might be an early warning that medications need to be changed or adjusted or that a relapse is beginning. Insomnia may also mean that the patient is having difficulty managing external stressors and needs psychological help in improving coping skills. It should be apparent that these are not mutually exclusive phenomena and could occur simultaneously, requiring interventions by both therapists. In fact, either therapist could perform an intervention such as instructing the patient about sleep hygiene. This also highlights the need for communication among therapists, which will be addressed in a later section.

Role definition also must address practical administrative issues, or else confusion and conflict may arise. Each therapist needs to know what the expectation of the other therapist is during the course of treatment. Coverage issues also need to be clarified. Who fills in for therapists' absences needs to be understood. In an adjunctive therapy it is often tempting for each therapist to cover for the other during vacations. This approach can blur roles, causing confusion and leading to conflict. If the psychopharmacotherapist covers for the individual therapist and an emotional crisis occurs, for example, he or she may need to temporarily take over the role of the therapist. Later, it may be difficult for

the psychopharmacotherapist to revert to his role, and it may prove confusing to the patient. Similarly, it must be clear whether the individual therapist is expected to monitor side effects and/or report them. This will directly affect the frequency of visits to both therapists. It is obvious that gross side effects will be reported, but obviously it is not the role of the individual therapist to perform screening tests examining for side effects. Depending on the nature of the individual therapy it may have more or less of an impact on the therapist's role.

C. Theoretical Clarity

Adjunctive therapy often involves the collaboration of therapists with different theoretical orientations. For the most part, these theoretical orientations are not inherently conflictual, although they may vary in emphasis. A behavioral therapy that focuses on changing observable patterns of behavior or reported cognitive patterns does not conflict with a dynamically oriented couples therapy that views behavior as arising out of early family patterns and roles. If, simultaneously, a psychopharmacotherapist approaches the behavior as a manifestation of an underlying biological diathesis and prescribes medication, the approaches are not contradictory but do have enormous potential for confusion and conflict. It is imperative that each therapist involved in adjunctive therapy understand not only his or her own theoretical orientation but also the orientation of all other therapists involved in the treatment. No therapist can be hidebound by his or her approach and must be respectful and open to other points of view.

The potential to regard one's own approach as superior and the other therapies as merely supportive must be guarded against, for it inevitably sabotages the treatment. For example, if an individual therapist believes that medication may relieve symptoms and reduce the patient's need and motivation for individual therapy, he or she might discourage the patient from taking medication or convey to the patient that using medication is a crutch and interferes with the "real" treatment.

At times, differences in theoretical perspectives may lead to different treatment interventions for the identical clinical situation. While understanding each therapist's treatment boundaries may reduce the potential for misunderstanding, appreciating each theoretical perspective can prevent therapist conflicts. For example, an individual therapist with a dialectical behavioral therapy (DBT) orientation and a physician prescribing

medication following a medical model may approach a patient threatening suicide very differently. The DBT therapist may already have had an agreement with the patient that the patient go to an emergency room and only contact the therapist when all danger had passed. The psychopharmacotherapist may feel the need to take an active role in the patient's hospitalization and continue to treat the patient in a hospital setting. Only with an appreciation of the DBT therapist's orientation and of what he or she is attempting to achieve with the patient can the psychopharmacotherapist intervene, support the DBT therapist's position, and encourage the patient to return to the therapist when the danger of suicide has passed.

Before entering into an adjunctive therapy, each therapist should learn the theoretical orientation of the other therapist, understand areas of potential conflict, and be certain that they can all work compatibly together without feeling devalued or devaluing. If this is not possible, it is best to avoid adjunctive therapy collaboration.

D. Boundaries

Each therapist in an adjunctive therapy has his or her own boundaries that define the treatment parameters within which the therapist operates. This includes a definition of the therapist-patient relationship and an understanding of what the patient should expect from the therapist and what the therapist should expect from the patient. These expectations include fees, payment schedules, cancellation policies, frequency of sessions, availability out of session, length of treatment, treatment of emergencies, issues of confidentiality, and many therapy-specific requirements. How each therapist delineates the boundaries of therapy affects all the therapists involved in an adjunctive therapy. For example, the individual therapist and the psychopharmacotherapist must know that their patients will be thrown out of the substance abuse group they are attending if they test positive twice for drugs or if they fail to produce urine for testing twice. Without this knowledge of the group therapist's boundaries, they could not plan their treatment effectively. With knowledge of each other's boundaries, they can plan in advance for this situation and agree that such an event would lead to transfer to a rehabilitation facility. An individual therapist may tell the patient that he or she is unavailable for calls on weekends. The psychopharmacotherapist needs to know this limit and be prepared to respond if the patient chooses to call him instead.

One important aspect of therapist boundaries that overlaps with a following item, communication, is content boundaries. It must be clear to all the therapists involved in an adjunctive therapy and to the patient what information will and will not be shared among all therapists. Without this clarity, the patient will be anxious about confidentiality, and the therapists will be uncertain about what information they can share. Therapists need to be clear with each other about what information they need in order to practice comfortably. Without this knowledge, a treater may agree with a patient's request not to share information that other treaters feel they need to know in order to effectively treat the patient. Clearly, effective treatment planning cannot occur without each therapist involved in an adjunctive therapy understanding the boundaries of all the therapists and without a consideration of potential conflicts related to these boundaries.

E. Goals

The goals or expected outcome for adjunctive treatment need to be explicitly defined for both the patient and the therapists. Inherent in adjunctive therapy is a variation in goals and expected outcome for the different treatments involved. Not only will there be variation in goals for each therapy but the duration of treatment may vary widely in both length and in predictability of length. Group therapies may be rigid in length, particularly when the focus is psychoeducational, or more open-ended, with goals set differently for each individual patient. Psychopharmacotherapy may have a clear goal of symptom relief but can also involve more open-end goals—for example, prophylactic treatment or maintenance treatment with a need for indefinite followup. In addition, the goals of therapies are often fluid and change over the course of a treatment. Illness can evolve over time, requiring a change in goals. For example, a patient in treatment for alcoholism may after a period of abstinence—clearly a successful goal of treatment for substance abuse—manifest symptoms of an underlying mood disorder, requiring a different therapy and a change in treatment goals. Consequently, the goals of therapy need to be clearly understood, and communication among therapists is necessary to help them avoid conflict in goals, agree when goals are met, and change goals depending on the condition of the patient.

Outcomes can affect the other parameters of adjunctive therapy as well. A common occurrence is the successful termination of one therapy because the goals

have been met. Any of the individual therapies that comprise an adjunctive treatment may meet its goals first. This results in a termination of the therapy and a change in other parameters of the treatment. Termination of one component of the therapy, whether it is due to a successful outcome or a poor outcome, always necessitates a review of the other parameters. This is best carried out if the final parameter, communication, is working well.

F. Communication

The sine qua non for effective adjunctive therapy is communication. The therapists must agree on what to communicate, when to communicate, and how to communicate. In an adjunctive therapy, the patient has a therapist–patient relationship with each of the treaters and must give permission for communication. The therapists must agree on what can and cannot be communicated and convey this agreement to the patient. Without this clarity, one or more therapists may be working with a handicap. For example, a patient conveys to an individual therapist that she had several hospitalizations for psychosis as a young adult. The patient may express concern that the psychopharmacotherapist not be told because she is afraid the psychopharmacotherapist will hospitalize her. This historical information is crucial to making a correct diagnosis and in choosing the right medication. Without this information the psychopharmacotherapist is handicapped in his or her decision-making process. Consequently, in most adjunctive therapies the patient is told that no therapist will keep confidential information that is deemed crucial for the decision making of the other therapists. Without such a stipulation, the lack of communication can provide an avenue for acting out and resistance.

The therapists must also agree on how often to communicate and how to communicate. How often is usually driven by the frequency of the therapies, the time of expected change, and the clinical status of the patient. How to communicate depends on the situation and means available to the therapists. If the adjunctive therapy has all the therapists working in the same setting sharing a common chart, written communication may suffice. More commonly, therapists are working in disparate settings and unaffiliated programs, so communication occurs by a regularly scheduled integrated treatment meeting initiated by the principal therapist. Because such meetings can be resource intensive, they are often scheduled infrequently. Communication occurs

between meetings by phone conferences, faxing office notes, or more recently by e-mail.

The areas defining adjunctive therapy, treatment hierarchy, role definition, theoretical clarity, and boundaries are often fluid, with large areas of overlap. They are commonly in flux throughout the course of a treatment and require active communication as a glue to hold the treatment together and focused on common goals.

II. THEORETICAL BASIS

The reasons that individuals seek psychological help involve many domains—social, psychological, and biological, reflecting the complexity of human experience. With the growth of empirical evidence over the last half century, a consensus has built that confining a theory of mental illness to a single domain (often the biologic) is reductionistic and ultimately limiting to understanding the illness and likewise its treatment. When mental illness occurs, it affects all three domains of human activity to varying degrees. Consequently, treatment interventions are often made across these domains using a variety of therapies.

Starting with DSM-III, American psychiatry made a paradigmatic shift defining illness as occurring across biopsychosocial domains defined by multiaxial diagnoses. It is noteworthy that the model for this diagnostic structure was adapted from the New York Heart Association criteria for classifying heart disease. Explicit in this diagnostic approach is an acknowledgment that illnesses span these domains and that treatment interventions need to be planned across all three domains.

Although research has shown a variety of treatments, including individual treatments (e.g., cognitive behavioral therapy, interpersonal therapy, and dialectical behavior therapy); group therapies, and psychopharmacotherapy, to be effective treatment for psychiatric illness, no single treatment addresses dysfunction in all three domains of human experience. This fact is not confined to psychiatric illness but rather mimics what has been known about other disorders as well—that illness, regardless of its nature, involves biopsychosocial functioning to varying degrees. This has been well-illustrated in oncology by David Spiegel who in 1989 showed that women receiving chemotherapy for breast cancer had better survival rates if they received a time-limited structured group psychotherapy than women treated with chemotherapy alone.

The outcome of this research for psychological treatment has been to reinforce the need of the therapist to at least assess all three domains of function and, when indicated, to plan treatment interventions across all domains. Because of the training, orientation, and experience of a variety of treaters, it has become increasingly common to need the involvement of more than one therapist in treating an individual. This leads directly to the demand for adjunctive therapy.

III. HISTORICAL OVERVIEW

The use of adjunctive therapy had its earliest formal use in the United States during the late nineteenth century with the development of moral therapy. Prior to that time, ill individuals were treated with primarily physical interventions ranging from herbal treatments, bloodletting, isolation, wet packs, rest cures, and, for severely ill, agitated patients, imprisonment and even physical torture. Moral therapy was primarily a social intervention in which individuals were treated on large farm-like hospitals and required to participate in the work of the farm. The basic tenet of moral therapy was that if individuals who are profoundly ill are treated with respect and dignity and are required to participate in normal social activities rather than be imprisoned and punished, they will once again acquire the social attributes of normal members of society. The large mental institutions in the United States constructed in the late nineteenth century were largely working farms. While this earliest example of sociotherapy was often effective and Charles Dickens described it in glowing terms during his visit to America, it was often not enough. Physical therapies such as isolation, restraints, and wet packs were also used frequently to control disruptive behavior. Consequently, combinations of both physiologic and social therapies were in wide use beginning in the last quarter of the nineteenth century.

The beginning of the twentieth century saw the growth of psychological treatment led by Freud and his followers. Psychoanalysis focused on the psychological domain of the individual and on how it attributed to both illness and health. The overriding emphasis was on psychoanalysis as a general theory that both explained and could treat all mental illnesses. Psychoanalysis as a monotherapy largely dominated treatment for the first half of the century. Although gravely ill individuals at times received adjunctive therapy, usually, physical treatments such as wet packs, electroconvulsive therapy, and limited pharmacotherapy, confined largely to sedatives,

these treatments were viewed as more enabling the patient to take part in psychoanalysis as an individual treatment rather than adjunctive therapy *per se*.

The growth of adjunctive therapies began after World War II in terms of widespread use, theoretical interest, and empirical studies. With psychoanalysis as the preeminent treatment, the emphasis was on intrapsychic phenomena and intensive individual treatment. The effect of the war was to burden the health care system, producing more traumatized individuals than could possibly be seen in intensive and lengthy psychotherapy. Group psychotherapy and, in particular, the empirical and theoretical work of Wilfred Bion grew directly out of the need to help many psychologically traumatized individuals with limited resources. Frequently, less intensive individual psychotherapy was used in conjunction with group psychotherapy, forcing early theorists to conceptualize how these treatments worked together in complementary ways and, equally importantly, how the therapists collaborated.

Even as psychoanalysis grew as the preeminent theory and, consequently, the treatment modality, it became obvious that psychoanalytic treatment alone was often insufficient to treat ill individuals, particularly those requiring hospitalization. As the emphasis of hospitals shifted from social treatment and biological therapy to psychoanalytic treatment of the individual, the use of adjunctive therapies and the theoretical understanding of the relationship of these many different treatments grew. Talcott Parsons, Marshall Edelson, Otto Kernberg, and others addressed the issues of sociotherapy—that is, the use of the milieu to effect change and complement individual treatment, the roles of various therapists in treatment, the effective domains of varying treatments and how they complement and compete with each other, the need for a mechanism of communication between treaters, and a hierarchy of treaters.

The last quarter of the twentieth century produced an emphasis on expanding the empirical database, elucidating what therapies work and for what conditions. Led by the work of Aaron Beck, Mardi Horowitz, Myrna Weisman, Marsha Linehan, and others, we have vastly increased our knowledge of what kind of psychotherapy works and under what conditions. Similarly, pharmacotherapy research has provided data about what medication is effective for what condition.

This increase in empirical information has highlighted the fact that no single treatment addresses the ill individual's entire treatment needs. A leading example has been the treatment of Major Depressive Disorder. Both Beck

and Weisman have demonstrated that certain types of individual psychotherapy—in this case cognitive-behavioral therapy and interpersonal therapy—are effective treatments for this disorder. Pharmacotherapy research has shown that a variety of medications are effective in the treatment of severe and recurrent depression. Strikingly, both psychotherapy and pharmacotherapy when used together to treat depression have better outcomes than either used as monotherapy. These types of empirical studies have led to the increasing use of adjunctive therapy in the current treatment of the mentally ill.

IV. SUMMARY

Adjunctive therapy is the use of two or more therapies to treat the same individual with mental illness. This combination may be an individual therapy and group therapy, or couples therapy and individual therapy. Currently, the most common form of adjunctive therapy is the use of individual therapy with psychopharmacotherapy. The growth of empirical data on a variety of adjunctive therapies over the last quarter of a century and the acceptance of a biopsychosocial model of mental illness as the leading theoretical paradigm have made adjunctive therapy increasingly the common form of modern treatment of mental illness. Depending on the illness, a variety of adjunctive therapies are currently in use. These adjunctive therapies may be individual treatment and group treatment, family treatment and individual treatment, and psychopharmacotherapy and a variety of other therapies. While the combinations of treatment involved in adjunctive therapy are too numerous to exhaustively catalog identical elements give it structure. These elements are treatment hierarchy, role definition, theoretical clarity, boundary definition goals, and communication.

GLOSSARY

antithetical scheme of apperception The sharply divided way of interpreting people and situations with an “either/or,” “black and white” restriction of qualities; no “grey area” is acknowledged.

compensation A tendency to make up for underdevelopment of physical or mental functioning through interest and training, usually within a relatively normal range of development. Overcompensation reflects a more powerful impulse to gain an extra margin of development, frequently beyond the normal range. This may take a useful direction toward exceptional achievement or a useless direction toward excessive perfectionism. Genius may result from extraordinary overcompensation. Undercompensation reflects a less active, even passive attitude toward development that usually places excessive expectations and demands on other people.

eidetic imagery Vivid, detailed visualizations of significant figures in a person’s life used to yield projective impressions and stimulate emotional responses during the diagnostic phase of therapy. Later in therapy, these visualizations can be modified to promote therapeutic changes.

feeling of community (social interest) Translated from the German, *Gemeinschaftsgefühl*, as community feeling, so-

cial interest, social feeling, and social sense. The concept denotes a recognition and acceptance of the interconnectiveness of all people, experienced on affective, cognitive, and behavioral levels. At the affective level, it is experienced as a deep feeling of belonging to the human race and empathy with fellow men and women. At the cognitive level, it is experienced as a recognition of interdependence with others, that is, that the welfare of any one individual ultimately depends on the welfare of everyone. At the behavioral level, these thoughts and feelings can then be translated into actions aimed at self-development as well as cooperative and helpful movements directed toward others. Thus, at its heart, the concept of feeling of community encompasses individuals’ full development of their capacities, a process that is both personally fulfilling and results in people who have something worthwhile to contribute to one another.

feeling or sense of inferiority (primary and secondary) The primary feeling of inferiority is the original and normal feeling in the infant and child of smallness, weakness, and dependency. This usually acts as an incentive for development. However, a child may develop an exaggerated feeling of inferiority as a result of physiological difficulties (e.g., difficult temperament) or handicaps, inappropriate parenting (including abuse, neglect, pampering), or cultural or economic obstacles. The secondary inferiority feeling is the adult’s feeling of insufficiency that results from having adopted an unrealistically high or impossible compensatory goal, often one of perfection. The degree of distress is proportional to the subjective, felt distance from that goal. In addition to this distress, the residue of the original, primary feeling of inferiority may still haunt an adult. An inferiority complex is an extremely deep feeling

of inferiority that can lead to pessimistic resignation and an assumed inability to overcome difficulties.

fictional final goal An imagined, compensatory, self-ideal created to inspire permanent and total relief, in the future, from the primary inferiority feeling. Often referred to as simply the person's goal, it is usually unconscious until uncovered in psychotherapy.

missing developmental experience A belated therapeutic substitute for toxic, deficient, or mistaken early family, peer, or school experiences.

organ jargon An organ's eloquent expression of an individual's feelings, emotions, or attitude. Usually an ultrasensitive organ sends a symbolic message of the individual's distress about a subjectively unfavorable psychological situation.

private logic versus common sense Private logic is the reasoning invented by an individual to stimulate and justify a self-serving style of life. By contrast, common sense represents society's cumulative, consensual reasoning that recognizes the wisdom of mutual benefit.

psychological movement The thinking, feeling, and behavioral motions a person makes in response to a situation or task.

safeguarding tendencies Strategies used to avoid or excuse oneself from imagined failure. They can take the form of symptoms—such as anxiety, phobias, or depression—which can all be used as excuses for avoiding the tasks of life and transferring responsibility to others. They can also take the form of aggression or withdrawal. Aggressive safeguarding strategies include depreciation, accusations, or self-accusations and guilt, which are used as a means of elevating a fragile self-esteem and safeguarding an overblown, idealized image of oneself. Withdrawal takes various forms of physical, mental, and emotional distancing from seemingly threatening people and problems.

Socratic-therapeutic method An adaptation of the Socratic style of questioning specifically tailored to eliciting and clarifying information, unfolding insight, and promoting change in Classical Adlerian psychotherapy.

striving for significance The basic, common movement of every human being—from birth until death—of overcoming, expansion, growth, completion, and security. This may take a negative turn into a striving for superiority or power over other people. Unfortunately, many reference works mistakenly refer only to the negative “striving for power” as Adler's basic premise.

style of life A concept reflecting the organization of the personality, including the meaning individuals give to the world and to themselves, their fictional final goal, and the affective, cognitive, and behavioral strategies they employ to reach the goal. This style is also viewed in the context of the individual's approach to or avoidance of the three tasks of life: other people, work, love, and sex.

tendentious apprehension The subjective bending of experience in the direction of the fictional final goal.

unity of the personality The position that all of the cognitive, affective, and behavioral facets of the individual are viewed as components of an integrated whole, moving in one psy-

chological direction, without internal contradictions or conflicts.

I. DESCRIPTION OF TREATMENT

The primary indication of mental health in Adlerian psychotherapy is the person's feeling of community and connectedness with all of life. This sense of embeddedness provides the real key to the individual's genuine feeling of security and happiness. When adequately developed, it leads to a feeling of equality, an attitude of cooperative interdependency, and a desire to contribute. Thus, the central goal of psychotherapy is to strengthen this feeling of community.

The major hindrance to a feeling of equality and the development of the feeling of community is an exaggerated inferiority feeling for which the individual attempts to compensate by a fictional final goal of superiority over others. Thus, the therapeutic process is simultaneously focused on three aspects of change. One is the reduction of the painful, exaggerated inferiority feelings to a normal size that can be used to spur growth and development and a healthy striving for significance. A second is the dissolution of the patient's corrosive striving for superiority over others, embodied in a compensatory style of life. A third is the fostering of equality and feeling of community. Underlying this work is a firm belief in the creative power of the individual, to freely make choices and correct them, thus providing an encouraging perspective on responsibility and change.

Adlerian psychotherapy is a creative process in which the therapist invents a new therapy for each client. Six phases of the therapeutic process are as follows: (1) establishing the therapeutic relationship, (2) assessment, (3) encouragement and clarification, (4) interpretation, (5) redirection of the lifestyle, and (6) meta-therapy. These are briefly offered with the caveat that for any particular client, the actual therapeutic process may look quite different.

A. Phase I: Establishing the Therapeutic Relationship

Developing a cooperative working relationship is fundamental for any meaningful therapeutic progress. A warm, caring, empathic bond, established from the very beginning, opens the door for gradual, positive influence. Initially, the client may need to express a great deal of distress with little interruption. In response,

therapist offers genuine warmth, empathy, understanding, and empathy. An atmosphere of hope, reassurance, and encouragement enables the client to develop a feeling that things can be different.

The therapist also helps the client learn to participate in a cooperative relationship. The success of the therapy depends on how well the patient and therapist work together, each doing his or her part, which includes the client's thinking and action between visits.

The relationship with the therapist is a major avenue for significant change. The therapist provides belated parental influence to provide what was missing in the patient's early childhood or to ameliorate toxic early experiences. The therapist helps the patient experience a relationship based on respect, equality, and honesty—for some patients the first such relationship they have ever experienced. The therapist also provides a good model of cooperation and caring.

B. Phase II: Assessment

A thorough assessment is a critical step in Adlerian psychotherapy, for it will guide much of the therapeutic process. Although it is generally conducted during the first part of the treatment, information obtained throughout treatment may be used to refine and even correct initial impressions and interpretations. The objective of the assessment process is to conduct a comprehensive analysis of the patient's personality dynamics and the relationship among them—what Adler called the style of life. At a minimum, this analysis includes an identification of the patient's inferiority feelings, fictional goal, psychological movement, feeling of community, level and radius of activity, scheme of apperception, and attitude toward the three life tasks of occupation, love and sex, and other people.

A central assessment technique that Adler pioneered is the projective use of early memories. These memories—whether they are “true” or fictional—embody a person's core beliefs and feelings about self and the world and reflect the core personality dynamics. In addition to these early memories, the therapist uses the following: (1) a description of symptoms and difficulties, the circumstances under which they began, and the client's description of what he would do if not plagued with these symptoms; (2) current and past functioning in the domains of love relationships, family, friendships, school, and work; (3) family of origin constellation and dynamics, and extended family patterns, (4) health problems, medication, alcohol, and drug use, (5) previous therapy and attitude toward the therapist; (6) night

and day dreams, and (7) information about the larger contexts in which the patient is embedded (e.g., ethnic, religious, class, gender, or racial contexts). Although much of this information can be collected in the early therapy sessions, it can also be obtained in writing both to save time and to draw on information from a different mode. When appropriate, intelligence, career, and psychological testing are included.

The therapist uses both cognitive and intuitive processes to integrate this diagnostic information into a unique, vivid, and consistent portrait. This is key to treatment planning and will eventually and gradually be shared with the client. The therapist must always keep in mind, however, that these conclusions are somewhat tentative and are subject to refinement and revision. As the therapist gains more information, it must all fit in with this portrait in a consistent way; if not, the portrait may need revisions to accommodate this new information.

C. Phase III: Encouragement and Clarification

An ongoing central thread throughout the entire therapeutic process is encouragement. The therapist cannot give clients courage; this feeling must develop through the gradual conquest of felt difficulties. The therapist can begin this process by acknowledging the courage the client has already shown, for example, in coming to therapy. Then the therapist and client together can explore small steps that, with a little more courage, the client might take. For many clients, this is equivalent to doing the “felt impossible.” During and after these steps, new feelings about efforts and results are acknowledged and discussed.

In attempting to avoid failure, discouraged people often decrease their level and radius of activity. They can become quite passive, wait for others to act, and limit their radius of activity to what is safe or emotionally profitable. If this is true for a patient, the therapist and patient need to find ways to increase the patient's activity level—to increase initiative and persistence, completion of tasks, improvement of capacities, and enjoyment of progressively vigorous effort. If the activity radius is too narrow, a broadening of interests may provide stimulation, challenge, and more pleasure. In increasing activity level, however, a client may initially move in a problematic direction; for example, a timid person aggressively tells off his friend. But this is often a necessary first step that can be corrected after commencing the attempt.

During this still-early phase of therapy, Socratic questioning is used to clarify the client's core beliefs and feelings about self, others, and life. Here is a brief example of Socratic questioning in a therapy session with a depressed man who is stuck in his symptoms.

T: You may have a suggestion, you're kind of bright, you know.

C: What makes you think I'm bright?

T: By the way you talk, and the way you answer questions, and the way you do things in general. You're bright. You know how to avoid giving an answer, and how to aggravate people, and you know a lot of things. That's kind of bright. Dumb people don't do that.

C: You think that's a sign of brightness, to aggravate people?

T: Oh, sure! That's a way that you use it. I don't particularly think that people approve of the way you use it, but it is a sign of brightness. You could use the same brightness in a different way, you know?

C: That's true. A lot of people are very annoyed at me.

T: Uh huh. You like that?

C: Sometimes I don't mind. It bothers me when my parents get annoyed at me because then I can't go visit them. And they won't let me visit every week.

T: They won't let you visit every week. Now if I would be very annoying, would you like me to visit you every week?

C: (weakly) I don't think so.

C: No. Sounds as if your parents have a point.

The therapist builds on a strength of the client—his intelligence. Then she brings out the client's private logic, which could be expressed as, "I can annoy others with impunity." She then tests this private logic by extending it to others, asking whether this logic could also be applied to the therapist annoying the client. Using Socratic questioning to challenge the client's private logic helps him to move closer to common sense.

As the client and therapist talk during these early sessions, the therapist focuses on the psychological movement within the client's expressions and imagines the goal toward which the movements lead. For example, while the client may talk about a conflict with his wife, two possible movements he could actually be describing are away from his wife (withdrawal) or against his wife (aggression). By doing this, the therapist begins to identify the client's immediate and long-range hidden goals. He may be trying to protect himself from psychological harm, or he may wish to punish her for real or imagined hurts. Frequently, the immediate so-

cial result is the best clue to discovering a goal. Translating actions, thoughts, and feelings into movement and interpreting them in clear, simple, nontechnical language provides a useful mirror for the client. Buzzwords, jargon, and typologies do not help as much, frequently obscuring the uniqueness of the client's experience. The therapist uses everyday terminology and even tries to form insight in terms of images that are familiar to the client.

In the therapeutic dialogue, the therapist will also dialectically question the client's *antithetical scheme of apperception*. The client is likely to resist this process because the scheme of apperception provides certainty and supports the pursuit of the childlike, egocentric, final goal. The client's scheme of apperception depends on cognitive rigidity to generate very strong feelings. It locks the client into a dichotomized, superior/inferior way of seeing the world, evaluating experiences, and relating to others. Thus, to loosen and dissolve the antithetical scheme of apperception, the therapist must help the client see the real and subtly distinguishing qualities of people and experiences rather than dividing impressions into "either or," rigidly absolute categories.

All behavior is purposive and is aimed at moving toward the final goal. Client's emotions and symptoms will all serve the goal. The purpose may be hidden, and the client may not want to acknowledge responsibility for his intention. Both emotions and symptoms can be used to avoid responsibility for actions or as excuses for not doing what the client really does not want to do. For example, fear, confusion, and anger can all be used as excuses for not developing better relationships with others. The client needs to understand how he uses or abuses emotion. Does he create feelings that help him do the right thing? Does he use strong emotion as an excuse for indulgent and irresponsible action? What emotions does he avoid? Does one client, for example, aggressively ward off tender emotions, while another avoids anger with his "nice guy" approach? What is the impact of the client's emotions on other people? Does he want this result? Emotions are not the cause of behavior: rather, they serve one's intentions.

One of Adler's favorite diagnostic questions was, "If you did not have these symptoms, what would you do?" The answer frequently revealed what responsibility or challenge the person was trying to avoid. Symptoms, like crutches, will be discarded when they are no longer needed. Trying to treat the symptom is like blowing away smoke without extinguishing the fire that causes it.

D. Phase IV: Interpretation

After the client has made some movements toward change and she and the therapist have examined the meaning of her movements and immediate goals, they eventually engage in an interpretation of the client's style of life. Discussing and recognizing these core personality dynamics, such as the inferiority feeling or the goal, can be both painful and even embarrassing. The interpretation process requires diplomacy, exquisite timing, and sensitivity. Doing this interpretation too soon is discouraging. The style of life is interpreted gradually, as the client gains success and strength in a new direction, discovers capacities that she has neglected, and begins to correct what she has omitted in her development. Once she has moved sufficiently in a new direction, the results of her new and old attitudes are then compared.

This insight enables the client to take greater initiative in interpreting situations more on her own, sharing her own ideas with the therapist. Many clients are tempted to terminate at this point, feeling that they know enough, even though they have not actually applied their insight and changed their main direction in life. However, profound change occurs after the client and therapist have together identified and discussed the client's style of life. Insight and newly found courage are mobilized to approach old difficulties and neglected responsibilities. On the basis of this insight, then, the client can work toward lifestyle redirection, that is, changing the main direction of movement and approaching the three central tasks of life (community, work, and love).

E. Phase V: Style of Life Redirection

This phase represents the depth work that is done for the client to redirect the lifestyle. This requires reducing and using inferiority feelings, redirecting the superiority striving, changing the fictional final goal, and increasing the feeling of community.

Clients may have exaggerated inferiority feelings that they want to eliminate totally, believing that if they realize their goal, these painful feelings will disappear. A client may use his feeling of inferiority to build a wall in front of him, thereby excusing himself from difficult effort and from risk to his fictional ideal. His depreciation of others, fictional superiority posturings, alcohol, or drugs may temporarily give him some relief from his semi-hidden and dreaded feeling of deficiency. The therapeutic aim is to help the client put an

inferiority feeling behind him so that it pushes him ahead. That's the purpose of the normally sized inferiority feelings—to motivate development. If, however, the client's feeling of inferiority is quite exaggerated and seems to immobilize him or thrust him into wildly ambitious plans that are destined for failure, the therapist helps him change his thinking about his assumed great deficiency.

When the client's inferiority feelings are exaggerated, the superiority striving gets corrupted into striving for superiority over others rather than for development and growth. Thus, another therapeutic process involves redirecting this striving into a more positive direction—the conquest of real personal and social difficulties that benefit others rather than the superiority and power over other people.

A thread that runs through the therapy and that underlies efforts to reduce inferiority feelings is the way the therapist promotes the feeling of equality. The therapist's offer of equality may be a new experience that the client can gradually transfer to other people.

As the client begins to feel more able and less inferior, she may be able to begin changing her fictional final goal. The compensatory, fictional final goal, originally formed to relieve the primary feeling of inferiority, can gradually be modified to a more cooperative form, or dissolved and replaced by a different form of motivation. Abraham Maslow described this higher level of functioning as "growth motivation," in contrast to the lower level of "deficiency motivation." A client makes the choice to abandon his former direction and pursue the new one because it yields a more positive feeling of self and greater appreciation from others. As the goal changes, the rest of the style of life also changes as old feelings, beliefs, and behaviors are no longer required in the new system.

Parallel to the process of reducing inferiority feelings and changing the goal is the process of increasing the feeling of community. Initially, through his contact with the therapist and later through his application of social interest with other people, the client learns the meaning and value of contact, connectedness, belonging, and empathy. *Gemeinschaftsgefühl*, the original German term for community feeling, expresses a very profound philosophical perspective on life—a very deep feeling for the whole of humankind, an attitude of vigorous cooperation and social improvement, and a sense of the interconnectedness of all of life and nature.

Perhaps skeptical of the therapist's good-will at first, the client has felt and appreciated the genuine caring and encouragement. The conquering of obstacles has

generated courage, pride, and a better feeling of self that now lead to a greater cooperation and feeling of community with the therapist. This feeling can, and should, now be extended to connect more with other people, cooperate with them, and contribute significantly to their welfare. As the client's new feeling of community develops, she will become motivated to give her very best to her relationships and to her work.

Throughout the therapeutic process—both before and after the formal interpretation process—the therapist and client have been working on correcting the client's private logic and dissolving the antithetical scheme of apperception. In addition to these processes, it may be helpful to engage in therapeutic strategies that change the negative imprints from the past.

If the client's early childhood experience was very negative or deficient, it may be helpful to help the client counteract the haunting memories of abuse or neglect with creative, nurturing images. Some people respond to a vivid description and discussion of how they could have been parented. It gives them a picture of what might have happened, how it could have felt, and the outcomes that could have resulted. It may also serve as a model for what the client could do in his or her own parenting.

Other clients prefer the use of guided imagery to change the negative imprints of significant others that weigh heavily on them and often ignite chronic feelings of guilt, fear, and resentment. Still others prefer role-playing both to add missing experiences to their repertoire and to explore and practice new behavior in the safety of the therapist's office.

To provide missing experiences—for example, support and encouragement of a parent—a group setting is recommended. Group members, rather than the therapist, can play the roles of substitute parents or siblings. In this way, a client can engage in healing experiences, and those who participate with him can increase their own feeling of community by contributing to the growth of their peers.

The client and therapist can engage in role-playing for learning and practicing new behaviors. The therapist can model possible behaviors as well as coaching, encouraging, and giving realistic feedback about probable social consequences of what the client plans to do. This is somewhat equivalent to the function of children's play as they experiment with roles and situations in preparation for growing up.

A final issue of therapeutic change in the Classical Adlerian model is the person of the therapist. Clients constantly observe their therapists and may use them as

positive or negative models. How the therapist behaves is critical, for it may interfere with the therapy process if a client sees that his therapist does not embody what she is trying to teach him. Thus, providing an honest example of cooperation and caring is fundamental. It is not enough for a therapist to understand and talk about Adler's ideas; they must also be lived. If a client sees any contradiction between the therapist's words, feelings, and actions, he has good reason to be skeptical.

F. Phase VI: Meta-Therapy

A few clients may reach the quest for full personal development. The challenge is to stimulate each client to become her best self in the service of others, to awaken her inner voice, and to fully use her creative powers. Müller described the last phase of therapy as a "philosophical discourse." For those clients who need and desire this experience, Classical Adlerian psychotherapy offers the psychological tools and philosophical depth to realize their quest.

Maslow labeled this latter aspect of therapy "meta-therapy." He suggested that the fullest development of human potential might require a more philosophical process, one that went beyond the relief of suffering and the correction of mistaken ideas and ways of living. As clients improve, the therapist can help them see that they can use new, more liberating and inspiring guides for their lives. These alternative guides are what Maslow called meta-motivation or higher values—for example, truth, beauty, justice. The values that individual clients choose will depend on their unique sensitivities and interests.

II. THEORETICAL BASES

Classical Adlerian psychotherapy is both similar to and distinctively unique to some contemporary schools of psychology and psychotherapy. In its focus on the importance of the relationship between the client and early childhood significant others, between the client and therapist, and between the client and significant others in his life, it is similar to self psychology and object relations psychotherapies. In its recognition of the embeddedness of the individual within a social context, it is similar to social psychology and family systems therapy. In its focus on the subjective meaning the client makes of the world and his relationship to it, it is similar to constructivist theories and cognitive-behavioral psychotherapy.

But several conceptual aspects of Classical Adlerian psychotherapy set it apart from all others. First and foremost is the conception of the creative power of the individual that is directed toward a goal, a fictional future reference point that pulls all movements in the same direction. An Adlerian psychotherapist never asks the question, “What makes the client do that?” The question is always, “What is the client trying to achieve by doing that?” Underlying this teleological approach is a belief in active, free will to creatively move toward a goal of one’s own choosing. But once having adopted a fictional final goal, the goal functions unconsciously, out of full awareness. (This concept of fictional final goal is similar to that of a strange attractor in chaos theory, a magnetic end point that pulls on and sets limits for a process.)

This goal also organizes the psychological movements of the person so that there is a unity of the personality. One part of the personality never wars with another; all cooperate together in the service of the goal. What may look like conflict—for example, a client is ambivalent about whether to remain monogamous in his marriage or to have an affair—is really in service of a final goal—to avoid giving himself completely to one woman. Emotions are also the servants of this goal—for example, fear used to avoid, anger used to dominate, punish, or create distance. Dreams reflect this goal, as do daydreams, early recollections, and everyday behaviors. (This concept of unity, in which one central theme is reflected in every psychological expression, is similar to the concept in physics of the hologram, wherein each part of a whole is an enfolded image of that whole.)

Another central aspect of Classical Adlerian psychotherapy is the values on which it is based. Adler used to say that if humans didn’t learn to cooperate, they would annihilate the world. Thus, therapy encompasses much more than simple relief from symptoms. The goal of therapy is to increase the client’s feeling of community so that she can better cooperate with others and make a contribution to the whole of life. Over the course of his theoretical development, Adler moved from viewing humans as simply attempting to compensate for inferiority feelings (what Maslow called “deficiency motivation”) to a focus on growth and development (what Maslow called “growth motivation”). Thus, in Classical Adlerian psychotherapy, the aim is to move towards optimal psychological, philosophical, and even spiritual health for the benefit of both self and others.

Unlike traditional psychoanalysis, Classical Adlerian psychotherapy does not utilize transference or countertransference as cornerstones of treatment. Transfer-

ence, from an Adlerian perspective, is the tendency of the client to transfer inappropriate positive or negative feelings, originally experienced toward a parent, sibling, or other significant figure from childhood, toward the therapist. Adler considered the client’s transference a device to justify and protect the pursuit of the hidden, fictional final goal. Consequently, the therapist diplomatically unveils the transfer of perception and feeling as a long-standing habit that needs to be corrected. In this perspective, transference is a resistance to the cooperation that is necessary between client and therapist. The client usually tries to draw the therapist into a familiar relationship where she can imagine an eventual secret victory.

Countertransference, the therapist’s reactions to the client, are used by the Adlerian therapist as clues to the effect that the client has on others in her life. If, however, the therapist finds that the client triggers his own unfinished personal issues, this should prompt the therapist to deal with these in his study analysis with a senior training analyst.

III. APPLICATIONS AND EXCLUSIONS

The strategies of Classical Adlerian psychotherapy are similar in individual, couple, family, and child psychotherapy. The central dynamic is the encouragement of each individual to develop his or her capacities so as to reduce the inferiority feeling, to feel more equal with others, to become more cooperative, and to contribute to the improvement of all relationships for mutual benefit. In order to accomplish this, the style of life of each person usually needs to be redirected. Abbreviated adaptations of Classical Adlerian psychology have also been developed for use in brief therapy, career assessment and guidance, organizational consulting, and child guidance for parents and teachers.

IV. EMPIRICAL STUDIES

As of yet, there have been no empirical studies of Classical Adlerian psychotherapy.

V. CASE ILLUSTRATION

Arthur, a lonely, angry man in his mid-40s, was referred to therapy after completing an outpatient alco-

hol treatment program. He was very frustrated with his career as a criminal investigator, experienced very little intimacy with his wife, and had no friends. Although he conducted extremely thorough investigations that resulted in convictions, sentences rarely included jail time. His cold and isolated childhood left him very bitter: his memories were of an unhappy mother; a remote father; and a hell-raising older brother whom he hated, but who was the center of the parents' attention and frequently got away with illegal behavior. By contrast, he was a compliant youngest child who didn't make any trouble and was ignored. His sister, the oldest sibling, acted as a substitute caretaker for the distracted and critical mother.

The felt neglect of his father and the lack of love from his mother were at the roots of his inferiority feelings—a painful sense of being unloved and ignored. Discouraged and pessimistic about gaining affection and attention, he directed his compensatory lifestyle toward catching as many “bad guys” as he could and seeing that they were locked up. Since most were not, in his estimation, adequately punished, he was perpetually frustrated. He also viewed his parents and brother as unpunished criminals. His unconscious goal was to secure compensation and revenge for his miserable childhood. Revenge was not working out to his satisfaction, but at least he could look forward to a comfortable retirement, a symbol of what he felt entitled to.

Initially, his attitude toward the therapist was guarded and minimally expressive. What made him competent in surveillance work, observing others without being seen, was a handicap in making a personal relationship. However, two strengths could be built on. First, he had conquered both alcohol and nicotine dependencies. Second, his intense curiosity about hidden information and details provided a stimulus for examining his own style of life thoroughly through a discussion of the vivid clues embedded in his earliest childhood recollections. His most revealing recollection featured his brother spoiling a family fishing trip by making trouble and then getting away with it. His antithetical scheme of apperception sharply divided the good guys who obeyed the laws and the bad guys who broke the laws.

His private logic dictated that those who followed the rules were entitled to generous rewards and that the criminals deserved harsh punishment and confinement. Through his work, he dreamed of the ultimate compensation denied him as a child: punishing lots of bad people. Gradually, he realized how much his crusade had driven his life and what he had been missing,

as a child and as an adult—warm, friendly contact with other people. He appreciated the therapist's understanding of his early family situation and empathy for his lonely childhood suffering. Socratically, he became aware of his narrow focus of interest on the people who made trouble and his exclusion of those who offered affection and caring.

Eventually, he softened enough to respond to healing, eidetic images of warmer, caring “substitute” parents. These images elicited his first experience of crying in therapy. After opening up emotionally and experiencing a gradual series of missing developmental experiences through guided and eidetic imagery, he overcame a socially corrosive depreciation tendency toward wrongdoers, and was willing to redirect his striving for significance into an interest in promoting understanding and fairness, instead of administering punitive justice. He concluded treatment with a more comfortable, closer relationship with his wife, and an optimistic perspective on making new friends.

VI. SUMMARY

In its most basic of descriptions, Adler conceived of the goal of therapy to help clients connect themselves with fellow men and women on an equal and cooperative footing. Therapist and client simultaneously focus on three therapeutic processes: (1) reducing painful, exaggerated inferiority feelings to a normal size that can be used to spur growth and development and a healthy striving for significance; (2) redirecting the lifestyle away from a useless and corrosive striving for superiority over others and fictional final goal and toward a more useful and cooperative direction; and (3) fostering equality and a feeling of community. Thus, not only does therapy benefit the individual, but it also contributes to the improvement of life for other people.

GLOSSARY

5-hydroxytryptophan (See five-hydroxytryptophan).

agonist A drug that works by stimulating its receptor (as opposed to an antagonist, which works by blocking receptors).

anesthetics Drugs used for general anesthesia.

Aristolochia fangchi Also called *guang fang ji*, an herb marketed over-the-counter for weight loss in products labeled “Chinese herbs.”

aristolochic acid A chemical found in the Chinese herb *Aristolochia fangchi*, which is sold over-the-counter in various weight-loss products.

autonomic nervous system The branch of the nervous system that regulates internal body processes requiring no conscious awareness.

barbiturates A class of drugs (including pentobarbital and phenobarbital) used to induce sleep, relieve anxiety, treat certain types of seizures, or for general anesthesia.

benzodiazepines A class of drugs (including Valium, Librium, and Xanax) that decrease anxiety and induce sleep by facilitating GABA neurotransmission.

carbidopa A prescription drug used to treat Parkinson’s disease, available in pill form.

carcinogenicity Cancer-promoting properties.

cyclosporine Prescription immunosuppressant medication used to prevent organ rejection in transplant recipients, available in pills, oral solution, or IV injection.

digoxin A prescription cardiac medication that strengthens and regulates the heartbeat, available as pills, IM injection, or IV injection.

dopamine A neurotransmitter involved in motor control, increased levels of which are associated with psychosis.

EMDR (See eye movement desensitization and reprocessing).

ephedra Also known as *ma huang*; an herbal compound with amphetamine-like qualities sold over-the-counter in a number of weight-loss and energy-boosting products.

eye movement desensitization and reprocessing (EMDR) An alternative to psychotherapy that utilizes eye movements or other left-right stimulation to treat psychological problems.

five-hydroxytryptophan (5-hydroxytryptophan) Also called 5-HTP, an herbal supplement marketed for the treatment of depression, which is metabolized into serotonin in the body and may enhance serotonin neurotransmission.

fluoxetine (Prozac) A selective serotonin reuptake inhibitor.

formulary A list of drugs that are included as covered benefits by a particular insurance company, as opposed to non-formulary drugs that must be purchased out-of-pocket or with a higher co-payment.

GABA (See gamma-aminobutyric acid).

gamma-aminobutyric acid The major inhibitory neurotransmitter of the central nervous system.

Griffonia simplicifolia An African plant, the seeds of which are used to derive 5-hydroxytryptophan.

guang fang ji (See *Aristolochia fangchi*).

heliotrophe (See *Valeriana radix*).

hematocrit A measure of the proportion of red blood cells to the total blood volume.

hemoglobin The oxygen-carrying component of red blood cells.

homocysteine A substance in the blood, high levels of which are associated with increased risk of heart disease.

Hypericum perforatum Also called St. John's wort; an herbal compound marketed over-the-counter for the treatment of depression, which likely affects the serotonin system.

immunosuppressant A drug used to prevent transplant rejection or to treat autoimmune disorders or severe allergies, which suppresses the functioning of the immune system.

inhibitory neurotransmitter A neurotransmitter, the presence of which decreases the probability of neuronal firing (as opposed to an excitatory neurotransmitter, the presence of which increases the probability of neuronal firing).

kava (See Piper methysticum).

kava kava (See Piper methysticum).

kavalactones Fatlike compounds with sedative qualities found in Piper methysticum (kava).

LeShan An alternative therapy used to heal medical and psychological problems when the treatment provider and patient are a distance apart.

ma huang (See ephedra).

MAO inhibitors (See monoamine oxidase inhibitors).

MAOIs (See monoamine oxidase inhibitors).

monoamine oxidase inhibitors (MAO inhibitors; MAOIs) A class of antidepressants (including Nardil, Marplan, Parnate, and Deprenyl) that work by blocking the enzyme that breaks down serotonin and norepinephrine.

noradrenaline (See norepinephrine).

norepinephrine Also called noradrenaline; a neurotransmitter that interacts with epinephrine to affect autonomic activity and mood.

perturbations Hypothesized structures throughout the body believed by proponents of thought field therapy to contain the energy that creates psychological disturbances.

Piper methysticum Also called kava or kava kava; an herbal compound marketed over-the-counter for the treatment of anxiety and insomnia.

platelets Cell-like particles in the blood, smaller than red or white blood cells, which clump together and promote clotting.

psychotropic medications Medications used to treat mental and emotional problems, including antidepressants, antipsychotics, and tranquilizers.

Reiki (Pronounced "ray-key") an ancient Buddhist practice of manual healing therapy, used to treat both medical conditions and psychological problems.

REM (rapid eye movement) sleep A stage of sleep characterized by rapid eye movements, behavioral activity, high electrical activity in the brain, increased rate and depth of breathing, and dreaming.

S-adenosylmethionine (SAMe) An herbal compound marketed over-the-counter for the treatment of depression and some medical conditions, including osteoarthritis and liver disease; may affect brain levels of serotonin, noradrenaline, and dopamine.

SAMe (See S-adenosylmethionine).

scleroderma A chronic disease characterized by blood vessel abnormalities, as well as degenerative changes and scarring of the skin, joints, and internal organs.

selective serotonin reuptake inhibitors (SSRIs) A class of antidepressants (including Prozac, Zoloft, and Paxil) that work by blocking the reuptake of the neurotransmitter serotonin.

serotonin A neurotransmitter, decreased levels of which are associated with depression.

serotonin syndrome A syndrome caused by high levels of serotonin and associated with agitation, restlessness, insomnia, tremor, nausea, vomiting, rapid heart rate, and seizures.

sertraline (Zoloft) A selective serotonin reuptake inhibitor.

SSRIs (See selective serotonin reuptake inhibitors).

St. John's wort (See Hypericum perforatum).

thought field therapy An alternative to psychotherapy in which the practitioner helps the client tap a series of points on the body in order to alter thoughts.

transductive points Specific places on the body that the client taps as part of thought field therapy.

tricyclic antidepressants A class of antidepressant drugs, including Elavil, Anafranil, Tofranil, and Pamelor, which work by blocking norepinephrine reuptake, with some blocking of serotonin reuptake.

tryptophan An amino acid from which serotonin and melatonin are manufactured in the body, which was sold as an over-the-counter sleep aide until an impurity in one bad batch caused severe medical problems and death in a number of users.

valerian (See Valeriana radix).

Valeriana officinalis (See Valeriana radix).

Valeriana radix Also called valerian, Valeriana officinalis, or heliotrophe; an herb with mild tranquilizing effects, sold over-the-counter to treat insomnia and mild anxiety.

warfarin (Coumadin) A prescription anticoagulant (blood thinner) medication, available in pills or IV injection.

Because of advances in modern medicine during the 20th century, homeopathic and naturopathic medicine had all but vanished in the United States. However, the past few decades have seen a revival of alternative medical treatments, with Americans making an estimated half-billion visits to alternative practitioners annually. Unfortunately, most alternative treatments, although promising, remain unvalidated by well-controlled scientific study at this time.

Many American consumers are now seeking alternative therapies for their psychological problems as well as for their medical problems. Alternative therapies for psychological problems include nutritional programs for the management of mental disorders, various techniques of bodywork and body alignment for clearer

thinking and peace of mind, aromatherapy, various types of touch therapy for emotional healing, magnet therapy, moving meditations such as tai chi and yoga, music therapy, and various forms of prayer. Such a vast array of alternatives to psychotherapy exists that it would be impossible to cover them all in detail in this article. Therefore, this article will focus on two types of alternative psychological treatments: technical and pharmacologic (herbal). Examples of each will be offered.

I. TECHNICAL ALTERNATIVES TO PSYCHOTHERAPY

A. Reiki

Reiki (pronounced “ray-key”) is an ancient Buddhist practice of manual healing therapy that was rediscovered in Japan by Mikao Usui in the mid 1800s. It has become increasingly popular in the United States during the past few decades and is used for treating heart attacks, emphysema, hemorrhoids, prostate problems, varicose veins, hiccups, nosebleeds, and various mental and emotional problems. It is based on the belief that life is dependent on a universal, nonphysical energy. Because health requires a sustained and balanced flow of this energy throughout the body, disturbances in that flow result in physical, emotional, and mental illnesses. The Reiki practitioner attempts to correct life energy imbalances and blockages by gently resting his or her hands in specific ways on 12 standard sites throughout the body. The practitioner generally begins with the head and spends a few minutes at each site, with a complete session taking an hour or more. In some cases, the practitioner will expand the therapy beyond the standard 12 sites. Advanced practitioners believe themselves to be as effective even when physically absent from their patients by simply visualizing their hand movements with patients. These practitioners believe that they can send spiritual energy to their patients through a process similar to prayer, and thus are able to perform effective Reiki from a distance.

Some researchers have proposed that Reiki changes the blood's oxygen-carrying capability as shown by hemoglobin and hematocrit levels. However, the few studies conducted to date have yielded mixed results and some of those studies showing changes in hemoglobin or hematocrit levels actually show changes for the worse rather than for the better. One study by Wirth and Barrett in 1994 actually showed slower wound healing time in patients receiving a combination of Reiki, therapeutic

touch, and LeShan (a distance healing technique) than in controls. Studies by Schlitz and Braud in 1985 and Thornton in 1966 examined the claim that Reiki induces relaxation and found that the autonomic activities of subjects receiving Reiki did not differ significantly from those of controls.

No adverse effects on patients have been reported with Reiki. However, no therapeutic benefits of Reiki have been demonstrated through well-controlled, scientific studies. The few studies on Reiki have generally been poorly designed, with such confounding variables as lighting, candles, and music. Although interest in Reiki is growing among alternative practitioners, there is no strong scientific evidence to date for its effectiveness, and Reiki remains unvalidated.

B. Thought Field Therapy (TFT)

Thought field therapy (TFT) is an alternative to psychotherapy used to treat depression, anxiety, phobias, addictions, anger, trauma, grief, and other emotional and mental conditions. It was developed by Roger Callahan, Ph.D., after his reported discovery of the existence of certain structures of active information (called perturbations) in the bioenergy thought field, which he believes cause psychological disorders. Through a long process of trial and error, Dr. Callahan developed TFT to diagnose and treat these perturbations in the energy field.

Proponents of TFT view psychological change as occurring via quantum leaps rather than by a step-by-step linear process. In order to treat psychological problems, the TFT practitioner is able to see and feel the reality of a perturbation. Once the diagnosis of a perturbation is made, the practitioner helps the client to tap a series of “transductive points” on the body in order to alter the structure of the thought field specific to the problem. Proponents of TFT believe the treatment to be so powerful that it need only be used once to result in significant change for a number of psychological problems.

Although the proponents of TFT claim that it has been proven to be more effective than psychotherapy, its effectiveness has not been demonstrated using well-controlled scientific studies. The evidence presented is generally anecdotal and lacks any comparison (control) groups. For example, Leonoff in 1996 reported a study in which he replicated a 1986 study by Dr. Callahan. Both studies used 68 subjects who called a radio program to receive on-the-air treatment by the researchers, and both studies claim a 97% success rate with a 75%

average improvement based on clients' reports of distress using a 10-point rating scale. However, neither study used a control group, and the comparison of the two studies by Leonoff in 1996 simply compares the use of TFT by practitioners in 1985 to the use of TFT by practitioners in 1996 without comparing TFT to any other treatment modality. Therefore, TFT remains unvalidated at this time.

C. Eye Movement Desensitization and Reprocessing (EMDR)

EMDR was first introduced in 1989 by Francine Shapiro, Ph.D., and has since been taught to thousands of clinicians and has received considerable media attention. It is used for the treatment of trauma and the various psychological symptoms that are believed to result from traumatic experiences. EMDR practitioners use an eight-phase protocol to help trauma victims reprocess distressing thoughts and memories, which includes using eye movements or other left-right stimulation:

- Phase I: Client history
- Phase II: Preparation (in which the theory is explained, expectations are set, and the client's fears are addressed)
- Phase III: Assessment (in which negative cognitions are identified, positive cognitions are developed, emotions are named, and body sensations are identified)
- Phase IV: Desensitization (in which eye movements are utilized to reduce the client's anxiety about a certain situation or event)
- Phase V: Installation (in which a positive cognition is enhanced and linked to the original target issue or event)
- Phase VI: Body scan (which focuses on any body tension produced by the original memory or the positive cognition that has been linked to it through the treatment)
- Phase VII: Closure (in which the client is returned to a positive frame of mind and is determined to be able to safely return home before being dismissed)
- Phase VIII: Reevaluation and use of the EMDR standard protocol (in which the clinician assesses how well the trauma has been resolved and determines whether or not the client needs any further processing)

Shapiro in 1995 theorized that EMDR utilizes the same brain processes as REM sleep, although she admits that current knowledge of neurology and neurobiology does not provide an explanation of exactly how EMDR works. Even though the precise impact of EMDR on the brain remains unknown, EMDR has received more rigorous, scientific study than the previously mentioned alternatives to psychotherapy. Shapiro and Forrest in 1997 cited a number of case reports and nonrandomized studies in order to demonstrate the efficacy of EMDR. In addition to these studies, the authors cite 12 randomized and controlled studies that serve to validate EMDR. Some of these studies have compared EMDR to other psychological treatment modalities, to no-treatment controls, or to delayed EMDR treatment, while other studies compare standard EMDR to variations of EMDR such as engendering eye movements by tracking a light bar rather than by tracking the clinician's finger or using forced eye fixation, hand taps, and hand waving instead of the standard eye movements.

These randomized and controlled studies indicate that EMDR is superior to other treatment modalities for the populations studied. However, some of the differences are small even though they are statistically significant. They also indicate that, in general, standard EMDR is as effective or more effective than the variations studied. Although this research seems promising, more study is needed before EMDR can be considered a validated treatment method. Shapiro and Forrest in 1997 reported studies that indicate that EMDR is at least as effective as other treatments, but do not state whether or not any studies conducted have indicated that EMDR is less effective than other treatment modalities for any conditions. Furthermore, some of the studies reported are flawed by confounding variables, such as the secondary gains of chronic inpatient veterans receiving compensation from the VA system. Some studies compare EMDR to treatment modalities unlikely to be effective for the condition being studied, such as biofeedback relaxation for veterans who have experienced chronic PTSD symptoms since the Vietnam War. The gains shown from EMDR as compared to no-treatment controls may be due to the EMDR itself or to the placebo effect, which is generally accepted as about 35% in magnitude. It is unknown whether the gains from EMDR are due to the eye movements themselves or to other aspects of the protocol that closely resemble traditional psychotherapy (such as replacing negative cognitions with positive ones). Therefore, EMDR has

some supporting evidence, but more research is needed.

II. PHARMACOLOGIC (HERBAL) ALTERNATIVES TO PSYCHOTHERAPY

Herbal remedies have become such a major factor in American health care in recent decades that the *Physician's Desk Reference* (PDR) has had a companion volume (*PDR for Herbal Medicines*) updated annually since 1998. In 1997, about 12% of Americans used herbal products, compared to about 3% in 1990. Most consumers who use herbal products do so for the management of chronic conditions, such as psychiatric disorders (particularly anxiety and depression).

Although the American public tends to equate "natural" and "herbal" with "safe," the efficacy and safety of these products have only recently been studied in controlled clinical trials. These recent studies indicate that not all herbal supplements are safe. For example, ephedra (also known as ma huang) is an herbal ingredient found in a number of weight-loss and energy-boosting products available without prescription. It has amphetamine-like qualities and can be dangerous, particularly for people with high blood pressure or heart conditions and is responsible for dozens of deaths. The amino acid tryptophan had been sold as an over-the-counter sleep aid until 1989 when the FDA banned its sale after at least 38 people died and numerous others were left with painful, crippling nerve damage, severe joint pain, and scarring of internal organs from an impurity in a bad batch of the supplement from one manufacturer. Recent evidence indicates that various combinations of herbs marketed as weight-loss products and labeled "Chinese herbs" can cause kidney failure and death. Most likely, aristolochic acid from the Chinese herb *Aristolochia fangchi* (also called *guang fang ji*) is a potent kidney toxin responsible for the reported kidney problems and deaths from kidney failure.

Since Congress passed the Dietary Supplement Health Education Act (DSHEA) in 1994, most herbal supplements have not been regulated by the FDA. Products labeled "dietary supplement" are exempt from FDA control, as long as they do not claim to cure any disease. Therefore, herbal products are not subjected to the same rigorous testing and standards as over-the-counter and prescription drugs. Because most

herbal supplements are exempt from FDA control, many products sold do not contain the amount of active ingredient indicated on the label. Occasionally the products contain more of the active ingredient than indicated, while often the products contain substantially less of the active ingredient than the label indicates. For this reason, research done using standardized dosages of herbal remedies may not be a valid indication of the efficacy of the unstandardized herbs available to the American public.

Most of the American public is unaware that most herbal products have side effects and interaction effects with medications. Some of the side effects and interaction effects will be discussed with each example of herbal alternatives to psychotherapy.

A. St. John's Wort (*Hypericum perforatum*)

St. John's wort was used by the ancient Greeks and has been used in Germany for many years as a prescription drug. It has recently become one of the most common herbal products sold in the United States, with retail sales surpassing \$140 million in 1998. Its effectiveness has been studied in Europe. Linde provided a meta-analysis of 23 randomized trials in Europe, 15 of which compared St. John's wort to placebo and 8 of which compared it to active treatments. These studies indicate no significant difference in efficacy between St. John's wort and tricyclic antidepressants for mild to moderate depression and that St. John's wort is more efficacious than placebo. However, these studies were generally short (about 6 weeks) in duration. Research comparing St. John's wort to selective serotonin reuptake inhibitors (SSRIs) is in its infancy. One recent trial compared St. John's wort to fluoxetine (Prozac) and showed similar improvements in both groups. A clinical trial sponsored by the National Institute of Mental Health (NIMH) is currently under way to compare St. John's wort to sertraline (Zoloft).

One study by Shelton and colleagues, which appeared in the April 18, 2001 issue of the *Journal of the American Medical Association* (JAMA), indicated that St. John's wort is no more effective than placebo for treating major depression. The study has gained significant media attention and has called into question previous studies indicating that St. John's wort is effective. However, the recent JAMA study looked at St. John's wort and major depression whereas the previous studies had looked at St. John's wort for the treatment of mild or

moderate depression. Taken as a whole, the body of research available to date indicates that St. John's wort may be useful for cases of mild to moderate depression, but that it is ineffective for the treatment of severe depression (major depression).

The mechanism of action of St. John's wort is uncertain. Early studies suggested it was similar to a monoamine oxidase (MAO) inhibitor in its action, but recent data indicate it is closer to an SSRI, except that it does not affect the serotonin system in the spinal cord and, therefore, does not produce the decrease in sexual drive experienced by at least one-third of SSRI users. Use of St. John's wort in conjunction with MAO inhibitors or SSRIs is contraindicated, as the combination increases SSRI-like side effects and could result in serotonin syndrome, a condition causing dizziness, confusion, anxiety, and headaches. The syndrome is potentially fatal.

Side effects of St. John's wort are similar to those of SSRIs and include gastrointestinal symptoms, dizziness, confusion, sedation, dry mouth, photosensitivity, and induction of hypomania according to Barrette, in 2000, and *PDR for Herbal Medicines* in 2000. A number of drug interactions may occur with St. John's wort. It can reduce blood levels of the HIV drugs (such as indinavir) by more than 50%, which may in turn lead to drug-resistant strains of the virus, noted the University of California, Berkeley, in 2000. It reduces the effects of blood thinners such as warfarin (Coumadin), the heart drug digoxin, some oral contraceptives, and the immunosuppressant drug cyclosporine (which helps prevent organ rejection in transplant recipients). It increases photosensitivity when used in conjunction with other photosensitizing drugs.

B. 5-HTP (5-Hydroxytryptophan)

5-HTP is an herbal supplement manufactured from the seeds of the African plant *Griffonia simplicifolia*. It is metabolized into serotonin and is thought to alleviate depression by enhancing serotonin neurotransmission. It is also used to treat fibromyalgia, insomnia, binge-eating, attention deficit disorder, and chronic headaches.

Studies conducted in the 1970s and early 1980s have shown 5-HTP to be more effective than placebo in treating depression. Several small studies have compared 5-HTP to standard antidepressant medications. However, these studies have some notable flaws (small sample sizes, short durations, no placebo group, poor definition of depression, and the inclusion of patients with bipolar depression).

The most common side effects of 5-HTP are nausea, vomiting, diarrhea, and anorexia. Euphoria, hypomania, restlessness, rapid speech, anxiety, insomnia, aggressiveness, and agitation have also been reported. It is possible that 5-HTP causes seizures in children with Down syndrome, and its safety for pregnant or nursing women and those with liver and kidney disease has not been established. People with kidney disease, peptic ulcers, or blood platelet disorders should not use 5-HTP.

There is some concern about contamination, even though the manufacture of 5-HTP is different from that of the standard tryptophan, which was banned in 1989. There have been a few reports of symptoms similar to those caused by contaminated tryptophan, and researchers have identified at least one contaminant in some batches of 5-HTP.

5-HTP interacts with MAO inhibitors, with an increase in risk of hypertension. 5-HTP should not be used in conjunction with tricyclic antidepressants or SSRIs due to the possibility of serotonin syndrome. 5-HTP also interacts with carbidopa (used to treat Parkinson's disease), and the combination can cause skin changes similar to those that occur with scleroderma.

C. SAME (S-adenosylmethionine)

SAMe (pronounced "Sammy") was first discovered in Italy in 1953. It became commercially available in Europe in 1977, and was not available in the United States until 1999. SAMe is used to treat osteoarthritis and liver disease, as well as depression, as noted by Gaster, and by Tufts University, in 1999. SAMe's mechanism for dealing with depression is not understood, but some researchers speculate that it affects brain levels of the neurotransmitters serotonin, noradrenaline, and possibly dopamine.

More than 40 trials have been conducted to evaluate SAMe for the treatment of depression. However, only five trials have tested oral forms of the herb, whereas the remaining studies have tested injectable formulations. Only three of the five trials of oral SAMe were randomized controlled trials. The trials that have tested injectable SAMe have generally shown it to be effective in the treatment of depression, although it is not valid to assume that oral SAMe is effective since it is very poorly absorbed from the gastrointestinal tract. It is too early to tell whether SAMe will prove to be a safe and effective treatment for depression.

Stomach upset is the most common side effect reported with SAMe use. Enteric-coated products are less likely to cause nausea, and are also less likely to break down in the stomach before they reach the small intestine

where SAME is absorbed. SAME is contraindicated for individuals with bipolar disorder, as it can trigger manic episodes. Those with obsessive-compulsive or addictive tendencies should not take SAME, as it may worsen their problems.

Safety concerns provide compelling reasons to avoid using SAME pending further research. Because the research has been very short term, it is not known whether taking the herb long term could cause problems with toxicity or carcinogenicity. Because SAME raises blood levels of homocysteine, it may also raise the risk of coronary disease. Until it is understood how SAME acts on the central nervous system, it is best to avoid taking SAME in conjunction with other antidepressants, according to Gaster in 1999.

Even though SAME's effectiveness and safety remain unvalidated, it is considerably more expensive than other treatments for depression (16 times as costly as St. John's wort, 5 times as costly as most tricyclic antidepressants, and 3 times as costly as SSRIs). SAME cannot be recommended at this time for the treatment of depression due to its high cost, uncertain absorption, uncertain safety, and potential for inducing mania.

D. Kava, also known as kava kava (*Piper methysticum*)

Kava is a shrublike plant from the pepper family that is native to the South Pacific. It has traditionally been made into beverages, but can also be purchased in pill form. Kava is marketed in the United States as an over-the-counter drug to treat anxiety and insomnia and to promote relaxation, with millions of dollars being spent annually on the herb. The effectiveness of kava has been researched in placebo-controlled studies conducted in the United States and Germany. Meta-analysis of these studies provides evidence that kava is more effective than placebo for mild to moderate anxiety, but it is not effective for panic disorder. To date, the effectiveness of kava as compared to other antianxiety medications is unknown. Mild gastrointestinal upset is the main side effect of kava, and therapeutic doses are generally well-tolerated. However, large doses or prolonged use can cause rashes (allergic skin reactions); yellow discoloration of skin, hair, and nails; weight loss; and abnormal reflexes.

Kava root contains kavalactones, fatlike compounds that act as sedatives, muscle relaxants, and pain relievers. It is recognized by the FDA as being intoxicating and having abuse potential. Kava most likely works on the neurotransmitter GABA (gamma-aminobutyric acid) as an agonist (much like benzodiazepines), but since it is

only a partial agonist it may be somewhat less effective than benzodiazepines. Because GABA is an inhibitory neurotransmitter, stimulation of GABA receptors results in CNS depression, noted Cummings, in 2000.

Use of kava with other central nervous system depressants (such as alcohol, benzodiazepines, or barbiturates) is contraindicated, as the interaction can potentiate the sedative effect and possibly lead to coma. Use of kava with anesthetics is also contraindicated, as it may prolong the sedation time and its use is contraindicated with antipsychotic medications due to the potentiation of the sedative effects. In Parkinson's patients, it can cause tremors, muscle spasms, or other abnormal movements and may decrease the effectiveness of anti-Parkinson's medications.

E. Valerian, also known as Heliotrope (*Valerianae radix* or *Valeriana officinalis*)

Valerian is an herb with mild tranquilizing effects, sold over-the-counter and used to treat insomnia and mild anxiety. It was the 10th most popular herb in the United States in 1998, whereas it was ranked 18th the previous year. It was originally used in ancient Greece, and was used during World War I as a primary treatment for shell shock.

Like kava, valerian likely acts as a GABA agonist to produce its sedative effects, noted Hardy in 1999. Several good placebo-controlled studies indicate that it reduces the time it takes to fall asleep, but the research indicating that it improves sleep quality is very limited. The few available studies indicate that valerian is somewhat more effective than placebo for treating mild anxiety, but is likely ineffective for moderate to severe anxiety or panic disorder.

Valerian's side effects include mild morning sedation and headache, although one case of serious liver toxicity from an over-the-counter sleep remedy containing valerian has been reported. Valerian use in conjunction with other sedative drugs (such as benzodiazepines, barbiturates, or anesthetics) is contraindicated, as the interaction may potentiate the sedation. The research available to date indicates that valerian may not potentiate the effects of alcohol, but until more research is available it is advisable not to combine the two.

III. SUMMARY

In general, good studies demonstrating the effectiveness of most alternatives to psychotherapy are lacking.

In some cases, the research is yet to be conducted. In other cases, the body of available research indicates that the treatments are ineffective or, at best, only slightly more effective than placebo. However, more and more health care dollars are being spent on these and other alternative therapies. This trend toward increased utilization of treatments that are unverified and of dubious scientific validity is likely due to several factors: (1) The American consumer expects modern medicine to be able to cure every ailment and alleviate every pain. When it does not, the consumer often turns to alternative techniques. (2) The public erroneously equates "alternative" with "safe" and "natural." At the same time, the public is concerned about the dangerous side effects that may accompany prescription medications. (3) Many patients believe that managed care is limiting their access to medical treatment and medications. In many cases, the newer psychotropic medications are not included on some insurance companies' formularies. Even though herbal alternatives may be costly, they are often less costly than paying out-of-pocket for non-formulary medications. (4) Many consumers complain that their doctors do not really listen to them and involve them in health care decisions. On the other hand, health food store personnel and alternative practitioners are often much more willing to listen, spend time with patients, and offer patients the opportunity to participate in decisions. (5) Perhaps most important, the public is deluged with health information. Few people have the ability to read health information critically and to distinguish between good science and hype.

Although research to date may not be sufficient to draw conclusions about the effectiveness of many alternative therapies, some alternative therapies have

been demonstrated to be effective adjunct treatments for various medical conditions. For example, biofeedback has been shown to be helpful in the treatment of a number of medical conditions, particularly muscle tension headaches and Raynaud's disease. As a result, insurance companies are becoming increasingly willing to pay for such treatments as adjuncts to standard medical treatments.

GLOSSARY

aggression Behavior intended to cause psychological or physical harm to someone or to a surrogate target. The behavior may be verbal or physical, direct or indirect.

anger A negatively toned emotion, subjectively experienced as an aroused state of antagonism toward someone or something perceived to be the source of an aversive event.

anger control The regulation of anger activation and its intensity, duration, and mode of expression. Regulation occurs through cognitive, somatic, and behavioral systems.

anger reactivity Responding to aversive, threatening, or other stressful stimuli with anger reactions characterized by automaticity of engagement, high intensity, and short latency.

anger schemas Mental representations about environment-behavior relationships, entailing rules governing threatening situations. They affect anger activation and behavioral responding.

cathartic effect The lowering of the probability of aggression as a function of the direct expression of aggression toward an anger-instigator. The lowering of arousal associated with such catharsis is more or less immediate and can be reversed by re-instigation.

escalation of provocation Incremental increases in the probability of anger and aggression, occurring as reciprocally heightened antagonism in an interpersonal exchange.

excitation transfer The carryover of undissipated arousal, originating from some prior source, to a new situation having a new source of arousal, which then heightens the probability of aggression toward that new and more proximate source.

frustration Either a situational blocking or impeding of behavior toward a goal or the subjective feeling of being thwarted in attempting to reach a goal.

hostility An attitudinal disposition of antagonism toward another person or social system. It represents a predisposition to respond with aggression under conditions of perceived threat.

inhibition A restraining influence on anger expression. The restraint may be associated with either external or internal factors.

provocation hierarchy A set of provocation scenarios progressively graduated in degree of anger-inducing features for the client. It is constructed by the therapist in collaboration with the client during the early stages of treatment and is used in the stress inoculation procedure.

stress inoculation A three-phased, cognitive-behavioral approach to therapy, involving cognitive preparation/conceptualization, skill acquisition/rehearsal, and application/follow-through. Cognitive restructuring, arousal reduction, and behavioral coping skills training are the core treatment components. Therapist-guided, graded exposure to stressors occurs in the application phase, where the client's enhanced anger control skills are engaged.

violence Seriously injurious aggressive behavior, typically having some larger societal significance. The injury may be immediate or delayed.

I. DESCRIPTION OF TREATMENT

A. Topic Introduction and Definition

Providing psychotherapy for persons having recurrent anger problems is a challenging clinical enterprise. This turbulent emotion, ubiquitous in everyday life, is a feature of a wide range of clinical disorders. It is commonly observed in various personality, psychosomatic, and conduct disorders, in schizophrenia, in bipolar mood disorders, in organic brain disorders, in impulse control dysfunctions, and in a variety of conditions resulting from trauma. The central problematic characteristic of anger in the context of such clinical conditions is that it is “dysregulated”—that is, its activation, expression, and effects occur without appropriate controls. Anger control treatment, a cognitive-behavioral intervention, augments the client’s self-regulatory capacity. It aims to minimize anger frequency, intensity, and duration and to moderate anger expression. It is an adjunctive treatment for a targeted clinical problem and thus is not meant to address other or more general psychotherapeutic needs. Clinical interventions for problems of anger seek to remedy the emotional turbulence that is associated with subjective distress, detrimental effects on personal relationships, health impairments, and the manifold harmful consequences of aggressive behavior. The main components of anger control treatment are cognitive restructuring, arousal reduction, and enhancement of behavioral skills. A key feature of its implementation is therapist-guided progressive exposure to provocation, in conjunction with which anger regulatory coping skills are acquired.

B. Core Characteristics of Clients

A common characteristic of people having serious anger problems is that they resist treatment, largely due to the functional value that they ascribe to anger in dealing with life’s adversities. Because anger can be commingled with many other clinical problems (such as personality disorder, psychoses, or substance abuse), getting leverage for therapeutic change can be an elusive goal, particularly when referrals for anger treatment entail some element of coercion. Efforts to achieve clinical change are challenged by the adaptive functions of anger as a normal emotion, such that it is not easily relinquished. Anger is often entrenched in personal identity and may be derivative of a traumatic life history. Because anger activation may be a precursor of aggressive behavior, while being viewed as a salient clinical need, it may at the same time present

safety concerns for the clinician and be unsettling for mental health professionals to engage as a treatment focus. Although many high-anger patients present with a hard exterior, they can be psychologically fragile, especially those having histories of recurrent abuse or trauma, or when abandonment and rejection have been significant life themes. Because anger may be embedded with other distressed emotions, accessing anger is often not straightforward.

C. Assessment Issues

Anger treatment best proceeds from proficient anger problem assessment. However, assessment itself presents many challenges, because of the multidimensionality of anger (cognitive, physiological, and behavioral features) and because the true level of anger may be masked by the person in reaction to the testing situation. In many assessment contexts, particularly forensic ones, people are not inclined to report that they have high anger dispositions. Even when clients are treatment-seeking, they may not be altogether forthcoming about their anger because an “angry person” labeling carries unflattering connotations. Effectively targeting anger treatment, as well as ascertaining therapeutic gains, hinges on assessment proficiency, which is best done by a multimethod approach utilizing interview, psychometric, clinical rating, and behavioral observation methods, as well as archival and physiological methods when possible.

D. Levels of Intervention

Psychotherapy for anger control can occur at several levels of intervention: (1) General clinical care for anger; (2) psychoeducational “anger management” provision, typically delivered in a group format; and (3) anger treatment, which is best provided on an individual basis and may require a preparatory phase to facilitate treatment engagement. The intervention levels reflect the degree of systematization, complexity, and depth of therapeutic approach. Increased depth is associated with greater individual tailoring to client needs. Correspondingly, greater specialization in techniques and in clinical supervision is required at higher levels.

E. Anger Control Treatment: A Stress Inoculation Approach

Cognitive-behavioral anger treatment targets enduring change in cognitive, arousal, and behavioral systems. It centrally involves cognitive restructuring and

the acquisition of arousal reduction and behavioral coping skills, achieved through changing valuations of anger and augmenting self-monitoring capacity. Because it addresses anger as grounded and embedded in aversive and often traumatic life experiences, it entails the evocation of distressed emotions (e.g., fear and sadness) as well as anger. Therapeutic work centrally involves the learning of new modes of responding to cues previously evocative of anger in the context of relating to the therapist (“transference”), and it periodically elicits negative sentiment on the part of the therapist to the frustrating, resistive, and unappreciative behavior of the client (“countertransference”). Anger treatment that has followed a “stress inoculation” approach utilizes provocation hierarchy exposure. The inoculation metaphor is associated with the therapist-guided, progressive exposure to provocation stimuli. This occurs *in vitro* through imaginal and role-play provocations in the clinic, and *in vivo* through planned testing of coping skills in anger-inducing situations identified by the client’s hierarchy.

Stress inoculation for anger control involves the following key components: (1) Client education about anger, stress, and aggression; (2) self-monitoring of anger frequency, intensity, and situational triggers; (3) construction of a personal anger provocation hierarchy, created from the self-monitoring data and used for the practice and testing of coping skills; (4) arousal reduction techniques of progressive muscle relaxation, breathing-focused relaxation, and guided imagery training; (5) cognitive restructuring of anger schemas by altering attentional focus, modifying appraisals, and using self-instruction; (6) training behavioral coping skills in communication, diplomacy, respectful assertiveness, and strategic withdrawal, as modeled and rehearsed with the therapist; and (7) practicing the cognitive, arousal regulatory, and behavioral coping skills while visualizing and role-playing progressively more intense anger-arousing scenes from the personal hierarchies.

Provocation is simulated in the therapeutic context by imagination and role-play of anger incidents from the hierarchy scenarios, produced by the collaborative work of client and therapist. The scenarios incorporate wording that captures the client’s perceptual sensitivities on provoking elements, such as the antagonist’s tone of voice or nuances of facial expression. Each scenario ends with provocative aspects of the situation (i.e., not providing the client’s reaction), so that it serves as a stimulus scene. The therapist directs this graduated exposure to provocation and knows the moderating variables that will exacerbate or buffer the magnitude of the anger reaction, should the scene need

to be intensified or attenuated in potency. Prior to the presentation of hierarchy items, whether in imaginal or role-play mode, anger control coping is rehearsed, and arousal reduction is induced through deep breathing and muscle relaxation. Successful completion of a hierarchy item occurs when the client indicates little or no anger to the scene and can envision or enact effective coping in dealing with the provocation.

Following the completion of the hierarchy, an effort is made to anticipate circumstances in the client’s life that could be anger-provoking and the obstacles to anger control that might arise. This is done as a relapse prevention effort, especially as people having anger difficulties are often without adequate supportive relationships to provide reinforcement for anger control. Follow-up or booster sessions are typically arranged to provide support, to ascertain what coping skills have proven to be most efficacious, and to boost treatment in areas in need of further work. Because of the reputations acquired by high-anger people, the reactions of others to them can be slow to change. This can lead to relapse and requires therapeutic attention at follow-up.

F. Treatment Preparatory Phase Needed

Some seriously angry clients may be quite ambivalent about earnestly engaging in assessment and treatment, and in some clinical service contexts, particularly forensic settings, angry patients may be very guarded about self-disclosure. Because of the instrumental value of anger and aggression, many clients do not readily recognize the personal costs that their anger routines incur; because of the embeddedness of anger in long-standing psychological distress, there is inertia to overcome in motivating change efforts. In such circumstances, a treatment “preparatory phase” is implemented, involving a block of five to seven sessions, varying with client competence and motivation. The aim is to foster engagement and motivation, while conducting further assessment and developing the core competencies necessary for treatment, such as emotion identification, self-monitoring, communication about anger experiences, and arousal reduction. It serves to build trust in the therapist and the treatment program, providing an atmosphere conducive to personal disclosure and collaboration. Since the preparatory phase can be pitched to the client as a “trial period,” its conclusion then leads to a more explicit and informed choice by the client about starting treatment proper.

II. THEORETICAL BASES

A. Anger and Threat

The conception of anger as a product of threat perceptions, as having confirmatory bias characteristics (i.e., the perception of events is biased toward fit with existing anger schemas), as being primed by aversive precursors, and as having social distancing effects (i.e., expressing anger keeps people away) can be found in the writings of Lucius Seneca, who was Nero's tutor in first-century Rome. Seneca was the first to write systematically about anger control. Like other Stoic philosophers who negate the value of emotions, his view of anger was almost exclusively negative. Although his idea of anger control was largely that of suppression, Seneca recognized the powerful role of cognition as a determinant of anger, advocated cognitive shift and reframing to minimize anger, and saw the merit of a calm response to outrageous insult. However, he discounted the functional value of anger, which thereby led him to miss the principle of regulation.

Since the writings of Charles Darwin, William James, and Walter B. Cannon, anger has been viewed in terms of the engagement of the organism's survival systems in response to threat and the interplay of cognitive, physiological, and behavioral components. It is an elementary Darwinian notion that the adaptive value of a characteristic is entailed by its fitness for the environment; if the environment changes, that characteristic may lose its adaptive value, and the organism must adjust. The activation of anger may usefully serve to engage aggression in combat and to overcome fear, but in most everyday contexts, anger is often maladaptive.

Many theories of emotion have enlarged upon the Darwinian view of emotions as reactions to basic survival problems created by the environment and upon Cannon's idea that internal changes prepare the body for fight or flight behavior. Thus, emotion has commonly been viewed as an action disposition. Some contemporary theorists postulate that emotion is controlled by appetitive and aversive motive systems in the brain, with the amygdala serving as a key site for the aversive motivational system, and neurobiological mechanisms associated with amygdala involvement in aversive emotion and trauma are being studied in various laboratories. Most generally, when people are exposed to stimuli signifying present danger or reminders of trauma, they are primed for anger reactions. Anger is intrinsically connected to threat perception.

B. Anger and Cognition

Central to therapeutic prescriptions for anger control is the idea that emotion is a function of cognitive appraisal. That is, anger is produced by the meaning that events have and the resources we have for dealing with them, rather than by the objective properties of the events. Important work in this regard was done by Lazarus on appraisal processes and on stress coping styles, yet there is dispute about how pivotal is appraisal in the activation of anger. Berkowitz alternatively asserts that aversive events trigger basic associations to aggression-related tendencies as a "primitive" or "lower order" processing, which is then paralleled by anger in association. "Higher order" processing, such as appraisal, is then subsequent to the rudimentary reactions, and anger can be elaborated by the appraisal. Similarly, Beck has conjectured that anger derives from "primitive" processing in defense against threat, in which mode information is rapidly compartmentalized. Negative biases and overgeneralization lead to information-processing errors and anger activation. Appraisal processing (activation of beliefs and interpretations) may then follow this primal thinking mode. What Beck adds is that automatic thoughts are activated in the primal mode and that these are the roots of emotional distress.

This differentiation between "lower order" and "higher order" processing may otherwise be viewed as a distinction between "automatic" versus "controlled" operations. Sometimes anger occurs as a fast-triggered, reflexive response, while other times it results from deliberate attention, extended search, and conscious review. There is nothing necessarily "primitive" about automaticity in anger responding, as anger schemas and aggressive scripts, which are acquired through social learning, can produce rapid reaction to provocation stimuli. Furthermore, central cognitive processes can override reflexive responding to aversive stimulation. Otherwise we would be very angry on most trips to the dentist, and professional boxers in the ring would be in a continuous state of rage.

Social information processing models of aggressive behavior, such as that of Huesmann, view the human mind as analogous to a computer. Anger schemas are thus understood as macro knowledge structures, encoded in memory, that filter our perceptions and are used to make inferences. Aggressive scripts are subroutines that serve as guides for behavior, laying out the sequence of moves or events thought to be likely to occur and the behavior thought to be possible or appropriate for a certain situation.

The main thrust of such conceptions is that anger and its associated behavior are cognitively mediated. Correspondingly, anger control interventions target the way in which people process information, remember their experiences, and cognitively orient to new situations of stress or challenge. Therapeutic change of schemas linked to anger prevents the occurrence of anger, and the self-regulation of anger once activated is effected by controlled use of cognitive self-control techniques, such as calming self-instructions and relaxation imagery, combined with other arousal reduction and behavioral coping strategies.

C. Cognition, Arousal, and Behavior Reciprocities

Intrapsychic, dispositional systems are the principal focus of psychotherapy, and, in that regard, anger has three main subsystems or domains: cognitive, physiological, and behavioral. Cognitive dispositions for anger include knowledge structures, such as expectations and beliefs, and appraisal processes, which are schematically organized as mental representations about environment-behavior relationships entailing rules governing threatening situations. Arousal or physiological dispositions for anger include high hormone levels (neurotransmitters) and low stimulus thresholds for the activation of arousal. Anger is marked by physiological activation in the cardiovascular, endocrine, and limbic systems, and by tension in the skeletal musculature. Behavioral dispositions include conditioned and observably learned repertoires of anger-expressive behavior, including aggression but also avoidance behavior. Implicit in the cognitive labeling of anger is an inclination to act antagonistically toward the source of the provocation. However, an avoidant style of responding, found in personality and psychosomatic disorders, can foment anger by leaving the provocation unchanged or exacerbated.

Thus, it can be seen that these dispositional subsystems are highly interactive or interdependent. Anger-linked appraisals influence arousal levels, high arousal activates aggression and overrides inhibition, and antagonistic behavior escalates aversive events and shapes anger schemas and scripts for anger episodes as behavioral routines are encoded. In turn, the personal dispositional system interfaces with the environmental, such as when anger and aggression drive away pacific people, leaving one with angry and aggressive companions, who not only incite anger but from whom one continues to learn anger responding and anger-engendering appraisals, which further heighten arousal.

D. Person-Environment Context and Systems

Anger and anger control difficulties should be understood contextually. This assumes that recurrent anger is grounded in long-term adaptations to internal and external environmental demands, involving a range of systems from the biological to the sociocultural. The adaptive functions of anger affect the social and physical environmental systems in which the person has membership. Anger experiences are embedded or nested within overlapping systems, such as the work setting, the work organization, the regional economy, and the sociocultural value structure. Anger determinants, anger experiences, and anger sequelae are interdependent.

The interrelatedness of system components provides for positive and negative feedback loops. When a system moves away from equilibrium, negative feedback loops serve to counteract the deviation, such as when the self-monitoring anger reactions prompt deep breathing or cognitive reappraisal to achieve anger control. In contrast, anger reactions can be augmented by positive feedback, which is a deviation amplification effect. Anger displays in a situation of conflict tend to evoke anger and aggression in response, which then justify the original anger and increase the probability of heightened antagonism. Such anger-aggression escalation effects are well-known in conflict scenarios, whether interpersonal or international.

Intervention proceeding from a contextual model examines environmental, interpersonal, and dispositional subsystems that shape anger reactions. Although recurrent anger is often a product of long-term exposure to adverse conditions or to acute trauma, it is nevertheless the case that anger is a product of agentic behavior. People who select high-conflict settings or recurrently inhabit high-stress environments set the stage for their anger experiences. Those who are habitually hostile create systemic conditions that fuel continued anger responding that is resistant to change. As anger schemas solidify, anger is evoked with considerable automaticity in reaction to minimal threat cues. Aggressive scripts that program antagonistic behavior, which exacerbates anger difficulties, are socially and contextually learned. Focus on intrapsychic variables is transparently inadequate when the person remains immersed in anger-engendering contexts. Coordinated efforts of a multidisciplinary treatment team may be required.

III. APPLICATIONS AND EXCLUSIONS

Anger control therapy is an adjunctive treatment. Across categories of clients, the key issues regarding appropriateness for this therapy are (1) The extent to which the person has an anger regulatory problem, implying that acquisition or augmentation of anger control capacity would reduce psychological distress, the probability of aggression or other offending behavior, or a physical health problem, such as high blood pressure; (2) whether the person does recognize, or can be induced to see, the costs of his or her anger and aggression routines and is thus motivated to engage in treatment; and (3) whether the person can sit and attend for approximately 45 minutes. The latter criterion applies especially to hospitalized patients. The stress inoculation approach to anger has been successfully applied to institutionalized mentally disordered (schizophrenia and affective disorders) and intellectual disabled persons (mild to borderline). Because resolution on the issue of treatment engagement is often elusive, an anger treatment "preparatory phase" has been developed and implemented in work with forensic patients. Such preparatory work would also be appropriate for persons who have anger dysregulation in conjunction with trauma.

People with violent behavior problems are often referred for anger treatment (e.g., incarcerated offenders and spousal abusers or enraged drivers in the community). However, anger treatment is not indicated for those whose violent behavior is not emotionally mediated, whose violent behavior fits their short-term or long-term goals, or whose violence is anger mediated but not acknowledged. Little is known about the efficacy of cognitive-behavior therapy anger treatment with psychopaths, but it is doubtful that it would be suitable. As well, persons who are acutely psychotic or whose delusions significantly interfere with daily functioning are not suitable candidates for this self-regulatory treatment. Persons with substance abuse disorders also require prior treatment to engage in anger therapy. Successful case applications are given later.

IV. EMPIRICAL STUDIES

Research on anger treatment lags substantially behind that for problems of depression and anxiety, yet there is convergent evidence that various cognitive-

behavioral interventions produce therapeutic gains in anger control. However, there have been few randomized control studies with seriously disordered patients. Such studies have more commonly been done with college student volunteers, selected as treatment recipients by upper quartile scores on self-reported trait anger, by having expressed interest in counseling for anger management, and by volunteering over the telephone. Such sample inclusion criteria do not reflect the clinical needs of the angry patients seen by mental health service providers in community and institutional settings. Existing meta-analytic reviews of treatment efficacy are overloaded with college student studies and fail to include case study reports and multiple baseline studies, which have typically involved real patients with serious problems. Nevertheless, statistical computations in reviews across dozens of controlled studies have found medium effect sizes for anger treatments, indicating that the large majority of treated participants were improved.

Cognitive-behavior therapy approaches that have not followed the stress inoculation framework have produced significant treatment gains, such as those by Deffenbacher and his colleagues using cognitive and relaxation methods with college student volunteers without demonstrable clinical pathology or violence history. However, such treatment study participants do not reflect the clinical needs of the angry patients seen by mental health service providers in community and institutional settings. In contrast to college student volunteer studies, a controlled anger treatment trial with seriously disordered Vietnam veterans by Chemtob, Novaco, Hamada, and Gross in 1997, which was missed in the Beck and Fernandez meta-analysis in 1998, obtained significant treatment effects on multiple measures of anger reactions and anger control for the stress inoculation anger treatment, compared to a multimodal, routine care control treatment condition. The anger control treatment gains with these severe post-traumatic stress disorder patients, who had had intense, recurrent postwar problems with anger and aggressive behavior, were maintained at 18-month follow-up. Other control group studies involving successful outcomes for the modified stress inoculation approach to anger treatment with clinical populations have included adolescents in residential care, adolescent offenders, forensic patients, and mentally retarded adults. Exemplary work on anger control with adolescents has been done by Feindler and her colleagues.

Multiple case studies involving a variety of serious clinical disorders have provided empirical support for

the efficacy of cognitive-behavioral anger treatment and the stress inoculation approach. These include a hospitalized depressed patient, child abusing parents, chronically aggressive patients, an emotionally disturbed boy, a brain damaged patient, mentally handicapped patients, adolescents in residential treatment, and institutionalized forensic patients.

Brief cognitive-behavioral therapy "anger management" has been successfully used in prisons, often delivered in group format, varying from 3 to 16 sessions across studies. However, outcome evaluation assessments in these prison-based studies have been thin, and results of efficacy have been uneven. In this regard, the treatment engagement issues highlighted earlier are most relevant, and the interventions used have not been firmly based in a designated treatment protocol. Because the through-put client service needs of institutions and community agencies are formidable, greater attention needs to be given to the development of group-based intervention for anger.

V. CASE ILLUSTRATION

A. Case Description

Mr. A is a man in his thirties, who received anger treatment in a forensic hospital. He had a highly dysfunctional home background. He was truant from school and reported abnormal psychological experiences, resulting in the involvement of the psychiatric services. In his teens, he developed a substance abuse problem and associated with a delinquent peer group that encouraged a violent presentation. Persistent petty theft associated with substance abuse and aggression led to placement in secure facilities. There, the experience of both using violence and being bullied had a profound effect on him.

He married and had a child, but his wife left him while he was serving a short prison sentence. Following a period of homelessness, he was imprisoned for assault. He was diagnosed with schizophrenia and while he resisted this, he would allude to having a special destiny after an encounter with extraterrestrials who had given him the power to benefit mankind. He was subsequently transferred to a psychiatric hospital, where he made a number of attacks on staff. He was ultimately transferred to community accommodation, but he was ejected for theft and noncompliance. He was readmitted to a local hospital, following arrest for reckless damage and police assault. He then again as-

saulted one of the staff, so badly that this led to his admission to a maximum security hospital.

There, his psychotic symptoms soon remitted, but he was reported to be demanding and antiauthoritarian, continually challenging the rules and reacting aggressively to any perceived threat to his self-image. A transfer to a local hospital was unsuccessful due to his aggressive, demanding manner and drug misuse. He struggled to cope with his readmission and maintained an antiestablishment attitude. He made frequent threats toward staff and was physically assaultive. Making little progress, he made a serious attempt at suicide, which was related to despair at his continued detention. When under stress, his positive psychotic symptoms could emerge. His close relationships having disintegrated, he was very worried about future intimate relationships.

B. Treatment Application

Mr. A received anger treatment by staff psychologists. He was happy to attend sessions but initially found it difficult to engage in tasks. He was anxious about being not listened to and was resistant to being given advice. He often refused to participate, argued his own point, talked on a tangent, or reduced everything to a joke. He was insistent that he should not be rushed and feared being overwhelmed. Establishing a supportive relationship and a sensitive pacing of therapy was vital to engagement. As he came to view his therapists as being nonjudgmental and working in his interests, he became less defensive and more willing to complete tasks such as anger diaries and hierarchical inoculation exercises. As treatment progressed, he became more resilient to provocation and less likely to conclude that others were personally attacking him. He found alternative ways of viewing situations that previously had initiated angry attempts to restore his self-esteem. He became more aware of his heightened level of physiological arousal in problematic situations and used tension reduction methods, including relaxation and taking time-outs to create social distance from provoking events. He learned to approach staff to discuss matters of dispute and received support from his peers for anger control.

Illustrative incidents: (1) Another patient accused Mr. A of not repaying a debt. As this was said in public, Mr. A thought this was a deliberate attempt to humiliate him and being angry, wanted to show that he was not someone "to be trifled with." However, he managed to stay calm and avoid violence; instead he responded in a

way that minimized loss of face and reminded himself of the negative consequences of physical violence. Later, he reassessed the situation, reasoning that the other patient was struggling with a life sentence for murder and had been picking on others, not just targeting him. Discussing the event with friends, they reinforced his view and reassured him that they did not believe the accusation. (2) Having been recommended for transfer to a lower security hospital, a visit to that local hospital was arranged. One hour before leaving for his visit, it was cancelled because of events at the local hospital. Initially he was convinced that there was a sinister motive, feeling that the staff were trying to renege on the agreement. He became angry. However, he used arousal reduction techniques, and had a discussion with staff, who rearranged the visit. Staff remarked that he listened to their explanation and trusted them to resolve the situation, rather than behave self-destructively.

C. Treatment Gains and Transfer

Level of care staff observed that Mr. A generally began to take others' perspectives into account, and his psychiatrist reported that he was less impatient, less instantly demanding, and better able to listen and to discuss issues in a constructive manner. His gains in anger control led to a recommendation for transfer to his local hospital, and staff there reported being impressed with what they felt was a positive change in his presentation. His self-reported improvement in anger control and progress through the provocation hierarchy in treatment sessions thus received validation from ward staff observations of his behavior and by the judgment of his attending psychiatrist who arranged the transfer to a lower security hospital.

VI. SUMMARY

Anger control therapy is a cognitive-behavioral treatment. It aims to augment the regulation of anger that has become problematic in frequency, intensity, duration, and mode of expression. In its fullest form of intervention, it utilizes a "stress inoculation" approach, the heart of which involves therapist-guided, progressive exposure to provocations in the clinic and *in vivo*, in conjunction with which coping skills are modeled and rehearsed.

Training in self-monitoring, cognitive reframing, arousal reduction, and behavioral coping skills are the essential components of the treatment. Some clients require a preparatory phase for treatment engagement.

GLOSSARY

animal-assisted activities Therapy that involves animals visiting people for motivational and recreational benefits to enhance quality of life. The same activity can be repeated by the facilitator with the same or different people, unlike the therapeutic intervention that is tailored to the specific person.

animal-assisted therapy A goal-oriented intervention in which an animal meeting specific criteria is an integral part of the treatment process. This service is delivered by a health or human service professional working within the scope of his or her professional role.

I. DESCRIPTION OF TREATMENT

Louis Sabin once stated that “No matter how little money and how few possessions you own, having a dog makes you rich.” Being rich should not only encompass physical resources, but also the joy and love from being wanted and appreciated. Animals appear to demonstrate great compassion for others and enhance the quality of life of their human counterparts.

Florence Nightingale in *Notes on Nursing* stated that a small pet animal was an excellent companion for the sick. Her impressions in the mid-nineteenth century seemed to accurately represent how animals could be supportive to the physical and mental health of individuals. Her position represents the impressions of various health care professionals over the past century and a half. Nevertheless, it has been the seminal work of Boris Levinson which many have considered to provide one of the earliest published papers highlighting the therapeutic value of animals. Levinson’s first article was entitled “The Dog as a Co-Therapist” and was published in *Mental Hygiene* in 1962. His initial article was met with cynicism and skepticism by many of his colleagues. However, Levinson genuinely believed that animals could make a major contribution to the therapeutic process.

Although some strides have been made in developing concepts in animal–human relationships, there continues to be limited empirical support and limited research validating the overall effectiveness of this approach. Many researchers point out that although the utilization of animals may be highly appealing, the evidence that a patient has enjoyed an interaction with an animal does not imply that the procedure is therapeutic. It appears that the biggest challenge facing advocates of animal-assisted therapy who claim that it improves outcomes is the need for documentation. The author in a previous writing suggested that a concentrated stronger effort is needed in promoting more sound empirical investigations demonstrating

the therapeutic utility of animals in various clinical settings. He suggested that the investigators may want to study what populations animal-assisted therapy (AAT) are effective with and under what conditions animal-assisted activities (AAA) or AAT are the most valuable. Furthermore, practitioners must pay attention to the need for program evaluation and documentation. These efforts will assist the scientific community with the needed research priorities.

In September 1987, the National Institutes of Health held a workshop entitled Health Benefits of Pets. Data from the proceedings highlighted some scientific evidence that pet ownership appeared to correlate with improvements in quality of life. Results from the meeting also pointed out that attachments to animals might also be an important dimension in studying those who have experienced or are experiencing reduced social contacts with people (e.g., the elderly and isolated children). These meetings appeared to act as a catalyst for the development of numerous animal visiting programs (sponsored by the various humane societies) for residents in long-term facilities. These early programs were considered pleasant diversionary activities. They were welcomed by administrators as long as the program didn't pose any risks to patient health and safety.

It appears that the greatest benefit an animal brings to a therapeutic setting is its ability to enhance the relationship between therapist and client. Its presence seems to make the client more comfortable and at ease. Phil Arkow suggested that the animal may act as a catalyst for the conversation between the therapist and the client. He called this process a rippling effect. Others, such as Samuel Corson and Elizabeth Corson, call this process a social lubricant. The presence of the animal allows the client a sense of comfort, which then promotes rapport in the therapeutic relationship. Studies reported in the literature point out that a therapist who conducts therapy with an animal being present may appear less threatening, and, consequently, the client may be more willing to reveal him/herself. Some clinicians report that in interviews in the presence of their dogs, children appeared more relaxed and seemed more cooperative during their visit. The findings appear to conclude that the dogs serve to reduce the initial tension and assisted in developing an atmosphere of warmth. The animals appear to help many clients overcome their anxiety about going into therapy. Many therapy animals, especially dogs, are more than willing to receive a client in a warm and affectionate manner.

The author in his application of AAT in his work with children has also found that his clients seemed to benefit from the observations seen between the animal and the therapist. The most common response pertains to the interaction with the animals and how some clients compare these interactions with their own child/parent relationships (since most of his clients are children and their parents). Other clients comment on how well the animals are treated, including the elements of compassion, consistency, firmness, and love. These vicarious observations can be utilized for the purposes of teaching skills and vicarious learning.

A. The Therapeutic Environment— Animals as an Aspect of Milieu Therapy

One of the most valued aspects of having animals as part of a therapeutic alliance appears to be related to their impact on altering the therapeutic environment. This assumption has been strongly advocated by this writer in numerous previous publications. The assumption has also been supported by Alan Beck who also believed that animals seemed to have the capacity to modify a person's environment. In most cases, presence of an animal appears to modify the perceived environment and make it more friendly and comfortable to incoming clients. Herbert Sklar suggests that development of an effective therapeutic alliance may actually begin with the creation of a proper therapeutic environment. It appears that the client's readiness for psychotherapy could be disturbed by the simplicity of a clinic's decor and perhaps by its disorder.

It seems obvious that living beings could also be utilized to complement the work environment by making it more appealing and relaxing. Of utmost value is that animals appear to bring a certain sense of security and warmth into the environment. Alan Beck and his associates conducted a study in Haverford, Pennsylvania, where they hypothesized that animals would alter the therapeutic environment and make it less threatening to patients with various mental illnesses. The patients (who met in a room containing birds) attended sessions more faithfully and became more active participants in comparison to a control group. In addition, the researchers found a reduction in hostility scores (from the Brief Psychiatric Rating Scale) in the clients within the experimental milieu.

A variety of researchers have looked at animals and their apparent impact on reducing stress in an

environment. For example, Aaron Katcher, Arline Segal, and Alan Beck reported, in their study on anxiety and discomfort before and during dental surgery, that subjects viewing the aquarium appeared more comfortable and less anxious than those subjects in a control group not viewing an aquarium. Watching a school of fish can be quite relaxing for some. With proper lighting and an attractively designed tank, clients can feel more at ease when they enter an office or while in therapy.

B. Incorporating Theory in Practice: Animal-Assisted Therapy from a Life Stage Perspective

A clinician's theoretical orientation will have a strong bearing on the incorporation of animals within his or her therapeutic approach. An explanation that seems to naturally align itself is Erikson's theoretical orientation. Erikson views development as a passage through a series of psychosocial stages, each with its particular goals, concerns, and needs. Although the themes may repeat during a life cycle, Erikson noted that certain life concerns were more relevant during specific eras. For example, as people age and experience new situations, they confront a series of psychosocial challenges. Aubrey Fine, in an article written on AAT in psychotherapy in the *Handbook on Animal Assisted Therapy*, recommended that clinicians should consider the various eight stages of psychosocial development and reflect on how the application of animals may be appropriate. Table 1 briefly highlights the major tenets presented.

Clinicians should consider extending the boundaries of where they perform their psychotherapy with their clients beyond the traditional office. Utilizing dogs as part of a therapeutic regime promotes taking walks. While walking, a therapist has an opportunity to deal with issues in a more comfortable and less threatening manner. Clinicians should become cognizant of their own communities and plan out routes that may have different purposes. For example, if privacy is strongly needed, the therapist should try to plan a walk that secures the most privacy and the fewest disruptions. Most routes should have a place where the clinician and client can stop and sit. This may be a point during a session where more attention to details is needed.

Clinicians applying AAT in their practices may also find the utilization of metaphors and stories incorporating animals as an appropriate extension. Clients in most cases should feel comfortable with these topics (since they are already being exposed to animals in the

TABLE 1
Animal-Assisted Therapy from a Life-Stage Perspective

Suggested developmental goals and treatment purposes for children

Suggestion 1. Within the first series of life stages, the primary goals to be achieved pertain to a child's need to feel loved, as well as developing a sense of industry and competence. In a practical sense, animals can assist the clinician in promoting unconditional acceptance. The animal's presence in therapy (as discussed previously) may assist a child in learning to trust. Furthermore, the animal may also help the clinician demonstrate to the child that he is worth loving.

Suggestion 2. The animal-assisted therapy can eventually go beyond the office visit. A clinician may suggest to a family the value of having a pet within the home. The animal may help a child develop a sense of responsibility as well as importance in life.

Suggested developmental goals and treatment purposes for adolescence

Suggestion 1. A clinician may find an animal's presence valuable in making the teen feel more at ease during his or her visit. The teen may be more willing to take down some of the barriers, if she or he feels more comfortable. Furthermore, although a teen may project the need to be adult-like, the teen may appreciate the free spirit of an animal. The comfort the youth may receive may allow him or her to feel more appreciated.

Suggested developmental goals and treatment purposes for adults

Suggestion 1. A therapist may use a therapy animal as a starting point to discuss decisions about having children or, for that matter, child-rearing practices.

Suggestion 2. Adults experiencing parenting challenges and couples who are experiencing marital dysfunction may find the metaphors and the stories related to bringing up children and learning to share one's life with another person as all appropriate topics. The presence of animals, and examples incorporating animals, may give some clarity to the subject of generativity versus self-absorption.

Suggested developmental goals and treatment purposes for the elderly

Suggestion 1. Clients who have had a history of animals within their lives may find the animal's presence extremely advantageous in reminiscing about past life events. A clinician may ascertain that the presence of the animal may act as a catalyst for reliving past events.

Suggestion 2. The clinician may also recommend to elderly patients that they consider purchasing a pet. A client's sense of value could be tremendously enhanced as a consequence of feeling needed once again.

therapeutic environment). Stories portraying the challenges, obstacles, and successes that animals experience and overcome may be applied therapeutically to help clients see the world or the struggles they face from a different perspective.

II. THEORETICAL BASES

Although not directly related to psychotherapy, the following research will provide further insight into the value of the animal–human bond. Mental health professionals may find this information useful in developing a clearer perception of the impact of animals in the lives of people. Over the past 30 years there have been several controlled studies documenting the correlation of pet ownership and cardiovascular health. Erika Friedman and her associates designed a study investigating pet ownership with survival rates among patients who were hospitalized for heart attacks, myocardial infarctions, or severe chest pains. The results illustrated a significant difference in life expectancy between the subjects who did have a pet versus those who did not. The results pointed out that 5.7% of the 53 pet owners compared with 28.2% of the 39 patients who did not own pets died within one year of discharge from a coronary care unit. The findings within this study have been replicated with similar findings in a few other studies. This assumption was also noted by James Serpell, a leading authority on animal–human relations, who detected that seniors who adopted pets appeared to experience a decreased frequency of minor health problems. These minor health problems included headaches, painful joints, hay fever, difficulty paying attention, colds and the flu, dizziness, kidney and bladder problems, as well as a mirage of other mild illnesses. He suggested that the associated physiological benefits could have been the result of increased physical activity.

On the other hand, there have been numerous studies investigating the psychosocial benefits of pet ownership. Conclusions from a vast majority of these studies point out that pet ownership or interaction with animals in therapeutic settings should be viewed with the interaction of many other social influences. Those individuals who live highly stressed lives (families in poverty or dislocation) may benefit more from social supports, including support from animals.

Companion animals provide numerous benefits to the emotional well-being of humans. Animals at times take on numerous roles where there may be a void in

an individual's life, including functioning as a friend and a confidant. Animals comfort their companions and apparently serve as a buffer of protection against adversity. Companion animals also appear to satisfy the numerous psychosocial needs of their human counterparts, including enhancing social stimulation, as well as providing an outlet for leisure opportunities. Reports in the psychological literature suggest that unobtrusive animals evoke social approaches and conversations from unfamiliar adults and children. Presence of an animal may become a social lubricant for spontaneous discussions with passing strangers. The dog usually helps break the ice and makes it easier to initiate casual discussion. In most cases, the topics initially begin around the animal's presence.

A. Companion Animals and Children

Brenda Bryant reports that animal companions have been found to provide important social support for children. She also reports that animals within a home may assist children in developing a greater sense of empathy for others, and may enhance a child's self-esteem and social skills.

Bryant surveyed 213 children and identified four potential psychological benefits of animals for children. In 1990 she utilized the "My Pet Inventory" to assess the subjects' interests. A factor analysis of Furman's inventory indicated that, from a child's perspective, there are four factors in which the child–pet relationship can be viewed as potentially beneficial. Bryant defined the factor of mutuality as having to do with the experience of both giving and receiving care and support for the animal. The enduring affection factor identifies the child's perception of the lasting quality of his or her relationship with the pet. This factor focuses on the permanence of the emotional bond between the child and the animal. Enhanced affection, the third factor, identifies the child's perception that the child–pet relationship makes him or her feel good as well as important. Finally, the factor of exclusivity focuses on the child's internal confidence in the pet as a confidant. This factor appears to be extremely crucial for therapists to underscore. It is within this factor that a child may rely on the pet companion to share private feelings and secrets. This may be an important outlet, especially when there are limited friends and supports within the community or the home. There is evidence reported that a child may also use an animal as a confidant. This appears to be an obvious alternative that some children may confide in their animals for social support. Many parents

and clinicians over the years have remarked that they have observed children utilizing a family pet as a sounding board or as a safe haven to discuss their problems and troubles.

B. Therapeutic Benefits of Companion Animals for the Chronically and Terminally Ill, Persons with Disabilities, and the Elderly

Over the years, some reported studies have found that pet ownership appears to decrease depression and improve a healthier morale state. There have been studies indicating that war veterans found pet ownership to be associated with improved morale. Furthermore, Lynette Hart and her associates have reported that service animals appear to stimulate conversations and interactions between the people who used the service animals and those who were just walking by. People with the assistance animals noted that their dogs created social opportunities with people. The dog appears to normalize the environment for the person with a disability and to act as a catalyst for a discussion.

A benchmark study conducted by Roger Mugford on the therapeutic value of pets for the elderly found that older people (who live independently) who were given a budgerigar had significantly improved social attitudes and appeared to be happier than those subjects who were in the control group (after five months). Furthermore, animals living within the home of people with terminal illnesses or animals visiting those with similar constraints appear to lessen the individual's fears, their sense of loneliness, and stress levels. Similar findings have been reported in studies evaluating the impact of an animal on the lives of people with terminal illnesses such as cancer and AIDS. A synthesis from these studies suggests that these individuals seemed to feel more in control of their lives when they were able to take care of an animal. Taking care of the animal and being able to hold and caress it seemed to cause them to focus less on their illness.

Companion animals tend to help people use their own strengths to help themselves and to be sensitive to other people's feelings and emotions, and therefore recognize those occasions when they are needed or wanted. Animals can act as human surrogates in a number of roles, including friends and confidants. In times when people are secluded in their homes, the companionship of animals is extremely meaningful. They act as true friends.

Keith Cherry and David Smith suggest that persons with AIDS are especially susceptible to loneliness. Statistics point out that a high portion of patients with AIDS have diminished social support from friends, family, and significant others. Therefore, it appears that the pets owned by these individuals can act as important social supports. Programs such as Pets are Wonderful Support (PAWS) have been developed to help persons with AIDS keep their pets as long as possible. The PAWS model recognizes the importance of the companion animal in the quality of life of his or her human counterpart. This model appears to be applicable to any other special population living independently.

III. EMPIRICAL STUDIES

Animal-assisted activities and AAT are most widely incorporated in institutional settings and large mental health organizations. Historically, these services have been facilitated by mental health professionals in addition to nursing and other allied health specialists. In most cases, these services have been applied in long-term care facilities for the elderly, patients in hospitals, children in a variety of therapeutic settings, and inmates in prisons.

Research reports the tremendous value in developing an animal visiting program (or even having an animal living in residence) in facilities serving the elderly. In most studies reviewed, the authors stressed that the residents in most nursing homes appeared eager for the weekly AAT program. In some cases, residents kept track of the calendar in anticipation of interaction with the animals. Several studies investigating the impact of AAA or AAT on the elderly have concluded that the therapy (1) appears to have a positive impact on enhancing attention span; (2) is instrumental in positively enhancing elements of quality of life and well-being; and (3) appears to be effective in decreasing levels of depression among many residents as well as enhancing socialization and communication opportunities between the residents.

Most research studies investigating AAA or AAT in hospital settings have acknowledged similar outcomes to those originally noted with the elderly. The conclusions suggest that the animal-based programs appear to be a good distraction for the patients from their everyday medical treatment in the hospital. The services also appeared to have a positive impact on health factors, including decreasing pain and hyperactivity, helping the patients feel calmer, as well as reducing high blood pressure.

In a very revealing study, David Lee documented the incredible positive outcomes identified for an AAT program initiated at the Lima State Hospital for the Criminally Insane. Lee reported that the wards with animals seemed to have a calming effect on the patients. There was also a noticeable reduction in the patients' violent acts and suicide attempts. Similar outcomes were found in the Washington State Correctional Center for Woman program, which found that inmates who were involved in the training of service dogs appeared to be less depressed and proud of their abilities in training the animal.

An ultimate concern in most medical settings is the health effects of the animals on the clients. This process is now known as "zoonoses." Philip Wishon reports that most cats and dogs carry human pathogens, which along with those carried by other animals have been associated with more than 150 zoonotic diseases. However, Linda Hines and Maureen Fredrickson of the Delta Society point out that the data regarding the transmission of zoonotic diseases in any AAT program have been minimal. Practitioners are advised to work closely with veterinarians and other public health specialists to ensure the safety of the animals as well as the clients involved.

IV. SUGGESTIONS FOR CLINICAL APPLICATION

A. Training and Liability

Therapists considering incorporating animals within their practice must seriously consider the factors of liability, training, as well as the safety and welfare of both the animal and the client. The Delta Society's Pet Partner Program strongly advocates that health care professionals have training in AAT and AAA techniques. Clinicians also need to be aware of best practice procedures ensuring quality and safety for all parties.

Gary Mallon and his associates, in a chapter in the *Handbook of Animal Assisted Therapy*, provided guidelines for developing and designing AAT programs. Within their chapter, the authors identified 20 principles that a practitioner should consider in developing an AAA or AAT program. The following briefly highlights some of the major points:

1. All animals must be screened for their temperament to make sure they are appropriate candidates.

Clinicians are encouraged to utilize the standards of practice guidelines suggested by the Delta Society. These standards highlight the need for reliability of the animal's behavior, as well as the predictability that the animal's behaviors will occur on a constant basis and that the animal can always be controlled or managed.

2. All animals incorporated in AAA or AAT must be permitted to rest and have breaks from their working schedule. Attention must also be given to the suitability of the animal to meet the specific goals prescribed by the practitioner for the specific session.

3. All clients should be interviewed to assess their comfort level with various animals, specific allergies, and, if relevant, past abusive behavior toward animals.

4. The AAA or AAT must be integrated into the client's comprehensive treatment plan.

5. The practitioner should utilize the animal to aid in mastering developmental tasks and to promote responsibility and feelings of self-worth as well as independence.

B. Animal Welfare

It is evident that the safety of one's patient should have the highest priority. Nevertheless, the therapist should and must consider the safety and welfare of all the animals used in therapeutic practice. To help identify principles for animal safety and welfare, the author has elected to incorporate some of the guidelines that were identified in the Appendix of a chapter written on ethical concerns by James Serpell, Raymond Copinger, and Aubrey Fine.

The following briefly identify the concerns noted:

1. All animals must be kept free from abuse, discomfort, and distress.

2. Proper health care for the animal must be provided at all times.

3. All animals should have a quiet place where they can have time away from their work activities.

4. Interactions with clients must be structured so as to maintain the animal's capacity to serve as a useful therapeutic agent.

5. Situations of abuse or stress for a therapy animal should never be allowed.

6. As an animal ages, his or her schedule for therapeutic involvement will have to be curtailed. Accommodations and plans must be considered. The transition into retirement may be emotionally difficult for the animal as well. Attention must also be given to this dimension.

V. SUMMARY

Animal-assisted therapy and AAA represent two dynamic approaches that may become valuable therapeutic strategies in the treatment of children and adults (in individual and group therapy, in both outpatient and institutional settings). Although there still exist limitations in investigating the efficacy of this treatment as well as understanding best practice strategies, practitioners should become more open-minded to the potential contributions animals may make to the physical and mental wellness of humans. Introduction of animals into a therapeutic environment may provide a calming effect that contributes to the therapeutic outcome. When animals are introduced with a well-thought-out plan, clinicians will not be disappointed with the outcome. Although not a panacea, the impact of the human animal bond should not be underestimated as a positive therapeutic alternative.

I. DEVELOPMENT AND DESCRIPTION OF TREATMENT

Modern psychotherapy has its roots in Europe, and it was not until after the Second World War that the United States began to lead this field. During this period, psychotherapy flourished and grew at an enormous rate. Behavior therapy, and later cognitive behavior therapy (CBT), led the earlier growth and in 1974 when Michael Mahoney published his first book in cognitive behavior therapy, the term CBT became entrenched.

Accumulated empirical evidence shows that CBT is efficacious for the treatment of many psychological and psychiatric disorders, ranging from anxiety, to eating disorders and the psychoses. For many patients, it can be argued that CBT is the treatment of choice for these disorders. At the turn of the new millenium, CBT was generally accepted as an evidence-based psychotherapy that has benefited many people with mental health problems.

Although CBT can be delivered in individual or group settings, it is individual CBT that has received the most research and thus provides the most clear-cut support for its efficacy. The application of CBT to group work has a much later history than individual CBT, and accordingly the evidence-based research is not nearly

GLOSSARY

brief intensive group cognitive behavior therapy (BIGCBT)

A version of cognitive behavior therapy conducted in full-day sessions over a short time period (e.g., 3 consecutive days).

Brief intensive group cognitive behavior therapy (BIGCBT) is a version of cognitive behavior therapy conducted in full-day sessions over a short time period, for example, 3 consecutive days. This article presents the theoretical underpinnings and applications of BIGCBT, and a review of empirical studies showing the effectiveness of a BIGCBT program for outpatients with panic disorder with or without agoraphobia.

as comprehensive. Since the success of individual and group CBT, researchers and clinicians have experimented with the delivery format of CBT. The format has ranged from brief to extended CBT. Brief CBT treatments comprise from one to four sessions, with a 1-hr session per week, while extended CBT treatments range from 30 to 52 weekly 1-hr sessions. The average length of time for individual CBT is about 10 weekly sessions, and the average length of group CBT is a weekly 2-hr session for 12 sessions. More recent, we introduced a BIGCBT intervention and demonstrated that it has efficacy in the treatment of anxiety and mood disorders.

The BIGCBT is delivered over 3 consecutive days, with an attendance of 8 hrs per day. Psychiatrist Larry Evans and psychologist Bevan Wiltshire initially started the BIGCBT in the early 1980s for the treatment of patients with anxiety disorders, in particular panic disorder with agoraphobia. In 1984, a group of psychologists, Tian Oei, Justin Kenardy, and Derek Weir, joined the group and further developed and evaluated the treatment package.

The BIGCBT was developed with the following principles in mind:

1. Self-help: We wanted patients to take an active role in the management of their disorders. We strongly encouraged them to do so by providing a rationale, actively teaching them self-help skills and encouraging them to experiment with solutions to their problems.

2. Problem versus sickness: We informed patients that to view their problems as a sickness did not promote their active role in the management of the problems, but could in fact hinder it.

3. Control versus cure: We emphasized that the main aim was for patients to take control of their anxiety and fear rather than to attempt to cure it forever. Being cured is a passive process that depends on someone doing something to you, whereas gaining control is an active process. We explained that control was a realistic and attainable goal. Gaining control of anxiety and fear would enable patients to take charge and learn how to help themselves. In addition to learning what techniques to use and how to use them, patients also need to understand why they are using these techniques.

BIGCBT was delivered in a group format with the aim of making the program more cost effective. Referrals were made by the patients' medical officers. Group sizes averaged 8 participants. The group format provided a structured setting in which to learn the skills delivered by the program. It also provided social support, and a more socially relevant context for behavioral and attitudinal change and reinforcement than would an individual CBT context.

A team of experienced clinicians delivered BIGCBT, including psychiatrists, psychologists, and nurses. It was ensured that all clinicians had a good grounding of CBT and had observed the whole BIGCBT program before taking responsibility for the delivery of group sessions.

No one clinician delivered the entire BIGCBT program. Clinicians were allocated to a session or sessions of the BIGCBT program based on interest, knowledge, and time availability.

An example of the 3-day program with the contents of each session is presented in Table 1. There were three blocks of exposure sessions, taken by at least two clinicians. When group membership was greater than eight, three or more clinicians were used. Fellow clinicians were encouraged to "sit in on" other sessions in order to provide feedback and peer support to the therapist. The participation of Dr. Evans in every program provided stability, consistency, and quality assurance for the program.

II. THEORETICAL BASES

The theoretical basis of the BIGCBT was derived from the cognitive behavioral framework and encompassed the elements of clinical assessment and diagnosis, psychoeducation of cognitive and behavioral skill components, exposure, relaxation training, and homework assignments. The Quality Assurance Project of the Royal Australian and New Zealand College of Psychiatrists treatment guidelines also contributed to the design of the BIGCBT.

III. EMPIRICAL STUDIES

BIGCBT was run at a community outpatient clinic. Therefore, evaluation of the intervention used an effectiveness approach rather than an efficacy approach. Oei and colleagues' previous publications address a diversity of topics, including the development of new instruments to measure catastrophic cognitions; the validation of outcome measures such as the fear questionnaire (FQ); psychopathology of panic attacks and panic disorders; and treatment effectiveness. In 1991, Evans, Craig Holt, and Oei reported the first long-term follow-up data using the BIGCBT. They found that at posttreatment, BIGCBT was significantly better than the no treatment waiting-list control on the outcome measures of the FQ and the fear survey schedule (FSS). However, there was no difference in the scores for the Maudsley personality inventory (MPI) and the hostility and direction of hostility questionnaire (HDHQ), suggesting that neither of these personality variables was affected by the BIGCBT treatment. One-year follow-up results showed that treatment gains were maintained. Clinical interview data confirmed the FQ and FSS self-report data by demon-

strating that at one year follow-up, 85% of the patients treated with BIGCBT were either symptom free or had significant symptom reduction. The finding that personality variables were not changed by the BIGCBT treatment was supported by a study by Clair, Oei, and Evans in 1992, using the same measures with the addition of the Fundamental Interpersonal Relations Orientation-Behavior Scale (FIRO-B). This 1992 study showed that personality variables derived from the previously mentioned three instruments were no different between patients who responded and did not respond to the BIGCBT treatment. Similar to previous findings, personality characteristics did not predict treatment outcome.

A study by Weir in 2000, supervised by Evans and Oei, compared 71 waiting-list control patients with 206 patients with anxiety disorders, on clinical and functional outcome measures. Clinical outcome measures used were self-report scales such as FQ, MPI, FSS, the State Trait Anxiety Inventory (STAI) and the HDHQ. Clinician-rated measures such as Hamilton Anxiety Rating Scale (HAM-A) and Hamilton Depression Rating Scale (HAM-D) were also used. The functional outcome measures were the Medical Outcome Study Short Form Health Survey (SF 36), the Quality of Life Inventory (QOLI) and the Health Schedule Utilization (HSU). Pre- to posttreatment comparison between the BIGCBT and control groups showed that the BIGCBT group made significant improvements when compared to the control group, on all the clinical outcome measures. The reported effect sizes for the BIGCBT group ranged from large (HAM-A = 1.24; HAM-D = .99) to small (STAI = .22). There was a small but significant effect size for the change in MPI and HDHQ scores. This personality change was not consistent with the earlier studies.

An important part of Weir's study is that it reported on 6-year follow-up results. The results showed that the treatment gains made by BIGCBT patients were maintained over the long term. The findings also showed that most of the gains were made at posttreatment, and that the length of time of follow-up (ranging from 1 to 6 years) did not improve the posttreatment gains.

The most interesting finding from the Weir study was in regard to the functional outcome measures. The results from the SF-36 showed that up to 6 years after the BIGCBT treatment, the SF-36 profiles of the treated group were almost the same as those of the general population, and much better than the SF-36 profiles of people with anxiety disorder problems in the national survey. This implies that long after treatment, the patients with anxiety disorder who were treated with the

BIGCBT can expect to have almost the same general health perception as the general population. This finding was complemented by the results of the QOLI that indicated that patients treated with BIGCBT were relatively free of psychological distress and had a more realistic expectation of their living conditions.

The long-term effectiveness of BIGCBT was also reported in a 1997 study conducted by Oei and Evans with Michael Llamas. This study investigated the possible impact of concurrent medication use on the long-term outcome of BIGCBT for panic disorder with or without agoraphobia. The researchers found that preexisting medication (antianxiety, antidepressant, or a combination of these) did not significantly enhance or detract from the long-term outcome of the BIGCBT program.

The BIGCBT has also been applied to the treatment of patients with comorbid alcohol use disorder and panic disorder with or without agoraphobia. The 2000 report by Bialkowska, supervised by Oei and Evans, documented that concurrent addition of the BIGCBT for panic disorder to the standard hospital treatment for alcohol abuse produced better clinical outcomes than the standard hospital treatment and a placebo treatment. It was found that BIGCBT had an impact on self-reported anxiety but not on alcohol outcome measures.

IV. SUMMARY

There is enough evidence to suggest that the BIGCBT is an effective treatment for anxiety disorders, in particular for panic disorder with and without agoraphobia. The exact mechanism for the effectiveness of this treatment is still unknown. Furthermore, the effectiveness of the BIGCBT is demonstrated by a single group of researchers in one place and needs to be replicated by different researchers and in different locations before anything more substantial can be said about the general clinical utility of the BIGCBT. What can be said with some degree of confidence, however, is that our findings add to the robustness of the delivery of CBT in the treatment of psychological disorders.

GLOSSARY

AMT Acronym for anxiety management training.

anxiety management training A self-control intervention using relaxation as a coping skill to prevent or reduce anxiety arousal.

anxiety scene A concrete event from the client's actual experience associated with anxiety being aroused.

biofeedback Methods for relaxation training that employ equipment to monitor and provide feedback on physiological responses, such as changes in muscle tension or finger temperature.

early warning signs Internal cues such as tension in shoulders, upset stomach, or specific thoughts that indicate the onset or early stages of anxiety arousal. AMT trains clients to attend to these cues and initiate relaxation coping skills to abort anxiety or stress arousal.

progressive or deep muscle relaxation A method of relaxation training that has clients systematically tense and release the muscles of the body.

relaxation scene A concrete event from the client's actual experience that is associated with being relaxed.

relaxation training The process of developing a basic relaxation response, usually done through biofeedback or deep muscle relaxation.

I. DESCRIPTION OF TREATMENT

Anxiety management training (AMT) typically takes six to eight sessions after an assessment suggests that a self-managed relaxation approach is appropriate. It may take a few sessions longer if other emotions (e.g., anger) or psychophysiological disorders (e.g., tension or migraine headaches) are added to anxiety treatment goals. AMT can be conducted with individuals or in small groups.

The core characteristics of AMT include guided imagery, anxiety arousal, application of relaxation for self-managed anxiety reduction, and transfer of relaxation coping skills to the external environment. Guided imagery involves the introduction of relaxation imagery to strengthen the relaxation response, and it also includes anxiety imagery to precipitate anxiety arousal. Anxiety is precipitated during sessions in order to provide clients with the opportunity to become more aware of their anxiety arousal and to identify the early warning cues and employ relaxation that will reduce the actual experiences of anxiety. Thus, clients first practice controlling anxiety in the safe setting of therapy prior to real-life applications for anxiety reduction. As clients gain in self-control of anxiety over the course of AMT, the anxiety-arousing capacity of anxiety scenes is increased and the degree of therapist assistance in relaxation retrieval is decreased. Homework assignments to apply relaxation in specific situations and at any time anxiety is experienced are used to ensure the transfer of skills to in vivo application.

AMT is easily adapted to other distressing emotions and to physiological conditions associated with stress. For example, in applying AMT to anger, the training procedures remain the same, but the content of the scenes and homework focus on these emotions rather than on anxiety. In adapting AMT to tension headaches, stress-inducing scenes may be broader than anxiety, for other emotions may trigger tension headaches. Clients can also identify the early warning signs of headaches and apply relaxation skills when these cues are perceived.

A. Session 1

Session 1 is devoted primarily to deep muscle relaxation, whereby muscles are first tensed and then relaxed. An emphasis on awareness of tension is added by instructing clients to pay attention to feelings of muscle tension and to notice the contrast between the tensed and relaxed sensations. For most clients identifying a relaxation scene is useful for furthering control of relaxation. Such a scene should be a real-life event involving a specific relaxing moment from the client's life. The client and therapist develop this scene prior to initiating progressive relaxation. After deep muscle relaxation, the client is instructed to visualize the relaxation scene and to permit that experience to further increase the relaxation level. Progressive relaxation and relaxation scene visualization typically take about 30 minutes. Homework involves daily practice of progressive relaxation, self-monitoring and recording anxiety arousal, and the identification of one or two moderate anxiety scenes to be used in the next session.

B. Session 2

This session involves the development of an anxiety scene, inducing relaxation, and one or more trials of anxiety arousal followed by relaxation retrieval. The anxiety scene should be a real experience that elicits a moderately high level of anxiety (about 60 on a scale where 100 is extreme anxiety). Following determination of an anxiety scene, relaxation is introduced. Typically, clients will be able to become relaxed not by tensing muscles, by simply focusing on and relaxing each muscle group. When the client is relaxed, anxiety arousal is initiated through the therapist's instructions to switch on the anxiety scene, to use the scene to re-experience anxiety, and to signal the onset of this anxiety. The therapist includes both scene-setting and anxiety-arousal details from the scene and uses appropriate voice emphasis (e.g., volume and tone) to aid in anxiety arousal. After about 10 to 15 seconds of anxiety

exposure—that is, after the client signals anxiety—the anxiety scene is terminated, and the therapist reintroduces relaxation, first by visualization of the relaxation scene and then by a review of the muscles without tension. As time allows, this process is repeated, with the anxiety exposure interval lengthened to 20 to 30 seconds. Homework involves continued self-monitoring of anxiety, daily practice of relaxation without tension, and application of relaxation in nonstressful situations.

C. Session 3

This session follows the steps outlined in Session 2, with two major additions. Self-initiated relaxation and attention to the anxiety-arousal symptoms are prompted, so that clients can identify personal signs associated with anxiety. These might involve symptoms such as clenched fists, heightened respiration, feelings of panic, thoughts of self-doubt, images of great inadequacy, and the like. By training clients in becoming aware of the signs of anxiety and using their presence to initiate relaxation, AMT teaches clients not only how to reduce anxiety when it is experienced, but also to identify the early anxiety cues in order to prevent further anxiety buildup.

By this session the client should be able to achieve a relaxed state in a brief time, typically in one to three minutes. After the client has relaxed, the therapist initiates anxiety arousal by having the client visualize the 60-level scene. When the client signals anxiety, the therapist introduces the new instructions for attending to anxiety symptoms: "Pay attention to how you experience anxiety; perhaps it is in your body signs such as tension in your neck muscles, tightness across your stomach, or your heart rate or maybe in some of your thoughts." After about 30 seconds of anxiety arousal, relaxation is retrieved, with the therapist guiding the client through muscle reviews, relaxation imagery, or deep breathing-based relaxation. This process is repeated, usually three to five times, until the end of the session. Homework involves identifying a 90-level scene for the next session and using relaxation coping skills to control anxiety wherever it is experienced. Efforts are recorded in the self-monitoring log.

D. Session 4

In this session, a 90-level scene is developed. Use of the 90-level scene provides the client with the opportunity to cope with high levels of anxiety arousal. In addition, the client starts to assume more responsibility for controlling anxiety. Instead of the therapist terminating the anxiety scene and reinitiating relaxation, the

client initiates relaxation by using the relaxation scene, a muscle review, deep breathing-cued relaxation, or whatever method personally works best. The 60- and 90-level scenes are alternated to provide practice in anxiety management. Homework involves the self-monitoring of early warning signs of anxiety and the immediate application of relaxation to abort arousal any time anxiety is experienced. Clients are alerted to do this any time they encounter situations known to be anxiety arousing. Clients are also encouraged to routinely monitor anxiety signs four times a day (i.e., once in the morning, midday, afternoon, and evening). All efforts to monitor anxiety signs and apply relaxation are recorded in the client's self-monitoring log.

E. Session 5

In Session 5, the 60-level scene is often dropped and replaced with a higher level anxiety scene. This session also completes the fading out of therapist control and the completion of client self-control. Following client self-initiated relaxation, the therapist switches on the anxiety scene, but all activities from that point on are client-controlled. While in the anxiety scene the client initiates relaxation to deactivate arousal and decides when to terminate the scene. After signaling the therapist that this has occurred, the therapist readies the client for another scene and the process is repeated. Homework is the same as suggested in Session 4.

F. Sessions 6–8

With the exception of the introduction of new high level anxiety scenes, the same format used in Session 5 is used in Sessions 6–8. Moreover, application to other sources of distress is also encouraged. Length of time between sessions may be increased in order to provide more opportunities for application and to facilitate transfer and maintenance. Plans for maintenance and relapse prevention are discussed during these sessions as well. When self-control of anxiety is established, usually by Session 8 termination is initiated, or AMT is integrated with other interventions. Booster sessions may sometimes be employed prior to clients confronting future events to facilitate relapse prevention.

II. CASE ILLUSTRATION

Patient Characteristics. This case illustrates the basic AMT approach, with some modifications for the characteristics of the specific client. Jane, a 37-year-old married

mother of two teenagers, worked as a project manager for a computer company. She was diagnosed with generalized anxiety disorder (GAD). She also sought help regarding tension headaches and problems involving experiencing anger while driving. During intake, she reported being anxious and tense most of the time. Anxious feelings were marked by a general sense of unease and foreboding and by heightened general physiological arousal and agitation, a feeling of being jumpy and on edge, marked tension in the neck, shoulders, forehead, and hands, and a knot in her stomach, sometimes accompanied by nausea and stomach upset. She reported that the anxiety seemed to accumulate during the day, becoming worse in the afternoon and evening. She also reported moderately severe tension headaches on a nearly daily basis, headaches that were related to her chronic anxiety. In the past, her physician had prescribed benzodiazapines for this anxiety, and she currently took Valium approximately three times a week. She reported frequent periods of “stewing” (unrealistic worry) needlessly about several topics: (1) work performance (e.g., that she would fail and be fired, even though she had good to excellent performance reviews for several years; or that projects would not be completed or would be totally inadequate, even though this had not happened in the past); (2) the health and safety of her husband and children (e.g., continued preoccupation with a mole on her husband's neck, even though it had been checked by his family physician and a dermatologist; and frequent images that her husband or children had been killed or hurt in a car accident); and (3) finances (e.g., being worried that they would not be able to send their children to college, even though she and her husband had good, secure jobs). She indicated that the worry and anxiety led to such great weariness and fatigue that she often went to bed early or watched television to escape the anxiety, worry, and headaches. She also experienced frequent intense episodes of anger in her 40-minute commute to and from work. She indicated that this anger carried over into and influenced her work negatively and was another source of stress that contributed to her fatigue and headaches.

She was seen for two sessions for assessment involving interviewing, self-monitoring anxiety and tension headaches, and completion of psychometric instruments. AMT sessions are described next and are numbered to follow the outline presented earlier.

Initial portions of AMT Session 1 involved the therapist presenting the rationale for using AMT in the following way:

Rationale: Jane, it seems like the primary issues are the cycles of worrying and anxiety where you get tense

all over, especially in the neck, shoulders, and stomach. This only gets worse when you're angry and stressed when driving. All this seems to trigger the headaches and makes you worn out in the evening so that you just duck out by going to bed early or watching a lot of TV. You also indicated that you do much better when you relax, but most of that is by watching TV or sleeping off the stress, and you want to have better ways to relax and cope. Is that how it seems to you? (She responds affirmatively.) I think there are some ways we can do that and would like to describe them and see what you think. The first step is to help you learn how to really relax. If we agree, I will show you how to do this later in today's session. In the beginning, it will take you 20 to 30 minutes, but with practice you'll be able to do it much faster. Once you can relax yourself well, we'll develop several quick ways for you to relax whenever, wherever you start feeling anxious. The second step is to help you become more aware of when tension is coming on so that you can pay attention to those thoughts and feelings and initiate the relaxation skills. We've already started some of this when we had you keep track of your feelings in your diary (referring to self-monitoring log). The third step will really give you lots of practice in identifying the feelings of anxiety and relaxing away the tension so that you can have that "calm, clear-headed feeling" you like. We'll do this in the following ways. In the sessions, I will have you visualize situations that have made you anxious in the past, like a week ago when you were anxious about presenting your report at the project manager's meeting. Then, we will initiate relaxation and help you calm down and be relaxed again. We will do this over and over so that you get really good at recognizing anxiety and calming down by relaxing. Initially, we will start with moderate anxiety, but as you get better at relaxing away the tension, we'll increase the anxiety level, and have you take more and more control over the relaxation. You'll also practice the relaxation to cope with the worry and anxiety in real life. You'll write about those experiences in your diary, and we'll go over them each session. We'll also want to help you use the relaxation to abort those nasty headaches you get, and maybe on the anger you get when driving. Being able to relax should also help with that stewing or worrying you do. You indicated that when you are calm, you think things through pretty well, but not when you are uptight. The procedures I was describing should help you calm down and think things through calmly because you will be able to relax and calm yourself. This will take a lot of work on both our parts, but if we both

do our jobs, I think that we can develop these skills to relax whenever you are worried and tense in about 7 to 10 sessions. How does this sound to you?

The remainder of the session was spent developing a relaxation scene (see as follows), initiating progressive relaxation training, and presenting the relaxation scene twice. Homework included self-monitoring worry and anxiety and daily relaxation practice.

Relaxation Scene: It is last August when you were lying on that big rock out in the middle of the river near your favorite camping spot. It was about 3:30 in the afternoon, and you are there alone and can only hear the sound of the road off in the distant (general scene setting details). You are lying there on your back, looking up at the sky, the brilliant blue cloudless sky. The canyon is pretty steep on both sides, so the sky is framed in the gray of the rocks and green of the pine trees as you look up (more specific visual detail). You can hear the breeze rustling through the pines and hear the river gently gurgling as it flows over the rocks below you (auditory detail). The air is warm, but not hot and has that wonderful "early fall smell" you love so much (temperature and olfactory detail). You are warm, but not hot, feeling like the sun has soaked through you, that wonderful feeling like you have melted right into the rock (temperature, emotional, and kinesthetic detail). You are very peaceful, totally relaxed, and worry free, thinking that there is no place you would rather be. Feeling calm and clear headed. The colors and life seem clear and vibrant. Warm, relaxed, without worry, molded into that big rock in the river (cognitive and affective detail).

Session 2 involved a review of homework, the development of a moderate anxiety scene (i.e., approximately 60 on a 100-point scale), further relaxation training, anxiety arousal/relaxation coping, and assignment of homework. Relaxation training included practice with three new relaxation coping skills introduced for this client: (1) relaxation without tension (review of the muscles without tensing them); (2) breathing cued relaxation (taking three to five slow, deep breaths, relaxing more on each breath out); and (3) cue-controlled relaxation (pairing slow repetitions of the phrase "calm control" with relaxation). Focus was then directed to identifying an anxiety scene. The anxiety scene at the 70-level was as follows:

Anxiety Scene: It was Friday evening, three weeks ago. You were home alone as Jim (husband) and the kids had gone to the movies (scene-setting detail). It had been a tough day at work, and once again, you were frazzled and tired and avoided more stress by stay-

ing home (general emotional detail), sitting on the couch trying to zone out and watch TV, but couldn't stop thinking about work. You know it's stupid because you were well ahead of schedule, but kept thinking about how far behind you were and how much you had to do. You kept worrying that it was all going to fail and be your fault, how they were going to find out how incompetent you are. Also, you were worrying about Jim and the kids. He said they might get a bite to eat and catch the late movie, but you were worrying that they had been in an accident. You were a mess and couldn't stop thinking about all of this stuff (cognitive detail). You had that anxious-all-over feeling, like you couldn't sit still, all wound up, but no place to go. That sense of doom and bad things happening just sort of hung on you. Your shoulders were hard as rocks, stomach was churning away, and your head just kept turning over all the problems at work. You had another of those terrible headaches. That dull constant ache in the back was really wearing on you (emotional and physiological detail).

After the details of the anxiety scene were confirmed, relaxation was initiated through therapist-directed relaxation without tension. After the client signaled being relaxed, the anxiety scene was introduced, and relaxation was practiced (see sample instructions below).

Anxiety Scene Introduction: In a moment, we are going to have you practice reducing your anxiety. I will ask you to imagine the anxiety scene involving being home alone worrying about work and the kids. When I do, I want you to put yourself into that scene. Really be there and experience that worry and anxiety. As we discussed earlier, signal me when you are feeling anxious by raising your index finger. After a few seconds of being anxious, I will ask you to erase that scene and will help you retrieve that relaxed clear-headed feeling. When you are relaxed signal me again. So right now, put yourself into this scene ... (therapist describes the anxiety scene using voice inflection to increase attention to and the experience of anxiety) ... After 20 seconds, the client signals ... Ok, I see your signal. Now continue to pay attention to that anxiety. Let it build and pay attention to how you're feeling it ... maybe in the neck and shoulders ... maybe across the stomach area ... let it build and notice it ... really worry and be anxious about work ... (after 25 seconds) ... Ok, now erase that scene from your mind and once again switch back on your relaxation scene. You're there on the rock, relaxed and warm. Signal me when you are relaxed again ... (When the client signaled, this was followed by relaxation without tension.)

This process was repeated five times. Two relaxation coping skills were employed with each repetition. Homework involved self-monitoring, daily practice of progressive relaxation, and practice of relaxation coping skills at least once per day in nonstressful conditions (e.g., waiting for a friend for lunch).

Sessions 3 and 4 followed the format of Session 2, except that the client relaxed herself by "whatever method works best for you" prior to rehearsal of relaxation in response to anxiety scenes. An additional 60-level scene was added, and scenes were alternated during the session. During anxiety scene arousal, Jane was asked to pay attention to the signs associated with her experience of anxiety; these turned out to be tension in the neck and shoulders and clenching of the hands. Homework involved continued daily practice of relaxation without tension, application of relaxation coping skills whenever anxious, but with the caveat not to expect success every time, and continued self-monitoring of anxiety with the addition of recording applications of relaxation coping skills. The client was also instructed to identify two anxiety/worry scenes at approximately the 70-level.

By the beginning of Session 5, the client was showing some successful in vivo applications, having been able to partially reduce tension and anxiety on several occasions (i.e., she was able to lower her anxiety levels by 30 to 40 units, although she could not yet completely eliminate anxiety). Session 5 included two changes. First, two 70-level scenes were developed and alternated. Second, increased client self-control was fostered by having the therapist terminate the anxiety scene after a period of anxiety arousal, but having the client relax away the tension and signal the therapist when relaxation was achieved. For homework, in order to decrease the building stress and anxiety that appeared to trigger tension headaches, the client agreed to scan herself for cues of tension and to self-initiate a three-minute period of relaxation at the following times—in her car before she entered work, midmorning, after lunch, midafternoon, in her car before starting home, and at least once during the evening. She was also asked to apply relaxation coping skills any time she experienced any negative emotional arousal.

Sessions 6–9 followed a similar format. However, the anxiety level of the scenes increased to a 90-level as this was as anxious as the client felt when worried and anxious. Two driving anger scenes (see the following example) were also added to Sessions 7–9 to address her anger when driving. Instructions during rehearsal shifted to full client self-control. The therapist initiated

the visualization of the anxiety scene. The client signaled the experience of anxiety by raising her finger but kept her finger up. She then continued to visualize the scene and initiated relaxation coping skills, signaling by lowering her finger when she was relaxed. At that point, the therapist cleared the anxiety scene and instructed her to pay attention to her sense of control over the anxiety and her self-efficacy at anxiety management. Finally, to provide greater opportunities for in vivo practice and to initiate a transition to maintenance and relapse prevention, the time interval between Sessions 7, 8, and 9 was lengthened to two weeks.

Anger Scene: It was about two weeks ago. You were in the left lane on the two lane freeway ramp. You were following a woman driver in a blue Dodge with Nebraska plates. As the light change, the woman in front of you accelerated and swerved into the right lane in front of a large dump truck. The truck nearly hit her and blasted her with his horn. She then swerved back into your lane, nearly hitting you (setting detail). Instantly, you were angry, really pissed. Your hands were clenched around the wheel, shoulders knotted, stomach churning, and you had that hot flush come across your chest and into your neck and face (emotional and physiological detail). You were thinking, "Crazy bitch! She's going to get us all killed! Where the hell did she learn to drive, at some kind of destruction derby? I ought to run her off the road and save us all a lot of trouble (cognitive detail)."

Termination. The client had been demonstrating good anxiety management. She reduced significantly the frequency and intensity of worry/anxiety periods per day, reduced headache frequency from almost daily occurrences to approximately one per week with an intensity of a 3 on a 10-point scale, down from an intensity of 7 prior to therapy, and reported lessened anger while driving. A staggered termination was undertaken in order to facilitate maintenance and relapse prevention. Booster sessions were scheduled at one- and four-month post-therapy intervals, and continued self-monitoring and application of relaxation coping skills were underscored as the cornerstones of maintaining gains. The client contracted to continue self-monitoring and AMT application through at least the next four months. She developed a written contract and agreed to set aside \$1 per day toward the purchase of new clothes for every day she managed her anxiety and stress as well as an additional \$5 for a week in which she did so every day. The client mailed in her self-monitoring logs every two weeks. These were followed by therapist phone calls to

support gains and troubleshoot issues. Termination was achieved at four-month followup, although the client was seen for two additional booster sessions when her daughter became ill, and the client began worrying about potential health complications.

III. THEORETICAL BASIS

AMT was developed in 1971 as a solution to the inappropriateness of desensitization for dealing with what is now called generalized anxiety disorder (GAD). Desensitization is effective for phobias but requires the identification of the stimuli precipitating the anxiety response. In GAD, clients experience a more chronic, generalized state of anxiety, and the external cues eliciting anxiety cannot be identified so precisely. Desensitization was, therefore, not applicable, and alternative interventions were needed.

AMT is based on Richard Suinn's suggestion that clients can be taught to identify the internal signs, both cognitive and physical, that signal the presence of anxiety and to react to those signs by engaging in responses that remove them. This formulation was based on learning theory that conceptualized anxiety as a drive state and postulated that behaviors could be learned to eliminate the drive. Anxiety was viewed as having both response and stimulus properties. It was a response to prior internal and/or external anxiety-arousing stimuli. Its stimulus properties involve the potential to elicit new responses such as avoidance and escape. As such, it was argued that anxiety's stimulus properties could become associated with new responses, such as coping responses. AMT, therefore, does not require clients to identify the stimuli that precipitate their anxieties. Instead, the experience of anxiety itself is used to train the client in coping. The goal is to provide the client with a relaxation coping skill with which to deactivate anxiety once it occurs and to train the client in recognizing and using arousal as the cue to initiate that coping skill. In theoretical terms, AMT trains clients in responding to the response-produced cues of anxiety with relaxation, leading to the development of a new self-managed coping habit pattern.

Although some AMT procedures may appear similar to other behavior therapy methods using relaxation, there are several distinguishing characteristics of AMT. AMT initiates anxiety arousal during sessions rather than minimizing it as in desensitization. The goal of arousal is not extinction, but the opportunity to attend to the internal cues of anxiety arousal and to practice relaxation for

anxiety reduction. AMT uses homework to ensure transfer of training. Homework requires that clients apply relaxation coping skills in vivo. This practice ensures that skills acquired in therapy are transferred to real-life situations outside of treatment. Self-control is also emphasized. AMT actively fosters self-management by gradually requiring clients to assume more and more responsibility. Early in treatment therapists provide a great deal of control over both anxiety arousal and relaxation retrieval. However, clients gradually assume these responsibilities. Therapeutic instructions, fading of therapist control, and homework assignment help clients develop skills that increase their ability to control their anxiety. Because of the self-control element, AMT often leads to increased self-efficacy.

IV. APPLICATIONS AND EXCLUSIONS

Applications—Group AMT. AMT may be employed with individuals or groups. Groups can be relatively similar in their source of anxiety (e.g., groups of social phobics) or quite heterogeneous with widely differing sources of anxiety and stress. Group size should probably be limited to about eight. Research suggests that groups of over 25 are ineffective.

Group AMT requires several modifications from individual AMT. Therapy session duration should be extended by 20 to 30 minutes per session in order to attend to the increased number of clients and their various issues. If the treatment session cannot be lengthened, then the number of sessions should be lengthened to accommodate clients. Although individual AMT uses homework to develop both relaxation and anxiety scenes, this is particularly important in groups, if time is to be used efficiently. That is, clients must come to the early sessions with proposed scenes outlined in detail, so that group discussion time is saved for shaping up or crystallizing scene content. Since scene content varies across clients in group AMT, the therapist cannot provide detailed descriptions of the scene in order to stimulate visualization and anxiety arousal.

Group clients are asked to bring two scenes to each session, which are labeled “anxiety scene 1” and “anxiety scene 2.” Anxiety is elicited by giving the general instruction for clients to visualize “your first” or “your second anxiety scene.” Scenes are alternated by referring to the first or second anxiety scene, and clients are instructed that if one scene is not eliciting anxiety they are to continue to visualize the one that does. Exposure

length is also difficult to standardize during group sessions because clients might signal anxiety after different intervals of visualization. Therefore, in the initial sessions, the anxiety scenes should be visualized for 30 to 60 seconds, with timing started after approximately half of the group has signaled anxiety. In group applications, it is likely that clients will report various other sources of emotional distress (e.g., anger, guilt, embarrassment, depression, etc.). Therefore, it is important to make sure that clients apply relaxation to all sources of emotional distress. Often the final two to three sessions are used to focus on other emotionally distressing scenes in order to provide clients with in-session practice in dealing with such emotional issues.

Applications—Anxiety Conditions. Originally, AMT was developed and evaluated for use with chronically stressed and anxious individuals and for GAD. Over the years, there has been empirical support for its use with other anxiety conditions such as panic disorder, PTSD, simple and social phobias, multiple sources of anxiety and stress (e.g., an individual who is dealing with both work- and health-related stress), generally anxious and stressed medical outpatients, and anxiety- or stress-related health issues such as Type A behavior, tension headaches, diabetes, dysmenorrhea, and essential hypertension. AMT has also proven helpful to individuals who experience performance-related anxiety (e.g., anxiety that interferes with athletic performance, public speaking, or music recitals), even if the anxiety level is not sufficient to be diagnosed a phobic disorder. AMT has also been adapted to high general anger and situation-specific angers such as anger while driving.

Applications—Integration with Other Interventions. The coping skills in AMT can serve as one treatment component in complex treatment plans. For example, depressive disorders are often mixed with anxiety, tension, and worry. In such cases, a treatment plan could rely on AMT to address anxiety and could be followed by other psychological and biological interventions for the depressive disorder. Some studies using AMT to treat anxiety report that depression also declined. Possible reasons include the tendency for anxiety and depression to be correlated, or the reduction of depression due to the increase in efficacy from AMT.

AMT is easily included as an element of other psychological interventions. For example, AMT-like interventions have been successfully combined with cognitive restructuring in the treatment of GAD, panic disorder, social phobia, Type A behavior, and anger.

AMT has also been effectively combined with cognitive and behavioral interventions in the treatment of vocationally anxious individuals.

AMT may be used as an initial step to enable clients to respond to other psychotherapeutic interventions. For example, AMT might be used with a sexually abused client. Providing anxiety management skills may facilitate clients' ability to discuss and confront emotionally charged topics. Another potential application of AMT is in prevention or simply as a general coping skill for daily life stresses.

In summary, AMT can be a valuable part of an overall treatment plan. In integrated interventions it is suggested that AMT be implemented as the first step. It helps the client achieve anxiety reduction skills while at the same time building the therapeutic relationship and alliance. It can also reduce resistance to confronting anxiety-related therapeutic content, content that might be essential for other psychotherapeutic interventions. Since a side benefit of AMT is an increase in self-efficacy, possibly due to the self-control that is achieved, clients might feel more confident when facing other personal-emotional problem areas.

Exclusions and Contraindications. Few contraindications for AMT have been identified. The AMT model suggests several treatment considerations. AMT is an intervention that requires clients who have the cognitive-attentional processes and motivation necessary for performing its procedures. Clients must be able to follow instructions, develop and maintain anxiety imagery, and follow through on homework assignments. Individuals who cannot or are unwilling to engage in these activities are not good candidates for AMT. For example, a small number of individuals have great difficulty in visualizing events. An alternative intervention is required such as in vivo presentation of anxiety-arousing situations.

AMT is based on clients' readiness to develop self-control over their anxieties. Some clients do not hold such self-control expectancies and may prefer treatments involving minimal personal behavior change (e.g., anti-anxiety medication). Therapists must address client expectations about treatment goals and techniques before AMT is adopted.

Research suggests that some individuals develop relaxation-induced anxiety (i.e., relaxation training increases rather than reduces anxiety). Sometimes, this problem can be resolved by repeated practice of small relaxation training steps, a switch to an alternative relaxation training methodology, or counter-demand ex-

pectancies. However, if this issue cannot be resolved, other interventions should be employed.

Few studies have been reported concerning the effectiveness of AMT with children and the elderly. However, anecdotal evidence has shown that ethnic minority youth can respond to AMT and that children can develop relaxation skills and use imagery.

V. EMPIRICAL STUDIES

Many studies support the efficacy of AMT. In 1990 Richard Suinn reviewed the literature and concluded AMT to be effective with a wide variety of disorders.

AMT is effective with various phobias and situational anxieties. For example, AMT reduced social, math, test, and public speaking anxieties, and in some cases improved performance in these areas as well. A more recent study showed that both AMT and a cognitive intervention lowered math anxiety and improved math performance in math-anxious college students. Anxiety surrounding vocational indecision was reduced by AMT as well. Throughout these studies, AMT was as effective as or more effective than other interventions such as systematic desensitization, self-control desensitization, systematic rational restructuring, social skill building, and vocational counseling. Moreover, although AMT targeted specific phobias or anxieties, reductions of general anxiety were reported in several studies, suggesting that AMT was associated with response generalization.

High trait anxiety, GAD, panic and posttraumatic stress disorder have also been treated successfully with AMT. Effects were maintained at long-term followup, and, where measured, generalized effects were found on measures of depression and anger. AMT lowered anxiety levels and use of anxiety medications in a group of GAD and panic-disordered psychiatric patients. AMT and cognitive therapy lowered anxiety in outpatients with GAD and tended to be more effective than psychodynamic therapy. Also, AMT reduced anxiety, avoidance, and intrusions of trauma-related memories in Vietnam veterans with posttraumatic stress disorder. In addition, general anxiety, ratings of anger and anxiety, and overall psychiatric status were improved in schizophrenic outpatients receiving AMT.

Stress- and medically related conditions have also responded favorably to AMT. For example, AMT has lowered Type A behavior and general anxiety in Type A individuals, blood pressure levels in individuals with essential hypertension, stress in individuals with

diabetes, gynecological symptoms and general anxiety in women with dysmenorrhea, and stress in gynecological outpatients. Again, AMT tended to be as effective as other interventions and, where assessed, to show long-term maintenance.

AMT has also been successfully adapted to anger reduction. The procedures of AMT have been successfully adapted to control general anger and anger while driving. In these studies, the adaptation of AMT was generally as effective as cognitive and combined cognitive-relaxation interventions.

In summary, AMT is an empirically supported intervention. It is effective with situational anxiety and phobic conditions, as well as GAD, general anxiety, and posttraumatic stress disorder. It is also effective with stress-related medical conditions and anger. Where comparisons have been made to other interventions, it is generally significantly more effective than control conditions, and as effective as certain other cognitive-behavioral interventions. Where long-term follow-ups have been conducted, effects were well maintained. In all, there is a solid empirical literature supporting AMT. Moreover, since many of the outcome studies of AMT have been conducted in a group format, there is considerable support for group AMT as well.

VI. SUMMARY

Anxiety management training (AMT) is a brief behavioral intervention involving the use of relaxation as a skill for reducing anxiety. It may be conducted individually or in small groups, and it typically takes about eight sessions. AMT is founded on the principle that anxiety has stimulus properties that can serve as cues for relaxation as a coping response. AMT relies on relaxation training, in-session anxiety arousal through imagery and practice of relaxation as a coping skill, and graduated homework assignments to ensure transfer for real-life anxiety reduction. The first session is devoted primarily to relaxation practice and anxiety scene development. The next seven sessions are devoted to eliciting anxiety through anxiety-arousing imagery and initiating relaxation coping skills for anxiety reduction. In early sessions, anxiety arousal is moderate, and the therapist provides considerable structure and assistance in relax-

ation retrieval. However, over time and with client success in anxiety management, the therapist assistance is faded to client self-control, and the level of anxiety arousal is increased. Homework assignments involve applying relaxation coping skills outside of the treatment sessions to ensure transfer of relaxation coping skills to real-life application. Portions of latter sessions address issues of maintenance and relapse prevention and may address application to other distressing emotions as well. AMT is empirically supported with many anxiety- and stress-related disorders and conditions. AMT may be employed as a stand-alone intervention or be integrated with other behavioral and nonbehavioral interventions in a comprehensive treatment plan.

GLOSSARY

antecedents Stimuli, settings, and contexts that occur before and influence behaviors. Examples include instructions and gestures from others.

baseline rate The frequency with which behavior is performed prior to initiating a behavior modification program; operant rate of behavior.

behavior Any observable or measurable response or act.

consequences Events that follow behavior and may include influences that increase, decrease, or have no impact on what the individual does.

contingency The relationship among antecedents (e.g., prompts, setting events), a behavior (the response to be changed), and consequences (e.g., reinforcers).

contingent on behavior An event (e.g., praise, tokens, time out) is contingent on behavior when the event is delivered only if that behavior is performed.

differential reinforcement Reinforcing a response in the presence of one stimulus (S^D) and extinguishing the response in the presence of other stimuli (S^A). Eventually, the re-

sponse is consistently performed in the presence of the S^D but not in the presence of the S^A .

discrimination Responding differently in the presence of different cues or antecedent events; control of behavior by discriminative stimuli.

discriminative stimulus (S^D) An antecedent event or stimulus that signals that a certain response will be reinforced. A response is reinforced in the presence of an S^D . After an event becomes an S^D by being paired with reinforcement, its presence can increase the probability that the response will occur.

experimental design The plan for evaluating whether the intervention, rather than various extraneous factors, was responsible for behavior change.

extinction A procedure in which the reinforcer is no longer delivered for a previously reinforced response.

functional analysis Evaluation of the behavior and of antecedent and consequences associated with the behavior. A functional analysis identifies the “causes” of behavior, that is, current conditions that are maintaining the behavior. These conditions are determined by directly assessing behavior, proposing hypotheses about likely factors that are controlling behavior, and testing these hypotheses to demonstrate the conditions that cause the behavior. The information from functional analysis is then used to guide the intervention by direct alteration of conditions so that the desired behaviors are developed.

functional relation The relation of behavior and an experimental condition or contingency. A functional relation is demonstrated if behavior systematically changes when the contingency is applied, withdrawn, and reapplied.

multiple-baseline design An experimental design that demonstrates the effect of a contingency by introducing the contingency across different behaviors, individuals, or situations at different points in time. A causal relationship between the experimental contingency and behavior is demonstrated if each of the behaviors changes only when the contingency is introduced.

negative reinforcement An increase in the likelihood or probability of a response that is followed by the termination or removal of a negative reinforcer.

operant Behavior that is emitted rather than elicited. Emitted behavior operates on the environment and responds to changes in consequences (e.g., reinforcement, punishment) as well as antecedents (e.g., setting events, stimuli).

operant conditioning A type of learning in which behaviors are influenced primarily by the consequences that follow them. The probability of operant behaviors is altered by the consequences that they produce. Antecedents too are involved in learning as cues (S^D , S^A) become associated with different consequences and can influence the likelihood of the behavior.

operational definition Defining a concept (e.g., aggression, social skills) by referring to the specific operations that are to be used for assessment. The “operations” or methods of measuring the construct constitute the operational definition.

positive opposite A behavior that is an alternative to and preferably incompatible with the undesired behavior. Suppression or elimination of an undesirable behavior can be achieved or accelerated by reinforcing a positive opposite. When the goal is to reduce or eliminate behavior, it is helpful to consider the positive opposite behaviors that are to be developed in its stead.

positive reinforcement An increase in the likelihood or probability of a response that is followed by a positive reinforcer.

positive reinforcer An event whose presentation increases the probability of a response that it follows.

prompt An antecedent event that helps initiate a response. Instructions, gestures, physical guidance, and modeling cues serve as prompts.

punishment Presentation of an aversive event or removal of a positive event contingent on a response that decreases the likelihood or probability of the response.

reinforcement An increase in the likelihood or probability of a response when the response is immediately followed by a particular consequence. The consequence can be either the presentation of a positive reinforcer or the removal of a negative reinforcer.

response cost A punishment procedure in which a positive reinforcer is lost contingent on behavior. With this procedure, unlike time out from reinforcement, no time limit to the withdrawal of the reinforcer is specified. Fines and loss of tokens are common forms of response cost.

response maintenance The extent to which changes in behavior are sustained after the program or the intervention phase is ended.

S^A An antecedent event or stimulus that signals that a certain response will not be reinforced.

schedule of reinforcement The rule denoting how many or which responses will be reinforced.

S^D See **discriminative stimulus**.

setting events Antecedent events that refer to context, conditions, or situational influences that affect the contingencies that follow. Such events set the stage for behavior-consequence sequences that are likely to occur.

shaping Developing a new behavior by reinforcing successive approximations toward the terminal response.

single-case experimental designs Arrangements for evaluating whether the intervention was responsible for change. The designs require continuous assessment of the target behavior(s) over time and changes in how and sometimes to whom or when the intervention is applied. The unique feature of the designs is that they permit causal inferences to be drawn about interventions as applied to the individual case.

spontaneous recovery The temporary recurrence of a behavior during extinction. A response that has not been reinforced may reappear temporarily during the course of extinction.

stimulus control The presence of a particular stimulus serves as an occasion for a specific response. The response is performed only when it is in the presence of a particular stimulus.

target behavior The behavior to be altered or focused on during the intervention. The behavior that has been assessed and is to be changed.

time out from reinforcement A punishment procedure in which access to positive reinforcement is withdrawn for a brief period contingent on behavior. Isolation from a group exemplifies time out from reinforcement, but many variations do not require removing the client from the situation.

token A tangible object that serves as a reinforcer. Poker chips, coins, tickets, stars, points, and check marks are commonly used as tokens. They derive their value from being exchangeable for multiple backup reinforcers.

token economy A reinforcement system in which tokens are earned for a variety of behaviors and are used to purchase a variety of backup reinforcers.

transfer of training The extent to which the changes in behavior during and after the program extend to settings, situations, or circumstances that were not included in the program.

I. DESCRIPTION OF TREATMENT

Applied behavior analysis is a specific area of research and intervention within behavior modification. Several characteristics of behavior modification include an emphasis on overt behavior, a focus on current determinants of behavior, and reliance on the psychology of learning as the basis for conceptualizing clinical problems (e.g., anxiety, depression) and their treat-

ment. The psychology of learning refers broadly to theory and research derived from different types of learning, including classical conditioning, operant conditioning, and observational learning (modeling). Applied behavior analysis draws primarily on operant conditioning as the basis for developing interventions.

Applied behavior analysis is not a technique or indeed even a set of techniques. Rather, it is an approach toward conceptualizing, assessing, and evaluating behavior and devising interventions to effect behavior change. The interventions focus on antecedents, behaviors, and consequences and how these can be altered to influence behavior. What is particularly remarkable is the scope of applications that have derived from applied behavior analysis. Apart from applications to many clinical problems seen in treatment, interventions have focused on a vast array of behaviors in everyday life. This contribution describes applied behavior analysis, the underlying principles and techniques, central features of the approach to assessment and evaluation, and how treatment and evaluation are intertwined.

II. THEORETICAL BASES

The underpinnings of applied behavior analysis derive from the work of B. F. Skinner (1904–1990), who developed and elaborated operant conditioning, a type of learning that emphasizes the control that environmental events exert on behavior. The behaviors are referred to as operants because they are responses that operate (have some influence) on the environment. Operant behaviors are strengthened (increased) or weakened (decreased) as a function of the events or consequences that follow them. Operants can be distinguished from reflex responses, such as a startle reaction

in response to a loud noise or squinting in response to bright light. Reflex responses are unlearned and are controlled by eliciting stimuli. Most of the behaviors performed in everyday life are operants. Examples include reading, walking, working, talking, nodding one's head, smiling, and other freely emitted responses. Operant conditioning is the type of learning that elaborates how operant behaviors develop and the many ways in which their performance can be influenced.

Beginning in the 1930s, Skinner's animal laboratory work elaborated the nature of operant conditioning, including the lawful effects of consequences on behavior. These lawful effects generated various principles of operant conditioning, highlighted in Table 1. These principles provide general statements about the relations between behavior and environmental events. Basic experimental and animal laboratory research has continued to flourish and is referred to as the experimental analysis of behavior. The principles have also served as the basis for developing interventions in applied settings such as the home, school, hospitals and institutional settings, business and industry, and the community at large. The application and evaluation of interventions derived from basic research on operant conditioning has emerged as its own area of research and is referred to as applied behavior analysis.

Laboratory work on the study of operant conditioning was characterized by a focus on overt behavior, assessment of the frequency of behavior over time, and the study of one or a few organisms (e.g., rats, pigeons) at a time. The focus on one or two organisms over time permitted the careful evaluation of how changes in consequences influenced performance and the lawfulness of behavior under diverse circumstances. Eventually, the approach was extended to humans. The initial goal was to see if lawful relations between behavior and

TABLE 1
Summary of Key Principles of Operant Conditioning

<i>Principle</i>	<i>Relation between environmental events and behavior</i>
Reinforcement	Presentation or removal of an event after a response that increases the likelihood or probability of that response.
Punishment	Presentation or removal of an event after a response that decreases the likelihood or probability of that response.
Extinction	No longer presenting a reinforcing event after a response that decreases the likelihood or probability of the previously reinforced response.
Stimulus control and discrimination	Reinforcing the response in the presence of one stimulus but not in the presence of another. This procedure increases the likelihood or probability of the response in the presence of the former stimulus and decreases the likelihood or probability of the response in the presence of the latter stimulus.

consequences demonstrated in animal laboratory research could be replicated in laboratory studies with humans and to investigate how special populations (e.g., adult psychiatric patients, mentally retarded children) responded.

By the late 1950s and early 1960s, operant conditioning methods were extended to human behavior outside the laboratory and focused on behaviors that were more relevant to everyday life. Initial demonstrations were conducted merely to see if environmental consequences could influence behavior outside of the context of a laboratory task. For example, could the irrational speech of psychiatric patients or interpersonal interactions of such patients with the staff be influenced by systematically providing attention and praise for positive, prosocial behavior? Several dramatic demonstrations in the early 1960s showed that marked behavior changes could be achieved. These demonstrations were unique because they included extensions of procedures developed in laboratory research, systematically applied consequences to develop behavior, carefully assessed behavior to evaluate the immediate effects of consequences, and demonstrated experimental control of the consequences. Experimental control was evident by showing that behaviors (e.g., delusional speech of psychiatric patients) could be increased and decreased as a function of systematically altering consequences in the environment (e.g., staff attention and praise). Of course, the control did not mean or imply that all behaviors could be influenced by environmental events or that current influences in the environment are the only causes of behavior. However, the early demonstrations raised the prospect that one way to intervene on many behaviors would be to alter antecedents and consequences and to do so in a systematic way. Laboratory research provided guidelines on how this might be accomplished. The early extensions of operant conditioning principles to human behavior began an area of research that is now formally recognized as applied behavior analysis.

III. ESSENTIAL FEATURES OF APPLIED BEHAVIOR ANALYSIS

Applied behavior analysis is an approach to intervention. The approach is characterized by attention to a specific set of influences and how they can be used to develop behavior as well as methods of assessment and evaluation. It is useful to describe these substantive and methodological components separately before conveying how they are intertwined.

A. Contingencies: The ABCs of Behavior

Behavior change in applied behavior analysis is achieved by altering the contingencies of reinforcement. The contingencies refer to the relationships between behaviors and the environmental events that influence behavior. Three components are included in a contingency, namely, antecedents (A), behaviors (B), and consequences (C). The notion of a contingency is important not only for understanding behavior but also for developing programs to change behavior. Antecedents refer to stimuli, settings, and contexts that occur before and influence behaviors. Examples include verbal statements, gestures, or assistance in initiating the behavior. Behaviors refer to the acts themselves, what individuals do or do not do, and the actions one wishes to develop or change. Consequences refer to events that follow behavior and may include influences that increase, decrease, or have no impact on what the individual does. Table 2 illustrates the three components of a contingency with simple examples from everyday life.

Antecedents include a number of potential influences on behavior. Setting events are one category of antecedents and refer to contextual factors or conditions that influence behavior. They are broad in scope and set the stage for the behaviors and consequences that follow. Examples include features of the situation, features of the task or demands presented to the individual, conditions within the individual (e.g., exhaustion, hunger, expectations of what will happen), or behaviors of others that influence the likelihood of specific behaviors that follow. For example, stress at work can influence the subsequent behavior of an individual when he or she returns home at the end of the day. The stress may influence interactions at home and reactions to other events (e.g., comments from a spouse, "bad" habits of a spouse). Setting events are important influences on behavior. The "same" request delivered to a child may lead to quite different responses depending on how the request is delivered, when, and in the context of other influences. Prompts are another type of antecedent event and refer to specific antecedents that directly facilitate performance of behavior. They are distinguished from setting events, which are more contextual, indirect, and broader influences. Common examples of prompts include instructions to engage in the behavior (e.g., "Please wash up before dinner"), cues (e.g., reminders or notes to oneself, lists of things to do), gestures (e.g., to come in or leave the room), ex-

TABLE 2
Three Components of a Contingency and Illustrations from Everyday Life

<i>Antecedent</i>	<i>Behavior</i>	<i>Consequence</i>
Telephone rings	Answering the phone	Voice of person at the other end
Wave (greeting) from a friend	Walking over to the friend	Visiting and chatting
Parent instruction to a child to clean the room	Picking up toys	Verbal praise and a pat on the back
Warning not to eat spoiled food	Eating the food	Nausea and vomiting

amples and modeling (e.g., demonstrations to show this is how the behavior, task, or skill is performed), and physical guidance (e.g., guiding a person's hands to show her how to play a musical instrument).

Behavior, the second part of the contingencies of reinforcement, refers to what an individual does and the goal of the program, that is, what one wants the individual to do. The goal of the intervention may be to increase performance in some way (e.g., initiating a behavior that never occurs, developing more frequent performance of behavior that is occurring, fostering longer periods or more consistent performance of the behavior, or fostering the behavior in new situations). In these instances, providing antecedents and consequences may be sufficient to increase or extend the behavior. In many other cases, the individual does not have the behavior in his or her repertoire or only has the behavior partially. The desired behavior may be so complex (e.g., driving a car, reading a story) that the elements making up the response are not in the repertoire of the individual. In these cases, one cannot merely wait for the behavior to occur and provide consequences; the response may never occur. The behavior can be achieved by reinforcing small steps or approximations toward the final response, a process referred to as shaping.

Consequences, the third component of the contingencies, refers to what follows behavior. For a consequence to alter a particular behavior, it must be dependent or contingent on the occurrence of that behavior. Behavior change occurs when certain consequences are contingent on performance. A consequence is contingent when it is delivered only after the desired behavior has been performed and is otherwise not available. When a consequence is not contingent on behavior, this means that it is delivered independently of what the person is doing. For example, praise might be used to increase the compliance of an oppositional child. To exert influence, praise would need to be contingent on performance, in this case on

instances of compliance. The example is helpful in another way. For a very noncompliant child, there may be no instances of the performance to praise. The use of antecedents to prompt compliance (e.g., prompts of precisely what the child could say), shaping to approximate compliance (e.g., partial compliance to simple requests), and praise contingent on performance can readily develop the behavior.

The principles of operant conditioning include the many ways in which consequences follow behavior. The principles can be translated into a very large number of techniques. For example, positive reinforcement was mentioned as a principle (Table 1). The positive consequences that can be applied contingently to alter behavior can include food, praise, attention, feedback, privileges, and activities. Indeed, often many of these are combined into a single reinforcement program where the individual can earn tokens (e.g., points, stars, tickets, or money) contingent on the desired behavior. The tokens are then used to purchase a variety of other reinforcers available in the setting. Many reinforcers (praise, attention, tokens) have broad applicability across many individuals and generally are effective. However, individual preferences and special features of the situation (e.g., at home, at school) can be readily incorporated into a behavior-change program.

Providing positive reinforcers after behavior can have a potent effect. Yet, identifying the reinforcers that might be used can oversimplify the task of changing behavior. To be effective, the consequences must be provided in special ways; these ways have been well studied in research. Merely providing some positive consequence for behavior is not likely to achieve changes unless several conditions are in place. Table 3 conveys several conditions that influence the effectiveness of reinforcement.

Although it is useful to distinguish antecedents, behavior, and consequences, they are interrelated. Antecedent events (e.g., setting events and prompts) often

TABLE 3
Factors in the Delivery of Reinforcement That Influence
Effects on Behavior

Contingent Application of Consequences

The reinforcer is provided only if the desired response is performed and otherwise not given.

Delay of Reinforcement

The reinforcer should be delivered immediately after the desired behavior.

Magnitude or Amount of the Reinforcer

Larger magnitude reinforcers (e.g., quantity of food, number of points, amount of money) increase effectiveness of reinforcement, up to a point that the individual might be satiated (e.g., if food is used).

Quality or Type of the Reinforcer

Reinforcers that are highly preferred lead to greater performance than do those that are less preferred.

Schedule of Reinforcement

When behavior is being developed, reinforcement after every occurrence of the response (continuous reinforcement) is much more effective than reinforcement for only some of the responses (intermittent reinforcement).

become associated with a particular behavior and its consequences. For example, in some situations (or in the presence of certain stimuli), a response may be reinforced, whereas in other situations (in the presence of other stimuli), the same response may not be reinforced. The concept of differential reinforcement is central to understanding stimulus events and their influence. Differential reinforcement refers to reinforcing a response in the presence of one stimulus or situation and not reinforcing the same response in the presence of another stimulus or situation. When a response is consistently reinforced in the presence of a particular stimulus (e.g., at home) and not reinforced in the presence of another stimulus (e.g., at school), each stimulus signals the consequences that are likely to follow. A stimulus whose presence has been associated with reinforcement is referred to as a discriminative stimulus (S^D). A stimulus whose presence has been associated with nonreinforcement is referred to as a nondiscriminative stimulus or (S^A or S^Δ). The effect of differential reinforcement is that eventually the reinforced response is likely to occur in the presence of the S^D but unlikely to occur in the presence of the S^A . When responses are differentially controlled by antecedent stimuli, behavior is said to be under stimulus

control. When there is stimulus control, the presence of a stimulus increases the likelihood of a response. The presence of the stimulus does not cause or automatically elicit the response but rather merely increases the probability that a previously reinforced behavior will occur.

Instances of stimulus control pervade everyday life. For example, the sound of a doorbell signals that a certain behavior (opening the door) is likely to be reinforced (by seeing someone). Specifically, the sound of the bell frequently has been associated with the presence of visitors at the door (the reinforcer). The ring of the bell (S^D) increases the likelihood that the door will be opened. In the absence of the bell (S^A), the probability of opening the door for a visitor is very low. The ring of a doorbell, telephone, alarm, and kitchen timer all serve as discriminative stimuli (S^D) and signal that certain responses are likely to be reinforced. Hence, the probability of the responses is increased. In a quite different context, when a robber confronts us, this is not an S^D for really friendly and social behaviors on our part. The cues that robbers present (weapon, hostile demeanor, outfit, context) suggest that probably only one response will be reinforced (e.g., compliance).

Stimulus control and discrimination illustrate how antecedents, behaviors, and consequences become connected. In applied behavior analysis, often the goal is to develop behavior in some situations (e.g., at home) or in multiple situations. Usually, it is important to develop behavior, so it transfers across many stimulus conditions; this can be accomplished during training, as mentioned later in this entry.

B. Assessment

Implementing an intervention requires clearly stating the goal, carefully describing the behaviors that are to be developed, and measuring these before the program begins. The main goal of a program is to alter or develop a particular behavior, referred to as the target behavior. There might well be multiple target behaviors.

Identifying the goal of the program in most cases seems obvious and straightforward because of the direct and immediate implications of the behavior for the adjustment, impairment, and adaptive functioning of the individual in everyday life. For example, many interventions have decreased such behaviors as self-injury (e.g., headbanging) among autistic children, anxiety and panic attacks, and driving under the influence of alcohol, and have increased such behaviors as

engaging in practices that promote health (e.g., exercise, consumption of healthful foods) and academic performance among individuals performing poorly at school.

More generally, behaviors are selected for intervention for any of several reasons. First is impairment, or the extent to which an individual's functioning in everyday life is impeded by a particular problem or set of behaviors. Impairment consists of meeting role demands at home, at school, and at work, interacting prosocially and adaptively with others, and not being restricted in the settings, situations, and experiences in which one can function. Second, behaviors that are illegal or rule-breaking too are brought to treatment. Illegal behaviors would include driving under the influence of alcohol, using illicit drugs, and stealing; rule-breaking that is not illegal might include a child leaving school repeatedly during the middle of the day or not adhering to parent-imposed curfew. Third, behaviors that are of concern to individuals themselves or to significant others serve as the basis for seeking interventions. For example, parents seek interventions for a variety of child behaviors that affect daily life but may or may not be severe enough to reflect impairment or rule-breaking. Examples might include toilet training, school functioning, and mild versions of other behaviors that, if severe, might lead to impairment. Finally, behaviors are focused on that may prevent problems from developing. For example, premature babies and children from economically disadvantaged environments are at risk for later school difficulties. Early interventions within the first months and few years of life are intended to develop pre-academic behaviors and avert later school difficulties. Also, developing behaviors to promote safety (e.g., in business and industry or in the home) or health are selected to prevent later problems.

A behavioral program usually begins with a statement from someone that there is a problem or a need to intervene to address a particular end. Global statements of behavioral problems are usually inadequate for actually beginning an intervention. For example, it is insufficient to select as the goal alteration of aggressiveness, learning deficits, speech, social skills, depression, psychotic symptoms, and self-esteem. Traits, summary labels, and personality characteristics are too general to be of much use. Moreover, definitions of the behaviors that make up such general labels may be idiosyncratic among different behavior-change agents (parents, teachers, or hospital staff). The target behaviors have to be defined explicitly so that they can actu-

ally be observed, measured, and agreed upon by individuals administering the program.

The general complaint (e.g., the child has tantrums) must be translated into operational definitions. Operational definitions refer to defining a concept on the basis of the specific operations used for assessment. Paper-and-pencil measures (questionnaires to assess the domain), interviews, reports of others (e.g., parents, spouses) in contact with the client, physiological measures (e.g., arousal, stress), and direct observation are the among the most commonly used measures in psychological research to operationalize key concepts. Several measures might be selected in any given intervention program, and no single measure can capture all components of the concept. In applied behavior analysis, emphasis is placed on direct observation of overt behavior because overt behavior is viewed as the most direct measure of the treatment focus. For example, if tantrums are of interest, it is useful to observe the tantrums directly and to see when they occur, under what circumstances, and whether they change in response to an intervention.

Once the target behavior(s) is carefully defined, observations are made to collect data on the problem. The observations may be made by tallying their occurrence within a period of time or recording whether or not they occurred in a particular time interval. The behavior is sampled on a continuous basis, usually daily or multiple times per week. For example, if the goal is to increase the social behavior of a withdrawn psychiatric patient, to develop completion of homework in an adolescent with academic difficulties, or to increase the activity of an elderly person in a residential home, the specific target behaviors will be defined and assessed directly. The purpose is to obtain the rate of performance prior to the intervention, referred to as the baseline rate. Because interventions are often conducted in everyday settings, parents, teachers, and others may be involved in the collection of this information. Careful assessment is central because the assessment data are used to make decisions about the treatment while the intervention is in effect.

C. Functional Analysis: From Assessment to Intervention

Functional analysis consists of a methodology of identifying the relation of a target behavior to antecedents and consequences and using this information to select the intervention. "Functional" emphasizes identifying the functions of the behavior, that is, the

TABLE 4
Hypothetical Examples of the Consequences or Purposes of Behaviors

<i>Behavior</i>	<i>Outcomes that may maintain that behavior</i>
Tantrum of a child before going to bed	Attention from a parent, extra time with the parents, reduction of parent's arguing with each other
Arguing or fighting with a spouse/partner	Affection and promises of life-long commitment that result from making up after the fight, time away from the spouse as he or she walks out for a few days
Complaining	Attention and sympathy from others, not hearing the complaints of others, personal relief or stress reduction as a function of expressing unfortunate conditions
Attaining good grades in school	Praise from others, success, reduction in anxiety about failing

Note: The functions of a behavior are usually determined on an individual basis so there is no single function that a particular behavior invariably serves for all or even most individuals. Indeed, different behaviors can serve the same function for two individuals, and the same behavior may serve different functions for two individuals.

purposes the behavior may serve in the environment or the outcomes that maintain the behavior. Table 4 provides some examples of behaviors and some of the functions the behaviors may serve. "Analysis" emphasizes the careful assessment and systematic evaluation to isolate precisely the factors that control behavior. The analysis consists of obtaining data about the hypothesized purposes that the behavior may serve and testing whether these purposes actually control or influence behavior.

The elements of functional analyses are assessment, development and evaluation of hypotheses about factors that control behavior, and intervention. Initially, assessment is designed to identify the relations of antecedents and consequences to the behavior of interest and hence the purposes or functions of the behavior. This assessment is likely to suggest circumstances or stimulus conditions with which the behavior is associated. For example, the behavior may appear to be more frequent at some times of the day rather than others, when some persons are present rather than others, and when certain effects or consequences occur.

The patterns raise hypotheses about what may be maintaining or controlling behavior. If at all possible, the hypotheses are tested directly by assessing the target behavior as various conditions are changed. The conditions in which the hypotheses are tested may be brief and transient merely to see if different conditions systematically influence behavior. This is an experimental phase designed to evaluate if the controlling conditions can be identified.

The information gained from manipulating conditions and from assessment under different conditions is used to help the client directly. Specifically, the conditions shown to influence behavior are altered to de-

crease inappropriate or deviant behavior and to foster appropriate, prosocial behavior. This is the intervention phase of functional analysis. The purpose of this phase is to put into place the condition that controls behavior to achieve a significant therapeutic change.

Consider, as an example, a child (Kathy, age 8) who frequently fought (physically) with her younger sister (Mary, age 4). The parents wanted to eliminate fighting. Both children were in the home from late afternoon (after school and day care) and were observed by the mother for several days from the afternoon until the children's bedtime. We asked the mother to chart two related behaviors when the children were together (in the same room). The first behavior was fighting and included arguing, shouting, and hitting. The second behavior was playing cooperatively or being together in an activity without the above behaviors. We recorded these latter behaviors because developing positive opposite behaviors typically serves as the focus of interventions that are stimulated by interests in decreasing deviant behavior. The behaviors were observed using a frequency count, that is, merely tallying the occurrence of any instance of the behavior. One minute of either behavior was scored as an instance of that behavior.

Table 5 includes two charts the mother was asked to use to track fighting (Chart A) and playing cooperatively (Chart B). The purpose of using a chart was to identify whether any patterns emerged and suggest the conditions that may contribute to the behavior. The entries in the chart are samples and reflect some of the information collected from the mother. After several days, it appeared (from Chart A) that Kathy's fighting with her sister occurred mostly during the following antecedent conditions: after school but before dinner, in the presence of the mother when she was by herself,

TABLE 5
Charts to Record Fighting (Chart A) and Playing Cooperatively (Chart B)—Sample Entries from the Charts

Chart A Episodes of Fighting

<i>Time/day/date</i>	<i>Antecedents situation/setting conditions/others present</i>	<i>Consequences</i>
Monday, 3:45 P.M.	Watching TV, no else home	Separated children, sent Kathy to her room, read to her for 15 min
Tuesday, 5:00 P.M.	Playing on the computer	Took Kathy to her room and talked with her about playing better with her sister, talked about what happened at school
Wednesday, 4:10 P.M.	Playing on the computer	Sent Kathy to her room and she showed me drawings and a poem she made at school.

Note: The behavior observed is the fighting of Kathy with her younger sister. Any entry (row) on the chart refers to a time in which an episode of fighting with her younger sister.

Chart B Episodes of Playing Cooperatively

<i>Time/day/date</i>	<i>Antecedents situation/setting conditions/others present</i>	<i>Consequences</i>
Monday, 7:00 P.M.	Watching TV; Bill (husband) and I watching with them	None
Tuesday, 4:00 P.M.	Watching TV; Marge (neighbor) in the kitchen with me	None
Thursday, 7:30 P.M.	Watching TV; no one else present	Watched until bath time and then went to bed

Note: The behavior observed was playing cooperatively, that is, together in the same room and without fighting. Any entry (row) on the chart refers to a time (5 minutes or more) in which the sister played cooperatively.

and when the girls were playing a game or watching television together. The consequences usually consisted of the mother intervening to stop the fight, sending Kathy to her room, and remaining in the room with Kathy until she calmed down. Chart B was rather interesting as well. Playing cooperatively was associated with the following antecedent conditions: the presence of another adult in the home (the father or a neighbor visiting the mother) and the time in which one or both parents were also in the room. No consequences systematically followed playing cooperatively. The parents felt that they ought to leave well enough alone—a strategy that is not helpful when one wants to develop specific behaviors. Here the undesired behavior was positively reinforced (with attention, time with mom), and the desired behavior was not.

Using information from the charts, we hypothesized that Kathy's fighting served as an occasion to have private time with the mother. Quite likely, time with the

mother was a positive reinforcer that inadvertently contributed to or maintained fighting. Kathy's interest in attention from the mother, obviously "normal" for any child, was heightened according to the mother, because of the strong sibling rivalry she had felt since her younger sister was born. Also of interest were the observations (Chart B) that playing cooperatively among the two children was not systematically associated with positive consequences.

Based on the baseline observations of the target behaviors (fighting, playing cooperatively) and the use of the charts, we generated the following simple hypothesis. Kathy's fighting served to provide time alone with her mother. The fighting only occurred when the mother was home without another adult because only on these occasions was the mother likely to provide the private and alone time with Kathy. That is, the mother probably was less likely to leave conversations with the husband or visiting friend even when Kathy was fight-

ing. We decided to begin directly with a simple intervention to test this hypothesis.

The intervention consisted of providing positive reinforcement (time with the mother) for cooperative play and time out from reinforcement (a period of time when opportunities for reinforcement were removed) for Kathy for fighting. When the girls came home from school/day care, Kathy was told she and the mother could have some play time together if she and her sister played cooperatively for 30 minutes. (Time alone also was provided afterwards with the sister.) Briefly, after the time elapsed without fighting, the mother effusively praised the girls and then played with Kathy in her room. If Kathy had a tantrum, she was sent to her room for 10 minutes and the mother did not remain in the room with her. Requiring longer periods of cooperative play to earn time with the mother and adding father and mother praise for cooperative play essentially eliminated all fighting within the first five days of the program. The functional analysis was helpful in conveying the many factors associated with fighting and suggesting what might be used to increase cooperative play.

In this simple example, the initial assessment suggested a pattern of factors related to the behavior. The pattern suggested a hypothesis, and this led directly to an intervention. In research, there is a separate step of testing the hypotheses experimentally before moving into the intervention. Usually, the tests are conducted in controlled laboratory conditions. The conditions are sometimes referred to as analogue testing because the behavior and events associated with it are evaluated in a contrived situation that is only roughly analogous to conditions in everyday life. Yet, if the laboratory conditions can identify and isolate possible influences (antecedents and consequences), these conditions are likely to exert similar effects in everyday life.

Several studies have evaluated self-injurious behavior among children and adults diagnosed with autistic disorder. A challenge has been eliminating such behavior. Functional analyses have evaluated several possible controlling factors. Three possibilities have been evaluated frequently, including (1) social attention provided for self-injurious behavior (i.e., positive reinforcement), (2) escape from the situation to reduce demands from others (i.e., negative reinforcement), or (3) the stimulation resulting from the behavior itself (i.e., reinforcement from tactile stimulation). Assessment is conducted for brief periods by an experimenter who presents these conditions in alternating order.

Each condition might be presented for one to several 10-minute periods. Plotting data separately for each condition often shows that one of the conditions is associated with changes in self-injury and others are not. More often than not escape from task demands seems to negatively reinforce self-injury. That is, the rate of self-injury is much higher when the experimenter ends the task as the person engages in self-injury. Once this is demonstrated, one can make escape from task demands contingent on noninjurious behavior rather than injurious behavior. Escape reinforces positive behavior, and in this way self-injury is no longer reinforced and can be eliminated.

Functional analysis represents a significant contribution of applied behavior analysis. The analysis can suggest specific antecedent conditions that promote or give rise to the behavior as well as identify the consequences maintaining behavior. Scores of demonstrations have shown how functional analysis can be used to identify controlling influences and then move to an effective intervention (see Sturmey, 1996). Consequently, a main benefit of functional analysis is in the treatment gains that have been achieved in many applications of reinforcement, punishment, and extinction.

Functional analysis is not merely a method of assessment and intervening but also a way of thinking about behavior. The way of thinking alerts us to the importance of considering a range of antecedents and consequences that may influence behavior. Also, the method provides a way of testing hypotheses to help the individual client. What in fact is controlling behavior, and how can this be translated into effective treatment? Functional analysis provides a means for answering these questions.

Functional analysis also provides a methodology for addressing important complexities of behavior. The first of these is that two (or more) individuals may be performing identical behaviors (e.g., getting into fights at school on the playground, coming late to work or to class, arguing with one's boyfriend or girlfriend), but for quite different reasons. Moreover, a given child may engage in two or more quite different behaviors that in some way serve the same purpose. For example, a child may have a tantrum at the dinner table every night and also get into trouble at school and be placed on detention. These are quite different behaviors; they bear no obvious resemblance, and they occur in different settings. It is possible that they serve a similar function, which might be, for example, that both bring the mother and father together to discipline the child.

Conducting a functional analysis is not always feasible. Also, controlling factors may not be obvious or evident in the day-to-day life of an individual if, for example, the consequences are intermittent or the behavior is reinforced by its own performance (e.g., the stimulation it provides). Detailed analyses and extended observations may not be feasible, either because the resources for observation are limited or because of the urgency to intervene (e.g., to stop a child's fighting).

Many of the techniques based on reinforcement, punishment, and extinction, and other contingency manipulations have proven to be enormously effective in situations in which functional analyses have *not* been done. This is useful to know especially because systematic but simple interventions are often surprisingly effective if they are carried out systematically. Even so, functional analysis has provided a powerful tool to identify the current factors in the environment that control behavior and to move to an intervention phase in which these factors are altered to promote prosocial and adaptive behavior.

D. Evaluation and Single-Case Designs

Assessment of the target behavior(s) is quite valuable for identifying the scope of the problem, and possible factors contributing to the problem as well as for evaluating whether there has been a change over the course of the intervention. Assessment may reveal that a change has occurred, but it does not show what *caused* the change. Proponents of applied behavior analysis are extremely interested in determining the causes of behavior change. The short-term benefits of interventions to the individual client and the long-term benefits of interventions for society at large will derive from understanding what produces change, the bases or reasons for the change, and the factors that one might alter to optimize the change. The prior comments on functional analysis convey explicitly how assessment can be used to identify factors that control behavior and then how this information is used to develop effective interventions. Evaluating the basis or reason for change extends beyond functional analysis. Whether or not one conducts a functional analysis, there is an interest in evaluating whether the intervention was responsible for change.

The cause of behavior change can be demonstrated in different ways. The clinical investigator who designs the intervention usually plans the situation to identify whether the intervention was responsible for

behavior change. The plan to demonstrate the cause of behavior change is referred to as the experimental design. The purpose of the experimental design is to identify the variables that influence, control, or are responsible for behavior change. In applied behavior analysis, this is referred to as the demonstration of a functional relation between the target behavior and the intervention. A functional relation is demonstrated when altering the experimental condition or contingency systematically changes behavior. Behavior is shown to be a function of the environmental events that produced change.

Different experimental designs can be used to show that the intervention, rather than extraneous events, was responsible for behavior change. The designs are referred to as single-case experimental designs. These designs are true experiments, which means that they represent a strong basis for drawing causal inferences. Although such designs can be used with large groups of individuals, their unique characteristic is that they can be used with individual cases (e.g., one patient or student). In single-case research, inferences are usually made about the effects of the intervention by comparing different conditions presented to one or a few individuals over time.

There are a number of basic requirements that single-case experimental designs share and that are fundamental to understanding how conclusions are drawn. The most fundamental design characteristic is the reliance on continuous assessment, that is, repeated observations of performance over time. The client's performance is observed on several occasions, usually before the intervention is applied and continuously over the period while the intervention is in effect. Typically, observations are conducted on a daily basis or at least on multiple occasions each week. These observations allow the investigator to examine the pattern and stability of performance. The pretreatment information over an extended period provides a picture of what performance is like without the intervention. When the intervention eventually is implemented, the observations are continued and the investigator can examine whether behavior changes coincide with the intervention. There are a number of experimental designs in which causal relations can be drawn between the intervention and behavior. An example of one design is provided here to illustrate the approach.

The multiple-baseline design demonstrates the effect of an intervention by showing that behavior change accompanies introduction of the intervention at different points in time. The key feature of the design is evalua-

tion of change across different baselines. Ideally, change occurs when the intervention is introduced in sequence to each of the baselines. Multiple-baseline designs vary depending on whether the baselines refer to different behaviors, different individuals, different situations, or time periods. For example, in the multiple-baseline design across behaviors, a single individual or group of individuals is observed. Data are collected on two or more behaviors, each of which eventually is to be altered. The behaviors are observed daily or at least on several occasions each week. After each of the baselines shows a stable pattern, the intervention is applied to only one of the behaviors. Baseline conditions remain in effect for the other behaviors. The initial behavior to which treatment is applied is expected to change, while other behaviors remain at pretreatment levels. When the treated behavior stabilizes, the intervention is applied to the second behavior. Treatment continues for the first two behaviors, while baseline continues for all other behaviors. Eventually, each behavior is exposed to treatment but at different points in time. A causal relation between the intervention and behavior is clearly demonstrated if each behavior changes only when the intervention is introduced and not before. (Examples of multiple-baseline designs are presented later in the chapter.)

Multiple-baseline designs are user friendly in clinical and other applications because the intervention is applied in a sequential fashion. The investigator may wish to change many different behaviors of an individual, a behavior of an individual across many different situations, or the behavior of many different individuals. Rather than introducing the intervention to all of these at once, the program initially focuses on only one behavior, situation, or individual. If the intervention is effective, then it can be extended to all of the other behaviors for which change is desired. As importantly, if the intervention is ineffective or insufficiently effective to achieve important changes, it can be altered or improved before it is extended.

Implementing a single-case experimental design during an intervention program is not always possible because of constraints of the situation. There are, however, many designs, some of which are more feasible and flexible than others. Whether or not a formal design or some approximation is used to evaluate the causal influence of the intervention, in applied behavior analysis some evaluation is conducted. It is essential to see if behavior changes occur with treatment, if these changes are important (i.e., have a palpable impact on the problem), and, to the extent possible, if the

intervention is likely to be responsible for change. Among approaches to treatment, the collection of ongoing data during the intervention, the use of this information to make changes in treatment, and the experimental evaluation of intervention effects are rather unique.

Use of the information collected during treatment and as part of an evaluation of that treatment warrants additional comment. Continuous assessment, unique to single-case designs, provides the investigator or clinician with feedback regarding how well the intervention is working. This is perhaps the main applied advantage of single-case designs, namely, the ability to see how or whether treatment is working and making changes as needed while the treatment or intervention is still in effect. Indeed, the success of interventions studied in applied behavior analysis not only stems from powerful procedures (e.g., reinforcement), but also from being able to identify weak treatment effects early and rectifying them. Clearly, the main advantage of the designs is that they allow careful investigation of an individual client. Thus, both the target focus and the interventions can be individualized to the circumstances and situation of the individual.

IV. EMPIRICAL STUDIES

Many different techniques can be derived from operant conditioning principles. It is not possible to review the evidence for each technique variation because of the scope of applications and weight of the evidence (see Further Reading). Examples are provided to illustrate the approach, selected techniques, and the type of evidence used to demonstrate effectiveness.

A. Reinforcement

Techniques based on positive reinforcement serve as the core interventions of applied behavior analysis. If the goal is to develop positive, adaptive behavior, reinforcement is obviously suitable because reinforcement operates to increase the behavior. Even if the goal is to reduce or eliminate behavior (e.g., stealing, aggression, gambling), positive reinforcement usually plays a central goal. Developing positive, prosocial behavior is effective as a way of eliminating or reducing maladaptive behavior. The positive prosocial behaviors that are reinforced are often opposite to or incompatible with the undesired behavior, so that increasing such behaviors (e.g., positive marital communication)

can be quite effective as a way of reducing undesirable behavior (e.g., arguing).

Intervention programs based on positive reinforcement have used attention, praise, feedback, and activities in which people like to engage as the reinforcing consequences for behavior. Often, multiple reinforcers are incorporated into a single program, referred to as a token economy. In a token economy, tokens function in the same way that money does in national economies. Tokens are earned and then used to purchase backup reinforcers, such as food and other consumables, activities, and privileges. The basic requirements of a token economy include specification of (1) the target behaviors, (2) the number of tokens that can be earned for performance of the behaviors, (3) the backup reinforcers that are available, and (4) the number of tokens the backup reinforcers cost.

As an illustration, token economies have been used extensively in psychiatric hospitals. In one of the most carefully evaluated programs, patients received tokens (colored plastic strips) for such behaviors as attending activities on the ward, group meetings, and therapy sessions; grooming, making one's bed, showering, and engaging in appropriate mealtime behaviors; and socially interacting. Tokens could be exchanged for a variety of backup events such as purchasing cosmetics, candy, cigarettes, and clothing; renting chairs or bedside stands for one's room; ordering items from a mail-order catalog; using a piano, record player, or radio; spending time in a lounge; watching television; having a private room, and sleeping late. As patients improved in the ward, they advanced to higher levels within the program, in which more reinforcers were available and higher criteria were set for performance. Patients could "buy" themselves off the system by doing well, and each carried a "credit card" that allowed free access to all of the available reinforcers as long as personal performance was up to standards. The program was very successful in reducing bizarre behaviors, improving social interaction and communication skills, and developing participation in activities. The gains were reflected in the number of patients discharged and in their adjustment in the community from one and a half to five years after the program ended.

Token reinforcement can be used with a group or with one or two individuals. For example, a token system was used to treat patients referred for drug addiction. Two adult males (Phil, age 28; Mike, age 35) were seen separately for cocaine addiction. Both also used marijuana, which apparently is the case for 40 to 50 percent of persons addicted to cocaine. Assessment of

cocaine and marijuana use was accomplished by urinalyses that detected use within the previous 72 hours. Assessment was conducted four times a week to provide opportunities for earning tokens. Points were provided when the assessment indicated no sign of cocaine use. Bonus points were given for extended periods without a sign of drug use. Points could be exchanged for small amounts of money or goods and services, including movie tickets, sporting events, ski-lift tickets, and dinner certificates. The purpose of using these backup rewards was not only to imbue the points with value but also to involve the individuals in prosocial activities and, it was hoped, to develop a reinforcing, drug-free lifestyle. After 12 weeks of the program, a maintenance phase was initiated to reduce the frequency of the checks on drug use. In the final phase, marijuana use was added to the program. To earn tokens, the tests had to show that the individual did not use cocaine or marijuana.

Figure 1 plots the number of negative urine specimens (no sign of drug use) in a cumulative graph for each person. The figure shows that when reinforcement was given for cocaine abstinence, tests for cocaine use were negative. Marijuana continued to be used until the final phase, in which abstinence from both cocaine and marijuana was reinforced. The sequence of interventions across two individuals seen at the clinic and across two drugs follows the criteria of a multiple-baseline design. The pattern suggests that the token reinforcement program was responsible for the change. Followup assessment, including reports from others (girlfriend, roommate) and from the clients themselves, indicated no use of cocaine but some occasional use of marijuana.

The adaptability of the token economy can be illustrated by moving from the focus on one or two individuals, in the previous example, to a larger-scale application in business and industry. For example, in one study the focus was on worker safety. The study was conducted at two open-pit mines, one in Wyoming and the other in Arizona. Uranium was extracted and processed at one of the mines; coal was extracted and processed at the other. The two mines used similar equipment (trucks, bulldozers) and procedures (strip mining, crushing, storing materials). The goals of the program were to decrease job-related injuries, days lost from work due to such injuries, and costs (due to medical care, insurance, and equipment damage) among employees in each mine.

An incentive in the form of tokens (trading stamps) was provided at the end of each month to workers who

FIGURE 1 Cumulative number of negative cocaine and marijuana urinalysis results obtained with Phil and Mike during three phases of treatment as a function of tests conducted throughout treatment. Cocaine and marijuana test results are presented by closed and open symbols, respectively. Steep slopes in the cumulative record indicate change; horizontal lines indicate no change. [Budney, A. J., Higgins, S. T., Delaney, D. D., Kent, L., & Bickel, W. K. (1991). Contingent reinforcement of abstinence with individuals abusing cocaine and marijuana. *Journal of Applied Behavior Analysis*, 24, 657–665.]

had not been injured or had not required medical care because of an accident. Trading stamps were also given to all members of a group that worked under a particular supervisor if no one in the group had been injured.

Bonus stamps were available to workers whose suggestions for improving safety in the facility were adopted. Trading stamps could also be lost (response cost) for missing work due to injury or for causing an accident.

The trading stamps could be exchanged at a nearby redemption center that carried hundreds of items, such as small appliances, barbecue grills, spice racks, and clocks. The program was introduced to each mine in a multiple-baseline design and integrated with the mine's routine practices for several years. Figure 2 shows a marked reduction in the number of accidents among workers (upper panel) as well as a reduction in monetary costs to the company (lower panel).

Token economies have been used with a variety of populations, including persons with mental retardation, prisoners, geriatric or nursing home residents, persons who abuse alcohol and drugs, outpatient children and adults, and members of the armed forces (e.g., in basic training). Similarly, the various settings in which token economies have been applied include the home, schools, institutions, hospitals, day-care centers, nursing homes, and business and industry. Probably the setting most often used is in the home where parents use points, marks on a chart, or stars on a temporary basis to foster behaviors such as completing chores, homework, and taking care of pets. Simple reinforcement programs are an excellent way to manage behavior, to move away from nagging, reprimands, and punishment in general. Usually in such applications tokens are not "needed." That is, the behavior could be changed with prompts, praise, and shaping. Yet, the tokens provide a useful way to structure and prompt parent behavior so that the consequences are applied systematically.

The discussion of reinforcement has emphasized token reinforcement because this is an adaptable system for integrating several behaviors and reinforcers. In many applications, reinforcers such as praise and privileges have been extremely effective in changing the behavior of children, adolescents, and adults in the diverse settings, mentioned previously. Apart from the diversity of reinforcers (e.g., praise, activities), programs can vary on whether the reinforcers are delivered on the basis of how the individual or group performs and who administers the program (e.g., parents, teachers, peers). Indeed, the range of options accounts for the broad applicability of reinforcement procedures. For example, in school settings, peers (older classmates at the school) often are involved in administering reinforcers to others for academic behavior (e.g., completing assignments correctly) or social interaction (e.g., appropriate initiations of contact with others). Peer-administered reinforcement programs have been effective in many applications. Interestingly, the individual whose behavior is reinforced changes, as would be expected. In addition, the peers

who administer the program often show marked improvements in the target behaviors and hence share in the benefits of the intervention.

B. Punishment

The types of aversive events used and how they are applied in behavioral programs differ greatly from punishment practices in everyday life. In behavioral interventions, rarely is punishment used by itself. Rather, punishment is part of a larger program based on positive reinforcement that develops adaptive behavior. There are many reasons for emphasizing positive reinforcement, even when the goal is to suppress or eliminate some undesirable behavior. Perhaps most significantly, deviant behavior often can be eliminated effectively with little or no punishment. There are a variety of ways of delivering reinforcement to support behaviors incompatible with the deviant behavior that work quite well to eliminate undesired responses.

Punishment is also deemphasized because it does not train an individual regarding what to do. Merely suppressing behavior and training the individual in what not to do will not necessarily foster the desired or appropriate behaviors. Indeed, without an effort to develop behaviors through positive reinforcement, punishment may not be very effective as a way of changing behavior in the long term. The suppressed responses are likely to return unless some other behaviors have replaced them.

Punishment often is associated with undesirable side effects, such as emotional reactions (crying), escape from and avoidance of situations (e.g., staying away from a punitive parent), and aggression (e.g., hitting others). None of these is necessary for behavior to change. Punishment can foster undesirable associations with regard to various agents (parents, teachers), situations (home, school), and behaviors (doing homework). An important objective in child rearing, education, and socialization in general is to develop positive attitudes and responses toward these agents, situations, and behaviors; their frequent association with punishment may be counterproductive. For example, screaming at a child to practice a musical instrument is not likely to develop a love of music. For all of these reasons, programs emphasize positive reinforcement.

Proponents of behavioral techniques are extremely concerned with abuse and misuse of punishment. Such abuse and misuse have been shown to foster serious problems in children and adolescents. For example, use of harsh punishment in the home is related

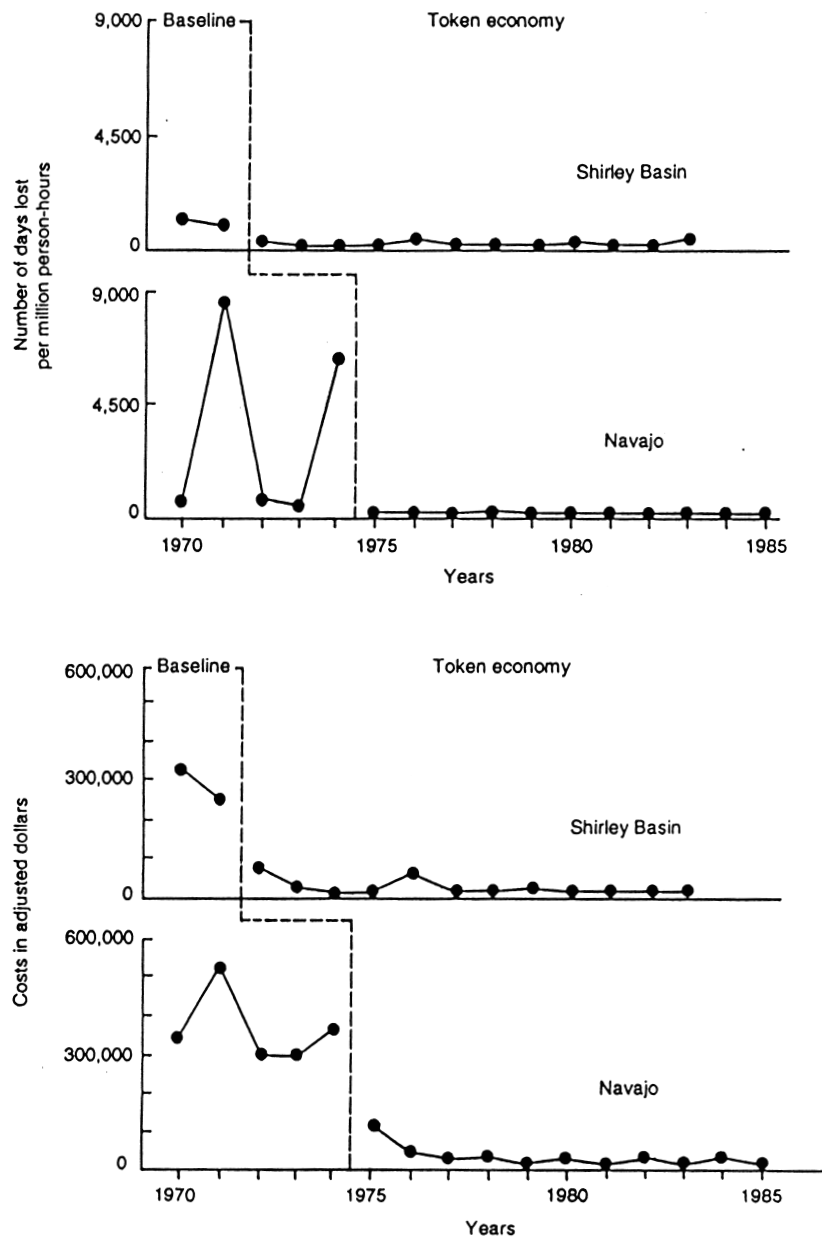

FIGURE 2 Yearly number of days lost from work per million person hours worked, resulting from work-related injuries (upper figure) and yearly cost, adjusted for hours worked and inflation, resulting from accidents and injuries (lower figure). [Fox, D. K., Hopkins, B. L., & Anger, W. K. (1987). The long-term effects of a token economy on safety performance in open-pit mining. *Journal of Applied Behavior Analysis*, 20, 215-224.]

to later deviant and delinquent behavior of the child. Both physical and verbal punishment (reprimands) can increase the very behaviors (noncompliance, aggression) that parents, teachers, and others wish to suppress.

In applied behavior analysis, when punishment is used, it usually consists of withdrawing positive events. The most commonly used form is time out from reinforcement, which refers to the removal of a positive reinforcer for a brief period of time (e.g., a few minutes).

During the time-out interval, the client does not have access to the positive reinforcers that are normally available in the setting. For example, a child may be isolated from others in class for five minutes. During that time, he or she will not have access to peer interaction, activities, privileges, and other reinforcers that are usually available.

A variety of time-out procedures have been used effectively. In many variations, the client is physically isolated or excluded in some way from the situation. The client may be sent to a time-out room or booth, a special place that is partitioned off from others (in the classroom, at home, or in an institution). In other variations, the client is not removed at all. For example, in one variation, developed initially in a special education classroom, children received praise and smiles (social reinforcement) from the teacher for performing their work. Each child in the class was given a ribbon to wear around his neck. The ribbon signified to the child and the teacher that the child could receive social and, occasionally, food reinforcers that were administered while the children worked. When any disruptive behavior was performed, time out was used. It consisted of removing the child's ribbon for three minutes. Without the ribbon, the child could not receive any of the reinforcers normally administered (e.g., attention from the teacher). This time-out procedure effectively reduced disruptive classroom behavior.

In general, time out provides an excellent alternative to many of the forms of punishment used in everyday life, such as reprimands and corporal punishment. Very brief time out, for several seconds or a few minutes, has been effective. Longer periods of time out (e.g., 10, 20 minutes) do not necessarily increase the effectiveness of the procedure. Indeed, brief and contingent time out is quite effective, especially if many reinforcers are available in the setting and these are administered for positive behavior.

Another punishment procedure is referred to as response cost and also consists of loss of a positive reinforcer. Response cost entails a penalty of some sort contingent on behavior. With response cost, there is no time period during which positive events are unavailable, as is the case with time out. Typically, response cost consists of a fine. Examples of response cost in everyday experience include fines for traffic violations or overdue books, fees for late filing of income tax or for registering for classes beyond the due date, and charges for checks that "bounce." (Although these examples illustrate response cost, the examples do not reflect punishment administered in ways that maximize behavior

change. Conditions to maximize the impact of response cost include immediacy and schedule of the fine and reinforcement for alternate behavior, to mention a few.) In applied behavior analysis, fines usually consist of loss of tokens (chips, stars, points) that are provided for positive behavior in a token economy.

As an example, response cost was used to reduce aggressive and disruptive behavior in the classroom of four preschool boys (ages 3–5). The children engaged in such behaviors as throwing things, damaging other children's materials, hitting, and screaming. Response cost consisted of providing a child with five laminated smiley faces attached to a larger sheet. The chart was labeled Good Behavior Chart and posted in the classroom for all to see. Each time the child engaged in one aggressive behavior, a smiley face was taken away. The teacher stated the reason for the loss of the smiley face and provided a reprimand. If the child retained at least one smiley face at the end of the 40-minute period, he could purchase special rewards (e.g., being the teacher's helper, access to a favorite toy). Consistent performance over at least four or five days was reinforced with additional incentives (a special grab bag). Response cost was introduced in a multiple-baseline design across children. As is evident in Figure 3, aggressive behavior changed markedly as the intervention was introduced.

Many other punishment procedures are available such as the contingent use of effort (tasks, chores), loss of privileges, and requiring individuals to rectify or correct the situation their behavior may have altered. As noted previously, the primary use of punishment in applied behavior analysis is as a supplement to a positive reinforcement program. Punishment by itself raises all sorts of objections and concerns and often is not very effective. However, mild punishment (e.g., brief time out, response cost) when supplemented with positive reinforcement for prosocial behavior can be extremely effective. Although reinforcement by itself can often be used to eliminate undesirable behaviors, the addition of very mild punishment often augments the effectiveness of the reinforcement program.

A difficulty in using punishment at all is that people familiar with punishment in every day life may implement aversive events in ways that do not enhance efficacy or that promote problems (e.g., screaming, hitting, trying to evoke emotional responses). Shouting, hitting, screaming, making threats, or shaking someone, not all that rare in the home and classroom and indeed in parent-child and

FIGURE 3 Rate of aggressive behavior during baseline and treatment conditions across subjects. [Reynolds, L. K., & Kelley, M. L. (1997). The efficacy of a response cost treatment package for managing aggressive behavior in preschoolers. *Behavior Modification*, 21, 216–230.]

spouse–spouse interactions, are not events used in applied behavior analysis. A danger of implementing punishment is that well-designed programs (e.g., two minutes of time out contingent on behavior), if not

monitored carefully, may drift into one of these other punishment procedures.

C. Extinction

Many maladaptive behaviors are maintained by consequences that follow from them. For example, temper tantrums or interrupting others during conversations are often unwittingly reinforced by the attention they receive. When there is interest in reducing behavior, extinction can be used by eliminating the connection between the behavior and the consequences that follow. Extinction refers to withholding reinforcement from a previously reinforced response. A response undergoing extinction eventually decreases in frequency until it returns to its prereinforcement level or is eliminated.

Extinction has been successfully applied to diverse problems. As an illustration, extinction was used to reduce awakening in the middle of the night among infants. Nighttime waking, exhibited by 20 percent to 50 percent of infants often is noted as a significant problem for parents. Parents may play a role in sustaining night waking by attending to the infant in ways that reinforce the behavior. In this program, parents with infants (8 to 20 months old) participated in an extinction-based program to decrease nighttime awakening. Waking up during the night was defined as a sustained noise (more than one minute) of the infant between onset of sleep and an agreed-upon waking time (such as 6:00 A.M.). Over the course of the project, several assessment procedures were used, including parent recording of sleep periods, telephone calls to the parents to check on these reports, and a voice-activated recording device near the child's bed. After baseline observations, parents were instructed to modify the way in which they attended to night wakings. Specifically, parents were told to ignore night wakings. If the parent had a concern about the health or safety of the child, the parent was instructed to enter the room, check the child quietly and in silence with a minimum of light, and to leave immediately if there was no problem.

The program was evaluated in a multiple-baseline design across seven infants. Figure 4 shows the frequency of night wakings each week for the children during the baseline and intervention periods. As is evident in the figure, the frequency decreased during the intervention period. Followup consisted of assessment approximately three months and then two years later, which showed maintenance of the changes. The figure is instructive for other reasons. Two weaknesses of extinction programs were evident. First, extinction effects tend to be gradual.

FIGURE 4 Frequency of night wakings per week for seven infants treated with extinction. The program was evaluated in a multiple-baseline design across infants. Followup 1 and 2 represent evaluation at three months and two years after the initial intervention program, respectively. The solid, large dots denote nights in which the infant was ill. [France, K. G., & Hudson, S. M. (1990). Behavior management of infant sleep disturbance. *Journal of Applied Behavior Analysis*, 23, 91-98.]

Second, during extinction the behavior may momentarily recover (i.e., emerge for one or two occasions) even though it has not been reinforced, a phenomenon referred to as spontaneous recovery. Figure 4 shows both the gradual nature of extinction and repeated instances of spontaneous recovery during the intervention and followup phases. The prospect of accidental reinforcement (e.g., attention to the behavior) during these periods requires special caution on the part of parents.

A related issue pertains to Child 3 (in Figure 4), who did not profit from the program. Parents reported difficulty in distinguishing the usual night wakings from those associated with illness of their child. Additional data revealed that these parents attended relatively frequently to nonillness awakenings during the intervention but improved during the first followup phase. The parents cannot be faulted. The pattern of behavior and eventual improvement draw attention to the difficulty

in ignoring behavior and discriminating when behavior does and does not warrant attention. In any case, the demonstration is clear in showing that extinction generally was quite effective in decreasing night waking among infants.

Typically, extinction is used in conjunction with positive reinforcement. The main reason is that the effectiveness of extinction is enhanced tremendously when it is combined with positive reinforcement for behavior incompatible with the response to be extinguished. Also, the gradual effects of extinction, the emergence of the undesired behavior (spontaneous recovery), and untoward side effects are mitigated when extinction is combined with positive reinforcement. A limitation of extinction is that it is not always easy (without functional analysis) to identify what reinforcers are maintaining behavior, especially if the reinforcers are quite intermittent and hence not evident each time the be-

havior occurs. As with the use of punishment, extinction by itself does not teach the positive behaviors to be developed and may be associated with undesirable side effects. For all of these reasons, extinction usually is combined with positive reinforcement for appropriate or prosocial behavior.

Many reports have shown the successful application of extinction alone or in conjunction with other procedures (particularly reinforcement). Hypochondriacal complaints, vomiting, obsessive comments, compulsive rituals, and excessive conversation in the classroom are among the diverse problems that have been treated with extinction and reinforcement. Such applications are particularly noteworthy because they reveal that a number of maladaptive behaviors may be maintained at least in part by their social consequences.

D. General Comments

Interventions based on positive reinforcement, punishment, and extinction, merely sampled in this contribution, have been quite effective among diverse clients, settings, and target behaviors. The effectiveness can be traced to two features of applied behavior analysis. First, the principles of operant conditioning reflect potent influences on behavior. Positive reinforcement, for example, has a strong influence on behavior and has been demonstrated across multiple species and circumstances. Experimental and applied research have identified many of the conditions on which effective applications depend (e.g., immediacy and schedule of delivering consequences). Consequently, there are clear guidelines on how to apply many of the interventions effectively.

Second, the assessment and evaluation of applied behavior analysis contributes directly to program effectiveness. Ongoing measurement is made of client performance, whether the problem is changing, and to what extent. This means that during the intervention, weak, mediocre, or no effects of treatment can be identified and remedied. There are scores of applications in which programs produced mediocre effects. Alterations or additions were made in the program that then achieved the desired changes. Other approaches to treatment usually do not provide ongoing assessment and hence do not have the benefit of this immediate feedback to help decision making in treatment. Related, functional analysis is a special way in which assessment, evaluation, and intervention are interrelated. With functional analysis, the factors that are maintaining an undesired behavior or not supporting a desired behavior can be precisely identified. When functional

analysis is possible, current causes of behavior are demonstrated and the information is used to develop an effective intervention.

V. APPLICATIONS

Perhaps one of the most striking features of applied behavior analysis is the scope of applications. Table 6 samples some of the applications to illustrate the breadth of the approach. Interventions have been carried out in diverse settings such as the home, at school, institutions (hospitals, rehabilitation centers, nursing homes), business and industry, and the community. Indeed, it is safe to say no other psychological intervention or approach has been applied as widely to human behavior.

The focus of behavior analysis is often on the individual. Indeed, this is strongly suggested by reliance on single-case experimental designs. Already mentioned was the fact that these designs can be applied to groups or to interventions implemented on a large scale. For example, one program (Behavior Analysis Follow Through Project) was implemented in elementary school grades over a period of several years and grade levels. The program included more than 7,000 children in approximately 300 classrooms (from kindergarten through third grade) in 15 cities throughout the United States. The program relied heavily on token reinforcement to promote academic performance and several other components, such as instructing children in small groups within the class, using academic curricula that permitted evaluation of student progress, specifying performance criteria for teachers and students, and providing special training and feedback to teachers regarding their performance and the progress of their students. The gains in academic performance of students who participated in the program were markedly greater than were the gains of students in traditional classrooms. Moreover, those gains were still evident two years after the program had been terminated and the children in the program had entered classrooms where token reinforcement was not in effect.

In large-scale programs, as for example with all people who work in a corporation, who live in a particular city or neighborhood, or who live in a dormitory, it may not be feasible to provide consequences (e.g., positive reinforcers) based on the performance of each individual. Difficulties in monitoring individual performance or insufficient resources to administer reinforcers to each individual raise special obstacles. Yet, in such circumstances, group contingencies may play an especially

TABLE 6
Sample of the Scope of Applications of Applied Behavior Analysis

<i>Context/setting</i>	<i>Interventions have been effective in ...</i>
Therapy/treatment settings	Treating a broad range of psychological problems and psychiatric disorders including anxiety (e.g., fears, obsessive compulsive disorders, panic attacks), depression, substance use and abuse (e.g., drug, alcohol, cigarettes), conduct problems, hyperactivity, autism, and eating disorders.
Education	Improving academic performance, studying, achievement, grades, classroom deportment, creative writing, participation in activities, as relevant to elementary, middle, and high school students; mastery of the subject matter at all levels including college students. Many programs in school settings have focused on behaviors beyond the usual domain of education because schools provide a useful place to deliver the interventions. Thus, behavioral programs have been applied to reduce or prevent cigarette smoking, alcohol and drug use, and unprotected sex among adolescents.
Medicine and health	Teaching individuals to detect early signs of disease (e.g., cancer checks through self-examination), protect against sexually transmitted diseases, reduce pain associated with invasive medical procedures (e.g., lumbar taps) or postoperative recovery, and adhere to medical regimens (e.g., for cancer, diabetes).
Business and industry	Teaching workers to engage in practices that reduce accidents (e.g., when using equipment), improve health or overcome problems that compete with health and work (e.g., alcohol use, cigarette smoking). Helping individuals to obtain jobs (e.g., how to seek jobs, interview skills), improve on-the-job performance, reduce absenteeism, tardiness, improve employee customer interactions, and reduce shoplifting among customers.
Sports and athletics	Improving coaching practices, performance of athletes (e.g., in football, gymnastics, tennis, swimming, and track) and stress management among athletes.
Everyday life	Training parents to interact with their children for parents who are in special situations (e.g., handicapped child), for children who are in special situations (e.g., abused, neglected children) and parents without special difficulties or obstacles; training children to engage in safe behaviors (e.g., use of seat belts, crossing streets) or ward off dangerous situations (e.g., responding to would-be abductors). Training the elderly in nursing homes to increase physical activity and engage in more social interactions with others. Training individuals to engage in safe-driving practices, conserve energy in homes, and recycle wastes.

important role. For example, in some business organizations, special incentives are provided if a group (e.g., 90 percent of all employees) engages in a behavior of interest (e.g., donates to a charity, participates in an exercise program designed to improve health). In these situations, the interest in developing a particular behavior across many people lends itself well to group contingencies. The effectiveness of such contingencies is evaluated by charting the behavior of the group rather than the performance of one or a few individuals.

VI. ISSUES AND CHALLENGES

Although interventions based on operant conditioning principles have been extremely effective in diverse applications, many issues and challenges emerge in their application. Two salient issues pertain to the de-

mands of implementing the techniques effectively and the importance of ensuring that the behaviors are maintained and transfer to multiple settings or conditions beyond those in which the intervention program was in effect.

A. Implementation and Program Effectiveness

The principles of reinforcement, punishment, and extinction and the techniques derived from those principles are relatively simple. Moreover, the techniques resemble practices used in everyday life, which make the behavior-change programs deceptively simple. For example, parents who are learning behavioral techniques for managing their children invariably note that these techniques are not new and that they have been using the techniques all along. They often

assert that their use of reinforcement (praise or allowance) or time out (sending the child to his or her room) has not worked. Parents are usually correct in this assertion. Yet, careful inquiry or direct observation of parent behavior in the home reveals that the procedures they have tried are faint approximations of the ways in which reinforcing and punishing consequences are used in applied behavior analysis. For example, positive reinforcers need to be contingent on performance and delivered immediately after behavior and on a continuous or close to continuous schedule, especially at the beginning of the program. As important, the target behaviors need to be carefully specified, so that reinforcement can be applied consistently and the results can be measured to see whether the program is having an impact. Rarely are these conditions in place in the causal applications of incentives or disincentives for behavior (e.g., at home or at school).

Interventions usually require consideration of antecedents, behaviors, and consequences and quite specific ways of delivering consequences. In fact, what distinguishes behavior modification techniques from everyday uses of reward and punishment is *how* the techniques are applied and evaluated. Several conditions influence whether reinforcement, punishment, and extinction are effective, and hence the interventions are more than merely providing some consequence for behavior. Once these conditions (e.g., use of prompts, shaping) are faithfully rendered, one may be in a better position to say that the procedures have not worked.

Interventions based on the principles of operant conditioning bring to bear important influences to change behavior. Yet, the techniques do not always achieve the desired outcomes. There have been many instances in which behavioral programs failed to achieve the desired changes. No change may have occurred, or the change may be too small to make an important difference in the lives of the clients or those with whom they interact. The most common reason for program failures pertains to poor, mediocre, and inconsistent implementation of the contingencies. Interestingly, several studies have shown that slight modifications in the program when clients have failed to respond often produce the desired behaviors. In some cases, the changes occur from implementing the program in ways more conducive to producing change (e.g., more immediate reinforcement). In other cases, the procedures are changed. For example, defiant and aggressive child behavior in the home or at school may not be altered by simply having parents praise appropriate child behavior. The undesired behaviors may not decrease until mild punishment (time out, response cost) is added to the contingencies.

A significant challenge is the training of behavior-change agents (e.g., parents, teachers, staff of the institution, peers who carry out the program). Many successful programs have devoted considerable attention to ensuring that these behavior-change agents are well trained. Once these change agents have been trained, their behaviors are often monitored carefully to ensure that the contingencies are carried out correctly. Without careful training and monitoring, the care with which interventions are implemented may deteriorate over time. Assessment and monitoring of those who implement the intervention may need to become a permanent part of the setting (e.g., school, hospital). For example, large-scale applications of behavioral programs in schools often include assessment and monitoring of teacher and student behavior to ensure that the techniques are implemented correctly and that children are learning. The assessment and supervision practices are central to the effectiveness of the procedures, hence, their incorporation as part of the program is critically important. A major challenge is not just changing client behavior, but also changing the behavior of those responsible for implementing the program.

B. Response Maintenance and Transfer of Training

Interventions discussed in this chapter clearly show that behavior can be changed. Two critical questions are whether the changes will be maintained once the special programs are ended and whether the changes during and after the program will extend to settings, situations, or circumstances that were not included in the program. These concerns reflect response maintenance and transfer of training, respectively. Maintenance of behavior changes might not be expected after an intervention program is ended. If the client responds to changes in the contingencies of reinforcement, one might expect changes to be lost after the intervention is terminated. Similarly, if clients make discriminations about the situations in which the intervention is and is not in effect, one might expect changes in behavior to be restricted to those situations in which the program was in effect.

Early in the development of applied behavior analysis, almost exclusive attention was devoted to changing behavior and indeed seeing whether significant behaviors of impaired populations (e.g., persons with mental retardation or psychiatric disorder) could be significantly helped by the interventions. As change became demonstrated in diverse contexts and settings, further attention was accorded to procedures that can be used during a

program to promote response maintenance and transfer of training. Currently, there are several procedures that can be implemented during an intervention program that help to ensure that the desired behaviors are maintained and are not restricted to situations, persons, or settings associated with the intervention when it was initiated. Table 7 highlights several strategies that are used after behavior has been developed to foster maintenance and transfer of the changes.

As an illustration, transfer of training was systematically trained in one program to ensure that the behaviors extended to the situations of interest after training. In this program, adult mentally retarded women were trained in sexual abuse prevention. Sexual abuse of individuals with mental retardation is a significant problem rarely discussed in the media or in the con-

text of sexual abuse more generally. In this project, the investigators trained women to refuse sexual overtures from others, to say no, to leave the situation, to tell the incident to others, and to use similar behaviors when inappropriate approach responses were made to them. Training was conducted with pairs of women in which they practiced the target behaviors (what they would say and do) in a set of hypothetical situations. Training developed the desired behaviors using role play, practice, feedback, and praise. Then tests were provided in a realistic situation in which an unknown male made approach responses. The results revealed that the behaviors developed in the training sessions but did not transfer very well to ordinary situations. Then training was then conducted in more everyday situations with confederates (research assistants

TABLE 7
Selected Strategies to Develop Response Maintenance and Transfer of Training

<i>Technique</i>	<i>Brief description</i>
Programming naturally occurring reinforcers	After behavior has been established with a special program (e.g., token economy), the consequences that are more readily available in the natural environment (e.g., attention from others) are used to influence behavior.
Gradually removing or fading the contingencies	The intervention can be removed or faded by making the consequences increasingly intermittent or more delayed after the behavior is well established. Also, the intervention can be organized into levels so that as behavior is performed consistently, the incentives increase but there is less frequent and immediate control the contingencies exert over behavior.
Expanding stimulus control	During training, the desired behavior may become associated with specific stimulus conditions such as who administers the program, the setting, or circumstances (e.g., time of the day). After behavior is developed, stimulus control can be expanded by introducing a few other instances or examples (e.g., extending the program to more than one time). Behavior changes can be extended generally in this way and not all conditions or circumstances of interest need to be incorporated into training to achieve broad generalization across conditions.
Training the general case	A systematic way of ensuring transfer of training by specifying the set of stimulus situations across which a behavior is to be performed after training has been completed, defining the range of relevant dimensions or characteristics across which they vary, defining the range of response variations or the different behaviors required across the set of stimulus situations, and selecting and teaching examples that sample from the range of the stimulus and response domains of interest.

Note. For elaboration of these methods, see Kazdin, 2001.

working for the study) who made approach responses. As the behaviors developed, training ceased and assessments were made unobtrusively. The results indicated that the behaviors now carried over to everyday situations. In addition, assessment in everyday situations one month after the program ended indicated that the behaviors were maintained. The study conveys the importance of introducing into training the situations to which one wants the behavior to generalize.

Behaviors occasionally are maintained after the program is ended and transfer to novel settings, even if no special procedures are in place to foster these extensions. However, to ensure maintenance and transfer, special procedures often are introduced before the program is completely ended. Typically several procedures (e.g., as those identified in Table 7) are combined to ensure maintenance and transfer and have been shown to be effective in many applications of treatment.

VII. SUMMARY

Applied behavior analysis refers to an approach toward treatment that includes an emphasis on antecedents, behaviors, and consequences and how these can be arranged to promote behavior change and a methodological approach toward assessment and evaluation. The interventions rely on principles of operant conditioning (reinforcement, punishment, extinction, stimulus control) and the scores of techniques that can be derived from these principles. The scope of interventions has been remarkable and encompasses individuals ranging from infants to the elderly in diverse settings (e.g., home, school, nursing homes, facilities for delinquents, prisoners, psychiatric patients, businesses, and the community at large). Also, many medical (e.g., adherence to medication, recovery from surgery, dieting and exercise), psychological problems (e.g., various psychiatric disorders), and educational objectives (e.g., reading, academic competence) have served as target foci. The diversity of applications derive from the generality of the principles and their well-established bases in laboratory research.

Implementing the techniques that derive from the principles represents a significant challenge. Altering the contingencies of reinforcement has special requirements if behavior change is to be achieved. Consequently, the seeming simplicity of the interventions is deceptive. A program involving praise or token reinforcement for behavior can easily succeed or fail based on how systematically and consistently the consequences are provided. The special feature of applied behavior analysis that also

contributes to the effectiveness of the interventions pertains to the systematic assessment and evaluation of behavior-change programs. Collection of ongoing data while the program is in effect allows one to make changes to ensure that the desired outcomes are achieved.

GLOSSARY

application training The use of rapid relaxation in anxiety-arousing situations to reduce and eventually abort anxiety reactions.

cue-controlled relaxation The association of the cue “Relax” with the state of relaxation.

differential relaxation Practicing being relaxed in those muscles not necessary to tense for the activity at hand.

progressive relaxation The tensing and relaxing of 23 major muscle groups.

rapid relaxation A very brief relaxation used in natural situations to become relaxed quickly (20–30 seconds).

release-only relaxation Relaxing the muscle groups without the prior tension.

I. DESCRIPTION OF APPLIED RELAXATION

A. General Features of Applied Relaxation

Applied relaxation (AR) is a cognitive-behavioral coping technique first described by Chang-Liang and Den-

ney in 1976 and later extensively developed by Lars-Göran Öst during the late 1970s and early 1980s. Applied relaxation takes as its starting point the abbreviated progressive relaxation (PR) developed by Joseph Wolpe in the 1950s as part of systematic desensitization. However, PR is not suitable as a coping technique since it takes 15–20 minutes for the patient to go through the various muscle groups in order to become relaxed. The relaxation has to be reduced into a “portable” skill that patients can use in any situation when needed. Applied relaxation is a technique that in a number of steps teaches patients to relax rapidly, the goal being 20–30 seconds, in natural situations where their problems occur.

The first step of PR training, usually takes 2 weeks of practice and the time to become relaxed is 15–20 minutes. The second step, release-only relaxation, is commonly practiced for 1 week and the time to relaxation is reduced to 5–7 minutes. The third step, cue-controlled relaxation, also requires a week of practice, and relaxation is achieved in 2–3 minutes. The fourth step is differential relaxation, which is practiced for 2 weeks and relaxation is achieved in 1 minute and the time is reduced to 1 minute. The fifth step, rapid relaxation, is also practiced for 2 weeks allowing the patient to become relaxed in 20–30 seconds. The final step, application training, usually takes 2 weeks, and now the rapid relaxation is used in natural anxiety-arousing situations.

1. Rationale for AR

In any cognitive behavior therapy it is important that patients understand the rationale for the treatment in

question. The therapist should give an easily understandable theoretical description regarding the patient's problem and a description of how AR is scheduled and supposed to work. When presenting the treatment rationale it is also useful to give the patients a written version (1–2 pages) that they can read during the presentation and take home to examine more carefully. Below is an example of a rationale that might be used in the treatment of a person with panic disorder.

During a panic attack you are likely to feel very anxious and experience a lot of symptoms, such as palpitations, muscle tension, sweating, breathlessness, and dizziness. Usually, the attack seems to come “out of the blue” in other words without warning, making you want to leave the situation. As you leave and get home to safety the symptoms dissipate, but you are usually exhausted and fear what will happen the next time you have a panic attack.

There is a treatment method called AR that can help you cope with and eventually stop the anxiety symptoms altogether. The first thing you do in this treatment is to observe your panic attacks in order to become aware of the very first sign(s) of a panic attack coming on. The observations are recorded in a panic diary, and over the next couple of months you will realize that even if the panic attack starts rapidly there is usually a period of 30–60 seconds between the first sign and the full-blown panic attack. It is during this period you have a chance to do something to prevent the symptoms from developing further, such as “to nip it in the bud.” Thus, these signs are used as an “alarm clock” to apply a relaxation technique that will counteract the anxiety symptoms.

Most patients wonder how it is possible to relax in such a short time? What you do in AR is to start by learning PR which takes 15–20 minutes. In PR you briefly tense and then relax the big muscle groups of your body. After practicing that for two weeks you then work on relaxing by using the release-only procedure, omitting the muscle tensing portion of the technique. This reduces the time it takes for you to get relaxed to 5–7 minutes. The next step is called cue-controlled relaxation, a step in which you learn to associate the self-instruction “Relax” with the state of relaxation. Then follows differential relaxation with the purpose of teaching you to do various activities while being relaxed in the muscles that don't have to be actively engaged in those activities. In this phase you might practice relaxing while sitting, standing, and walking. The next step is called rapid relaxation, which usually takes 20–30 seconds, and during this step you practice to relax in natural, but not anxiety-arousing situations.

In the final phase, application training, you apply the skill of relaxing rapidly in those situations in which panic symptoms occur. Over the 8–10 weeks of training you record your panic attacks in the panic diary. This monitoring results in a lot of information about the first signs that tell you a panic attack is coming on. By applying rapid relaxation as soon as you experience the first sign you will learn that you can stop the anxiety symptoms from escalating to a high level. After a few weeks you will be able to abort the first signs or symptoms altogether. When the panic attacks have disappeared you will have the opportunity to follow a maintenance program to keep your relaxation skill fine tuned and ready to apply whenever you may need it in the future.

After the therapist has provided the treatment rationale patient questions are answered. The patient is then encouraged to take the written description home and read it carefully in order to discuss it with the therapist at the next session, during which time the treatment starts.

2. Homework Assignments

Since therapists usually only see patients once a week, the relaxation training requires that patients practice at home twice per day the skills presented in session. Practice is recorded on self-monitoring forms provided by the therapist. On these forms the patient records the degree of relaxation experienced immediately before and after the practice, the approximate duration of the practice, and any comments the patient may have. The scale for rating the degree of relaxation is a 0–100 scale, where 50 is the “normal state” (neither relaxed nor tense). A 0 means complete relaxation and 100 means maximal tension/anxiety. The same form is used for the first four steps of AR training, while alternative forms are used during rapid relaxation and application training.

It is also important to realize that it is rare to find patients that can complete every weekly practice assignment. Patients are instructed to make a note regarding the reason for missing a practice session. Furthermore, it is emphasized that it is better to practice only once a day in a calm and nonstressful situation than twice a day if both practice occasions are carried out during a fairly high level of time pressure. If patients do not have time to practice more than once a day, treatment will take longer.

3. Transitions

Patient records of the relaxation training progress at home serve as the therapist's guide in deciding when it is time to proceed to the next step in treatment. When patients experience an average increase in relaxation

from immediately before to after homework practice of 20–30 points, such as a prerating of 50 and a postrating of 20–30 on the 0–100 scale, it is time to continue. It is not necessary for patients to achieve very high levels of relaxation (ratings of 0–10) in order for the AR skill to be acquired.

B. Observation of Early Signs of Anxiety

In order for applied relaxation to work optimally patients must use the relaxation technique as early as possible in the response to an anxiety reaction or a panic attack. Reacting quickly to the first signs of anxiety greatly increases the patients' ability to employ AR effectively. In order to increase the patient's awareness of the initial signs of anxiety, homework assignments involve observing and recording these reactions. In the panic diary the patient records the situation, the symptoms of the panic attack, and the severity of the attack (0–100), as well as the very first signs that were experienced.

Therapist and patient examine the panic diary and focus on identifying the earliest signs of the onset of the panic attacks. An attempt is made to determine what the patient felt, thought about, or did just before the first symptom occurred. Sometimes it can be advantageous to let patients imagine their most recent panic attack. This procedure often assists patients in remembering things that they did not notice while recording the actual attack. Besides making the patient more aware of the early signs of anxiety, it is important to get an approximate estimate of the time between the first sign and the peak of the panic attack. As patients realize that this time period is perhaps as long as 30 seconds to several minutes, confidence that they will be able to apply AR to the early signs of anxiety and prevent it from developing into a panic attack begins to grow.

It is valuable to collect and summarize the reported early signs of anxiety. These recordings provide a database for use later in treatment. In particular, in the application phase of AR these data will allow the therapist to present to patients a systematic summary of early signs ranked by frequency and perhaps divided according to some systematic grouping. This list will prove useful as patients begin to apply AR in real life situations.

C. Progressive Relaxation

Before starting PR training, patients should be given a rationale for the PR. It should be noted that PR is easily learned and does not require any special abilities.

The method involves learning to relax by first tensing and then relaxing different muscle groups in the body. Briefly tensing muscles makes it easier to experience the contrast between a tensed and a relaxed muscle, and to notice tension in various muscles during daily activities. The different muscle groups that are included can be conceived of as a menu from which patients can choose. There is absolutely nothing sacred about the constellation of muscle groups. The important thing is that as patients achieve a high degree of relaxation, they need not always follow the PR instructions to the letter. For some patients the tensing/releasing of a certain muscle group can lead to an experience of increased tension in that muscle. If that is the case, that particular muscle group may be deleted from the relaxation training.

Progressive relaxation training begins with demonstrating to patients exactly how the different muscle groups are to be tensed and relaxed. The therapist sits opposite the patient and models the procedure across the different muscle groups, while the patients simultaneously perform these behaviors. Below is a list showing the muscle group and the order in which tensing/relaxing exercises are presented.

1. Tense your right hand (make a tight fist)
2. Tense your left hand (make a tight fist)
3. Tense both hands (make tight fists)
4. Tense your biceps
5. Tense your triceps (stretch your arms without lifting them)
6. Wrinkle your forehead by raising your eyebrows
7. Wrinkle your eyebrows (bring them tight together)
8. Close your eyes tight
9. Tense your jaw muscles by biting your teeth together
10. Push the tip of your tongue against the roof of your mouth
11. Press your lips together
12. Push your head back against the top of the chair
13. Bend your head forward, touching your chin to your chest
14. Raise your shoulders towards your ears
15. Raise your shoulders towards your ears, and move them in a circular motion
16. Breathe with calm regular breaths
17. Take a deep breath; fill your lungs and hold your breath
18. Tighten your stomach muscles
19. Pull your stomach inward
20. Bend your back in a curve

21. Tense your thighs by pressing your heels to the floor
22. Point your feet and toes down (forward)
23. Point your feet up towards your face

During relaxation training patients are prompted to sit as comfortably as possible, loosen tight fitting clothes, and close their eyes. Room lights can be dimmed and the therapist's tone of voice should be low and somewhat monotonous, without being sleep inducing. Furthermore, it is important to remember that it is the relaxation and not the tension that is the important part of PR. The tension is only included as a contrast to the relaxation. The relation between the duration of time the patient tenses and relaxes the different muscle groups must be 1:2 or 1:3; that is, if a muscle is tensed for 5 seconds, the following relaxation interval should be at least 10–15 seconds.

D. Release-only Relaxation

The introduction provided before the start of the release-only phase of PR is that this step is intended to reduce the time it takes for the patient to become relaxed from 15–20 minutes with the PR to about 5–7 minutes, and to help them learn to relax without having to tense muscle groups. Patients are told they will be instructed to focus on the different parts of the body and are asked to relax as much as possible. If, after having tried to relax they still feel tension in a muscle, they should tense the muscle briefly and then relax it (such going back to the procedure used during the PR). During this phase of training the therapist adjusts the instruction to a pace which allows patients time to perform the tension-release exercises when necessary.

Below is an example of the instructions used in this phase: "Breathe with calm, regular breaths and feel how you relax more and more with each breath ... Just let go Relax your forehead ... eyebrows ... eyelids ... jaws ... tongue and throat ... lips ... and your entire face Relax your neck ... shoulders ... arms ... hands ... and all the way out to your fingertips Breathe calmly and regularly ... and let the relaxation spread to your stomach ... waist and back Relax the lower part of your body, your buttocks ... thighs ... calves ... feet ... and all the way down to the tips of your toes Breathe calmly and regularly and feel how you relax more and more with each breath ... Continue to relax like that for a while [Pause for about 1 minute.] Now take a deep breath, hold it ... and let the air out slowly ... slowly ... Notice how you relax more and more."

E. Cue-Controlled Relaxation

The purpose of cue-controlled relaxation (CR) is for the patient to learn to associate the self-instruction "relax" with a relaxed state, and further reduce the time it takes to become relaxed. Cue-controlled relaxation may be introduced to patients as follows: "Most of us have probably been in situations where we or an acquaintance have been very nervous. In that situation we often get the advice to 'take it easy and relax.' This advice very seldom works since it is given when we are already mentally and physically at a high arousal level. In order to relax in these situations you must practice pairing the relax self-instruction with the relaxed state. Once you can successfully make yourself relaxed, you then need to start practicing this cued relaxation in increasingly more stressful settings."

The session starts by the patient relaxing on their own with the help of the release-only version of PR, which the patient has been practicing for 1–2 weeks. When having achieved a deep degree of relaxation the patient signals the therapist by lifting one index finger. Focus in CR is on the breathing and in following the therapist's instructions on the pace of their breathing pattern. Just before breathing in, the therapist says "inhale" and just before breathing out, the therapist says "relax." This is done 4–5 times. Then the patient is instructed to think "inhale" and "relax" silently in pace with the breathing rhythm. After the patient has been doing this on their own for about 2 minutes, the therapist comes back with the instruction "inhale ... relax" a further 4–5 times, after which the patient takes over and does this exercise covertly for a couple of minutes. This practice sequence only takes about 10 minutes and after a break of 10–15 minutes during which one can do other things (such as going over the panic diary), it is suitable to repeat the entire instruction during the session.

F. Differential Relaxation

1. Introduction to Differential Relaxation

In order for AR to be an effective coping skill it must be "portable," The patient should be able to use it in practically any situation and not be constricted to a comfortable armchair in the home or in the therapist's office. The primary purpose of differential relaxation (DR) is to teach the patient to relax in other situations besides in the comfortable armchair. The secondary purpose of DR is to learn not to be tense in the muscle groups not being used for the activity at hand.

2. Instruction of Differential Relaxation

The session starts with the patient sitting in the armchair relaxing on their own with the help of CR. When the patient has signaled that they are relaxed, they then follow the instruction to perform certain movements with different parts of the body while at the same time concentrating on being as relaxed as possible in the rest of the body. During the performance of these movements the patient should scan the body often (i.e., think through the different muscle groups) in order to discover possible tensions, and in that case they should relax away these tensions. After the patient has signaled that they are relaxed the following instruction is given.

“Continue to relax as much as possible in the entire body. While you do that ... open your eyes and look around in the room without moving your head. Look to your left ... and to your right ... up to the ceiling ... and down to the floor. Concentrate on relaxing as much as possible in the rest of the body ... Now do the same thing but also turn your head in order to take in a larger field of vision. Look to the left ... and to the right ... up to the ceiling and down to the floor. Good! Take the head back to a comfortable position and relax as much as possible. Let your arms rest against the elbow rests and now lift the right hand a bit from the support. Concentrate on the relaxation in the left hand and arm ... now stretch the arm straight out ... and straight up in the air ... focus on the relaxation in the left arm ... and now take the right arm back to a comfortable position on the armrest. Relax as much as possible in your right arm and do the same thing with the left arm. Lift the left hand a little bit from the armrest. Concentrate on the relaxation in the right hand and arm ... Now stretch the arm straight out ... and straight up in the air ... Focus on the relaxation in the right arm ... and take the left arm down to a comfortable position on the armrest. Relax as much as possible in the left arm and the entire body ... Now bend the right foot up towards the face while you concentrate on relaxing in the left foot ... and stretch the right leg straight out. Focus on the relaxation in the left leg ... and take the right leg down and relax. Relax as much as possible in the right leg and now do the same thing with the left leg. Bend the left foot up towards the face while you concentrate on relaxing in the right foot ... and stretch the left leg straight out. Focus on the relaxation in the right leg ... and take the left leg down and relax. Relax as much as possible in the left leg and the entire body; the head, the arms, the chest, and legs.”

After finishing the instruction you should ask the patient to note the degree of relaxation after using CR

when signaling to the therapist, before starting to do the movements, and after all the exercises have been completed. What you often find is that the patient has achieved a good degree of relaxation and performing the movements has not led to less relaxation; in many cases the relaxation has instead been deeper after the exercises. You should also ask the patient to estimate how long it took them to become relaxed, which almost always gives the instructor the chance to praise the patient for achieving the relaxation in a shorter time than was estimated.

3. Further Steps in Differential Relaxation

After practicing in an armchair, the same procedure is repeated while the patient is sitting in an ordinary chair. Then you can let the patient sit in an office chair by a desk and perform various activities that are natural to that situation, such as writing, typing, and making phone calls. These three components usually cover one session and during the next session you proceed by teaching the patient to relax while standing, and doing the same activities as while sitting, except for the use of their legs. Finally, the patient should practice being relaxed while walking. In this situation it is an advantage to have a fairly long corridor to practice in.

G. Rapid Relaxation

1. Introduction to Rapid Relaxation

The purposes of rapid relaxation (RR) are to teach the patient to relax in natural but not anxiety-arousing situations, and to further reduce the time it takes to become relaxed. The goal for this is 20–30 seconds. In order to reach these goals the patient should use rapid relaxation 15–20 times a day in natural situations. At this stage it is very important that the therapist spends some time to thoroughly go over the goals with the patient and to write down suitable situations that function as signals for RR training. The therapist asks the patient to describe what an ordinary day looks like to them and what they do between getting out of bed in the morning through going to bed at night. Among those activities that the patient does one can choose signal situations in such a way that it make up at least 15 practice occasions per day.

2. Instruction of Rapid Relaxation

When the patient is relaxing in natural situations during this phase of AR the relaxation has largely been reduced. The patient is instructed and the therapist models the following sequence:

1. Take a deep breath and slowly let the air out
2. Think "relax" quietly each time you breathe out
3. Scan your body for any signs of tension and relax as much as possible in the situation
4. Stay in the relaxed state for 30–60 seconds.

If, after doing all the above, the patient still feels that they haven't achieved a deep enough degree of relaxation, one can take one more deep breath as described above. In some cases the entire sequence can be repeated for a third time. After this the patient should be content with the degree of relaxation achieved. Otherwise there is a risk that the patient will trigger symptoms of hyperventilation, which of course counteracts the purpose of RR.

H. Application Training

1. Introduction to Application Training

The only rationale you give the patient at this stage is that it is now time to start practicing in reality what they have learned in theory. Before starting this phase it is very important to give the patient an instruction that sets their expectations at the right level. You remind the patient that applied relaxation is a skill and as with any other skill it takes practice to refine it. This means that the patient should not expect that AR functions at 100% the first time it is applied, such as with a panic attack. Instead, one must be satisfied with the anxiety not increasing as much as it had before, but that it levels out at a mild to moderate level. It is very important that the patient does not get demoralized but that they continue to apply AR every time they are in an anxiety situation. Relatively soon one will notice an effect from AR, and eventually the anxiety reactions will dissipate altogether.

Before the patient goes out into real life situations and starts applying the relaxation in these situations, one must go over the list of early signs that the therapist has put together during the course of the treatment. First, the patient should try to describe by heart the early signs that have been recorded during their panic attack. Second, the patient should be given the list that the therapist has collected as a memory aid for them to start applying the relaxation technique in real-life situations. In this way, the patient's awareness of these early signs is increased directly during the phase where the application is going to take place.

2. Practical Application Training

A majority of panic patients do not think that they have a need for any special form of application training.

For these patients it is enough to give them a rationale before starting the application training. This is to get their expectations at the right level, after which they are confident enough to start applying the relaxation skill in real life panic situations.

In some panic patients it has turned out to be useful to provoke a "mini-attack" during therapy for which one can practice applying AR. In this situation different methods to provoke a panic reaction can be used and the choice of the method used is dependent on which of the techniques most readily provoke panic symptoms in the patient. Voluntary hyperventilation during 1–2 minutes with 30 breaths per minute will in 50–60% of the patients produce symptoms that remind them of, or are the same as, a naturally occurring panic attack. If this technique is used, it is appropriate to let the patient breathe normally using stomach breathing instead of taking a deep breath at the beginning of rapid relaxation, since the latter might be a continuation of the hyperventilation. Another technique that can be useful in some patients is using physical exercise such as letting the patient run up and down the stairs for a couple of minutes in order to get them to palpitate, which in turn one fears is the beginning of a panic attack. In patients where dizziness is an important panic symptom one can spin the patient around on an office chair for 20–30 seconds.

One further possibility is to let the patient imagine a difficult panic attack that has occurred to them before or during treatment. In this situation it is suitable to have the therapist describe the situation and the panic symptoms to the patient and letting the patient signal by raising a finger when they experience the first sign of anxiety in the current situation. When the patient has signaled, one should let them keep the image of that situation for a while (4–5 seconds) and then you should instruct the patient to stop thinking about the described situation and use AR to counteract the reactions.

II. THEORETICAL BASIS FOR APPLIED RELAXATION

So far there are no developed theoretical models to explain the mechanism of AR. However, it is possible to use a modification of the type of vicious circle explanation that has been developed for cognitive therapy in panic disorder. This model assumes that independently of what kind of an eliciting stimulus or what type of initial reaction follows there is an interaction between physiological and cognitive reactions, culminating in a

panic attack. The purpose of AR is to break the vicious circle as quickly as possible in order to stop the first signs of anxiety from escalating into a panic attack. As the patient starts using the application skill they are fully occupied by concentrating on that skill and thus the probability is lower that the chain of negative thoughts will start to develop.

Since there are no studies regarding the mechanism of change for AR at this time one can only speculate concerning this issue. Personally, I believe that AR works through the patient having acquired the skill to rapidly achieve a state of relaxation, which counteracts the anxiety reactions both on a physiological and a cognitive level. Perhaps Bandura's self-efficacy theory can be used in this regard. There are at least three contributing factors which cannot be disregarded:

1. *The reduction of the general tension level in the body.* As this happens the probability is reduced that small stressors will, when they are added to the ambient tension level, lead to the patient ascending over the panic threshold.

2. *Increased awareness and knowledge about anxiety reactions.* As the patient learns to identify early signs of anxiety they will learn more about what anxiety is and experience it in a more differential way instead of a "big black lump" or "lightning out of the blue."

3. *Increased self-confidence.* By using the relaxation skill in natural situations and noticing that it works, one can reduce or abort the anxiety altogether. The patient develops an increased confidence in their own ability to do something proactive. The patient is no longer a helpless victim of panic.

III. APPLICATIONS AND EXCLUSIONS

Applied relaxation is a coping technique that was primarily developed for the treatment of nonsituational anxiety or panic attacks. However, research and clinical applications show that it is a method that is useful for many different disorders.

In randomized clinical trials, AR has been evaluated for specific phobias such as social phobia, agoraphobia, panic disorder, generalized anxiety disorder, tension headache, mixed headache, migraine, pain (low back and upper extremities), epilepsy, tinnitus, Ménière's disease, hearing impairment, nonulcer dyspepsia, and also to improve the immune defense system in cancer patients. Furthermore, nonrandomized pilot studies

have evaluated AR for stress reactions, insomnia, menopausal symptoms, genital herpes and as a stress-management technique for collegiate field hockey players, soccer players, and novice rock climbers.

In some of the disorders, not including anxiety, a combination of AR and other behavioral methods have been used. In general, AR seems to be a suitable treatment method for problems where the main component is anxiety or stress reactions, or at least is an important part of the problem. Different physiological reactions should also be part of the problem picture of the patient.

So far there are no direct contraindications in the research or clinical application of AR. The fact that AR has been used for schizophrenic patients, without the predicted "psychotic breakthrough" that psychodynamic therapists talk about, speaks for its utility in a wide range of psychiatric, psychosomatic, and somatic problems.

IV. EMPIRICAL STUDIES

There are 33 studies published between 1981 and 2000, 15 of those studies included various anxiety disorder patients, while the remaining 18 focused on different somatic disorders (headache, pain, epilepsy, tinnitus, Ménière's disease, hearing impairment, dyspepsia, and cancer).

In 19 of the studies, AR was compared to a control condition (waitlist or attention-placebo). In all instances, AR yielded significantly better results.

These studies contain 28 comparisons between AR and another active treatment. AR was found significantly more effective than progressive relaxation in panic disorder, than cognitive treatment in agoraphobia, and nondirective therapy in generalized anxiety disorder. AR was less effective than cognitive therapy in two studies of panic disorder.

AR was found as effective as exposure in claustrophobia, blood phobia, and agoraphobia; as with cognitive therapy in panic disorder, GAD, and tinnitus; as with self-instructional training in social phobia and dental phobia; as with social skills training in social phobia; as with applied tension and the combination of AR and applied tension in blood phobia; as with imipramine in panic disorder; as with anxiety management training for anxiety in schizophrenic patients; as with the combination of AR and cognitive therapy in GAD; as with progressive relaxation in mixed headache; as with biofeedback and the combination of

AR and biofeedback in pain; as with the combination of AR and an operant program in pain; and as with transcutaneous nerve stimulation in Ménière's disease. Finally, the combination of AR and an operant program was as effective as CT and the operant program, and the operant program alone, in pain patients. This combination was also more effective than regular treatment in another study of pain patients.

The conclusion that can be drawn from this is that (with two exceptions) AR is more effective than, or as effective as, other well established treatment methods for various anxiety disorders and psychosomatic/somatic disorders.

Twenty-four of the 33 studies report follow-up results on average 11 (range 4–24) months after the completion of treatment. A comparison of the percent improvement on the most important measure in each study showed that the mean pre-post change was 53% and the mean pre-follow-up change was 60%. Thus, not only were the treatment effects for AR maintained almost a year after treatment, but there was a small further improvement during the follow-up period.

V. SUMMARY

Applied relaxation is a coping technique consisting of a series of steps which teaches the patient to reduce the time it takes to become relaxed from 15–20 minutes to 20–30 seconds and to apply this skill in naturally occurring anxiety situations. The treatment usually takes 8–10 weeks to complete and clinical experience and research show that 90% of the patients acquire the skill of being able to relax rapidly. While first developed for nonsituational anxiety disorders, AR has successfully been applied to other anxiety disorders as well as various psychosomatic and somatic disorders, such as headache, pain, epilepsy, tinnitus, dyspepsia,

and cancer. A summary of the randomized clinical trials shows that AR is significantly more effective than control conditions and as effective as various well-established treatment methods with which it has been compared. Follow-ups, on average 11 months after the end of treatment, show that not only have the treatment effects been maintained, but also on average there is a further improvement.

GLOSSARY

application training The application of the tension technique when experiencing the early signs of a blood pressure drop while being exposed to blood stimuli.

blood-injury-injection phobia The fear and avoidance of seeing blood, injuries or receiving an injection or other invasive medical procedures.

diphasic pattern The initial increase followed by a sharp decrease of blood pressure when exposed to blood stimuli.

early signs The very first (idiosyncratic) signs that the blood pressure is dropping.

tension technique The tensioning of the arms, the chest, and the leg muscles.

I. DESCRIPTION OF APPLIED TENSION

A. General Features of Applied Tension

Applied tension (AT) is behavioral coping technique, first described by Kozak and Montgomery in 1981 in a

case study and later developed within Öst's research project on the treatment of blood-injury-injection phobia. It consists of two components: the learning of an effective tension technique, and the application of this technique while being exposed to blood-injury stimuli. In its original form AT is a five-session treatment with homework assignments to carry out between sessions, but later research has shown that a one-session (2 hours) version is as effective. Both versions will be described.

B. The Physiological Response Pattern

When a patient with a specific phobia encounters the phobic stimuli the typical response pattern is an immediate activation of the sympathetic branch of the autonomic nervous system (i.e., increase of heart rate, blood pressure, skin conductance, etc.). If the patient remains in the situation there is a gradual reduction back to baseline levels. In contrast to this, patients with blood-injury phobia, and to a lesser extent those with injection phobia, usually show a diphasic pattern. After an initial increase in blood pressure and heart rate there is a sharp decrease in these variables, which eventually leads to fainting when the cerebral blood pressure has fallen below a critical level. This is illustrated by Figure 1 describing the blood pressure of a blood phobic patient treated in our clinic. The 10-minute baseline shows a rather stable systolic blood pressure (SBP) around 120 mmHg and diastolic blood pressure (DBP)

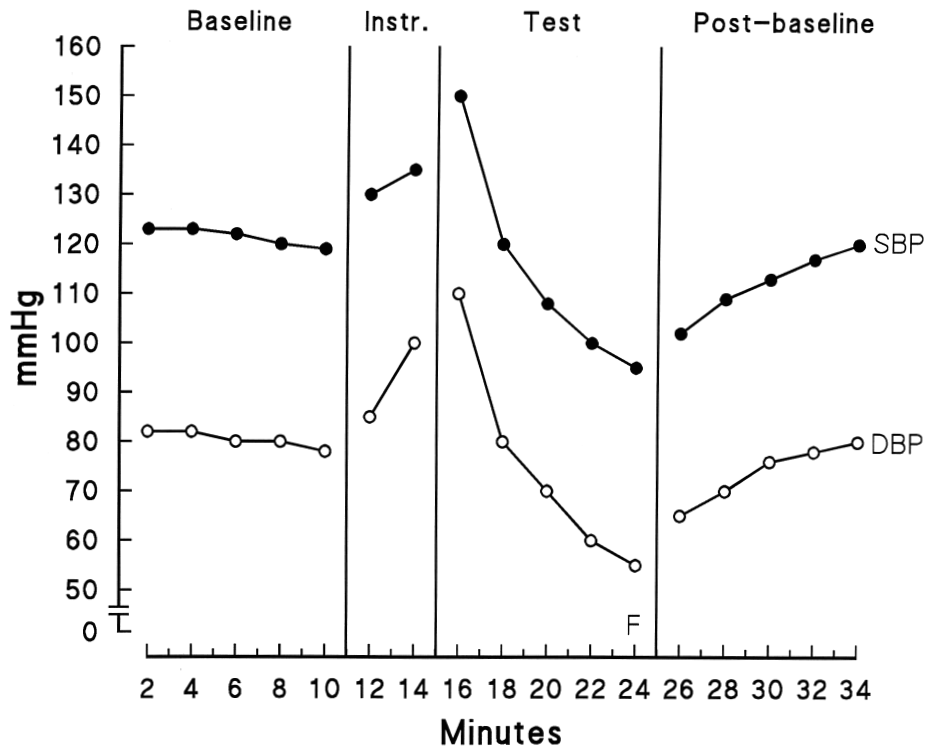

FIGURE 1 Systolic (SBP) and diastolic (DBP) blood pressure during the different phases of the blood phobia test situation. Baseline = 10 minutes rest, Instr. = instruction about the upcoming test and waiting for it, Test = watching a 30-minute videotape of thoracic surgery, Post-baseline = 10 min of recording after the patient had regained consciousness, F = fainting.

around 80 mmHg. During the 4-minute instruction phase there is an increase in both SBP (to 135) and DBP (to 100), which is continued during the first assessment of the test period (150 and 110, respectively) when the patient is watching a videotape of thoracic operations. This is the first phase of the diphasic reaction. Then there is a drop in both SBP (to 95) and DBP (to 55) 10 minutes into the tape when the patient fainted. This is the second phase. During the post-baseline there is a gradual recovery back to baseline levels.

There are different hypotheses in the literature attempting to explain this diphasic response pattern but so far none has very much research evidence.

C. Rationale for AT

After having described the diphasic pattern the therapist gives the following explanation of how AT is going to work.

Since the second phase of the response consists of the drop in blood pressure your blood flow in the brain is

also reduced and before fainting you will feel dizziness and other fainting sensations. In order to reverse this progression you need to acquire a coping skill that can be applied rapidly in any situation which triggers these sensations. Applied tension is this skill which produces an increase in blood pressure and cerebral blood flow. The method has three parts: (1) learning the actual tension technique, (2) learning to identify the very first signs of the drop in blood pressure, and (3) applying the tension technique when being exposed to various blood-injury stimuli that trigger the fainting sensations. The tension technique consists of tensioning the large body muscles; the arms, the chest, and the legs for short periods of time. By being exposed to different stimuli under my supervision you will gradually be more and more efficient at identifying the early signs and apply the tension technique so that the reduction in blood pressure will not be so dramatic, and you will get the curve to turn upward. The tension technique is easy to learn but like any other skill it takes practice to master it. You cannot expect to be perfect at it at once but with experience you will be better and better. The goal is that you should be able to encounter these situations without having stronger reactions than people in general.

After giving a rationale like this the therapist should encourage the patient to ask questions if there is something that is not clear to him or her. One frequently asked question is what happens if the first signs come on very rapidly and I am not good or quick enough to prevent the fainting; will everything be in vain? The answer is that it is no disaster if you faint during a therapy session. On the contrary, this will give you the opportunity to practice applying the tension technique as soon as you regain consciousness. Then you will learn that you recover much more rapidly than you have done so far, in 15 to 20 minutes instead of 3 to 4 hours.

D. Outline of the Treatment Program

1. The First Session

The initial part of session 1 consists of a behavior analysis concerning the patient's experiences when encountering blood-injury stimuli. This should focus on what the patient usually does in the situation, if he or she has fainted, how often this has occurred, how long the patient has been unconscious, and particularly what were the symptoms that the patient experienced before fainting. These early signs can be idiosyncratic, for example, dizziness, cold sweat, tunnel vision, ringing in the ears, a queasy sensation in the stomach, and nausea. It is important to list these symptoms carefully and in their order of occurrence since they are used as cues for applying the tension in later sessions. After having completed the behavior analysis the therapist describes the rationale as outlined earlier.

The last part of the first session consists of teaching the patient the correct tension technique. However, before starting with this it is imperative to assess the patient's blood pressure to get a baseline measure before tensing and to rule out high blood pressure. Then the therapist models the tension technique by sitting in front of the patient and showing him or her to tense the gross body muscles—arms, chest, and legs—and to keep tensing for 10 to 15 seconds, or long enough to feel a sensation of warmth rising in the face. Then the tension is released and the patient goes back to normal without attempting to relax. After a pause of 20 to 25 seconds there is a new tension of 10 to 15 seconds followed by a release and pause. After five cycles of tensing–releasing the therapist once more assesses the patient's blood pressure, and usually this will indicate an increase from baseline with 4 to 5 mmHg of DBP and 8 to 10 mmHg of SBP.

As homework assignment the patient should do five practice sessions per day, which only takes about 4 minutes when it includes five cycles as described above. One

problem that a few of our patients have reported while carrying out the homework is headache. This is probably due to a tension that is too intensive and/or too frequent, and is solved by instructing the patient to reduce both intensity and frequency of the tension practice.

2. The Second and Third Sessions

During the second and third session the patient is shown a series of slides (about 30) of wounded or mutilated people. When the first slide is shown on the screen in front of the patient he or she is instructed to introspect and scan for the very first sign that the blood pressure is dropping, while watching the picture. As soon as the first symptom is detected the patient describes what it is, and if the reaction is not too strong the therapist assesses the patient's blood pressure to obtain a pretensing level. Then the patient applies the tension and keeps applying it (with brief periods of release) until he or she can watch the slide without experiencing the symptom. Then the therapist once more assesses the blood pressure to obtain a post-tensing level, and at the end of the session pre- and post-tensing levels can be compared. When the patient can watch the slide for about a minute it is time to continue with the next slide and repeat the process. The aim is to complete the first 15 slides during session 2 and continue with the next 15 slides during session 3.

During these two sessions the job of the therapist is very similar to a sports coach: setting the stage for the initial BP drop, encouraging the patient to observe the first signs, and coaching him or her to apply the tension technique quickly enough and persistently, in order to reverse the physiological response.

Between sessions the patient has the same homework assignment as after the first session, that is, five practice occasions of tension–release tension per day.

3. The Fourth Session

For the fourth session the patient is taken to the hospital's blood donor center in order to provide him or her with a natural situation in which the application of tension technique can be practiced. To begin the patient is guided around the center by a nurse who also describes how the blood is managed. Then the patient watches other blood donors donating blood, and finally has a blood sample of his or her own withdrawn. The purpose of this is to assess if the patient is suitable to become a blood donor, since donating blood regularly is one way in which the patient can maintain the skill he or she has acquired during the treatment period.

One problem that might arise is if the patient has to use the tension technique during the venipuncture,

which may make it difficult, or impossible, for the nurse to draw blood. The therapist should anticipate this problem and teach the patient differential tension, that is, to be relaxed in the nondominant arm while at the same time tensing the dominant arm, the chest, and the legs.

4. The Fifth Session

For the final session the patient is brought to the department of thoracic surgery at the university hospital where he or she can observe an open-heart or lung surgery from an observation room one story above the operating theater. During this session the patient has many opportunities to practice application of the tension technique, and the therapist's primary responsibility is to coach the patient to do so. Should the patient faint, which rarely happens, the therapist will help the patient to regain consciousness and then use the tension technique for a while in order to be able to resume exposure to the operating scene as soon as possible. First the patient should be lying on the floor, then sitting on the chair but turned away from the operating table, and then gradually turning toward it while tensing continuously if necessary.

5. The Maintenance Program

At the end of session 5 the therapist describes the maintenance program to the patient. This starts with a review of the progress that the patient has made so far, and then follows a description of what the patient could do in the next 6 months in order to maintain, and further, this improvement. An agreement is made between therapist and patient that the latter should continue exposing himself or herself to blood-injury stimuli at least twice a week. Examples of situations are looking at pictures of wounded people, watching TV programs of surgical procedures, talking to others about such things, watching others donate blood, and donating blood oneself. The patient has specific forms to fill out and mail to the therapist once every four weeks. Upon receiving a form the therapist calls the patient on the phone and talks with him or her for 10 to 15 minutes about the experiences of the past period. The patient also is taught the difference between a setback and a relapse, and is given a set of instructions on what to do in case a setback occurs.

E. A Brief Version of AT

In an attempt to investigate whether the five-session version of AT described above could be abbreviated into a one-session treatment a study was undertaken in my clinic. The one-session AT was maximized to 2 hours, since pilot cases indicated that the large amount

of muscle tension during an ordinary 3 hour session would lead to quite a lot of muscle soreness. This would, in turn, make it difficult for the patient to focus the concentration on what is necessary (i.e., observing the very first signs of drop in blood pressure).

The one-session AT starts with the same rationale as above. Then follows 15 minutes of tension training with the blood pressure assessment before and after to demonstrate to the patient that he or she can increase the blood pressure in a nonexposure situation. The application training uses 10 of the 30 slides used for the five-session AT, but the procedure is the same as described earlier. If time permits further exposure to blood-injury stimuli can consist of talking about blood situations, looking at blood in a test tube or at a bloody bandage, having a finger pricked, and so on. The purpose of the application training is the same as for the longer version, that is, for the patient to acquire the skill to recognize the drop in blood pressure and to apply the tension technique to reverse this curve, and abort the reaction altogether. After the session the patient is given the same homework assignment as in the five-session AT: to practice the tension technique five times a day.

The outcome of the study indicated that the one-session AT was as effective as the five-session treatment on almost all of the measures. Thus, from a clinical point of view the brief treatment may be preferable since it does not involve taking the patient to a blood donor center or a thoracic surgery department.

II. THEORETICAL BASIS FOR APPLIED TENSION

According to the rationale for AT this coping technique works because by tensing the large body muscles the patient can stop the blood pressure from falling too low, and then increase it to a normal level for the individual patient. As a consequence of this the cerebral blood flow will not decrease below a critical level and the patient will not faint.

What evidence is there for this explanation? In the three randomized clinical trials of AT done at my clinic the patients ($N = 40$) increased their blood pressure significantly from the pre- to the post-tensing phase while being continuously exposed to slides of wounded people. The mean SBP increases were 13.6, 17.0, and 16.2 mmHg, and the corresponding means for DBP were 5.8, 7.8, and 12.4, respectively. This indicates that blood phobic patients can acquire the tension skill after 1 week of practice and use it effectively during the treatment sessions at the clinic. Unfortunately, we have not been able

to assess BP during sessions 4 (blood donor center) and 5 (thoracic surgery). Furthermore, our physiological equipment has not allowed us to assess cerebral blood flow, but other researchers have shown that the tension technique also leads to an increase in this parameter.

Another question concerning the mechanism of change for AT is whether the whole package consisting of the tension technique and exposure to blood-injury stimuli is necessary to obtain a good result. If this is not the case, which of the two components is the most important for the treatment effect? In one of our studies AT was compared with tension-only and exposure-only, and the results showed AT and tension-only to be equally effective and more so than exposure-only. In a subsequent study AT for one session and tension-only for one session were as effective as AT for five sessions. Thus the conclusion that can be drawn is that it is the coping technique (i.e., learning to tense and when to use it) that is the important component in AT.

III. APPLICATIONS AND EXCLUSIONS

AT was specifically developed for patients with blood-injury phobia and it has turned out to be the treatment of choice for this subgroup of specific phobia. In DSM-IV injection phobia is included in the same diagnostic category and about 50% of patients with injection phobia have a history of fainting in their phobic situations. For these I recommend teaching them the tension technique, but this is not enough; they also must be exposed to various injections, venipunctures, and pricking of fingers so that they acquire the skill of differential tension of the muscles (if necessary) while the nurse carries out these procedures.

Since very few patients with other anxiety diagnoses have a history of fainting when encountering their phobic stimuli there is very little need for AT in other instances. Patients with panic disorder often experience dizziness in their panic attacks, but they do not have a drop in blood pressure. Whether AT could have a beneficial effect on this subjective feeling of dizziness requires systematic research. However, there might be a risk of increasing the BP too much in patients who have a normal or elevated BP to start with.

If a patient has a diagnosed hypertension, temporal arthritis, or previous stroke one should be cautious with the tension training and assess the BP frequently to make sure that the BP does not rise to a level that is too high. However, it may be the case that blood phobic

patients with essential hypertension do not react as readily with the drop in blood pressure that is characteristic of blood-phobic patients.

IV. EMPIRICAL STUDIES

So far we have completed three clinical trials of AT in patients with blood-injury phobia. These are summarized in Table 1. The conclusion that can be drawn from these studies is that AT is an effective treatment, which yields better effects than exposure. However, it also seems that the application phase is of less importance than acquiring the coping skill; learning the tension technique well and having the knowledge of when and how to use it seem to be the most important factors in AT. Our latest study also indicates that an abbreviated one-session (2 hours) treatment is as effective as the full 5-hour AT, which is good news to the practicing therapist who may not have easy access to a blood donor center and a thoracic surgery department.

V. CASE ILLUSTRATION

A 24-year-old female patient had suffered from her blood phobia for 10 years, but never actually fainted in the phobic situation since she had always managed to escape or avoid these situations altogether. She had a father and a sister who also had blood phobia. When testing her before treatment her mean baseline values were SBP 122 and DBP 79 mmHg. During the instruction phase these values increased to 133 (SBP) and 87 (DBP) and at the beginning of the test phase there was a large increase to 161 (SBP) and 100 (DBP). This was, however, followed by a dramatic decrease to 94 (SBP) and 54 (DBP), and the patient fainted after watching the videotape of thoracic operations for 4 minutes. After being unconscious for a brief period (10 to 15 seconds) the patient's blood pressure gradually approached baseline without quite reaching the initial level. After receiving the AT the patient managed to watch the entire videotape (30 minutes) without any drop in blood pressure and no fainting behavior whatsoever. She did not have to use the tension technique at the posttreatment assessment and when asked about this she explained that she now felt very confident that she could cope with a drop in blood pressure, should it occur. At the 1-year follow-up the improvements were maintained and during that year the patient had encountered a number of blood-phobic situations and coped very well with them. At one occasion she even

assisted at the scene of a traffic accident without experiencing any fainting sensations.

treatment for blood phobia and the effects are maintained at follow-up 1 year later.

VI. SUMMARY

Applied tension is a coping method specifically developed for the treatment of blood-injury phobia (and to some extent injection phobia). This method specifically focuses on the original physiological responses, which are characteristic of blood phobia: the diphasic pattern with an initial increase and then a rapid decrease in blood pressure. The first step of AT consists of teaching the patient an effective tension technique, which leads to an increase in blood pressure. The patient is taught to tense the arms, the chest, and the leg muscles, and by assessing the patient's blood pressure the therapist can demonstrate that the tension really increases blood pressure. The second step is to expose the patient to various blood-injury stimuli (slides of wounded people, blood donation, and thoracic surgery) so that he or she can practice applying the tension as soon as the very first signs of a drop in blood pressure, are experienced. Randomized controlled trials show that AT is an effective

GLOSSARY

classical conditioning The main feature of this form of conditioning is that the originally neutral conditioned stimulus, through repeated pairing with the unconditioned stimulus, acquires the responses originally given to the unconditioned stimulus.

operant conditioning This type of conditioning involves the strengthening of an operant response by presenting a reinforcing stimulus if the response occurs.

I. DESCRIPTION OF TREATMENT

Arousal training is a technique that is used in the treatment of a number of clinical conditions. The essential aspect of the treatment involves training individuals to detect their levels of arousal, which are then the focus of treatment. Patients are trained either to further enhance arousal levels or to reduce levels of arousal, depending on what is required for a successful outcome.

This article focuses on two quite different conditions that utilize arousal training: enuresis and inorgasmia in

females. These two conditions have been selected because (1) there is a reasonable body of literature that relates to the use of arousal training with these conditions; and (2) the treatment of enuresis involves training the individual to lower arousal levels, whereas the treatment of inorgasmia involves training to increase arousal levels.

Arousal training among children with enuresis generally involves teaching the child to use a waking device to prevent them from wetting the bed. Parental involvement is an important aspect of therapy. The focus of the therapy is on teaching the child the physiological sensations that precede nocturnal enuresis (i.e., their arousal levels), so that he or she wakes and goes to the bathroom to urinate rather than wetting the bed. Thus, the focus of the training is on increasing the percentage of dry nights rather than on eliminating bed-wetting.

This technique uses a signal alarm device. When the child wets the bed, a moisture-sensing device near the genitals is activated and triggers an alarm. This alarm can either be a sound or a vibrating device. Both mechanisms have been found to be effective in waking children. Only a couple of drops of urine are necessary to trigger the alarm. Through this process the child gradually learns the physiological sensations associated with a full bladder and wakes to urinate in the bathroom without the sound of the alarm.

Reward systems are very important for this training to work (e.g., rewards for dry nights). Both the parents and child must be highly motivated. Involvement in training

entails recording the child's responses to the alarm and monitoring his or her progress. The success rate for therapy is in the 92% range, but the course of therapy can be two or three months. Reward systems need to remain in place for at least three weeks after complete dryness has been achieved. Relapse rates are higher if the alarm system is removed after shorter dry periods.

Arousal training for inorgasmia among women involves utilizing mechanisms that enhance sexual arousal. Women with inorgasmia generally demonstrate low levels of arousal, so therapy needs to focus on mechanisms designed to increase arousal levels. The focus of this arousal training needs to be directed toward both subjective and physiological levels of arousal. In an excellent 1995 review of the literature, Laan and Everaerd demonstrated how research studies have indicated the independence of these two dimensions of arousal, particularly among women. Thus, arousal training needs to focus on mechanisms that will enhance both aspects of arousal.

The most commonly used measure of physiological sexual arousal among women is vaginal vasocongestion. This is generally achieved by using a vaginal photoplethysmograph which measures both vaginal blood volume and vaginal pulse amplitude, with vaginal pulse amplitude generally being seen as the most accurate measure of sexual arousal. Strategies to increase physiological levels of sexual arousal include measures to reduce anxiety and sexual threats and also increasing the salience of the sexual stimulus. Although there is some speculation about the factors that need to be addressed to increase sexual arousal, the exact mechanism whereby this is achieved has not been developed or evaluated. Subjective sexual arousal generally involves an assessment of the woman's subjective evaluation of her arousal levels on a rating scale.

Sexual arousal in women has been shown to be enhanced using arousal training. Marita McCabe and her colleague have suggested that training focus on both response imagery (that is, sexual fantasy which relates to the woman's own sexual responses) and stimulus imagery (that is, sexual fantasy which relates to sexually stimulating situations), as well as relaxation. Thus, arousal training needs to focus on both a woman's responses to sexual fantasy and her generation of sexually stimulating scripts in order to effectively increase her levels of subjective sexual arousal. They also suggested that arousal training should focus on strategies to decrease performance concerns, since levels of performance anxiety were inversely related to subjective sexual arousal.

Clearly, more research needs to be conducted on the most useful treatment strategy to increase female sexual arousal. It would appear that arousal training is effective in the treatment of subjective sexual arousal, but the specific elements to include in this training process still need to be clarified. Enhancement of physiological sexual arousal among women has been largely neglected. Research needs to focus on the elements that are most useful in arousal training programs to improve the physiological levels of arousal, and also on the relationship between physiological and subjective arousal in the treatment of inorgasmia.

II. THEORETICAL BASES

Enuresis may have either an organic or a psychological etiology. This discussion focuses on the psychological explanation for development of the disorder and on the reason for the effectiveness of arousal training in its treatment. It has been proposed that the waking alarm described earlier works through classical conditioning. Repeated pairings occur between the sensation of a full bladder, the child wetting the bed, the sound of the alarm, and the child waking up. In time, the child learns to wake to the sensation of a full bladder prior to wetting the bed. Thus, the training is focused on the eventual association between a full bladder and waking up. Arousal training for enuresis also utilizes operant conditioning. Children may perceive the sound of the alarm, waking in the night, and cleaning up as an aversive condition, and so may learn to avoid this situation by learning to keep dry.

Both of these behavioral approaches use the theoretical underpinning of conditioning to increase the child's self-control of nocturnal bed-wetting behaviors. The basic assumption behind this approach is that lack of bladder control is a learned response. Arousal training, using either classical or operant conditioning, is designed to reverse change these behaviors.

Inorgasmia is viewed as being due to low physiological levels of arousal or perceived low levels of arousal for the subjective dimension, and arousal training is needed to alter this situation. Imagery training, which focuses on both stimulus and response imagery, is used to increase arousal levels. Consistent with proposals regarding imagery training among inorgasmic women, it would appear that reinforcement of appropriately recalled stimulus or response imagery during imagery training is an essential ingredient in the treatment of inorgasmia. Thus, operant conditioning would seem to

be an appropriate theoretical position to explain the effectiveness of arousal training with this disorder. Such an explanation is consistent with other approaches used to explain the treatment of inorgasmia.

Sexual arousal has been conceptualized as an emotion, which results from the interaction between cognitive processes and physiological response systems. Therefore, in order to experience subjective sexual arousal, individuals need to be able to accurately detect these bodily sensations. There appear to be substantial individual differences in the awareness of basic bodily sensations, which are related to genital responsiveness, perception thresholds, and attentional focus. A stimulus may convey different meanings, depending on the learning experiences of the individual (i.e., the individual's history), and so the interpretation placed on the current circumstances.

It has been argued that people learn to be sexual. For women, this learning process involves tuning into a wide range of situational and physiological cues. Appraisal of the current situation (based on prior learning experiences), in combination with feedback from genital sensations, combines to lead to subjective sexual arousal in women. Thus, arousal training to treat inorgasmia needs to reverse this learning process by dealing with feedback from both the interpretation of the situation and genital responses.

III. EMPIRICAL STUDIES

Arousal training has been shown to be extremely effective in the treatment of enuresis, provided it is maintained for a sufficient period of time, and implemented appropriately by parents. Clearly, if the enuresis is due to a physiological condition, the problem needs to be treated using appropriate medication. These medications, and their effectiveness, will not be considered in this chapter, for this discussion focuses primarily on the treatment of enuresis due to a psychological etiology.

Van Londen and colleagues demonstrated that arousal training obtained a 98% success rate with nonclinical boys and girls with nocturnal enuresis between the ages of 6 and 12 years. Even 2½ years after the initial training, 92% of children were continent. This compared with a success rate of 84% where reward reinforcement only was used, and 73 percent where the urine alarm was used without any rewards. The 2½ year success rate for these two approaches was 77% and 72%, respectively. The majority of children in the arousal training condition who experienced a relapse did so only once (62%),

and most of these relapses were treated successfully by parents reinstating arousal training techniques (60%), without seeking professional help.

In contrast to these results, Walling only reported a success rate of 70% using an alarm. However, Walling's paper does not make clear if the respondents were drawn from a clinical population and if all aspects of arousal training (reinforcement as well as the alarm) were used in treatment. Schulman, Colish, von Zuben, and Kodman-Jones also found a success rate of 56% using an alarm in the treatment of their clinical patients with enuresis. However, this rate was significantly better than the use of medication (18% and 16% for two different medical interventions).

In reviews of studies to treat nocturnal bed-wetting, it was found that the most effective treatment for enuresis was dry bed training and an enuresis alarm. The data also demonstrated that success was more likely when the problem was maturational and less likely in situations where there was a psychiatric disorder of the child, severe family stress, lack of concern by child and parents, or urological dysfunction. Medication was shown to have limited usefulness and was effective primarily when there was a physiological cause for the enuresis.

Other researchers have reported up to 90% effectiveness with a short-term conditioning techniques for enuresis. However, closer examination of these techniques demonstrates that they involved the use of an alarm, but this was not accompanied by reinforcement from the parents for dry nights. Within this literature there are major difficulties in comparing results across different studies. The severity of the children's enuresis, the level of support provided by the parents, the number of treatment sessions, as well as the focus of the treatment program, all show substantial variability across studies. These factors will undoubtedly impact on the effectiveness of the arousal training procedure.

It appears that arousal training in its various forms is the most effective treatment for enuresis. This is most likely to be successful if both the child and the parents are highly motivated, and the therapist acts to clearly communicate the strategies to be employed and assists in the maintenance of motivational levels within the family.

A number of studies have evaluated the effectiveness of arousal training in the treatment of inorgasmia in women. In a review of studies that examined the factors that contributed to sexual arousal among women, it was found that masturbation frequency, coital frequency, and having a positive opinion about erotic stimulus and a

higher awareness of vaginal lubrication were the most significant predictors of both subjective and physiological sexual arousal. These results would suggest that respondents who have a positive attitude to their sexual responses, and who are attuned to their levels of arousal, are more likely to experience higher levels of both physiological and subjective sexual arousal. Thus, arousal training would be expected to be an effective therapy with women experiencing inorgasmia.

This prediction is supported by studies by McCabe and her colleagues that employed imagery training to enhance sexual arousal among inorgasmic. Imagery training was used in both of these studies to desensitize inorgasmic women to the anxiety and fears that they held regarding sexual arousal and orgasmic responding. This process of desensitization was designed to enhance both physiological arousal and subjective levels of arousal. It was, therefore, a form of arousal training that was designed to operate at both the physiological and subjective level. The data from both studies demonstrated some level of effectiveness using these techniques.

A problem with using arousal training among women who experience inorgasmia is that there may be habituation to stimuli. As yet, there appear to be no clear data on the circumstances under which habituation occur, and some sexual stimuli continue to retain their sexual-arousing capacities despite repeated exposure.

Further studies need to be conducted on arousal training for inorgasmia, and the effectiveness of the treatment programs needs to be contrasted with both alternative treatment programs that do not utilize arousal training strategies and wait-list controls. Although theoretically one would expect arousal training to be a useful approach for the treatment of inorgasmia, until these studies are completed it is difficult to draw any confident conclusions about the effectiveness of this type of therapy among inorgasmic women.

IV. SUMMARY

Arousal training is a therapeutic technique that uses learning principles to either decrease or increase levels of arousal in order to achieve an appropriate therapeutic outcome.

This approach has been used effectively in the treatment of nocturnal enuresis among children. Interventions are most likely to be effective if both the child and the parent are highly motivated, and if the arousal alarm in combination with reinforcement is used in the treatment regime. It is also important to continue treatment

for a number of weeks after the child has a dry bed in order to firmly establish the new learning processes.

Arousal training also appears to be effective in the treatment of inorgasmia in women. Learning theory can be used to explain the development of this sexual dysfunction, and inorgasmic women have been shown to experience low levels of sexual arousal. Although further research is needed to determine other strategies to enhance arousal, preliminary research would suggest that imagery training is an effective mechanism to increase arousal levels.

Further research needs to be conducted to determine the effectiveness of arousal training with other clinical disorders.

interests, concerns, and conflicts. Art therapy practice is based on knowledge of human developmental and psychological theories, which are implemented in the full spectrum of models of assessment and treatment.

Art therapy is an effective treatment for the developmentally, medically, educationally, socially, or psychologically impaired. It is practiced in mental health, rehabilitations, medical, educational, and forensic institutions. Populations of all ages, races, and ethnic backgrounds are served by art therapists who provide services to individuals, couples, families, and groups.

GLOSSARY

art therapy A human service profession that utilizes art media, images, the creative process, and patient/client responses to art productions as reflections of an individual's development, abilities, personality, interests, concerns, and conflicts.

American Art Therapy Association (AATA) A 5000-member association founded in 1969 that is governed and directed by a nine-member board elected by the membership.

I. DEFINITION

Art therapy is a human service profession that utilizes art media, images, the creative process, and patient/client responses to art productions as reflections of an individual's development, abilities, personality,

II. BACKGROUND

Art therapy emerged as a distinct profession in the 1930s. Since that time art therapy has grown into an effective and important method of communication, assessment, and treatment. Sound theoretical principles and therapeutic practices govern the modality. The theoretical orientation of art therapy includes psychoanalytic theory as well as art education.

III. THEORETICAL CONSTRUCTS

Two schools of thought are fundamental to the profession of art therapy: Art Psychotherapy and Art as Therapy. Both have contributed to the progressive de-

velopment of the field. Often basic tenets associated with both schools of thought are integrated in the practice of art therapy. Psychoanalytic tenets provide the basis for both methods of practice.

Margaret Naumburg is credited with the first use of art expression as a therapeutic modality. She encouraged her patients to draw spontaneously and to free associate to their drawings in the 1940s. Her use of art was based on psychoanalytic theory and practice. She believed that art therapy was dynamically oriented and was dependent on the transference relationship between patient and therapist. For Naumburg therapeutic art expression allows for a symbolic communication, which bypasses difficulties encountered with verbal communication. Naumburg encouraged the patient to discover for himself or herself the meaning of his or her artwork. Art psychotherapy is a process-oriented approach that involves art behavior, clinical behavior, and the associations of the patient. The latter is fundamental to comprehending a client or patient's understanding of his or her imagery.

In contrast, Edith Kramer concentrated on the integrating and healing properties of the creative process itself. Her theories evolved out of her work with children in the 1950s. For Kramer the healing quality inherent in the creative process explains the usefulness of art in therapy. In art as therapy, the therapist functions as an auxiliary ego and assumes a supportive role. Sublimation is a key component associated with Kramer's work. Judy Rubin in 1984 explained that in the creative act (art making), conflict is reexperienced, resolved, and integrated.

For Naumburg, art making assisted the therapeutic process. Kramer focused on the art making believing that the creative process in and of itself was intrinsically therapeutic.

Myra Levick in 1983 recognized the correlation between emotional development, intellectual development, and creative expression that is fundamental to art therapy. Levick also developed criteria for the identification of defense mechanisms of the ego in graphic productions. This knowledge assists with the identification of areas of fixation as well as conflicts and issues that are central to the individual.

IV. MATERIALS/MEDIA

Media is a term used to describe art materials. Media encompass a variety of items including two- and three-dimensional materials. An art therapist is familiar with the inherent properties and resulting qualities of the

media as well as what may be evoked by the introduction of certain materials. The art therapist assesses the stimulus potential of the media in conjunction with the coping skills of the client/patient in an effort to introduce appropriate materials and tasks. The art therapist is trained to comprehend what is being expressed with regard to the media. Different media evoke different responses and convey different messages.

Art materials exist on a continuum from structured to unstructured. Structured media have a definitive shape and form and make a definitive mark. Two-dimensional art materials are representative of structured media, including pencils, crayons, markers, and pastels. Unstructured media, such as clay or paint, require the user to give the media shape and form. It does not make a consistent line and is more subject to gravity. The art therapist's capability to comprehend and interpret what is being expressed with regard to the media is fundamental to the practice of the modality. This information provides the art therapist with insight regarding underlying issues, conflicts, and concerns.

V. ARTISTIC DEVELOPMENTAL LEVELS

A phase-specific developmental sequence has been associated with children's drawings. Although different phases or stages have been identified by different researchers, children's artistic development is sequential and contingent on mastery of skills. Knowledge of typical developmental variants is essential to understanding the graphic productions created by children. Many factors and influences will contribute to maturation in developmental spheres including artistic. Cathy Malchiodi in 1998 explored developmental aspects of children's drawings in her text, *Understanding Children's Drawings*.

VI. THE ART THERAPIST

Art therapists are skilled in the therapeutic use of art. Art therapists use their backgrounds as artists and their knowledge of art materials in conjunction with clinical skills. The art therapist treats clients/patients through the use of therapeutic art tasks. While the art therapy process uses art making as a means of nonverbal communication and expression, the art therapist makes use of verbal explorations and interventions. Art therapists do not own art or the healing that comes from its use.

The therapeutic use of art distinguishes the art therapist from other helping professions. The art therapist may act as a primary therapist or as an adjunct within the treatment team, depending on the needs of the institution and the treatment objectives of the patient. Art therapists function in many capacities including supervisors, administrators, consultants, and expert witnesses.

VII. EDUCATIONAL REQUIREMENTS

Professional qualification for entry into the field requires a master's degree from an accredited academic institution or a certificate of completion from an accredited institute or clinical program. Specialized training programs include didactic instruction and practicum experience. Graduate art therapy training programs are commonly associated with medical colleges or universities. The designation art therapist registered, ATR, is granted to individuals who have successfully completed the required educational and professional experience.

VIII. ART THERAPY CREDENTIALS BOARD

The Art Therapy Credentials Board, Inc. (ATCB), an independent organization, grants postgraduate registration (ATR) after reviewing documentation of completion of graduate education and postgraduate supervised experience. The Registered Art Therapist who successfully completes the written examination administered by the ATCB is qualified as Board Certified (ATR-BC), a credential requiring maintenance through continuing education credits.

IX. AMERICAN ART THERAPY ASSOCIATION

The American Art Therapy Association (AATA) was established in 1969 as a nonprofit organization. AATA is governed and directed by a nine-member board that is elected by the membership. Current membership is approximately 5000 members in five membership categories. Affiliate chapters exist throughout the country and promote the field of art therapy at the local level. Educational, professional, and ethical standards for art therapists are regulated by the American Art Therapy Association.

The Mission statement of the American Art Therapy Association is as follows:

The American Art Therapy Association, Inc. (AATA) is an organization of professionals dedicated to the belief that the creative process involved in the making of art is healing and life enhancing. Its mission is to serve its members and the general public by providing standards of professional competence, and developing and promoting knowledge in, and of, the field of art therapy.

Conceptually, AATA's philosophy, goals, and objectives endeavor to ensure credentialed art therapists deliver the highest standard of care possible to the general public. AATA's mission fosters the highest level of quality services from professional, highly trained art therapists. AATA's vision for the 21st century is the inculcation and recognition of art therapy as an integral part of all health care delivery systems.

For more information regarding the profession of art therapy and the National Association contact: The American Art Therapy Association, Inc. (AATA), www.arttherapy.org. For more information regarding registration and certification contact: The Art Therapy Credentials Board, Inc. (ATCB), atcb@nbcc.org.

Resources available from AATA include professional preparation literature as well as art therapy literature. Sample brochures include: *Art Therapy the Profession*, *Art Therapist Model Job Description*, *Fact Sheet*, *Membership Survey*, *Ethical Considerations Regarding The Therapeutic Use Of Art By Disciplines Outside The Field Of Art Therapy*, *Art Therapy in the Schools*, *Educational Programs*, and *Ethics Document*.

GLOSSARY

- behavior rehearsal** Practicing behaviors of interest.
- coaching** Providing corrective feedback to develop a skill.
- cognitive restructuring** Helping clients to increase self-statements that contribute to attaining valued outcomes and to decrease self-statements that have the opposite effect.
- discrimination training** Reinforcing a behavior in one situation and not in others in order to increase the rate of a behavior in situations in which it will be reinforced (followed by positive consequences or avoidance or decrease of negative consequences).
- exposure** Being in the presence of certain stimuli.
- generalization** The occurrence of a behavior in situations similar to the one in which it was established.
- hierarchy** A ranked order of items such as situations ranked in relation to degree of anxiety they create.
- maintenance** The continuation of a behavior over time.
- model presentation** Presenting exemplars of behavior that observers can imitate.
- self-management** Setting goals and arranging cues and consequences to attain certain goals.
- stimulus control** Procedure for altering the rate of behavior in a situation by rearranging antecedents to behaviors of interest.

The aim of assertion training is to enhance interpersonal effectiveness in social situations. Positive consequences may be forgone because of anxiety in social situations. Assertion training emphasizes the extent to which we can influence our social environment by being active in its construction. In 1973 Joseph Wolpe defined assertive behavior as “The proper expression of any emotion other than anxiety toward another person.” Lack of effective social skills may result in a variety of maladaptive behaviors. Assertion training often in combination with other methods, has been used to address a wide variety of presenting complaints including substance abuse, aggressive and explosive behaviors, and obsessive-compulsive behaviors. It has been used to help people make friends, arrange dates, and acquire needed help (e.g., on the part of individuals with learning disabilities). Essentially, assertive skills are effective social influence skills acquired through learning.

The terms “assertive behavior” and “assertion” (or “assertiveness”) training have been replaced by the terms “effective/competent social behavior” and “social skills training.” Some authors use the term “assertive behavior” to refer to a circumscribed set of behaviors such as refusing requests. One problem with use of the term “assertive behavior” is confusion of “assertion” with “aggression.” Another potential disadvantage is encouraging a trait approach to social behavior that obscures the situational specificity of social behavior; that is, a client may be appropriately assertive in some situations (effective in achieving desired outcomes such as arranging

future meetings with a friend), passive in other (e.g., refusing favors), and aggressive in others (e.g., requesting changes in behavior). Assertion training differs from social skills training in emphasizing individual rights and obligations. For example, an advantage of the phrase “assertive behavior” for some groups such as women is an emphasis on taking the initiative to enhance social and other opportunities. There is an activist stance. If intervention is successful, anxiety in interpersonal situations decreases and assertive responses are used when a client believes these would be of value in attaining personal and social goals; clients may be indifferent to situations that previously caused discomfort, such as minor digs and slights, and misconceptions of situations as rejecting (perhaps due to oversensitivity) should decrease. Discussion of the limiting effects of stereotyping and role expectations may result in greater sensitivity to certain situations (such as belittling sexist remarks) and greater likelihood of assertive reactions in such situations.

I. DESCRIPTION OF TREATMENT

Assertion training usually consists of a variety of components, including instruction, model presentation, behavior rehearsal, feedback, programming of change, and homework assignments. Other procedures that may also be used, depending on what is found during assessment, include self-instruction training, relaxation training, cognitive restructuring (e.g., decreasing unrealistic expectations or beliefs), and interpersonal problem-solving training (helping clients to effectively handle challenging situations that arise in social situations such as reactions of anger that get in the way of maintaining friendships). Written material may be used to provide instructions and to clarify differences among aggressive, assertive, and passive behaviors in a situation. For example if you believe you have been treated unfairly by a professor, you could appropriately speak to your instructor about your concerns (be assertive), say nothing (be passive), or yell at the instructor (be aggressive). Selection of intervention methods should flow directly from assessment. This provides information about the nature of a client’s current cognitive (what they say to themselves), emotional (what they feel), and behavioral (what they do) repertoires in relation to desired goals and related situations, as well as likely consequences of and options for rearranging the environment. Role-playing during assessment (acting out what is usually done as well as what a client thinks

he or she should do) may reveal that the client has many effective components of needed skills, and it may be decided that instructions and prompts during rehearsal will be sufficient to develop and refine needed skills. If effective behaviors are not used because of anxiety, intervention may focus on enhancing anxiety management skills. However, if needed social skills are absent, procedures designed to develop them, such as instructions, model presentation, and practice, may be needed. Discrimination training is required when skills are available but are not used in situations in which they would result in valued outcomes. This is designed to increase a behavior in situations in which it will be followed by positive outcomes and/or decrease it in situations in which negative outcomes are likely. Assessment may reveal that effective behaviors simply have to be placed under new stimulus control (i.e., prompted, perhaps by self-instructions, in certain situations). For example, effective ways of requesting favors from a friend may be of value in work situations but not be used there. Training may be carried out individually or in a group setting. A session may focus on developing effective behavior in one situation or on increasing a specific behavior of value in a range of similar situations (friendly reactions such as smiling).

A. Instructions

Instructions concerning effective behavior may be given verbally or presented in written, audiotape, or filmed form. This is often combined with model presentation and coaching during role-plays. Specific behaviors are identified to increase, decrease, stabilize, or vary and their relationship to desired goals described. Instructions may be given concerning only one behavior at a time, which is then role-played, or more than one behavior may be reviewed depending on the available skills (entering repertoires) of each client. What not to do (e.g., smile or giggle while requesting a change in an annoying behavior) as well as what to do (e.g., look at the person, face the person) are described.

B. Model Presentation

Instruction, model presentation, rehearsal, and coaching can be used when clients lack requisite behaviors in certain situations or when there is a need to refine behaviors. The need to use modeling will be influenced by the complexity of the skill to be acquired and nature of the entering repertoires (available skills) of clients. The greater the complexity of the skill and

the more lacking the initial repertoire, the greater the value of model presentation is likely to be. An advantage of model presentation is that an entire chain of behavior can be illustrated and the client then requested to imitate it. Nonverbal as well as verbal behaviors can be demonstrated and the client's attention drawn to those that are especially important. For example, a client can be asked to notice the model's eye contact, hand motions, and posture. Models of both effective and ineffective behavior may be presented. The model may verbalize (say aloud) helpful positive thoughts during role plays if effective social skills are hampered by negative thoughts such as "I'll always be a failure," "I'll never succeed." At first, appropriate self-statements can be shared out loud by the client when imitating the model's behavior (e.g., "Good for me for taking a chance"), and then, by instruction, gradually moved to a covert level. Donald Meichenbaum in 1972 found that models who display coping responses (for example, they become anxious and then cope effectively with this) are more effective than are models who display mastery response (they do not experience any difficulty in a situation).

Effective behaviors may be modeled by the counselor, or written scripts, audiotape, videotape, or film may be used. Essential elements of various responses can be highlighted and written models offered. The advantage of written material is that it can be referred to on an as-needed basis. In addition, the client may be asked to observe people with effective behavior who are in similar roles and to write down the situation, what was done, and what happened. This increases exposure to a variety of effective models, offers examples to use during rehearsal and may increase discrimination as to when to use certain behaviors and when not to do so, and offers opportunities for vicarious extinction of anxiety reactions through observation of positive outcomes following assertive behavior (that is, negative emotional reactions decrease via observation of what happens to others). The opportunity to see how negative reactions to assertive reactions can be handled may be offered as well. Client observations are discussed, noting effective responses as well as other situations in which assertive behaviors may be usefully employed.

C. Behavior Rehearsal and Feedback

Following model presentation, the client is requested to practice (rehearse) the modeled behavior. Corrective feedback is offered following each rehearsal.

Specific positive aspects of the client's performance are first noted and praised. Praise is offered for effective behaviors or approximations to them, and coaching provided as needed. The focus is on improvements over baseline levels (what a client can do before intervention is initiated). Thus, approximations to hoped-for outcomes are reinforced. Critical comments such as "You can do better" or "That wasn't too good," are avoided. The client is encouraged to develop behaviors that are most likely to result in positive consequences. A hierarchy of scenes graduated in accord with the client's anxiety may be used for role-playing. Role-playing starts with scenes that create low levels of discomfort. Clients who are reluctant to engage in role-playing can be requested to read from a prepared script. As comfort increases, role-playing can be introduced. If a client is too anxious to read from a script, relaxation training may be offered as a prelude to role-playing. When there are many skills to be learned, one behavior at a time may be focused on. Each role-play may be repeated until required levels of skill and comfort are demonstrated.

Models and instructions are repeated as needed, and rehearsal, prompts, and feedback continued until desired responses and comfort levels are demonstrated. Rehearsal alone (without previous model presentation or other instructions), may be effective when skills are available or relevant behaviors are simple rather than complex. The situations used during role-playing should be clearly described and closely resemble real-life conditions. Instructions prior to practice or signals during practice can be used to prompt specific responses. Instructions given before a client practices a behavior "prompt" her to engage in certain behaviors rather than others. Perhaps a client did not look at her partner during the role-play and is coached to look at others while speaking. Checklists may be prepared for clients as reminders about effective behaviors. Covert modeling or rehearsal in which clients imagine themselves acting competently in social situations may be as effective as actual rehearsal if clients possess needed social behaviors (but do not use them) and if social anxiety is low. Home sessions in which clients engage in covert rehearsal can be used to supplement rehearsal in office sessions. Not only does behavior rehearsal provide for learning new behaviors, it also allows their practice in a safe environment and so may reduce discomfort. Rehearsal involves exposure to feared situations. This exposure is considered to be a key factor in decreasing social anxiety, especially if people remain in the situation even when they are anxious and act effectively in spite of their discomfort.

D. Programming of Change

Specific goals are established for each session. Perhaps only one or two behaviors will be focused on in a session, or the initial repertoire might be such that all needed verbal and nonverbal behaviors can be practiced. Assessment of the client's behavior in relation to given situations will reveal available behaviors and training should build on available repertoires. Hierarchies ranked in terms of the degree of anxiety or anger that different social situations create can be used to gradually establish effective assertive skills and lessen anxiety. Rehearsal starts with situations creating small degrees of anger or anxiety. Higher-level scenes are introduced as anxiety or anger decreases. Thus, introduction of scenes is programmed in accord with the unique skill and comfort levels of each client. Improvements are noted and praised. Praise for improvement should be in relation to a client's current performance levels.

E. Homework Assignments

After needed skill and comfort levels are attained, assignments, graded in accord with client comfort and skill levels, are agreed on to be carried out in the natural environment. Assignments are selected that offer a high probability of success at a low cost in terms of discomfort. Careful preparation may be required if negative reactions may occur in real life. A clear understanding of the social relationships in which assertive behavior is proposed is needed to maximize the likelihood of positive consequences and minimize the likelihood of negative outcomes when assertive behaviors are used. For example, a parent may be likely to become verbally abusive if his son makes certain requests. This possibility should be taken into account (e.g., by encouraging behaviors unlikely to result in abuse, or by using some other form of intervention such as family counseling). Coping skills should be developed to handle possible negative reactions before asking the client to carry out new behaviors. With some behaviors, such as assertive behaviors in service situations, unknown individuals may be involved. Clients can be coached to identify situations in which positive reactions are likely. For example, in service situations such as returning a defective purchase, clients can be coached to approach clerks who appear friendly rather than ones who scowl and look as if they have had a bad night.

When effective social behavior occurs without difficulty in easy situations, more difficult ones are then attempted. Clients are instructed to offer positive self-

statements ("I spoke up and it worked!") for effective behavior. Practice, coaching, and model presentation provide instruction concerning the essential elements of effective behavior, and clients are encouraged to vary their reactions in appropriate ways. As with any other assignment, a check is made at the next meeting to find out what happened. Client logs (records) describing relevant behaviors and the situations in which they occurred can be used to provide a daily record of progress and guide selection of new assignments. Information reviewed may include what was said and done; when it was said and done; how the client felt before, during, and after the exchange; whether positive self-statements were provided for trying to influence one's social environment (even though the attempt failed); and what consequences followed the client's behavior. If an ineffective response was given in a situation, clients can be asked to write down one that they think would be more effective. This will provide added practice in selecting effective behaviors. Positive feedback is offered for effective behaviors, additional instructions given as necessary, and further relevant assignments agreed on. Motivation to act assertively may be enhanced by encouraging clients to carry out mini cost-benefit analyses in situations of concern in which they compare costs and benefits of acting assertively (versus passively or aggressively).

F. Cognitive Restructuring— Changing What Clients Say to Themselves

Thoughts relevant to assertive behavior include helpful attributions (casual accounts or behavior), realistic expectations ("I may not succeed; no one succeeds all the time"), helpful rules ("when in doubt think the best"), self-reinforcement for efforts to improve and positive consequences, problem-solving skills, and accurate perception and translation of social cues (e.g., noting and accurately interpreting a smile as friendly). In addition, cognitive skills (e.g., distraction) are involved in the regulation of affect (e.g., anger or anxiety). Unrealistic beliefs (such as "I must always succeed") and other kinds of thoughts such as negative self-statements that get in the way of assertive behavior should be identified and replaced by helpful self-statements and beliefs. This process is initiated during assessment and continues during intervention. Discussion of beliefs about what is proper assertive behavior and who has what rights

should be held during assessment in the process of selecting goals. Cognitive restructuring may include altering unrealistic expectations, altering attitudes about personal rights and obligations, and/or self-instruction training in which clients learn to identify negative self-statements related to effective social behavior and to replace them with positive self-statements.

Self-management aspects of assertive behavior include identifying situations in which assertion is called for (and when it is not), monitoring (tracking) the consequence of assertion, and offering helpful self-feedback. The likelihood of effective social behaviors may be increased by covert (to one's self) questions that function as cues such as What's happening?, What are my choices?, What might happen if...?, Which choice is better?, How could I do it?, How did I do?

G. Anxiety Reduction Methods

Relaxation training could be provided if anxiety interferes with use of assertive skills. The specific method selected to alter anxiety will depend on the cause(s) of anxiety (e.g., negative thoughts, a past history of punishing consequences because of lack of skills), and/or unrealistic expectations ("Everyone must like me").

H. Encouraging Generalization and Maintenance

Generalization refers to the use of assertive behaviors in situations other than those in which training occurred. *Maintenance* refers to their continued use over time. Steps that can be taken to increase the likelihood of generalization and maintenance of assertive behaviors include recruiting natural reinforcers (e.g., involving significant others), reinforcement for using behaviors in new situations (e.g., self-reinforcement), and use of a variety of situations during training. Generalization and maintenance can be encouraged by use of homework assignments and self-monitoring (e.g., keeping track of successes). Situational variations that may occur in real life that influence assertive behavior should be included in practice examples to encourage generalization and maintenance. For example, a woman may have difficulty refusing unwanted requests in a variety of situations (e.g., with friends as well as supervisors at work). If so, practice should be arranged in these different situations. Self-reinforcement may encourage the development and maintenance of new behaviors. Such reinforcement may be of special relevance in maintaining behaviors that are

sometimes followed by punishing consequences. Clients can be encouraged to reward themselves for making efforts to exert more effective influence over their social environment, even though they are not always successful (e.g., if a woman tries to speak up more during a meeting and fails to gain the floor, she should reward herself for trying).

II. THEORETICAL BASES

A key assumption behind assertion training is that we often lose out on positive outcomes or suffer negative ones because of ineffective social behavior. For example, we may not get a job that we want because we lack the skills to speak up and present ourselves well in a situation. We may not be effective in meeting friends because we do not initiate conversations. A value stance as well as an intervention strategy is associated with assertion training. It is assumed that people have a right to express their feelings in a manner that subjugates neither others nor themselves, and that well-being includes this expression. Joseph Wolpe and Andrew Salter emphasized the importance of expressing our feelings, both positive and negative, in a way that does not detract from the rights and obligations of others. This applies to the overly reticent as well as to those who are overly aggressive. Those in the former group fail to assert their rights, whereas those in the latter group achieve their goals at the expense of others. Individual rights and obligations are emphasized in a context of increasing positive gains both for oneself and others. Such training implies that it is adaptive to express ourselves in appropriate ways, and distinguish situations in which restraint is called for from those in which assertion would be best. It is considered maladaptive and unfair to be taken advantage of, to allow oneself to be unduly imposed on, and to be intimidated. It is assumed that life will be more reinforcing if we are active in the construction of our social environments. Obligations include considering the rights of others. Clients are encouraged not only to consider their own rights and obligations in a situation but those of others as well. What is viewed as a right or obligation varies in different cultures and ethnic groups, and counselors will have to be careful not to impose their cultural standards on groups in which these are not appropriate (e.g., negative consequences and/or loss of positive consequences may result). Steps are taken to deal with anxiety about possible negative reactions by the development of positive self-instructions and effective social and relaxation skills (as needed).

It is assumed that behaviors, thoughts, and feelings are interrelated. For example, negative thoughts about ourselves may interfere with expressing and acting on our feelings (e.g., initiating conversations, answering questions in class). These thoughts and lack of action may, in turn, create anxiety or feelings of depression because of a loss of positive consequences or negative consequences. If we speak up (assert ourselves) and acquire valued consequences in situations in which we were reticent in the past, this makes it easier to act on future occasions because we are less anxious. Joseph Wolpe emphasized the importance of reciprocal inhibition; that is, if we engage in a response that is incompatible with anxiety in a certain situation, this will “countercondition” anxiety reactions and it will be easier to perform this opposite type of response in the future. Speaking up rather than not saying anything was viewed as one kind of incompatible response (i.e., to anxiety). Research in this area suggests that it is exposure that contributes to positive effects. That is, simply getting in a situation in which we are anxious and performing effectively in that situation seems to be the effective ingredient in decreasing anxiety and encouraging assertive behavior on future occasions.

III. APPLICATIONS AND EXCLUSIONS

Assertion training requires a careful descriptive analysis of relevant interpersonal relationships. If this analysis indicates that assertion would have unavoidable negative effects, as it may for example in abusive relationships, this would not be recommended. Other methods must be explored. Clients must be willing to act differently in real-life situations and have the self-management skills to do so (e.g., remind themselves to act differently). Cultural differences regarding what behaviors will be effective in certain social situations must be considered. Effective social behavior is situationally specific; what will be effective in one situation may not be in another.

Assertion training may be carried out in groups. A group offers a number of advantages including a variety of models, multiple sources of support, normalization and validation of concerns, and the availability of many people to participate in role-plays. Groups usually include from 5 to 10 sessions lasting one and a half to two hours each. Decisions must be made about how to structure sessions (for example, each session could be structured around a specific kind of assertive reaction). Assertion training in groups has been carried out with a

variety of individuals, including college students, parents, public welfare clients, people with various psychiatric diagnoses, and women. Group training may be especially important for women. Because of their socialization, women compared to men may require more social support and more opportunities to observe assertive women in order for them to express their preferences.

IV. EMPIRICAL STUDIES

Both single case and group designs have been used to evaluate the success of assertion training. Single-case designs are uniquely suited for evaluating progress with individual clients. Here, baseline levels of performance of an individual are compared with performance levels of that individual during intervention. Research suggests that assertion training can be effective with a number of different types of clients in pursuit of a number of different outcomes. Programs focused on altering cognitions believed to be related to ineffective social behavior have sometimes been found to be as effective as those focused on altering overt behavior, suggesting an equivalence of effect across cognitive methods and assertion training. There are some indications that a combination of methods is most effective. However, some studies that purport to show that cognitive methods are as effective as social skills training in enhancing social skills do not include individual assessment of specific entry level skills and do not design individually tailored programs based on this assessment. This lack may underestimate the potential value of assertion training. A number of studies show that instructions alone (without modeling) are not sufficient to develop appropriate social behaviors with some clients labeled “schizophrenic.”

Comparison of the effectiveness of assertion training in different studies is often hampered by the use of different criteria for selection of subjects, different training programs, and different criteria for evaluating progress. Evaluation is sometimes limited to changes in self-report or role-play measures, leaving the question unanswered as to whether beneficial changes occur in real life. Altering behavior in one kind of situation such as refusing requests, does not necessarily result in changes in behavior in other kinds of situations such as initiating conversations. Package programs may be used leaving the question “What are the effective ingredients of assertion training?” unanswered. Use of package programs may also be a waste of time and effort in including unneeded components. Use of global self-report

measures to assess change in specific areas may result in underestimating success of assertion training in relation to behavior in specific situations. Assertion training may do little to alter political, social, and economic sources of inequity; it is individually focused. There is thus the danger of blaming clients for problems that do not originate with them. The ideology of success through "mind power" (changing what you think), which is especially prevalent in America where assertion training flowered, requires vigilance to discourage programs that offer only the illusion of greater influence over one's social environment.

V. CASE EXAMPLE

Richard Eisler and his colleagues Michel Hersen and Peter Miller in 1974 used assertion training with a 28-year-old house painter admitted to a hospital after he had fired a shotgun into the ceiling of his home. His history revealed periodic rages following a consistent failure to express anger in social situations. His behavior was assessed by asking him to role-play in social situations in which he was unable to express anger. These included being criticized by a fellow employee at work, disagreeing with this wife about her inviting company to their home without checking with him first, and his difficulty refusing requests made by his 8-year-old son. An assistant played the complementary role in each situation (wife, son, or fellow employee). The client's reactions were videotaped and observed through a one-way mirror. Review of data collected revealed expressive deficits in four components of assertion: (1) eye contact (he did not look at his partner when speaking to him), (2) voice loudness (one could barely hear what he said), (3) speech duration (responses consisted of one- or two-word replies), and (4) requests (he did not ask his partner to change his or her behavior).

Twelve situations that were unrelated to the client's problem areas but that required assertive behavior were used during training. Each was role played five times in different orders over sessions. Instructions were given to the client through a miniature radio receiver. Instructions related to only one of the four responses at any one time. Thus during the initial scenes he was coached to look at his partner when speaking to him, and during the second series he was coached to increase the loudness of his voice but received no instructions concerning any other response. During the fourth series, he was coached to speak longer, and during the last, instructed to ask his partner for a behavior

change. Feedback was provided concerning his performance after each role-play. Each response increased after specific instructions regarding this were given and effects generalized to the specific situations that were problematic for this client. Ratings of his behavior were made by reviewing videotapes of his performance.

VI. SUMMARY

Assertion training is designed to increase competence and decrease social anxiety in social interactions. It may be carried out in individual or group meetings. Both broad and narrow definitions of assertive behavior have been used, ranging from definitions that restrict the term to behaviors such as refusing unwanted requests to broad definitions that include a wide range of behaviors involving the expression of both positive and negative feelings. The distinctions among assertive, passive (doing nothing), and aggressive (e.g., yelling) behavior are made with assertion referring to effective behavior. Assertive training differs from social skills training in its emphasis on personal rights and obligations. There is a philosophy or ideology that accompanies assertion training that does not accompany social skills training. A number of procedures are usually involved in assertion training, including instructions, model presentation, behavior rehearsal and coaching, feedback, programming of change, homework assignments, and the cultivation of attitudes and beliefs that encourage assertive behavior. The more outstanding the behavior deficits and need for behavior refinement, the more likely that instructions, model presentation, and rehearsal will be required. Intervention may also include efforts to replace negative thoughts with positive self-instructions. Homework assignments are a component of assertion training, and client-recorded logs can be reviewed to offer feedback and to encourage use of effective skills. Careful assessment is required to identify skills needed and relevant situations, to determine whether there are discrimination problems in relation to when certain behaviors can most profitably be used, to identify unrealistic beliefs or expectations that may interfere with assertive behavior, and to determine whether negative self-statements or lack of effective self-management skills interfere with effective behavior. Sources of assessment data include the interview, self-report measures such as the Assertion Inventory, role-playing, and observation in the natural environment.

Research to date indicates that assertion training is effective in helping clients achieve a variety of valued

outcomes in real-life settings. Assertion training is usually individually focused. It thus may not redress political, social, and economic inequities that impede change. Planning for generalization and maintenance will be required to increase the likelihood that desired behaviors will occur in relevant situations and will be maintained. Has the term “assertive behavior” outlived its usefulness? As a term connoting a traitlike approach to behavior, it has. As a term that is sometimes confused with aggressive reactions, it has not been helpful. As a term that highlights our potential for influencing our social environments, it has been helpful.

GLOSSARY

assisted covert sensitization A behavioral strategy in which standardized scripts are employed to guide the client through clinically relevant scenarios in which ultimately aversive imaginal consequences are presented.

covert conditioning A family of behavior therapy procedures which combine the use of imagery with the principles of operant conditioning.

I. DESCRIPTION OF TREATMENT

Covert sensitization represents one of the major psychotherapeutic, behavioral techniques to be applied to the remediation of sexual deviations. Techniques such as covert sensitization, olfactory aversion, and faradic or electrical aversion therapy have in common the clinical goal of reducing sexual arousal to deviant stimuli through the introduction of aversive events. Covert sensitization is a form of conditioning therapy in which a behavior and its precipitative events are paired with some aversive stimulus in order to promote avoidance

of the precipitative events and thereby to decrease the undesirable behaviors. In 1990, the originator of the procedure, Joseph Cautela and A. J. Kearney defined the conditioning procedure as follows:

Covert conditioning refers to a family of behavioral therapy procedures which combine the use of imagery with the principles of operant conditioning. Covert conditioning is a process through which private events such as thoughts, images, and feelings are manipulated in accordance with principles of learning, usually operant conditioning, to bring about changes in overt behavior, covert psychological behavior (i.e. thoughts, images, feelings) and/or physiological behavior (e.g. glandular secretions).

In covert sensitization, the aversive stimulus usually consists of an anxiety-inducing or nausea-inducing image that may be presented verbally by the therapist or imagined by the client. The aversive scene is individually created, and is specific to each client's problem behavior. Covert sensitization has frequently been successfully employed by itself (as described by Brownwell and Barlow in 1976; Curtis and Presley in 1972; Dougher, Crossen, Ferraro, and Garland in 1987; Haydn-Smith, Marks, Buchaya, and Repper in 1987; Hayes, Brownwell, and Barlow in 1978; Hughes in 1977; King in 1990; McNally and Lukach in 1991; and Maletzky and George in 1973) as well as in combination with other techniques (as discussed by Kendrick and McCullough in 1972; Moergen, Merkel, and Brown in 1990; Rangaswamy in

1987; and Stava, Levin, and Schwanz in 1993) in the treatment of sexual deviance.

Assisted covert sensitization is a basic variant of the covert sensitization procedure in which standardized scripts are employed to guide the client through clinically relevant scenarios in which ultimately aversive imaginal consequences are presented. A study conducted by Plaud and Gaither in 1997 illustrates the clinical methodology used in assisted covert sensitization, and will now serve as a case illustration of the use of assisted covert sensitization in the treatment of a paraphilia.

II. THEORETICAL BASIS

The principles of learning and behavior have been integrated into many of the most commonly employed therapy techniques in use today with sexual deviations, or the paraphilias, as discussed by Gaither, Rozenkranz, and Plaud in 1998. Abel and Blanchard in 1976 stated 25 years ago that "The problem of deviant sexual behavior was one of the earliest areas of psychopathology to which behavioral techniques were applied, and it continues to be a major area of research and treatment." The earliest behavioral theories of sexual deviations were based on a classical conditioning paradigm. Theorists such as Binet in 1888, Jaspers in 1963, and Rachman in 1961 believed that these deviations were the result of accidental pairings between stimuli that naturally elicited sexual arousal and originally neutral stimuli. According to Jaspers in 1963, "Perversion rises through the accidents of our first experience. Gratification remains tied to the form and object once experienced, but this does not happen simply through the force of simultaneous association with that former experience."

Why some individuals choose to incorporate deviant stimuli into their masturbatory fantasies is also explained using a conditioning hypothesis. One factor is the stimulus value of "deviant" stimuli, which is continually strengthened through the pairing of these stimuli with ejaculation. According to a conditioning model, nondeviant stimuli or fantasies, at the same time, undergo extinction (a decrement in responding) as a result of their lack of pairing with ejaculation. Another contributing factor is a common belief held by sexual deviants that a normal sex life is not possible. This belief, according to McGuire and colleagues in 1965, may develop from a number of different sources including aversive adult heterosexual experiences, or feelings of physical or sexual inadequacy. These re-

searchers found that in 45 cases, all of the patients held this belief before their first deviant sexual encounter. This leads one to the conclusion that the belief (a covert behavior) may play a precipitating role in the development of sexual deviations (overt behaviors) rather than being an effect of the deviation.

Sexual deviations may be best understood through a combination of classical and operant conditioning processes, according to O'Donohue and Plaud in 1994, and Plaud and Martini in 1999. Deviant sexual behavior begins with an accidental pairing of an "abnormal" or deviant stimulus with sexual arousal and/or ejaculation, giving this stimulus a high amount of erotic value. Thus, through a classical conditioning process, the deviant stimulus begins to elicit sexual arousal. The deviant stimulus is then incorporated into sexual fantasies during masturbation, which is reinforced by ejaculation. Thus, ejaculation serves as a reinforcer for the covert behavior of deviant fantasizing.

III. EMPIRICAL STUDIES

McGuire and colleagues in 1965 discussed the implications of their hypothesis for the treatment of sexual deviations. First, the authors stated that "since the original conditioning was carried out in most cases to fantasy alone, treatment also need only be to fantasy." Thus, in the treatment of deviations such as pedophilia, it is not necessary to present the subject with children, but only with fantasies involving children. Another implication of this hypothesis is that therapists can warn their patients of the conditioning effects of orgasm on the immediately preceding fantasy. Finally, according to McGuire and colleagues, "positive conditioning to normal heterosexual stimuli can follow the same lines as it is deduced that the deviation followed."

A study conducted by Lamontagne and Lesage in 1986 nicely illustrates the use of covert sensitization in the treatment of exhibitionism. The subject in this study was a 37-year-old male who had been exposing himself several times per week. The treatment consisted of covert sensitization techniques and allowing the client to privately expose himself at home with his wife. Before treatment, this client had fantasized about exhibitionism approximately 60% of the time during masturbation, and 30% of the time during sexual intercourse with his wife. In the covert sensitization sessions, the subject imagined exposing himself to a woman who would then angrily scold him. As another part of the aversive image, he imagined losing his wife

because of the exhibitionism. Thus, the deviant fantasy was paired with two powerfully aversive images. In combination with the covert sensitization procedures, the client was allowed to expose himself two times per week at home with his wife. This private exposure was always followed by either masturbation or sexual intercourse without deviant fantasies. Also, the client was instructed not to masturbate unless his wife was present, so that nondeviant sexual fantasy and behavior could be promoted. A posttreatment follow-up indicated that the subject had not publicly exposed himself for 2 years. It would seem that the treatment rendered the exhibitionism appropriate, and even socially acceptable, since it occurred in the privacy of the home. Interestingly, the couple even reported that their sex life improved following treatment.

The underlying theory of this treatment approach is probably best thought of as a combination of classical and operant conditioning processes. The therapist works with a client to develop an aversive image that will be paired with the precipitative events, and with the image of the deviant behavior itself, according to a classical conditioning paradigm. The aversive image serves as the unconditioned stimulus (UCS). The images of the precipitative events, being continually paired with the UCS, become the conditioned stimulus (CS). Both the conditioned response (CR) and the unconditioned response (UCR) consist of a negative reaction that may be emotional (e.g., fear), physiological (e.g., nausea), or in some other way repulsive. Once the client's deviant behavior has been classically conditioned, the client should begin to actively avoid or escape the situations associated with the deviant behavior. The precipitative events, as well as the behavior itself, should elicit a negative reaction, and thus be aversive.

According to the principles of operant conditioning, and specifically of negative reinforcement, the client should behave in ways that would minimize contact with the aversive stimulus, in this case the precipitative events and the deviant behavior. If the client does pursue the deviant behavior further, hopefully the treatments will have at least reduced the effectiveness of the reinforcement for the deviant behavior, which should lead to a lower frequency of the behavior. It would also be possible for classical conditioning to work alone, if the CR was so powerful that it rendered the person unable to engage in the deviant behavior, or consisted of a response that was incompatible with the deviant behavior. For example, if the CR was extreme anxiety or fear, and the deviant behavior required an erect penis, it may be the case that the CR would preclude the possibility

of erection, and thereby preclude the occurrence of the deviant behavior.

Lamontagne and Lesage in 1986 combined classical conditioning and operant conditioning in their covert sensitization treatment approach. Another important part of their treatment consisted of the operant reinforcement of private exposure through orgasm from masturbation or intercourse, both of which took place with the client's wife. Essentially, only the context of the exhibition behavior changed, not the behavior itself. The client learned that the behavior would be reinforced in one situation (at home with his wife), while it would either be extinguished or punished in any other situations.

IV. CLINICAL CASE STUDY

The client in this case study of the use of assisted covert sensitization was a 24-year-old male. The client was originally referred for a penile plethysmographic evaluation by a local human service center psychologist in relation to a show cause hearing for his failure to progress in group treatment at the human service center, which ultimately led to his termination from the group. The group treatment focused on psychoeducational issues relating to human sexuality, consent and victim empathy issues, appropriate and inappropriate sexual behavior, and disclosure to other members of the group. The client chose not to participate actively in any phase of the group treatment. The client had an extensive history of sexually abusive behavior. He earlier pled guilty to a charge of sexual assault, and was serving probation at the time of the initiation of therapy services. According to police records, when he was 19 years old the client engaged in sexual activities with a 15-year-old male. The victim reported that the client attempted anal intercourse on approximately 15 occasions. It was reported that the client ejaculated on a "couple" occasions, although there was no notation of anal penetration, oral sexual contact, or masturbation. The victim also reported on several of these sexual encounters that the client would gain compliance by the victim through purchasing soft drinks, and that consent by the victim to sexual interactions was verbally coerced by the client. The client denied engaging in anal intercourse and verbally coercive activities, and indicated that the victim engaged in sexual activities, including masturbation, in a mutual fashion.

The client's penile responses during the course of therapy were recorded by a penile plethysmograph utilizing a Type A mercury-in-rubber penile strain gauge.

During the original assessment of the client's sexual preferences, penile tumescence was continually monitored as he listened to sexually explicit audiotapes. A total of 18 standard audio scripts were presented during the initial assessment. These were descriptions of two adult homosexual interactions, two adult heterosexual interactions, two acts of adult female exhibitionism, two adult female rapes, one male child physical aggression, one female child physical aggression, one male child nonphysical coercion, one female child nonphysical coercion, three male child fondling, and three female child fondling. The client's subjective reports of sexual arousal were assessed by having him rate how aroused he felt using a 10-point Likert scale (0 = not at all aroused, 9 = extremely aroused).

Results of this assessment component before initiating assisted covert sensitization indicated that the client was aroused by adult females; however, he also displayed an active pattern of arousal toward stimuli depicting sexual activities with a male child, specifically anal intercourse. Based on these data, three "deviant" categories that elicited the greatest levels of sexual arousal—fondling a male child (MPF), coercing a female child into sexual activity (FPC), and fondling a female child (FPF)—were noted, and a follow-up recommendation was made for the client to participate in eight sessions of assisted covert sensitization in addition to being readmitted to group treatment at the local human service center.

Shortly after the initial assessment was conducted, an assisted covert sensitization protocol was begun. The client was given a consent form and full explanation of the procedure, and all questions were answered concerning the procedure. The initial assisted covert sensitization session was scheduled for the following week. During the week, audiotapes were developed for treatment. These tapes contained 3-minute descriptions of a deviant sexual activity (MPF, FPC, or FPF) followed by a description of a possible negative (aversive) consequence for this type of activity. The consequences were either legal (e.g., being beaten up by the father of the child and then being arrested) or physiological (e.g., feeling very nauseous and vomiting) in nature. The development and implementation of these guided scripts represents the "assisted" component in assisted covert sensitization.

When the client arrived for the first session, an abbreviated assessment was conducted to obtain baseline measurements of his sexual arousal to MPF, FPC, and FPF stimuli, as well as mutually consenting heterosexual (FAD), and mutually consenting homosexual (MAD) activity.

Following a 10-minute break the treatment was initiated, involving the presentation of 10 MPF stimuli described earlier. At the end of the session, the client was given a copy of the tape and instructed to listen to and visualize the sexual activity as well as the aversive consequences being delivered five times per day. The remaining five sessions were conducted at 1-week intervals apart beginning with Session 1.

During Session 2, the client was presented with the same 10 MPF stimuli from the previous session, and again instructed to listen to the tape five times per day until the next session. In Sessions 3 and 4, the same procedures were followed with the exception that MPF stimuli were presented only two times and FPC stimuli were presented the other times. The client was again provided with a copy of the new tape and instructed to listen to it five times per day between sessions (with explicit instructions to visualize the stimuli being presented). In Sessions 5 and 6 FPF stimuli were presented six times, MPF two times, and FPC two times each.

After completion of Session 6, the client returned to the clinic for a 30-day follow-up assessment. The same stimuli from the baseline assessment were used to determine present patterns of sexual arousal. The same procedure was again followed 3 months later in a final follow-up assessment.

The client's physiological data for the initial assessment, pretreatment assessment, 30-day follow-up, and 90-day follow-up were calculated and converted to percentages of full erection. This was computed by subtracting his minimum penile circumference for an entire session (e.g., assessment period) from his maximum penile circumference for each trial (the presentation of one audiotaped stimulus represents a trial) and dividing this number by 3. Three centimeters is thought to reflect the circumference change most males undergo from flaccidity (no sexual arousal) to complete engorgement (maximum sexual arousal). This number was then multiplied by 100 to give a percentage of full erection. Thus, percentage of full erection data give an indication of absolute levels of arousal. In other words, the client's response to each stimulus is viewed in this manner independently of the other stimuli presented in the session. It was found that the stimuli elicited less arousal each time the client was assessed during the assisted covert sensitization procedure.

The client's physiological data for the assessments were next converted to standardized scores (z-scores). Z-scores form a distribution in which the mean of the

distribution equals zero (0) and the standard deviation is 1.0. Using this scoring method, the client's sexual preferences are expressed as positive z-scores, while negative z-scores reflect sexual aversions. The greater that a score falls from zero, the stronger the preference or aversion. Thus, a score of +2.0 indicates a greater preference than a +1.2, while a score of -2.0 indicates a greater repulsion than a score of -1.2. Z-scores, then, give an indication of relative arousal or preferences and aversions among a group of stimuli. It was found that in the initial assessment, four of the five categories including the three that were treated, were positive and above 0.50. Looking across the assessments for each of the deviant categories, it was clear that the client's arousal to these decreased across time, although his arousal to adult mutually consenting sexual activity (FAD) indicated that this was clearly his most preferred stimulus in all assessments except for the 30-day follow-up, in which mutually consenting heterosexual activity (MAD) was the most preferred stimulus.

The client's self-report of sexual arousal using the 10-point Likert scale (0 = not at all aroused, 9 = extremely aroused) for each category of stimulus across the four assessments, yields an indication of an individual's subjective experience of arousal, which is not always perfectly related to his physiological responding. Once again, it was found that FAD stimuli elicited the greatest levels of arousal, whereas all others dropped off to 0.

The client clearly showed clinical progress in both his physiological and self-report of arousal toward sexually deviant stimuli that were the main areas of concern, using the assisted covert sensitization procedure. Recall that the underlying behavior principle of covert sensitization is most often theorized to be a combination of classical and operant conditioning, as described earlier. Given decrements in physiological arousal and self-report normally observed in covert sensitization procedures, such as in the present case study, it is logical to conclude that the aversive image associated with deviant sexual arousal (the UCS) becomes a CS by virtue of its being contingently paired with the UCS (classical conditioning). Also, it is logical and theoretically coherent to conclude that both the conditioned response (CR) and the unconditioned response (UCR) consist of a negative reaction that may be emotional (e.g., fear), physiological (e.g., nausea), or in some other way repulsive, which further serves to negatively reinforce avoidance or escape behavior (operant conditioning).

V. SUMMARY

Assisted covert sensitization represents an empirically validated approach to treating sexually deviant behavior patterns, focusing on both the covert and overt behavioral manifestations of inappropriate sexual arousal patterns, and therefore assisted covert sensitization is a main line behavior therapy technique in the treatment of sexual offenders.

 - IV. Summary
- Further Reading

Attention training refers to the procedures used to improve attention deficits as they impact on cognitive and social aspects of functioning. This article reviews the various training techniques that are used, the conceptual underpinnings of the treatment procedures, and studies of treatment efficacy.

GLOSSARY

- anhedonia** A psychological condition evidenced as an inability to experience pleasure in activities that normally produce it.
- avolition** Lack of intent or will to perform activities.
- contextualization** Placing the learning exercise in a context so that the practical utility and link to everyday interests and activities are obvious to the learner.
- errorless learning** The elimination of trial and error approaches to learning by beginning with easily mastered exercises and slowly increasing the difficulty level.
- generalization** The transfer of a learned skill or behavior to other situations besides the one where the training occurred.
- intrinsic motivation** The motivation to do an activity because performance of that activity is in and of itself rewarding. Contrasts to extrinsic motivation, which occurs when there are external rewards for performing an action.
- reaction time** Time taken to respond to an auditory, visual, or proprioceptive stimulus.
- shaping** Process of systematically reinforcing an individual for demonstrating behaviors that increasingly approximate a target behavior.

I. DESCRIPTION OF TREATMENT

Remediation of attentional impairments is approached with different techniques depending on the aspect of attention that requires improvement, and the specific characteristics of the population being treated. The actual process of remediating attention typically includes various exercises that are done in a controlled treatment setting with the ultimate goal of increasing attention performance in everyday life. Before treatment begins, assessment of the particular needs of the patient is done. This assessment forms the basis for a treatment plan, and also can serve as a baseline measure in studies of treatment effectiveness.

A. Assessment

The assessment includes a thorough history that helps to identify the etiology of the attention problems. Medical and psychiatric history identifies conditions known to affect attention and other cognitive functions, and establishes the extent to which attention problems are

state (episode) versus trait (interepisode) related. Current medications and other treatments are reviewed with note made of how they are tolerated by the individual. Medication and electroconvulsive therapy (ECT) induced attention impairment is treated by titrating the dose, or changing drug class to minimize cognitively toxic effects. Assessment also includes educational and occupational history to identify baseline/premorbid functioning. Current functioning is reviewed with an emphasis on identifying how attentional impairments are evidenced in everyday life. Ability to attend during therapeutic activities, at school, in work, and in social situations is evaluated. Some formal testing of attention is done to provide objective data on how the patient's attention compares to a normative group. This testing includes measures of different aspects of attention such as ability to encode, focus, and sustain attention. Some of the commonly used tests are Digit Span, Coding, Cancellation Tests, Continuous Performance Test (CPT), as well as others. Ability to stay on task in therapeutic or vocational activities may be quantified as time on task or rated with scales. Some assessment of differences in ability to attend to auditory versus visual stimuli can be done.

Learning style is discussed as a way of increasing and assessing patient awareness of cognitive strengths and weaknesses. Patient awareness of attention deficit and how it impacts on their functioning is assessed, as is motivation for treatment and attitude about learning. Ultimately, this assessment identifies how attention processes are functioning relative to those of an age (and education) matched group, possible etiologies for the impairment, areas to focus on in attention remediation, and treatment techniques most suited to the learning style and needs of the patient. The assessment, inasmuch as it is done in one of the first meetings with the cognitive remediation staff, should also serve to engage the patient in treatment. As in any first therapeutic encounter, the cognitive remediation assessment not only assesses but also lays the groundwork for a productive therapeutic collaboration between the patient and the provider.

B. Treatment Plan

A treatment plan in cognitive remediation delineates the overall goal, the specific objectives, and the interventions. For example, the overall goal may be to improve ability to focus and sustain attention. The specific objectives may be to increase ability to stay on task from 15 minutes to 45 minutes, or to improve performance on the CPT. Specific objectives include some measures of test performance and some functional

measures to show that the attention training has generalized outside the remediation setting. The interventions indicate the actual attention training procedures to be used and the person who will be doing them.

C. Treatment Interventions

1. Computer-Based

There are several computerized attention training exercises that have been developed for head-injured patients and these have also been used with psychiatric populations. The Orientation Remedial Module (ORM) is a program developed at NYU Rusk Institute that has a number of attention training exercises and a reaction time test that can be administered before and after each training session. The tasks are intended to improve arousal, alertness, rapid and well-modulated responsiveness, scanning, target detection, and rapid processing of simple information. There are five modules (attention reaction conditioner, zeroing accuracy conditioner, visual discrimination conditioner, time estimates, and rhythm synchrony conditioner) that involve receiving auditory and visual stimuli and eliciting a series of simple visual-motor responses. Progression through one module builds skills necessary for subsequent modules. The tasks are somewhat engaging and feedback is provided to the patients about their performance.

Captain's Log software, available through BrainTrain, and the training exercises developed by Bracey are examples of other computer-based cognitive training packages that include tasks intended to improve auditory and visual attention. There are a number of software exercises available through different vendors, all designed to improve attention, in head-injured or ADHD populations. Although there is no software designed specifically for use by psychiatric populations, some success has been reported in the application of the exercises to this patient group. Psychiatric patients often have severe motivational problems that can affect response to any treatment. Characteristics of software that are best suited to populations with motivational problems include engaging presentation of material, options for personalizing and controlling aspects of the task, frequent feedback, and placing the activity in appealing, relevant contexts. Educational software, developed for use in primary and secondary curriculums, is frequently designed with these features, and some include exercises to improve attention and memory.

Computer-based software exercises are intended to be worked on by individuals, but it is possible to have several individuals working simultaneously at separate computer stations. Depending on the patient profiles,

one therapist typically works with one to four clients. The therapist monitors and facilitates productive engagement in the activity and guides the patient to appropriate exercises.

2. Noncomputer-Based

Attention is sometimes the focus of group exercises done within the context of psychiatric rehabilitation. These exercises are rarely as purely cognitive as those done on the computer and are often done in conjunction with the computer exercises to facilitate generalization to an ecologically meaningful context. For example, Integrated Psychological Therapy (IPT) is a highly structured group therapy approach that includes five subprograms, three of which are devoted to development of those cognitive abilities thought to be the prerequisite for effective social interaction. Attention is the focus of a few of these IPT exercises; for example, one task requires verbatim repetition and paraphrasing of what another group member said. A wide variety of other group exercises that target attention can be accessed through occupational therapy manuals. For example, a group exercise to tone visual scanning and vigilance may involve a version of I Spy, whereby patients search a highly intricate picture for target objects.

For those clients who are so severely attentionally impaired that they are unable to tolerate group formats, behavioral techniques such as shaping can be integrated into the skills training. Shaping refers to the systematic reinforcement of behaviors that increasingly approximate a target behavior. When the goal is to enhance social attention, the behaviors that indicate attentiveness, such as keeping eyes open or looking at the speaker, can be reinforced. Shaping techniques can be used to enhance social aspects of attention or to develop attention in nonsocial contexts such as target detection.

Other noncomputer-based attention tasks can be done individually or in a group with each patient working on his or her own exercises. Some exercises are actually versions of attention tests that are instead used to train performance. For example, cancellation tasks that require the patient to scan a paper and mark all the target stimuli, and coding tasks that are similar to Digit Symbol, can be used as a remediation or assessment tool. These exercises are best used in conjunction with other tasks since there is a disadvantage associated with exclusive use of outcome measures as a remediation tool. Generalization of skill is promoted when target behaviors are paired with multiple cues in multiple contexts, something that does not happen when the outcome measure is the only remediation tool used.

3. Holistic versus Targeted Treatment Approaches

Attention training is typically done in the context of a comprehensive treatment program. Whereas a targeted approach would focus on the purely cognitive, nonsocial aspects of attention, a holistic approach addresses both the cognitive and social aspects of attention. Issues of awareness, self-esteem, and learning style are appreciated as having a potential impact on cognition, and they are therefore addressed in the remediation sessions.

4. Intensity and Duration of Treatment

There are no conclusive data to provide guidelines on these treatment parameters. Many studies of treatment efficacy used a model of three sessions per week. There is considerable variability in the duration of treatment. The more comprehensive programs, which target several cognitive functions in addition to psychosocial skills, typically involve 6 to 12 months. More focused programs, which target nonsocial aspects of cognition, typically involve 10 to 24 sessions. The length of each treatment session may vary from 30 to 60 minutes.

II. THEORETICAL BASES

Impairment in attention is a common symptom of severe psychiatric illness. Patients with schizophrenia perform poorly on tasks that require vigilance, quick responses, or sustained attention. Because these deficits are evident during and between episodes of active psychosis and have been noted in individuals at risk for schizophrenia, they are considered to be trait or vulnerability markers of the disease. Patients with bipolar and unipolar depression, especially if the illness is treatment refractory or has accompanying psychotic features, also have severe problems with attention. Attention has several aspects, and it is possible for some elements of attention to remain intact while others are deficient. For example, the ability to encode information, which can be measured by Digit Span, is differentiated from the ability to sustain attention and maintain readiness to respond to a signal. Tasks such as the CPT measure vigilance or ability to sustain attention, ability to be ready to respond to a target, and not to respond to noise or nontargets.

Impairments in attention have been associated with functional outcome in psychiatric patients. In schizophrenia, impaired encoding and vigilance has consistently been associated with poor social problem solving and difficulty benefitting from rehabilitation

services. Psychosocial skills training is a form of rehabilitation that is widely available for people with persistent psychiatric illness, and it is intended to teach basic life skills such as social interacting, illness management, independent living, and leisure skills. The patients with schizophrenia who have more severe attentional problems are least likely to acquire skills in these programs. The attentional problems make it difficult for them to process the information given in groups, and they may not be able to sustain attention for the duration of the sessions.

Medication does not have a major impact on attention in schizophrenia. There appears to be a positive impact on the gross attentional problems associated with acute psychotic decompensation but the enduring attentional problems that are seen throughout the course of the illness are surprisingly resistant to medication. In the affective disorders, medication can significantly reduce attention problems if attentional deficits are state related and the illness responds to psychopharmacologic intervention. In the treatment refractory patients, attentional problems tend to persist. Furthermore, some medications, such as lithium, can impair attention. Many medications, if not in the therapeutic range, or if idiosyncratically tolerated, can cause attention impairment.

Because attentional problems are so prevalent in the psychiatric disorders, often so unresponsive to pharmacological intervention, and because they are associated with outcome and ability to benefit from treatment, they are targeted for remediation. This remediation is typically done within the context of rehabilitation programs, serving people who have persistent psychiatric illness. As acute care has become increasingly triage oriented, remediation of cognitive deficits is more likely found in outpatient settings or long-term inpatient facilities. Major influences on the development of attention remediation models in psychiatry come from neuropsychology, behavioral learning theory, educational theory, and rehabilitation psychology.

A. Neuropsychology and Attention Remediation

Neuropsychology, and the related field of cognitive psychology, have made major contributions to our understanding of the attentional system, at the levels of both cognitive operations and neuronal activity. The attention system is believed to be composed of subsystems that perform different but interrelated cognitive functions. These different subsystems are mediated by

different anatomic areas that together work as a network. Neuropsychology has emphasized the importance of studying the cognitive origins of psychiatric disorders. From this perspective, the disorders in attention and information processing are seen as critical links in the causal chain leading to formation of schizophrenic symptoms. Attention impairments are not necessarily seen as directly causal in symptom formation but rather as a vulnerability factor that when coupled with other vulnerability factors and stresses, contribute to the onset of psychosis. Sometimes these attention deficits are referred to as nonsocial cognitive deficits, inasmuch as they refer to pure cognitive functioning, or the basic cognitive processes that operate regardless of environmental context. The profile of attention impairment informs the intervention strategy. Those deficits that are vulnerability factors or that limit functional outcome are considered the important ones to target for intervention.

Attention remediation has long been the focus of treatment in programs for the head injured and many remediation exercises have been developed to improve attention in the head injured. These exercises show the influence of neuropsychological models of attention in their singular focus on specific nonsocial aspects of attention. The ability to focus, encode, rapidly process and respond, maintain vigilance, and avoid distraction from competing stimuli, are all aspects of attention that may be isolated for remediation in these exercises. Often these exercises are computerized to facilitate standardization of presentation, precise measurement of response, and frequent feedback. Because nonsocial aspects of attention have been identified as vulnerability factors in schizophrenia, the exercises are considered relevant in psychiatric rehabilitation as well.

Given the ultimate goal of improving attention in real-life contexts it is important that the gains made on laboratory tasks of attention generalize outside the remediation setting. For this to happen there must be an appreciation of how skills are best learned and what factors influence recovery. It is in this regard that learning and educational theory, and rehabilitation psychology have had the most influence.

B. Learning Theory and Attention Remediation

The use of techniques such as shaping, errorless learning, and frequent positive feedback show the influence of behavioral and learning theory. Errorless learning refers to the careful titration of difficulty level

so that the patient learns without resorting to trial and error, and has a positive experience with increasing challenge. Shaping and positive feedback are integral components of the social learning approach of Paul and Lentz, and have been used extensively to decrease maladaptive behaviors in the chronic, highly regressed psychiatric patient. Although Paul's social learning approach was not developed for use with cognitively impaired individuals, methods such as shaping and positive reinforcement have since been found effective for treating attention impairment. Learning theory has also indicated some of the factors that promote generalization of skill. Within the remediation exercises, target behaviors need to be paired with multiple cues, ideally in various contexts, so that the behavior will be elicited in multiple settings. In attention training this occurs when the focus/execute response is paired with auditory, visual, and social cues in a variety of tasks. Patients who do multiple tasks that exercise the ability to focus and quickly execute a response are more likely to improve than those whose training is limited to repetitive execution of one task.

C. Educational Psychology and Attention Remediation

Apathy, anhedonia, and avolition are frequent symptoms in the severely mentally ill, and these motivational problems compromise engagement in treatment. Educational psychology has shown that engagement in a learning activity is most likely to occur when the person is intrinsically motivated, that is, when the person finds the learning experience compelling and not when the person is compelled by external forces to do it. Intrinsic motivation and task engagement occur when the tasks are contextualized, personalized, and allow for learner control. Contextualization means that rather than presenting material in the abstract it is put in a context whereby the practical utility and link to everyday life activities are obvious to the student. In attention remediation, a decontextualized focusing task would require the person to press a button every time a red square appeared on the otherwise blank computer screen. A contextualized focusing task would require the person to assume the role of pedestrian in a task that simulated the experience of responding to crosswalk signals. Personalization refers to the tailoring of a learning activity to coincide with topics of high interest value for the student. Learner control refers to the provision of choices within the learning activity, in order to foster self-determination. In attention training, this

occurs when the patient can choose task features such as difficulty level or presence of additional auditory cues when doing a visual vigilance exercise. Intrinsic motivation, depth of engagement in the task, amount learned, and self-efficacy can all be increased when task design incorporates educational principles.

D. Rehabilitation Psychology and Attention Remediation

Rehabilitation psychology emphasizes an integrated approach to the patient that appreciates the complex interaction of cognitive, emotional, and environmental variables in the recovery process. From this perspective, attention deficits are not seen simply as a manifestation of neuropsychological dysfunction, but rather social-cognitive dysfunction. Rehabilitation psychology favors a more interactive, learning process approach to attention remediation over the formal didactic exercises used in a purely cognition-oriented program. This allows for the social and emotional as well as the cognitive needs of the patient to be addressed and promotes a smooth interplay of cognitive and emotional variables in everyday functioning.

E. Rationale for Computer-Assisted Exercises

Computer-based technology is used in attention training because it is possible to give frequent and consistent feedback, there are opportunities for positive reinforcement, the learning experience can be individualized and personalized, there are opportunities for giving control over the learning process, difficulty levels can be individualized so that the task is challenging but not frustrating, and the student can be given ample opportunity to apply the targeted skill in contextualized formats. The computer itself simply provides the overall learning platform; the software provides the learning tools. The design of the software program and whether or not it incorporates basic educational principles, largely dictates whether the remediation experience will be frustrating or engaging. Computer exercises exert a remedial effect on attention through two broad categories of mechanisms: specific and nonspecific. Specific mechanisms refer to those aspects of the activity that focus specifically on attention. The nonspecific mechanisms refer to those aspects of computer activity that promote or facilitate skill acquisition without directly targeting attention. An example of a nonspecific mechanism would be self-pacing, an option many tasks provide. Self-pacing provides a measure of

control, which is known to facilitate learning. Both the specific and nonspecific mechanisms contribute meaningfully to the overall therapeutic effect.

III. EMPIRICAL STUDIES

The largest and best controlled studies of treatment efficacy indicate a positive effect of attention training. These effects can be seen both in terms of improved performance on pure measures of (nonsocial) attention and improvement in social and psychological functioning. Patients exposed to computerized attention exercises such as the ORM have been shown to improve both on the remediation exercises themselves and on the CPT, an independent measure of ability to focus and sustain attention. Noncomputerized attention training such as the IPT groups, which offer exercises to improve attention in social contexts, has also been demonstrated to improve performance on some aspects of pure, nonsocial attention. Performance on the Span of Apprehension, which requires rapid scanning of stimulus features, was improved in patients exposed to 6 months intensive IPT training. There is also evidence that computerized and noncomputerized attention training impacts on social competence and psychological status as measured by such instruments as the AIPSS and BPRS. Shaping techniques used in group therapy to improve social aspects of attention have been found to improve ability to stay on task as measured in minutes, in small samples of chronic treatment refractory patients, some who had low IQ. Well-controlled, large treatment efficacy studies are still rather scarce and replication of results is required. Many parameters have yet to be studied, for example, optimal intensity and duration of treatment, characteristics of treatment responders and nonresponders, and optimal balance of focus on social and nonsocial aspects of attention.

IV. SUMMARY

Attention impairment is a common symptom of psychiatric disease. In schizophrenia, attention impairment is associated with poor outcome, deficient social skills, and diminished ability to benefit from rehabilitation and skills training. The attention system is composed of subsystems that perform different but interrelated cognitive functions such as the ability to focus, encode, rapidly process and respond, maintain vigilance, and avoid

distraction from competing stimuli. These aspects of attention can be differentially impaired and the first step in designing a treatment program is to identify the type of attentional problems that will be the target of intervention. Both the purely cognitive and more social aspects of attention can be addressed in the remediation program. The procedures available for remediation of attention include computerized and noncomputerized exercises that may be done individually or in groups. Computerized exercises tend to focus on the more purely cognitive aspects of attention, whereas group exercises often target attention as it applies in a social setting.

Given that attention deficits are not simply a manifestation of neuropsychological dysfunction, but rather social-emotional-cognitive dysfunction, remediation procedures that emphasize an integrated approach to the patient are more likely to appreciate the complex interaction of cognitive, emotional, and environmental variables in the recovery process. Attention remediation has been found to be effective in improving performance on pure measures of (nonsocial) attention and social and psychological functioning. Replication of well-controlled treatment efficacy studies is needed. Many treatment parameters have yet to be researched, for example, optimal intensity and duration of treatment, characteristics of treatment responders and nonresponders, and the various contributions of specific and nonspecific treatment effects.

- Further Reading

GLOSSARY

aversion relief A therapeutic procedure in which the occurrence of desired behavior leads to the cessation of an aversive stimulus.

aversion therapy A variety of specific techniques based on both classical and operant conditioning paradigms intended to change maladaptive behavior.

covert sensitization The pairing in imagination of undesired behavior with covert negative consequences.

negative reinforcement Removal of an aversive stimulus that leads to an increase of the future probability of the desired response.

punishment A method of behavior control in which an undesired response is followed by a noxious stimulus, thus leading to a reduction of the future probability of the undesired response.

I. DESCRIPTION OF TREATMENT

Aversive methods were used widely in the 1960s and 1970s, but for a variety of reasons these methods are less accepted today. Aversive methods are used for treating maladaptive approach behavior, such as alco-

hol dependence, smoking, overeating, obsessive-compulsive behavior, and various forms of deviant sexual behavior. Furthermore, perhaps most controversial, aversive methods have also been used in patients with autism and mental retardation.

Aversive conditioning is intended to produce a conditioned aversion to, for example, drinking or deviant sexual interest. *Aversion therapy* includes a variety of specific techniques based on both classical and operant conditioning paradigms. With aversive conditioning in alcohol-dependent subjects, a noxious stimulus (unconditioned stimulus, UCS) is paired with actual drinking (conditioned stimulus, CS) or with visual or olfactory cues related to drinking. A variety of aversive stimuli have been used, the most popular of which were electric shock and nausea- or apnea-inducing substances. *Covert sensitization* is a variant of aversive conditioning wherein images (e.g., of drinking situations or of deviant sexual stimuli) are paired with imaginal aversive stimuli. It is actually “covert” because neither the undesirable stimulus nor the aversive stimulus is actually presented, but these are presented in imagination only. “Sensitization” refers to the intention to build up an avoidance response to the undesirable stimulus.

In *aversion relief* the subject is enabled to stop the aversive stimulus by performing more appropriate behavior, which will lead to feelings of relief. For example, deviant sexual stimuli (e.g., pictures of nude children) may be the UCS followed by the onset of shock (CS), while the cessation of shock is preceded by the appearance of pictures of nude adult women. The procedure is

intended to condition the pleasant experiences associated with the cessation of shock (aversion relief) to adult females, while the unpleasant experiences associated with the onset of shock are conditioned to children.

A classical example of aversion relief therapy in children with autism was presented by Lovaas and his co-workers. Autistic children were asked to approach the therapist. If the child did not approach, shock was delivered and continued until an approach was made. Subsequently, shocks could be avoided by approaching within 5 seconds of the request. This application of aversion relief led to a dramatic increase in the approach behavior of autistic children and had maintained its effect nine months later without further shocks.

A common example of aversion relief therapy is the application of bitter-tasting substances on the thumb in children who engage in thumb- or finger-sucking activity. Thumb- or finger-sucking will now lead to a bad taste, which will stop as soon as the child withdraws the thumb or finger out of the mouth (aversion relief).

Aversion relief has also been applied in treating anxiety disorders by Solyom and colleagues, including obsessive compulsive behavior, specific phobias, and agoraphobic avoidance. Solyom detailed an aversion relief procedure in the context of agoraphobic avoidance. Patients were repeatedly guided through audiotaped self-generated narratives of phobic avoidance. The vignettes might be interspersed with short pauses after which mild electric shocks (ES) were delivered. Patients could terminate the shock by pressing a button and continuing the taped approach scenario. For a particular female patient the narrative was: *"I am getting dressed ... 15 sec ... ES, button pressed (by patients to terminate ES) to leave my home, as I am getting prepared and put my make-up on ... 15 sec ... ES, button pressed, the bell rings ... 15 sec ... ES button pressed. My heart is beating very fast I answer the bell and my boyfriend comes in, he says ... 15 sec ... ES button pressed, let's go Mary, ... 15 sec ... ES button pressed, the party is already on."*

Covert sensitization might be considered an imaginal variant of aversion relief and is also referred to as aversive imagery. Before the formal treatment by covert sensitization begins, it is important to gather detailed information concerning the characteristics associated with the maladaptive approach behavior to be changed. This information is essential in order to develop realistic scenes for the patient. Furthermore, some time is spent in providing the treatment rationale. It is explained that the problem (e.g., drinking) is a strongly learned habit that must be unlearned by the association

of the pleasurable situation (e.g., drinking) with an unpleasant stimulus (feelings of nausea and vomiting).

The procedure will be illustrated with a case of a male alcohol-dependent patient. In this procedure, the patient first learns to relax. When he is able to relax, he is asked to close his eyes and to visualize very clearly a drinking situation. For example, he may be asked to visualize himself in a pub, looking at a glass full of beer, holding the glass in his hand, and having the glass touch his lips. Then he is asked to imagine that he begins to feel sick to his stomach and that he starts vomiting all over himself and the female bartender. Then he is told to imagine that he rushes outside, or that whenever he is tempted to drink but refuses to do so, the feeling of nausea goes away and he will feel relieved and relaxed (aversion relief).

It is important to use as many aversive details as possible. A verbatim account might run as follows: *Your stomach feels rather nauseous. As you look at the glass, puke comes up into your mouth. As soon as you smell the beer, you cannot hold it any longer: you vomit. It goes all over your hand, and your glass. Snot and mucous comes out of your nose, you can see it floating around in the beer. There is an awful smell. As you look at this mess you just can't help but vomit again and again. The female bartender gets some on her shirt and pants. You see her shocked and disgusted expression. You run out of the bar and you feel better and better.*

The patient is usually asked to repeat the scenes presented during the therapy sessions a number of times daily until the next appointment. These scenes can be written on pocket-sized cards. The patient is instructed to carry these cards and to read these scenes several times a day. Furthermore, the patient is also instructed to use this procedure immediately upon noticing an urge to drink. Thus, a lot of *in vivo* conditioning occurs in actual temptation situations, when the patient applies the procedure in the prescribed manner outside the therapist's office.

II. THEORETICAL BASES

Aversion relief procedures are rooted in learning theory. Decreasing the frequency of a behavior by presenting an aversive stimulus immediately after an inappropriate response is a case of punishment. Increasing the rate of a behavior by removing aversive stimuli contingently following a desired response is termed negative reinforcement. Escape responses produce relief from aversive stimuli; this procedure is

called aversion relief. For example, shock during alcohol sipping could be avoided or escaped by spitting out the alcohol. The aversion relief component of the treatment of alcoholics utilizes a desirable response (e.g., spitting out alcohol) as a potential positive reinforcing stimulus, deriving its positive quality from its contiguity with escape.

In covert sensitization, the imagining of an aversive situation (e.g., vomiting) as soon as the individual has an urge to perform the undesired behavior (e.g. drinking) is usually considered a punishment procedure: An aversive stimulus is made to follow the inappropriate response to be reduced. According to punishment theory, response frequency can be expected to decrease when the noxious stimuli are contiguous with that response. Initially, the aversive stimulus should be presented on a continuous basis, but later on a partial schedule can be used. The aversion relief part of covert sensitization can be considered an escape procedure, which occurs when a particular stimulus terminates the presentation of a noxious stimulus. Eventually, cues that initially led to urges will gradually become discriminatory stimuli for avoidance behavior.

Although there is some evidence that covert sensitization may lead to a favorable outcome in patients with addictions and deviant sexual interest a number of theoretical issues remain unresolved, which cast doubt on the presumed theoretical underpinnings of covert sensitization. First, although scene presentation in covert sensitization includes aversion relief, the addition of this component to the overall effectiveness of the procedure has not been evaluated. Moreover, Emmelkamp and Walta found that the effects of covert sensitization could better be explained by cognitive factors such as outcome expectancy than by conditioning. In their experimental study, half of the participants (smokers) were led to believe that they participated in an experimental study on the physiological effects of imagining smoking scenes, whereas the other half were informed that they received a bonafide treatment. All participants were treated with covert sensitization. Only the smokers who expected that they received an effective treatment showed a significant reduction in smoking rate. Thus, the results of this study suggest that cognitive factors (i.e., expectancy of improvement) rather than conditioning factors may account for the positive effects achieved with covert sensitization. Others have also questioned the conditioning explanation of covert sensitization, since covert sensitization using backward conditioning was found to be as effective as covert sensitization using forward conditioning. If covert sensiti-

zation acted by conditioning, the backward procedure should be considerably less effective than one administering the same conditioned and unconditioned stimuli, in the same number of trials, but in a forward conditioning paradigm.

III. EMPIRICAL STUDIES

Most of the studies attesting to the effectiveness of aversion relief as a principal treatment have been uncontrolled case studies. Procedures based on aversion relief have been successfully applied in specific phobias, obsessive compulsive behaviors, obesity, aphonia, torticollis, writing cramp, transvestism, fetishism, and other deviant sexual interests. Results with thumb-sucking are not always positive. Nathan Azrin and his co-workers compared aversion relief therapy (using a bitter-tasting substance) with habit reversal in 32 children with thumbsucking. At three-month followup, 47% of the habit-reversal children had stopped thumbsucking, compared to 10% of the aversion relief children. These findings suggest that aversion relief may be of little value in reducing thumbsucking. However, the parents in the aversion relief therapy were only instructed by phone, whereas the therapist saw the habit reversal children and their parents in a single session. Given this methodological flaw, the results must be viewed with caution.

Much of the research on the effectiveness of aversion relief in anxiety disorder patients comes from research conducted by L. Solyom and his colleagues. The largest study to date involved 50 phobic patients randomly assigned to flooding in imagination, systematic desensitization in imagination, aversion relief, phenelzine, or placebo. On psychiatric rating, aversion relief was found to be more effective than the other methods. However, results are difficult to interpret since the patients in the aversion relief therapy received twice as many therapy sessions (24 sessions) as compared to patients who received flooding or systematic desensitization (12 sessions). In an earlier study by the same research group, the effects of aversion relief were investigated in agoraphobics. In this study, overall improvement was rather small. Patients rated their main phobia as unimproved.

Although some uncontrolled case studies suggest that aversion relief may be of some value in patients with obsessive-compulsive rituals and patients with pure obsessions, the only controlled study into the effectiveness of aversion relief with obsessive-compulsive

patients found this treatment to be ineffective. Or, as Kapche concluded in an earlier review of Aversion Relief Therapy (ART): "While ART does not apparently hinder treatment, there is no strong evidence that it is beneficial." Perhaps as a byproduct of the demonstrated effectiveness of exposure *in vivo* procedures, little interest has since been shown in evaluating the effectiveness of aversion relief in patients with anxiety disorders.

Several studies have evaluated the effects of covert sensitization among alcoholics, but the findings of most of these studies are difficult to interpret due to severe methodological limitations. One study provided some evidence that conditioned nausea could be produced in a number of alcoholics receiving covert sensitization treatment. Approximately 90% of patients who remained in treatment for at least six covert sensitization sessions reacted with genuine nausea responses as evidenced by swallowing, muscular tremor, and facial grimacing and occasionally by actual vomiting, but only two-thirds of these subjects developed some degree of conditioned nausea. Conditioned nausea was defined as "nausea arising as a direct consequence of the subject's focusing on pre-ingestive or ingestive concomitants of typical drinking scenes." Significant degrees of extended abstinence were observed for conditioned nausea subjects as opposed to other participants. Another well-controlled study found covert sensitization more effective than insight-oriented therapy and routine milieu treatment in alcohol-dependent inpatients. In both studies, participants were inpatients in a traditional alcoholism rehabilitation program. Thus, conclusions with respect to covert sensitization as a primary form of treatment are not warranted.

A number of studies have been reported that used covert sensitization to reduce deviant sexual interest, primarily exhibitionists. The largest series ($n = 155$) was reported by Barry Maletzky, which included a followup ranging from one to nine years. Generally, results of covert sensitization were positive, but a number of issues preclude more definite conclusions. For example, in the Maletzky studies, about half of the exhibitionists received other procedures in addition to covert sensitization. Moreover, these studies did not include control groups, and progress was evaluated by means of self-report only. Furthermore, there is some support in a number of controlled case studies for the effectiveness of covert sensitization in pedophilic child offenders, but controlled group studies have not yet been reported. Maletzky addressed the issue of whether there is a difference in outcome between self-referred and court-referred pedophiliacs ($n = 38$). Treatment

consisted of 24 weekly sessions of covert sensitization and was followed by "booster" sessions every three months for three years. When assigning 75% reduction in covert and overt pedophile behavior as a criterion for improvement, 89% of the self-referred and 73% of the court-referred subjects were rated as improved. Several measures showed a slight superiority of response in the self-referred group. Inspection of the police records over a three-year period revealed that the self-referred group had no charges, while the court-referred group had four charges.

IV. SUMMARY

Despite its strong empirical basis in learning theory and the interest it evoked in the 1970s, few controlled studies have evaluated the effects of aversion relief therapies in clinical patients. Although a number of studies have reported successful treatment in a variety of disorders (e.g., alcohol dependence, smoking, overeating, and anxiety disorders), it should be noted that most reports involved (a series of) case studies. Apparently, the literature on aversion relief dried up in the early 1980s: A Psychinfo literature search revealed no new references in the 1990s, 7 references in the 1980s, and 18 and 5 articles in the 1970s and 1960s, respectively. This does not specifically concern aversion relief as such but involves nearly all aversive methods. Apparently, only covert sensitization has not gone totally out of fashion.

One of the main reasons behind the absence of recent controlled research into the effects of aversion relief procedures may be that aversive stimulation has become an increasingly controversial ethical issue. Some have argued that aversive methods are justified only when the behavior is seriously dangerous to the individual and when no alternative treatment options are available. Internationally, many institutions no longer allow aversive methods. In addition, in most institutions it is current practice to require that aversive methods using electric shock obtain prior approval by the human rights committee. To be approved, one typically needs to demonstrate that (1) alternative treatment options have failed or are unjustified, (2) the client (or parents) has given informed consent, and (3) colleagues have approved this technique as professionally justified.

Interest in aversion relief therapy may also have waned because alternative (and less intrusive/objectionable) treatments have been found to be at least as effective. For example, in the area of anxiety disorders

in vivo exposure methods are now considered the gold standard, and there is little reason to believe that aversion relief therapy will be able to surpass the effects achieved with exposure therapy. Similarly, in the area of alcohol dependence, alternative cognitive behavioral procedures (e.g., motivational interviewing, coping skills training, and relapse prevention) have been developed and evaluated in large multicenter trials, such as the MATCH project.

GLOSSARY

- avoidance-responding* Behavior that postpones (prevents) contact with an unpleasant consequence event.
- escape-responding* Behavior that terminates ongoing contact with unpleasant stimulation.
- negative reinforcement* An increase in behavior as a result of terminating or postponing an unpleasant stimulation or consequence event.

Avoidance training is an intervention approach used with children and adults that incorporates nonpreferred and unpleasant consequences to treat behavior disorders. Individuals are taught to refrain from problem responses or to demonstrate acceptable alternative responses by avoiding contact with the nonpreferred and unpleasant consequences. This entry reviews the conceptual foundations of avoidance training, use of the procedure in clinical psychology, and supportive research findings.

I. DESCRIPTION OF TREATMENT

An understanding of avoidance training can be gleaned from the following “everyday life” example. Motorists frequently exceed the speed limits posted on our highways. If a driver in such a situation sees a blinking light ahead and determines that it is a police vehicle, the driver responds by reducing speed and conforming to the specified limit. In this example, the driver’s behavior of slowing down avoids a possible encounter with law enforcement that, in turn, leads to a negative consequence (receipt of a speeding ticket). Responding occurs in this way because the driver may have previously been stopped by police or may have observed such activity with other motorists. As described subsequently, this description includes all of the components integral to avoidance training.

When implemented for therapeutic purposes, avoidance training follows a five-step process: (1) identifying the problem behavior to be reduced, (2) selecting a response to serve as replacement for the problem behavior, (3) choosing a negative consequence, (4) pairing the negative consequence with the problem behavior, and (5) allowing the child or adult to avoid the negative consequence. A more detailed description of each step follows.

Behaviors that are the target of avoidance training usually are those that interfere with personal well-

being, social adjustment, school performance, occupational functioning, and the like. Thus, a child may show extreme noncompliance with parental requests, or an adult may argue excessively with co-workers. However, skill deficits also are addressed through avoidance training. A child, for example, may have a health-compromising condition because she or he has a chronic problem of eating a very limited amount of food. Here the issue is not the presence of a specified “challenging” behavior but instead the absence of a skill. In most cases, simultaneous elimination of a problem and acquisition of a replacement behavior is the objective of avoidance training.

The issue of a skill deficit is most relevant to step 2 in the avoidance training paradigm: the selection of a replacement behavior. Recall that a primary objective of avoidance training is to strengthen one or more responses that can substitute for the problem. However, one must determine whether the replacement behavior is a skill that the child or adult possesses but does not perform regularly or is a skill that the child or adult has not learned. Failure to demonstrate a skill that is within a person’s repertoire is a difficulty with performance. Not using a skill because it has not yet been learned is a difficulty with acquisition. Accordingly, how a skill deficit is manifested will have implications for whether avoidance training is warranted as intervention and, if so, what the replacement behavior should be.

The third step in the process of avoidance training is to choose a negative consequence that eventually will be paired with the display of the problem behavior or the absence of the requisite skill. A negative consequence is unpleasant and produces distress for the individual. For this reason, certain ethical and clinical concerns must be embraced when considering avoidance training. During the 1960s and 1970s, many publications in the behavior modification and behavior therapy literature described avoidance training applications that relied on “noxious” (aversive) types of stimulation such as electric shock, distasteful solutions, and foul odors. These stimuli are highly invasive and, over time, have fallen out of favor with behavioral practitioners. As revealed in the subsequent section on empirical studies, the “later generation” research concerning avoidance training typically has incorporated negative consequences that are less restrictive and intrusive. Nevertheless, these interventions expose individuals to unpleasant conditions and, therefore, must be selected and formulated cautiously.

Step 4 of avoidance training is to implement the contingency in which the negative consequence is con-

tacted. The contiguous pairing of behavior and consequence allows the individual to learn the avoidance function that is intended to promote alternative responses. Repeated trials usually are programmed to hasten learning effects. It should be noted, however, that informing an individual about the relationship between behavior and the negative consequence may also produce a desirable outcome. In this situation, the negative consequence is not experienced directly, and controlling effects are achieved through verbal mediation (i.e., the individual is told “what will happen”).

The final step is the continued exposure of the individual to conditions where the negative consequence is avoided following the demonstration of the alternative behavior. The objective here is to maintain clinical improvement for an extended duration.

The following illustration depicts how the five steps in an avoidance training protocol would be instituted. The example is a school-age child who exhibits disruptive behaviors in the classroom such as talking out of turn, annoying other students, and using materials to make noise. Because of these behaviors, the child does not complete academic assignments. The classroom teacher determines that one way to reduce these interfering behaviors is to require the child to complete all assignments in order to participate in daily recess periods. If motivated to complete the assignments, it is likely that the problem behaviors will decrease. This depiction qualifies as avoidance training because the undesirable consequence of not having recess can be avoided when the child completes academic assignments. The child learns this contingency when she or he experiences the loss of recess because of incomplete performance. Or, to reiterate a previous point, simply informing the child about the conditions governing participation in recess may be sufficient to produce the behavior objective

II. THEORETICAL BASES

The theoretical foundation of avoidance training rests with the concept of negative reinforcement. Reinforcement principles form the basis of operant learning theory that is commonly associated with the research and writings of B.F. Skinner. Positive reinforcement is the presentation of a pleasurable consequence following a behavior, with the result that the frequency of the behavior increases over time. By contrast, negative reinforcement is the removal or postponement of a non-pleasurable consequence following a behavior. Negative

reinforcement has the same objective as positive reinforcement, which is to increase behaviors that are appropriate, useful, and functional for an individual. With negative reinforcement, the removal or postponement of undesirable consequences is an effect that is “pleasurable” to the individual and makes it more likely that the behavior producing that effect will occur more frequently.

Negative reinforcement can operate in two ways. In one instance, a behavior can occur that terminates or reduces the intensity of ongoing stimulation that is unpleasant. The behavior would be described as “escape.” With the second operation, a behavior can postpone or prevent the unpleasant stimulation and would be described as “avoidance.” Escape responding, therefore, requires that behavior be demonstrated in the presence of the unpleasant (negative) stimulation, whereas avoidance responding occurs in the absence of the unpleasant (negative) stimulation.

On a clinical level, the distinction between escape-generated and avoidance-generated behavior is an important one because it is defined by the presence or absence of negative conditions. Imagine an adolescent boy in a psychiatric hospital who is confined to a room (seclusion) because he becomes “out of control” on the inpatient unit. Being in the room is unpleasant for the boy, and he learns that this condition can be terminated by being released from the room when he composes himself. Regaining his control is reinforced negatively because it allows him to escape a contemporaneous, unpleasant condition. Learning by avoidance would be evident when confinement to the room is not encountered by the boy because he behaves properly without “losing control.” Here, negative reinforcement functions because the boy’s desirable behavior prevents room confinement.

Avoidance training can be traced to experimental animal research. Under conditions termed free operant avoidance, electric shocks were delivered automatically to a rat through a device on the grid floor of a small metal chamber. The shocks were programmed to occur at preset intervals via a recycling timer. A second timer postponed shock onset by a particular duration each time the rat pressed a lever. This type of experimentation revealed different patterns of lever-press responding as a function of variables such as shock intensity, temporal parameters between intervals, and the schedule of shock presentations. Related research concerned the study of “discriminated avoidance” in which a neutral stimulus was programmed to precede electric shock. The neutral stimulus functioned as a “warning

signal,” and if the rat exhibited a specific behavior during the time between the onset of the signal and the noxious stimulation, the electric shock would be prevented. The behavior of the rat is “discriminated” because it does not occur in the absence of the signal. This acquisition of discriminated avoidance with lower animals serves as an analog for avoidance training applications with humans.

III. EMPIRICAL STUDIES

As a preview to the presentation of research concerning avoidance training with children and adults, several considerations should be the focus of attention. First, in contrast to other procedures within behavior modification and behavior therapy, there has been less emphasis on avoidance training as a first-line strategy to clinical intervention. This fact likely results from the requirement that unpleasant consequences must be incorporated when programming avoidance training. For many professionals, it is unpalatable to add distress to the life of a child or adult who already is experiencing adjustment difficulties. Even in cases where avoidance training may be clinically justified, it can be an arduous task arranging the conditions wherein negative consequences are arranged contiguously with behavior or are introduced within everyday settings.

A second issue is that where avoidance training has been supported by empirical research, the procedure frequently is combined with other treatment methods. It is rare, in fact, to find studies that have not described such multicomponent intervention. Again, inclusion of negative consequences in the therapeutic process dictates that additional (e.g., positive reinforcement) procedures be used.

Finally, the early history of avoidance training in clinical practice addressed problems, and included certain negative consequences, that are not consistent with contemporary standards. One example is research conducted during the 1960s in which children who had autism and were not responsive to social interaction were treated through avoidance training with electric shock. A therapist issued the instruction, “Come here,” and an electric current was passed through the grid floor. The children “escaped” the aversive stimulation when they approached the therapist. They then learned to avoid the shock by responding quickly to the social instruction.

Other research, reported in the 1970s, used electric shock in an avoidance training paradigm to “treat”

women and men who were homosexual and wished to change their sexual orientation. The clients viewed slides that were projected on a screen and included pictures of same-sex adults, clothed and nude, that were rated as attractive. Viewing the slides for a fixed duration produced an electric shock. The shock could be avoided by pressing a switch, which terminated the slide, before the predetermined viewing time elapsed. Another component of this procedure was to have a slide of the opposite sex appear when the preceding same-sex slide was removed. This strategy was an attempt to build in counterconditioning in which opposite-sex adults would become appealing because they were paired with the relief (a positive event) experienced when shock was avoided.

The preceding examples provide an historical perspective from which to view avoidance training, but they do not represent acceptable, present-day treatments. For one, electric shock is extremely invasive stimulation that behavioral psychologists essentially have abandoned and ceased to defend as viable treatment. Relative to children with autism and other developmental disabilities, many training procedures and effective interventions have been validated that do not rely on aversive methods or subject individuals to painful consequences. As per the description of adult homosexuality, the professional community no longer judges this form of sexual orientation as an illness or pathology. Furthermore, if a homosexual woman or man sought assistance to change her or his sexual orientation, avoidance training of the type described would not be implemented.

More benign examples of avoidance training can be found in the treatment literature with children who received intervention for feeding disorders. Several studies have evaluated avoidance training that targeted chronic food refusal. Children with this problem do not consume food orally or may eat only select food items. In many cases, the food refusal is volitional in that there is no physical cause for the behavior. One type of intervention in such cases has been to place food on a utensil, bring the utensil to the child's lips, instruct the child to "take a bite," and wait several seconds for the child to consume the food. If independent eating does not occur, a therapist prompts mouth-opening by gently pushing against the child's jaw and depositing the food. The physical guidance delivered by the therapist functions as mildly unpleasant stimulation that can be avoided by the child opening his or her mouth after the verbal instruction is given.

Reference to the literature on child behavior problems reveals that avoidance training has been incorporated in many interventions that include contingent effort. Effort procedures require that when an individual exhibits a behavior that disrupts the environment or causes property destruction, the effects of such behavior must be corrected. Thus, children who break objects during an episode of agitation must clean up and restore the surroundings to their previous condition. This increased response effort associated with cleanings is avoided by refraining from the problem behaviors.

IV. SUMMARY

Avoidance training is an approach to clinical intervention that is founded on the principle of negative reinforcement. Children and adults learn to avoid negative and unpleasant consequences by not exhibiting problem behaviors or by demonstrating acceptable alternatives. Avoidance training as a therapeutic procedure can be linked to operant learning theory that was studied in the animal laboratory. In contrast to other behavior-change procedures, avoidance training is used less frequently in clinical practice. Because the procedure requires exposing a child or adult to unpleasant conditions, it must be considered cautiously and implemented with great care in those situations where it can be justified clinically.

number of other behaviors in individuals with developmental disabilities and who are typically developing. This article will present a description of the procedure along with the theoretical basis and empirical support for its use.

GLOSSARY

- chaining** Process by which an organism learns an ordered sequence of behaviors.
- discriminative stimulus** A stimulus in the presence of which a particular behavior is reinforced.
- reinforcement** A process in which a behavior is followed by the presentation of a stimulus and as a result, produces an increase in the future probability of that behavior.
- target behavior** The behavior of interest, or the behavior to be altered.
- task analysis** A step in the backward chaining procedure in which the entire target behavior is broken down into smaller sequential steps.

Backward chaining is a procedure used to establish relatively complex sequences of behaviors in organisms. Although the procedure was originally applied to nonhumans, it has been adopted for use with humans. Typically, backward chaining is used to improve the independent functioning of individuals with developmental disabilities, but it can also be used to establish a

I. DESCRIPTION OF TREATMENT

Many human tasks involve a number of simple, but separate, motor behaviors that when organized into a specific sequential fashion, produce a desired outcome. For example, the task of brushing one's teeth can be broken down into the following simple behaviors: picking the toothbrush up, reaching for the tube of toothpaste, grasping the tube of toothpaste, putting paste on the brush, putting the brush in the mouth, moving the brush back and forth across the teeth, rinsing the mouth, and rinsing the toothbrush.

Even a relatively simple task such as brushing one's teeth consists of a number of component behaviors (which themselves, could be further broken down) that must be completed in a specific sequence before an acceptable outcome can be achieved (i.e., clean teeth). In most cases, humans learn such sequences of behavior (called chains) without focused instruction. However, in some cases, focused instruction is required as may be the case for persons with developmental disabilities.

To aid in establishing chains of behavior in humans, applied psychologists have borrowed strategies

originally designed by basic researchers in the area of operant conditioning. Practitioners have adopted three such strategies including whole-task chaining, forward chaining, and backward chaining. The focus of this article is on backward chaining.

Backward chaining is implemented in the following fashion. First, the clinician must identify the chain of interest and the target behavior from completing the chain. For example, assume that the clinician wishes to train a client with low functioning to make sandwiches. In this case, the chain of interest is sandwich making and the target behavior would be consuming the sandwich.

After the target chain and target behavior have been identified, the clinician must conduct a task analysis. When doing a task analysis, the clinician breaks the target chain into discrete component behaviors. For example, the task analysis of the sandwich-making chain may consist of the following components: taking a plate out of the cupboard, taking two slices of bread out of the bag, taking the lunch meat and mustard out of the refrigerator, putting one slice of bread on the plate, putting the meat on the sandwich, putting the mustard on the meat, placing the remaining slice of bread on top, and lifting the sandwich to the open mouth.

Although it clearly can be seen that the aforementioned task analysis could be broken down into more specific behaviors, the level of specificity used in creating the task analysis should be matched with the client's level of functioning. Clients with lower functioning may require a task analysis that breaks the chain into very simple and specific components, whereas clients with higher functioning may do well with a less simplified task analysis.

On completion of the task analysis, the actual chaining procedure begins. In backward chaining, the first behavior learned by the client is the last component behavior in the chain. On completion of the final behavior in the chain, the person receives the reinforcer associated with the outcome of the chain (called the terminal reinforcer). In the aforementioned chain, the first behavior learned by the client would be lifting a prepared sandwich to the mouth, and the resulting reinforcing outcome would be consuming a bite of the sandwich. To teach the sandwich lifting, the clinician should start by providing a verbal prompt to engage in the chain of behavior (e.g., "Alice, make a sandwich for yourself.") and then model the behavior for the client. After the clinician models the behavior, he or she should then provide the verbal prompt again followed by a physical prompt for the client to do the same behavior. After the client lifts the sandwich to her mouth, she should be allowed to

take a bite and should be praised at the same time. After the final behavior in the chain occurs reliably when the verbal prompt is given, the clinician should begin to train the second-to-last step in the chain.

When training the second-to-last step, all the steps in the chain should be completed by the beginning of that step. Continuing with the previous example, in teaching the second-to-last step in the chain, the sandwich would be completely made except that the last slice of bread would not be on the sandwich. When training this task, the clinician would again provide the verbal prompt (e.g., "Alice, make a sandwich for yourself."), model the specific task (putting the last slice on the sandwich) and complete the remainder of the chain (lifting the sandwich to the mouth and taking a bite). After the modeling, the clinician would provide the verbal prompt then physically prompt the client to engage in the novel step (i.e., putting the last slice of bread on the sandwich), provide praise for doing so, and prompt the completion (if necessary) of the remaining steps in the chain.

After the client is reliably implementing the second-to-last link followed by the completion of the remainder of the chain, the clinician should begin training the third-to-last step using the aforementioned procedures. This sequence should continue until the client has learned the entire sequence and can implement the entire chain contingent on the verbal prompt (e.g., "Alice make a sandwich for yourself.").

II. THEORETICAL BASIS

Backward chaining was developed by operant learning researchers to systematically train complex sequences of behaviors. The term chaining refers to the way in which the behaviors pertaining to a specific sequence are linked together. In backward chaining, the behaviors are learned in a reverse order from how the chain is performed. In other words, the final step in the chain is learned first, followed by the next-to-last step and so on. Each link in the behavioral chain is evoked by a discriminative stimulus and reinforced by the consequences of the behavior involved in the link. For example, in early learning studies, a discriminative stimulus (e.g., a red light) was presented to the organism. If the organism made the correct response (e.g., pressing a lever), food was presented. Not only was the lever pressing reinforced, but the red light was also established as a reinforcing stimulus. When the operant chamber was rearranged so the organism had to do another behavior (e.g., wheel running) to produce the red

light, it soon did so and then completed the chain of pressing the lever and receiving food. In this case, the presence of the wheel became a discriminative stimulus for wheel running, which was reinforced by the appearance of the red light. The red light, in turn served as a discriminative stimulus for the lever pressing that was reinforced by the final outcome of food presentation.

In the applied arena, backward chaining is conceptualized in a similar fashion. The outcome of the chain is equivalent to the food received by the non-human organism in the operant chamber. The discriminative stimulus for the last link in the chain is the situation present immediately prior to engaging in the last behavior. Using the previous applied example, the discriminative stimulus would be the completed sandwich lying on a plate prior to being picked up. As the clinician moves backward to the next step in the chain, the completed sandwich will not only function as a discriminative stimulus for picking the sandwich up, but the sight of the completed sandwich will function as a reinforcer for the preceding behavior in the chain (e.g., putting the last piece of bread on top of the mustard-covered sandwich). This process will continue until the original verbal prompt begins to function as the discriminative stimulus that will initiate the entire behavioral chain.

As can be seen from these examples, an individual learning a sequence of behavior through backward chaining repeatedly experiences the effect of the terminal reinforcer presented at the end of the chain as each link is added. This theoretical advantage of backward chaining distinguishes it from other methods of chaining such as forward chaining, in which the first step of a sequence is taught first and then linked to the second step and so on, or whole-task chaining, in which all the steps, from start to finish, are attempted on each trial. In the latter two cases, the terminal reinforcer is not presented until the person has successfully learned all steps in the behavioral chain.

III. EMPIRICAL STUDIES

Backward chaining was first implemented in an operant laboratory by B. F. Skinner in 1938. After demonstrating the effectiveness of backward chaining in studies with non-human animals, the procedure was first applied to humans in an effort to develop more effective instructional methods in classroom settings. Since then, backward chaining has been applied in diverse settings and found to be effective in teaching specific skills. In this section, the clinical utility of backward chaining is briefly

reviewed. Included are brief discussions of variables to consider when using this technique, such as target populations and behaviors, treatment outcome variables, and a comparison of backward chaining to other chaining procedures, including a brief discussion on when backward chaining methods should be implemented.

A. Client Populations

Research demonstrates that backward chaining has been successfully used with diverse populations ranging from children to elderly adults. Although some research has demonstrated the effectiveness of this procedure with persons who are typically developing the majority of studies have focused on individuals with developmental disabilities. Within this latter population, backward chaining has been extensively used and found to be particularly effective in teaching skills to children and adults with mild to profound mental retardation and to children with other developmental disorders such as autism. It is not clear why research has focused so heavily on evaluating backward chaining in persons with developmental disabilities, but it may be the case that persons who are typically developing often do not require the intensive type of training to establish behavior sequences as provided by the procedure.

B. Targeted Behaviors

Among persons who are typically developing, backward chaining has been effective in treating children with specific speech problems such as misarticulation. In 1987, Edna Carter Young used backward chaining as part of a procedure to retrain the speech of two toddlers who frequently omitted weak syllables or consonants. Essentially, the procedure involved teaching the child to say the last part of a word first and then incorporating that part into the word. For example, to learn to say the word monkey, the child was first taught to say key, and then join it to the rest of the word, mon, thereby producing the word monkey.

Some evidence also suggests that backward chaining can be an effective teaching method for learning novel tasks. For example, in 1990, Daniel W. Ash and Dennis H. Holding used backward chaining as one method of teaching students without prior musical experience to play different sequences of musical notes on an electric piano. Likewise, other studies examining the effectiveness of backward chaining methods in flight simulation tasks have demonstrated it to be an effective method in teaching various components of aircraft landing.

Although the prior examples demonstrate the use of backward chaining with persons who are typically developing the procedure is most commonly used to teach skills to persons with developmental disabilities. Within this population, backward chaining has been widely applied in teaching various independent living skills to children and adults. Examples include hygiene skills such as self-grooming, teeth brushing, and toileting, socialization, and travel skills. For example, in 1979, Barbara Gruber and colleagues used backward chaining to teach four institutionalized males with profound retardation to walk independently from their place of residence to school. Such efforts have been instrumental in allowing persons with developmental disabilities to live in less restrictive environments such as group homes.

Not only has backward chaining been used to teach self-help skills to persons with developmental disabilities, it has also been successful in helping children with autism to learn to speak in short sentences. In addition, several studies have demonstrated the effectiveness of backward chaining in treating children who refuse to eat or drink. For example, in 1996, Louis P. Hagopian and colleagues used backward chaining as part of a procedure to treat a 12-year-old boy with autism and mental retardation who completely refused liquids. After obtaining a baseline measure of the boy's drinking and conducting a task analysis, backward chaining was implemented. In this case, drinking water from a cup was the target response, and the chain consisted of three segments: (1) bringing the cup of water to the mouth, (2) accepting water into the mouth, and (3) swallowing. To implement this backward chain, the boy was first reinforced by being given access to a preferred activity for 90 sec when he swallowed after being prompted to do so, and then he gradually swallowed a small amount of water from a syringe. In the third step, he was required to bring a cup containing a small amount of water to his mouth, accept the water into his mouth, and swallow the water before reinforcement was delivered. Using this procedure, Hagopian and colleagues were able to successfully teach the boy to gradually drink an increasing quantity of liquids.

C. Variables Used to Determine Outcome Effectiveness

As with most behavioral interventions, the structure and goal of an intervention is determined after an assessment is conducted. Similarly, depending on the goal of the intervention, the way in which its effectiveness is measured will vary across situations. Therefore,

there is no one set criterion against which to measure the effectiveness of a backward chaining procedure. Instead, there are a number of variables that are commonly used to gauge its effectiveness. In a review of chaining techniques by Fred Spooner and colleagues in 1984, the major dependent variables of interest include (1) time to criterion (predetermined number of successful performances of entire chain determined by the trainer), (2) number of incorrect responses (steps of the chain performed incorrectly), (3) number of correct responses (steps of the chain performed correctly), (4) rate of correct responses (number of correctly performed steps of the chain performed in a given period of time), and (5) rate of incorrect responses (number of incorrectly performed steps of the chain performed in a given period of time).

Although there has been some question regarding how to determine the effectiveness of a training procedure, variables should be selected based on the goal of the behavior that is being taught. For example, in 1980, Richard T. Walls and colleagues noted that number of errors often serve as the critical measure because errors may impede subsequent learning. On the other hand, if speed is more important than accuracy in learning the behavioral sequence, then rate should be selected as a measure of outcome effectiveness.

D. Comparing Backward, Forward, and Whole-Task Chaining

Comparative research on the effectiveness of the different chaining methods has produced mixed results. Several studies involving individuals with developmental disabilities have revealed that forward and backward chaining were more effective methods for teaching new skills compared to a whole-task approach. For example, in 1981 Richard T. Walls and colleagues compared all three chaining methods and found that forward and backward chaining resulted in fewer errors when teaching adults with moderate retardation to assemble objects, compared to the whole-task chaining method. In this study, there were no significant differences between forward and backward methods.

On the other hand, in 1983, Fred Spooner and colleagues compared only backward to whole-task chaining when teaching adults with profound retardation to assemble objects and found that whole-task chaining required fewer trials to reach criterion than backward chaining.

Research comparing the effectiveness of chaining methods remains equivocal. However, as Gregory J.

Smith suggested in 1999, the mixed results regarding the effectiveness of different chaining methods may be due to the fact that different populations were used in various studies, and different types of behaviors were taught. Therefore, no direct comparisons among chaining methods can be made without first taking these variables into account.

Similarly, as a review of the research suggests, there does not seem to be one method that is more effective than the others across all situations, rather, it is more probable that the effectiveness of the chaining method used is dependent on several factors, including variables associated with the learner (such as level of cognitive functioning) and the type of behavior being taught. Therefore, when deciding which chaining methods to use, clinicians should consider their client's level of intelligence and the type of behavior being taught.

E. When Backward Chaining Should Be Implemented

In general, the backward chaining method has been found to be effective and most appropriate for use with individuals with cognitively lower functioning including persons with developmental disabilities. However, it is also appropriate to use with individuals with higher functioning when a behavior is more complex and difficult, often involving many steps. In this case, backward chaining may be preferred over a whole-task approach because it can be particularly effective in teaching the person one component of the behavioral sequence at a time, before attempting to chain all the components together. Furthermore, backward chaining may be more effective than other chaining methods in situations when client motivation is low or when a response is infrequent or absent, because other chaining methods will limit the client's access to the terminal reinforcer.

IV. SUMMARY

Generally, backward chaining is an effective technique used to teach a complex sequence of behaviors to

humans. Although it has also been used with persons who are typically developing, it has been predominantly applied when teaching basic daily living skills to persons with developmental disabilities. The essential feature of backward chaining is teaching a sequence of behaviors in reverse order, starting with the last step in the behavioral sequence. Although it is unclear if backward chaining is more effective than other chaining procedures, one advantage of backward chaining is that the terminal reinforcer is always delivered as the individual completes each step.

be time limited, problem solving oriented, and structured. Both patient and therapist are quite active. The treatment emphasizes having patients learn to identify and modify their distorted or dysfunctional thoughts and beliefs and to change their dysfunctional behavior. In doing so, patients' mood, symptoms, functioning, and relationships improve.

GLOSSARY

automatic thought An idea that seems to arise in one's mind spontaneously, in verbal or imaginal form.

belief One's basic understandings of oneself, one's world, and other people.

cognition A thought, image, rule, attitude, assumption, or belief.

cognitive distortion A type of thinking error.

schema A relatively stable and enduring mental structure that exerts a significant influence over one's processing of information.

Cognitive therapy is a system of psychotherapy, based on a comprehensive theory of psychopathology and personality. Its theoretical underpinnings have been empirically supported, and the therapy itself has been demonstrated to be effective in over 325 outcome studies for a wide range of psychiatric disorders. Treatment is based on specific cognitive formulations of each disorder and on the individual cognitive conceptualization of each patient. Cognitive therapy tends to

I. DESCRIPTION OF TREATMENT

Cognitive therapy is based on the cognitive model that describes the relationship between people's perceptions and interpretations of situations and their reactions (emotional, behavioral, and physiological). When people are in distress, their thinking is often characterized by faulty information processing; their perceptions are often invalid, or not completely valid. For example, a depressed woman makes only two mistakes when word processing a long document at work and thinks, "I can't do *anything* right." This thought is called an "automatic thought," because it seems to pop up spontaneously in her mind. Before therapy, she may have been only vaguely aware of these kinds of thoughts, if at all. She may have been much more cognizant of her reaction: her affect (sadness), her dysfunctional behavior (leaving work early), and/or her physiological response (heaviness in her body).

In therapy, patients learn to cue themselves when they notice their negative reactions so they can identify

their automatic thoughts. Then they learn techniques of evaluating the validity and utility of their thoughts. When they correct their distorted thinking, they have a more positive reaction: their affect lifts, their behavior becomes more functional, they have an improved physiological response. Much of the therapy is organized around helping patients directly change their thinking and behavior and solve problems.

Treatment varies somewhat from disorder to disorder and patient to patient, though there are several basic principles described elsewhere by the author.

1. Cognitive therapy is based on an ever-evolving formulation of patients and their problems according to a cognitive framework.
2. Cognitive therapy requires a sound therapeutic alliance.
3. Cognitive therapy emphasizes collaboration and active participation..
4. Cognitive therapy is goal oriented and initially focuses on current problems.
5. Cognitive therapy is educative and emphasizes relapse prevention.
6. Cognitive therapy aims to be time limited.
7. Cognitive therapy sessions are structured.
8. Cognitive therapy teaches patients to identify, evaluate, and respond to dysfunctional thoughts and beliefs.
9. Cognitive therapy uses a variety of techniques to modify thinking, mood, and behavior.

These principles are described below.

Cognitive therapists conceptualize patients in cognitive terms, that is, they seek to understand how patients' beliefs give rise to specific thoughts in current situations and influence their reactions. When patients have long-standing personality problems, therapists also seek to understand how patients have historically interpreted events, often since childhood, and how these interpretations have influenced (and still influence) their ideas about themselves, their worlds, and others.

Therapists also identify the maladaptive behavioral "coping" strategies patients develop to get along in the world. For example, a therapist hypothesized that because of genetic predisposition and early abuse, Beth developed the belief that she was bad and defective. Fearful that others would view her negatively, she developed the coping strategy of always putting on a good face. Otherwise, she believed, people would see her "real" self and reject her.

Treatment is based on an ever-evolving conceptualization as therapists collect additional data to confirm,

disconfirm, or modify their hypotheses. A Cognitive Conceptualization Diagram (Figure 1) aids therapists in concretely formulating their conceptualization. Therapists check out their conceptualization with patients to ensure they are on the right track.

A strong therapeutic alliance is an essential part of cognitive therapy. Therapists build the alliance by working collaboratively with the patient as a "team," demonstrating care, concern, and competence; providing rationales before using various strategies; summarizing patients' narratives to ensure accurate understanding; checking hypotheses and formulations with patients; solving problems; eliciting feedback at the end of sessions (and during sessions, if they infer a negative reaction); and helping patients quickly to reduce symptoms.

It is often more difficult to establish a strong therapeutic alliance with patients who have dysfunctional relationships outside of therapy. They often bring dysfunctional beliefs about themselves and other people to the therapy relationship (e.g., "If I trust other people, I'll get hurt."). When such a belief interferes with a "standard" approach, therapists help patients elicit, test, and respond to patients' distorted ideas about the therapist and about therapy.

Therapists as well as patients are quite active during the therapy session. Therapists continually engage in Socratic questioning, as they ask patients open-ended questions to collect data, elicit key thoughts, uncover the meaning of their thoughts, identify beliefs, test the evolving conceptualization, and evaluate thoughts and beliefs. Collaboration is an important principle of cognitive therapy: therapist and patient work together to identify and understand the patient's problems and perspectives. They collaborate in setting goals, defining and solving current problems, and devising tests to assess the accuracy of their thinking.

Initially the focus is on the present, helping patients identify and modify their thinking about distressing situations, solving problems, and changing behavior. Toward the middle of therapy, there is an additional emphasis on modifying maladaptive beliefs. In the final stage of therapy, relapse prevention strategies are emphasized. In actuality, therapists use relapse prevention strategies from the beginning of therapy, as they not only help patients change their thinking and behavior but also instruct patients in how to do so themselves. An important goal of therapy is to teach patients to become their own therapists.

Cognitive therapy is generally a relatively brief form of psychotherapy. Most straight-forward depressed and anxious patients achieve remission with six to twelve sessions of therapy (weekly at first, then spaced further

apart). Patients with more complex disorders, comorbid diagnoses, severe or chronic symptoms, or personality pathology may require (sometimes significantly) longer treatment.

Cognitive therapy sessions generally follow a certain structure. At the beginning therapists obtain an objective and subjective account of patients' symptoms, general mood, progress, and behavior in the past week.

They jointly set an initial agenda; patients are asked to label the most important problem(s) they want to work on during the session. They make a “bridge” from the previous session, asking patients to recall important conclusions from the previous session, significant events during the past week, and what they gained or learned from the self-help assignments (“homework”) they did. They also ask patients whether they predict any special problems will arise in the coming week.

This additional data often leads to additional agenda items. The agenda is collaboratively prioritized. The session is then organized around the problems on the agenda. Patients and therapists collaboratively decide which problem to focus on first. In the context of discussing a problem, therapists gather data to refine their conceptualization and teach patients skills, such as identifying and critically evaluating their distorted thinking and using behavioral and problem-solving techniques. Homework assignments are also generated by the discussion.

Before moving on to another problem, therapists ask patients to summarize their conclusions from the discussion and ensure that they are likely to do the agreed-on assignments. At the end of each session, patients summarize the most important points of the session, and therapists elicit their feedback about the session.

Cognitive therapists use many different types of techniques to modify patients’ thinking, mood and behavior, including

- *Cognitive*: identifying, evaluating, and modifying thoughts, images, and beliefs
- *Behavioral*: activity monitoring and scheduling, skills training, graded tasks, distraction, exposure, response prevention
- *Problem solving*: specifying problems, responding to automatic thoughts and beliefs that interfere with problem solving, brainstorming and choosing solutions, implementing solutions and evaluating outcomes
- *Emotional*: regulation of affect through engaging in self-soothing activities, relaxation, controlled breathing, distraction, seeking support, reading therapy notes
- *Physiological*: medication (if indicated), exercise, reducing caffeine and other drugs, focusing externally instead of internally
- *Interpersonal*: correcting faulty beliefs, learning communication, assertiveness and other social skills, solving interpersonal problems (bringing family members or significant others into therapy, if indicated)
- *Environmental*: weighing advantages and disadvantages of making changes in living or work environments (if indicated), responding to thoughts that interfere with making needed changes
- *Supportive*: demonstrating empathy, regard, caring, acceptance, and accurate understanding of patients’ internal reality through verbal and non-verbal responses
- *Experiential*: roleplaying; using imaginal techniques to respond to automatic thoughts in the form of images; inducing images to heighten affect (to uncover key cognitions) or to reduce affect; restructuring the meaning of traumatic events through the re-experience of key memories in imaginal form in the presence of heightened affect, then using guided imagery and/or psychodrama techniques
- *Psychodynamic-like*: helping patients identify and evaluate automatic thoughts that arise and dysfunctional beliefs that become activated during the therapy session, particularly dysfunctional ideas about the therapist or therapy, then guiding them to generalize what they learned to relationships outside of therapy; drawing connections between beliefs (learned earlier in life and maintained throughout the patient’s life) and his/her interpretations and reactions to current situations

These techniques, whether they are specifically cognitive in nature or not, result in cognitive change. Much of the therapeutic work in cognitive therapy, however, is devoted toward directly identifying and modifying inaccurate or dysfunctional thoughts and assumptions. Therapists often use a worksheet, the *Dysfunctional Thought Record* (DTR) to help patients record and respond to their thoughts and assumptions in a structured way (Table 1).

Although DTRs are used with many patients, they generally are adapted for (or discussed verbally with) patients who might not be able to grasp them fully. Patients are encouraged to use questions such as the following to help them evaluate and devise alternative responses to their dysfunctional thinking:

- What is the evidence that my automatic thought is true? What is the evidence on the other side, that my automatic thought might not be true, or not completely true?
- What is an alternative explanation or an alternative viewpoint?
- What is the worst that could reasonably happen and how would I cope? What is the best that could happen? What is the most realistic outcome?

TABLE 1
Dysfunctional Thought Record

Directions: When you notice your mood getting worse, ask yourself, "What's going through my mind right now?" and as soon as possible jot down the thought or mental image in the Automatic Thought Column.

Date/time	Situation	Automatic thought(s)	Emotion(s)	Adaptive response	Outcome
	1. What actual event or stream of thoughts, or daydreams or recollection led to the unpleasant emotion? 2. What (if any) distressing physical sensations did you have?	1. What thought(s) and/or image(s) went through your mind? 2. How much did you believe each one at the time?	1. What emotion(s) (sad/anxious/angry/etc.) did you feel at the time? 2. How intense (0–100%) was the emotion?	1. (optional) What cognitive distortion did you make? 2. Use questions at bottom to compose a response to the automatic thought(s). 3. How much do you believe each response?	1. How much do you now believe each automatic thought? 2. What emotion(s) do you feel now? How intense (0–100%) is the emotion? 3. What will you do (or did you do)?
Friday, 2/23 10 A.M.	Talking on the phone with Donna.	She must not like me any more. 90%	Sad 80%		
Tuesday, 2/27 12 P.M.	Studying for my exam.	I'll never learn this. 100%	Sad 95%		
Thursday, 2/29 5 P.M.	Thinking about my economics class tomorrow. Noticing my heart beating fast and my trouble concentrating.	I might get called on and I won't give a good answer. 80% What's wrong with me?	Anxious 80% Anxious 80%		

Questions to help compose an alternative response: (1) What is the evidence that the automatic thought is true? Not true? (2) Is there an alternative explanation? (3) What's the worst that could happen? What could I do to cope? What's the best that could happen? What's the most realistic outcome? (4) What's the effect of my believing the automatic thought? What could be the effect of changing my thinking? (5) What should I do about it? (6) If (friend's name) was in the situation and had this thought, what would I tell him or her?

TABLE 2
Typical Thinking Errors

Cognitive distortions

1. *All-or-nothing thinking* (also called black-and-white, polarized, or dichotomous thinking): You view a situation in only two categories instead of on a continuum.
Example: “If I’m not a total success, I’m a failure.”
 2. *Catastrophizing* (also called fortune telling): You predict the future negatively without considering other, more likely outcomes.
Example: “I’ll be so upset, I won’t be able to function at all.”
 3. *Disqualifying or discounting the positive*: You unreasonably tell yourself that positive experiences, deeds, or qualities do not count.
Example: “I did that project well, but that doesn’t mean I’m competent; I just got lucky.”
 4. *Emotional reasoning*: You think something must be true because you “feel” (actually believe) it so strongly, ignoring or discounting evidence to the contrary.
Example: “I know I do a lot of things okay at work, but I still feel like I’m a failure.”
 5. *Labeling*: You put a fixed, global label on yourself or others without considering that the evidence might more reasonably lead to a less disastrous conclusion.
Example: “I’m a loser.” “He’s no good.”
 6. *Magnification/minimization*: When you evaluate yourself, another person, or a situation, you unreasonably magnify the negative and/or minimize the positive.
Example: “Getting a mediocre evaluation proves how inadequate I am. Getting high marks doesn’t mean I’m smart.”
 7. *Mental filter* (also called selective abstraction): You pay undue attention to one negative detail instead of seeing the whole picture.
Example: “Because I got one low rating on my evaluation [which also contained several high ratings] it means I’m doing a lousy job.”
 8. *Mind reading*: You believe you know what others are thinking, failing to consider other, more likely possibilities.
Example: “He’s thinking that I don’t know the first thing about this project.”
 9. *Overgeneralization*: You make a sweeping negative conclusion that goes far beyond the current situation.
Example: “[Because I felt uncomfortable at the meeting] I don’t have what it takes to make friends.”
 10. *Personalization*: You believe others are behaving negatively because of you, without considering more plausible explanations for their behavior.
Example: “The repairman was curt to me because I did something wrong.”
 11. *“Should” and “must” statements* (also called imperatives): You have a precise, fixed idea of how you or others should behave, and you overestimate how bad it is that these expectations are not met.
Example: “It’s terrible that I made a mistake. I should always do my best.”
 12. *Tunnel vision*: You only see the negative aspects of a situation.
Example: “My son’s teacher can’t do anything right. He’s critical and insensitive and lousy at teaching.”
-

From Judith Beck, *Cognitive Therapy: Basics and Beyond*. Adapted with permission from Aaron T. Beck. Reprinted with permission of Guilford Press.

- What is the effect of my believing this automatic thought? What could be the beneficial effects of changing my thinking?
- If [name of specific close friend or family member] were in this situation and had this thought, what would I tell him or her?
- What should I do now?

Teaching patients to identify their typical *cognitive distortions*, or types of thinking errors, also helps them understand the relative invalidity of many of their negative thoughts (Table 2). When emotionally distressed, people tend to make many more errors in their interpretations of events than usual. Matthew, for example, consistently displayed all-or-nothing thinking (“Either I’m the best or

I’m a failure.”), mind reading (“They [his co-workers] are probably laughing behind my back.”), fortune telling (“I’ll never catch up.”) and labelling (“I’m a total loser.”)

Other techniques used to help patients evaluate their automatic thoughts include:

- behavioral experiments (where patients directly test thoughts or assumptions such as, “If I try to get more done, I’ll just fail.”)
- imagery work (using imagery techniques in response to spontaneous, negative images)
- coping cards (collaboratively composing statements, graphics, or pictures for patients to read during the week to remind themselves of important learnings from previous sessions)

After patients learn the skill of modifying their automatic thoughts, therapists start emphasizing their cognitions at the belief level. An intermediate level of belief contains attitudes, rules, and assumptions that may have been understood, but unexpressed, before therapy. Therapists often seek to understand patients' intermediate beliefs in assumption form. For example, Peter had a dysfunctional attitude, "It's terrible to make a mistake." His rule was, "I can't make mistakes." His assumption, which was more easily subject to a behavioral test was, "If I make a mistake, terrible things will happen."

Core beliefs are a deeper level cognition. They are rigid, overgeneralized, global, dysfunctional, and largely inaccurate understandings that people have of themselves, their worlds, and other people, such as "I am unlovable," "I am helpless," "Other people will hurt me," "The world is a hostile place."

Key dysfunctional beliefs can be identified in several ways. Sometimes patients (especially depressed patients) express their beliefs directly, as automatic thoughts ("I'm a complete failure.") Beliefs may be inferred by examining the consistent themes in automatic thoughts across situations. Cynthia, for example, had frequent thoughts such as, "Mary won't want to spend time with me," "No one will want to talk to me at the party," "My friends don't really know me very well," "If I try to get closer to Jane, she'll reject me," and "People don't seem to like me much." One of Cynthia's central beliefs, expressed indirectly in the thoughts above, was that she was unlovable.

A third way to uncover beliefs is to ask patients the *meaning* of their typical automatic thoughts: "If this automatic thought is true,..."

- what does that mean?
- what's the worst part about it?
- what does it say about you as a person?

Many of the techniques used to help patients evaluate their automatic thoughts can be used to evaluate core beliefs as well. Before working on belief modification, however, therapists present an explanatory model to patients, so they can better understand why they are absolutely convinced of the validity of a belief, even though the belief may be inaccurate or largely inaccurate. An information processing model helps them understand how and why they easily assimilate data confirming their core belief but ignore or discount positive data that disconfirm their belief. Patients learn, with their therapists' help, to bring this kind of information processing under conscious control. Much of the therapy from this point on is directed toward helping patients develop alternative

(more accurate and functional) perspectives of negatively perceived events and to become aware of, and process without discounting, positive data and events.

Other methods for the modification of core beliefs about the self are the use of extreme contrasts ("How much of a failure are you compared to [a specific person whom the patient sees as an extreme failure]?"), metaphors, and cognitive continua (which help patients see that their beliefs are at an extreme, instead of on a continuum). Therapists may help patients recall childhood events from which their core beliefs arose (or through which their beliefs became strengthened) and then evaluate the validity of those beliefs at that time and at the current time. This process allows patients to restructure the meaning of important childhood or adolescent experiences at an intellectual level. They may need experiential techniques to restructure the meaning at an "emotional" or "gut" level.

II. THEORETICAL BASIS

Beck originally based his cognitive treatment for depression on his cognitive theory of depression that has been largely supported in hundreds of subsequent studies. Cognitive theory posits that people tend to perceive and interpret situations in characteristic ways that color their feelings and shape their behavior. People often have spontaneous "automatic thoughts" about their past, current, or future situations. Because automatic thoughts are generally "silent," people are more apt to be aware of their subsequent emotions, behavior, or physiological reactions. Automatic thoughts are often fleeting, sometimes telegraphic in nature, and, when recognized, highly plausible to the individual—even when incorrect or dysfunctional. When people are in emotional distress, their thinking becomes more rigid, primitive, and distorted. They make characteristic errors, or cognitive distortions, and may begin to ruminate or obsess.

At a deeper level, when people are emotionally distressed, their maladaptive beliefs (their basic understandings of themselves, their worlds, and other people) become activated. These beliefs influence their perception and interpretation of their experience. Individuals may begin to develop a preponderance of negative thinking.

Beliefs are ideas embedded in mental structures in the mind called "schemas." Relatively adaptive schemas may predominate when people are not distressed. When they develop a psychiatric disorder, however, their negative cognitive schemas, which may have been dormant or

latent, start to dominate and influence their thinking. A particular “mode” (composed of a network of interrelated cognitive, affective, motivational, and behavioral schemas) may become activated and profoundly affect individuals’ thinking, motivation, mood, and behavior. The mode represents the constellations at the core of full-blown disorders such as depression or paranoia.

How do people develop negative beliefs? These basic rules, formulas, and concepts are influenced by genetic predisposition and develop in response to environmental events. A child who is verbally abused at school, for example, may start to believe that she is unlikable. If she has supportive parents, however, her belief may be tempered, and she may see herself as predominately likeable. If, in her twenties, though, she is rejected by a significant other, her latent belief of unlikability may become activated again, and she may be vulnerable to developing a depressive disorder.

Cognitive theory posits a diathesis-stress model to explain the occurrence of emotional disorders. Individuals may be relatively psychologically healthy until a congruent stressor activates their dysfunctional beliefs. These beliefs start to bias how they process information. People who have relatively strong autonomous personalities, for example, are usually adversely affected when their efficacy, freedom, or mobility is threatened or reduced. If they are not also high in sociotropy, however, they may be relatively less affected by interpersonal disruption or loss (and vice versa).

Joe, for example, was relatively well-adjusted until three stressors occurred. In the first semester of his senior year in high school, he began to have difficulty in one of his courses, he was dropped by his school’s varsity basketball team, and he started a challenging and demanding after school and weekend job. He started to have negative thoughts about himself and his performance. “I must be stupid. I can’t believe I did so badly on those math tests.” “It’s humiliating to be dropped from the team. I’m such a loser.” “I don’t understand what to do. This job is too hard. I can’t do anything right.”

Joe had an underlying specific vulnerability to situations in which his sense of efficacy was challenged, and he began to attend selectively to experiences that supported his view of himself as inadequate. He began to interpret more and more situations in light of this belief (his performance in other classes, his estimation of his general intellectual and athletic abilities, his standing among his peers). Feeling inadequate, he began missing classes, avoiding basketball practice, doing his homework superficially, skipping work, and spending a lot of time in bed, watching television. A recognition of these dysfunctional behaviors strengthened Joe’s nega-

tive beliefs of inadequacy and failure that led to increasingly negative and dysfunctional thinking that led to a deteriorating mood and more dysfunctional behavior, in an escalating downward spiral.

Beck and colleagues have developed specific cognitive formulations for the major psychiatric disorders. Depression, for example, is characterized by negative thoughts about the self, experience, and future (“I’m worthless, the world presents too many obstacles, I’ll always be a basket case.”). Anxious patients’ thoughts reflect overestimations of threat and underestimations of resources (“It’s very likely terrible things will happen and I won’t be able to cope.”). Patients with panic disorder make catastrophic misinterpretations of physiological or mental sensations (“This unreal feeling in my head means I’m going crazy.”). Obsessive-compulsive patients make misinterpretations of their negative thoughts and images (“My imagining that I will stab my friend with this knife means I’m out of control. I really might harm her.”). Hypomanic patients have an inflated view of themselves and their future (“I am so powerful, I can do anything I want.”).

Specific beliefs for each personality disorder have also been identified. Patients with dependent personality disorder, for example, believe they are weak and helpless and others are strong. Paranoid patients believe other people are potentially dangerous and that they could be harmed if they are not watchful. Avoidant patients believe they are defective and others will reject them.

These kinds of negative, global, rigid beliefs may have originated in childhood or adolescence in people with long-standing problems, and their beliefs may be more or less continuously activated. Typically, they develop certain guidelines or rules to help them cope with these painful ideas. Histrionic patients may believe, “If I am dramatic, people will pay attention to me and they will accept me.” The corresponding negative belief, however, is “If people don’t pay attention to me, it means I’m nothing.” Obsessive-compulsive personality disorder patients believe, “If I control myself and others, setting up systems of order, then I’ll be okay. But if I don’t, my world will fall apart.” Narcissistic patients hold the belief, “If people give me the respect and entitlements I want, it will show I’m superior. But if they don’t, it means I’m inferior.” Eating disorder patients believe, “If I control my eating, I’ll be thin, and therefore acceptable. But if I don’t, my eating will go out of control, I’ll gain weight and be unacceptable to myself and others.”

When individuals’ beliefs are extreme, they display overdeveloped behavioral strategies (compensatory or coping) to protect themselves or compensate for their perceived deficiencies, and they tend to use these

strategies in an indiscriminatory manner, even when they are maladaptive. They fail to develop a broad range of strategies that would be more adaptive in many situations. Dependent patients, for example, inordinately rely on others, borderline patients reject others to avert being rejected themselves, substance abuse patients use drugs or alcohol to avoid intolerable emotion, hypochondriacal patients continually check their bodies for signs of disease or infirmity.

The relationships among an individual's developmental experiences, his or her core beliefs, assumptions, and compensatory strategies are illustrated in the top half of Figure 1. The bottom half shows how these underlying factors influence the individual's interpretation of and reaction to current situations. This conceptualization helps guide the therapist in modifying patients' dysfunctional thinking and behavior.

III. EFFICACY

Andrew Butler and Judith Beck conducted an analysis of fourteen meta-analyses of cognitive therapy outcome studies in 2000. They found substantial support for the efficacy of cognitive therapy in 325 studies, comprising 9,000 patients. Cognitive therapy was found to be somewhat superior to antidepressant medications in the treatment of adult unipolar depression. A significant finding was that depressed patients treated with cognitive therapy had half the *relapse* rate (30%) of those who had taken medication (60%). Cognitive therapy was found to be superior to supportive and nondirective therapies for adolescent depression and equally effective as behavior therapy for obsessive-compulsive disorder. Cognitive therapy was superior to a number of miscellaneous psychosocial treatments for sexual offenders. Cognitive therapy was also efficacious in the treatment of bulimia nervosa.

Other research studies have demonstrated the efficacy of cognitive therapy for generalized anxiety disorder, panic disorder, and hypochondriasis. It has also been shown to be effective for inpatient depression, posttraumatic stress disorder, substance abuse, phobias, social phobia, marital problems, and some personality disorders. Combined with pharmacotherapy, it is effective for the symptoms of bipolar disorder and even schizophrenia.

Recently, cognitive therapy has been used in medically related disorders, and there is substantial support for its efficacy in the treatment of chronic pain,

chronic fatigue syndrome, migraine headaches, and non-cardiac chest pain, among others.

IV. SUMMARY

Cognitive therapy is a form of psychotherapy that has been empirically supported in over 325 outcome studies for a variety of psychiatric disorders, psychological problems, and medical conditions with psychological components. It is based on the cognitive model: that individuals' interpretations and perceptions of current situations, events, and problems influence how they react emotionally, behaviorally, and physiologically. Treatment varies according to the cognitive formulation of patients' disorders and therapists' cognitive conceptualizations of specific patients. Generally, cognitive therapy is short term, structured, collaborative, educative, and focused on working toward specific behavioral goals, solving current problems, alleviating symptoms, and providing relapse prevention strategies.

GLOSSARY

accuracy The correctness, precision, and exactness of psychological measurement.

antecedent event A stimulus or event that occurs prior to a response or subsequent event.

content validity The degree to which elements of an assessment instrument are representative of, and relevant to, the targeted construct for a specific assessment purpose. Applied to behavioral assessment, content validity refers to the degree to which a selected assessment method facilitates collection of data that are representative of behavior in the client's natural environment.

context (setting) A naturally occurring environmental unit having physical, behavioral, and temporal properties. The context may affect the response of an individual to presented stimuli, often through classical or operant conditioning.

dimension, of a behavior problem or causal variable A property of an event, or series of events, that can be quantified

(e.g., frequency, duration, magnitude, cyclicity, or rate of an event).

facets The components that contribute to an overall whole, as in facets of a construct or variable.

functional analysis The identification of important, controllable, causal functional relations relevant to the expression of a target behavior for an individual. The term also is used to describe the experimental manipulation of hypothesized controlling variables as a means of determining functional relations.

functional analytic clinical case model (FACCM) A vector graphic representation of a clinical case formulation. Causal relationships between variables are expressed using unidirectional or bidirectional arrows. Clinical case models visually express (1) the importance of a target problem, (2) relationships among target problems, (3) relationships between target problems and their effects, (4) the modifiability of antecedent or causal variables, (5) the clinical utility or importance of antecedent or causal variables, (6) the role of unmodifiable causal variables (i.e., original causal variables), and (7) the role of moderating variables. Path coefficient calculations suggest which causal variables, if modified, would likely lead to the greatest amount of change in the client's presentation.

functional relation A relation between two events that may be expressed in the form of an equation. A functional relation does not imply a causal relation. Examples of a functional relation include the conditional probability that one event may occur given another event (e.g., permitting a child to play a video game after his or her homework is completed), covariation between two events (e.g., the correlation between increased heart rate and self-reported distress during an imaginal exposure trial), and the identification of

controlling variables for a behavior problem through experimental manipulation.

idiographic assessment An assessment strategy emphasizing the individual or individual case. Idiographic assessment procedures often are not standardized, and observed relations and results are not necessarily generalizable across persons or groups.

level of inference (specificity) The number of elements or components subsumed by the variable label. An example of a higher level construct is “depression” since the label subsumes multiple lower-level phenomena such as motoric slowness, sad affect, insomnia, eating disturbances, and other more specific variables.

nomothetic assessment An assessment strategy in which judgments are based on the comparison of measures from the target person with data on the same instrument gathered from other persons, such as the use of normative or comparison groups.

phase-space relationship The expected, or realized, time-course context of a variable. The phase state of a variable is its historical and projected curve at the time of measurement.

reactive effects The degree to which the behavior of an observed individual is modified by the assessment method.

response class A group of behaviors that are topographically dissimilar yet produce the same functional effect.

response contingency A conditional relationship between two variables such that the occurrence of one variable or event is dependent on the occurrence of the other variable or event.

response mode The form, type, or method of behavior. Response modes are organizational categories or a taxonomy of behavior. Response modes can include motor, verbal, cognitive, and physiological events (or a combination of these, such as emotion).

state of a variable The current level of the variable when measured. Unlike the phase of a variable, the state does not provide information on the variable’s historical course.

stimulus class A set of topographically dissimilar stimuli that evoke either the same behavior or a set of behaviors that have similar functions.

target behavior A response, or response class, that has been selected by the clinician for measurement and modification.

treatment utility The degree to which data from one or more assessment instruments, or from a model of clinical case formulation, are associated with increased treatment effectiveness.

I. DESCRIPTION OF BEHAVIORAL ASSESSMENT

Within the broad scope of psychological assessment, behavioral assessment is distinguished by its emphasis on empirically supported, multimethod, and multi-informant assessment of precisely defined, observable behaviors. Consistent with respondent, operant, and

social learning traditions, behavioral assessment emphasizes the measurement of contemporaneous causal variables and environmental response contingencies using empirically validated assessment instruments. Thus, behavioral assessment includes a family of methods and instruments that measure behavioral change through direct and indirect observation of clients’ behavior problems and the variables that maintain those problems. While the variables that cause or maintain a client problem often reside in an individual’s external environment, assessment of covert events (e.g., cognitions, physiological responses) have been incorporated within a behavioral assessment framework.

In pretreatment applications, data collected during behavioral assessment must be synthesized by the clinician and this synthesis, in the form of a behavioral clinical case formulation, often guides treatment selection. Clinical case formulations are a series of hypotheses that may be evaluated in light of an ongoing clinical information collection process. As such, behavioral assessment is an iterative process—it is an ongoing, hypothesis-testing approach to clinical assessment. Assessment methods and resulting clinical judgments may be adapted to new information that causes the clinician to reevaluate initial hypotheses of client functioning (see Fig. 1). Contemporary behavioral assessment emphasizes the dynamic and contingent relationship between assessment, clinical case formulation, hypothesis testing, and intervention.

II. THEORETICAL BASES

Behavioral assessment is an integral adjunct to behavior therapy and, like behavior therapy, evolved from basic behavioral research. Behavioral psychology has frequently been divided into two related models of learning: respondent conditioning and operant conditioning. Early work in respondent conditioning demonstrated that both humans and nonhumans learned new behavioral responses as a function of the association of extrinsic stimuli. Early in the twentieth century, Ivan Pavlov showed that dogs could learn new reflexive behavior after being presented with a series of paired stimulus associations. Shortly thereafter, John B. Watson and Rosalie Rayner showed that, in humans, emotional responding to a previously neutral stimulus could be acquired by pairing a neutral stimulus with a loud noise. Treatment methods based on respondent conditioning principles would later be refined by Mary Cover Jones, Joseph Wolpe, and others.

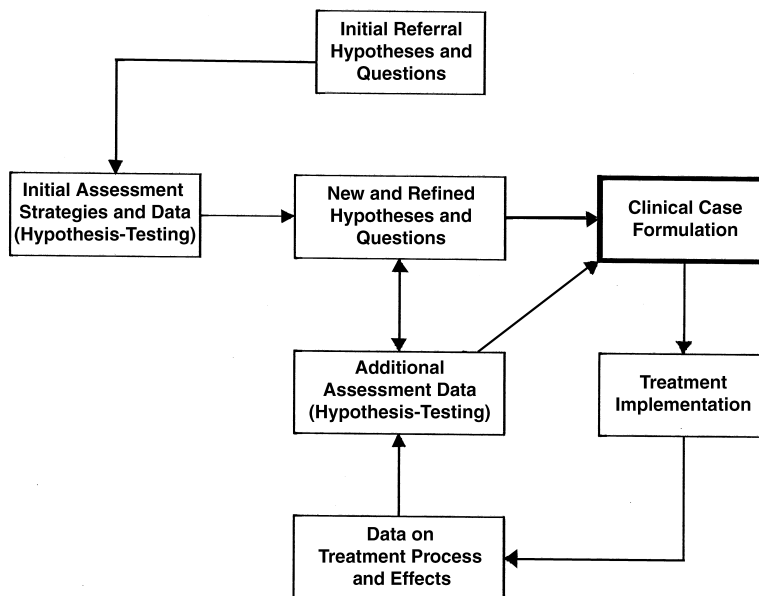

FIGURE 1 A dynamic model of behavioral assessment. Adapted from Haynes and O'Brien (2000), *Principles and practice of behavioral assessment*. New York: Kluwer Academic/Plenum Publishers.

The operant, or instrumental, model of learning is illustrated by the work of E. L. Thorndike and B. F. Skinner. Thorndike found that learning occurred when behavior was instrumental in, or had the effect of, achieving a reward (e.g., cats would learn a novel behavior if the effect of engaging in the behavior was instrumental in acquiring food). Thorndike called this principle “the Law of Effect.” Skinner extended Thorndike’s work by identifying the effects of specific types of consequences on behavior. According to Skinner, reinforcing consequences increased the rate of behavior while punishing consequences decreased the rate of behavior. Behavior that was not reinforced eventually was extinguished from the animal’s repertoire and the rate of extinction depended on the organism’s reinforcement schedule history.

Behavioral principles, initially studied in animal laboratories, formed the foundation of behavior therapy and have guided the development of behavioral assessment methods. Because antecedent events and response contingencies shape and affect an individual’s behavioral repertoire, a goal of behavioral assessment is to identify those events and contingencies that maintain behavior. Antecedent events and response contingencies that maintain the rate of behavior are called controlling or maintaining variables. The identification of controlling variables and their relationship to the target behavior is called a functional analysis. Thus, an important goal of behavioral assessment is to identify

variables that maintain a target behavior (i.e., the behavior to be modified) in a functional analysis.

For example, behavioral assessment with a Vietnam veteran diagnosed with posttraumatic stress disorder might identify certain conditional stimuli (e.g., the sound of a truck backfire, the whir of helicopter blades) as having a high probability of eliciting flashbacks and emotional responses because of their similarity to, or association with, aversive historical events. Operant responses may initially help the client cope with anxiety (e.g., drinking alcohol to induce intoxication and facilitate avoidance). Thus, a two-factor model of the patient’s behavior incorporating both respondent and operant principles would form the basis of a functional analysis for the patient (see Mowrer’s 1947 work).¹

III. GOALS AND OBJECTIVES OF BEHAVIORAL ASSESSMENT

The primary objectives of behavioral assessment include identifying (1) target behavior problems (i.e., the problems that are to be modified) and establishing

¹ Whereas Mowrer emphasized a two-factor model of conditioning, contemporary behavioral models stress the importance of family functioning, biological determinants, cognition, cultural processes, and other factors when assessing functional relations.

TABLE 1
Goals of Behavioral Assessment

-
1. Supraordinate goal: Increase the validity of clinical judgments
 2. Obtain informed consent from client
 3. Select an appropriate assessment method (e.g., direct observation, indirect observation, psychophysiological measurement)
 4. Determine if consultation and referral are appropriate (e.g., determine if medication consultation with a psychiatrist is appropriate when working with a child diagnosed with attention deficits)
 5. Development of a clinical case formulation
 - a. Identify behavior problems and their interrelations
 - b. Identify causal variables and their interrelations
 6. Design of intervention programs
 - a. Identify client intervention goals and strengths
 - b. Identify variables that may moderate intervention effects (e.g., occupational status, family support, other life stressors)
 - c. Assess client knowledge of goals, problems, and interventions
 - d. Evaluate any medical complications that could affect intervention process or outcomes
 - e. Identify potential side effects of intervention
 - f. Assess acceptability of intervention plan for client
 - g. Assess time and financial constraints of therapist and patient
 7. Intervention process evaluation
 - a. Evaluate intervention adherence, cooperation, and satisfaction
 - b. Evaluate client–therapist interaction and rapport
 8. Intervention outcome evaluation (immediate, intermediate, and ultimate intervention goals)
 9. Diagnosis (behavioral assessment strategies can be used to increase the validity of information on which diagnosis is made)
 10. Predicting behavior (e.g., dangerousness and self-harm assessment)
 11. Informed consent (i.e., inform clients and other relevant parties about the strategies, goals, and rationale of assessment)
 12. Nonclinical goals
 - a. Theory development (e.g., evaluating learning models for behavior problems)
 - b. Assessment instrument development and evaluation
 - c. Development and testing of causal models of behavior disorders
-

Note. Table adapted from Haynes & O'Brien (2000), *Principles and practice of behavioral assessment*. New York: Kluwer Academic/Plenum Publishers.

whether the problems involve behavioral excesses or deficits; (2) causal and moderating variables that influence target behavior dimensions; (3) immediate,

intermediate, and ultimate intervention goals; and (4) any adaptive or appropriate alternative behaviors to the target behaviors. In addition, behavioral assessment data form the foundation for a functional analysis, suggest appropriate intervention strategies, can be used to evaluate ongoing intervention efforts, may identify therapy process variables that can affect treatment outcome, and can inform diagnostic decision making. Table 1 outlines the multifaceted goals of behavioral assessment.

The supraordinate goal of behavioral assessment is to increase the validity of clinical judgments to facilitate clear formulation and treatment selection. Ultimately, the formulation should have treatment utility. Treatment utility is the degree to which data from one or more assessment instruments, or from a model of clinical case formulation, are associated with increased treatment effectiveness.

The selection, evaluation, and refinement of treatment goals and strategies can be among the most complex and vexing tasks that clinicians face. Haynes, Leisen, and Blaine in 1997 reviewed 20 studies that examined the relationship between components of a functional analysis and treatment outcome. They found that the studies were moderately supportive of the treatment utility of a functional analysis but that methodological limitations limited the inferences that could be drawn from the studies. At the very least, it is reasonable to assume that interventions are more likely to be effective if there is a close relationship between the causal variables identified in the preintervention assessment and those variables targeted for modification during the intervention.

Although an accurate functional analysis is a goal of behavioral assessment, factors other than the functional analysis can influence client responsiveness to treatment. Examples of other factors that can affect treatment outcome include the quality of treatment delivery, cooperation of persons in the client's environment, the client's cognitive and physical limitations, cultural and ethnicity factors, the developmental level of the client, and therapist–client rapport. Because so many factors may affect treatment outcome, isolating the putative effects of a functional analysis on treatment outcome is difficult.

Information collection can only occur in the context of a fully informed client who understands the rationale and strategies of the assessment. The goals of assessment and treatment should be carefully discussed with the client when possible and should reflect a cooperative approach. In addition, the clinician should discuss with the client hypotheses of functional relations operating in the client's life.

IV. FEATURES OF BEHAVIORAL ASSESSMENT

A. Assessment Strategies

Behavioral assessment emphasizes repeated measurement, quantification, multimethod and multimodal assessment, and assessment of behavior as it occurs naturally. Although assessment of behavior on just one occasion may provide an estimate of its current state, it does not provide information regarding changes in behavioral patterns over time, or the phase of the behavior. For example, how a therapist interprets a Beck Depression Inventory (BDI) score of 25, which suggests clinical levels of depression, depends significantly on the previous week's BDI score and the pattern of BDI scores over previous sessions. If a score of 25 represents a 10-point drop from the client's last BDI results, the clinician might infer that the depression may be less severe today than it was a week ago. However, a 10-point change in the opposite direction would be interpreted quite differently.

Interrupted time series designs are sometimes used in behavioral assessment to assess state–phase relationships. These strategies emphasize repeated measurement of behaviors, assessment of at least one causal variable across time, and systematic manipulation of hypothesized causal variables. They are powerful designs for measuring both the state and the phase of a behavior and assessing cause–effect relationships between a behavior and its hypothesized maintaining variables.

The behavioral assessment paradigm also emphasizes data quantification—the assignment of numbers to variables targeted in an assessment. For example, assessors may obtain measures of a client's self-reported level of anxiety in group social situations using a subjective units of distress scale. Measures might also include the frequency with which one marital partner compliments another during a problem-oriented discussion, the proportion of times a child's self-injurious behavior is followed by attention from a teacher, or blood pressure readings obtained during exposure to laboratory stressors. Although qualitative information and judgments are always part of a behavioral clinical case formulation, quantified data are very useful in time series assessment, can help identify functional relations, and facilitate the evaluation of treatment effects. Quantified data can also be presented in graphical form to facilitate inferences regarding behavior change.

In order to minimize error and make informed hypotheses about client functioning, behavioral assessment emphasizes repeated measurement across multiple as-

essment instruments, informants, contexts, settings, and response modes (e.g., behavioral, physiological, cognitive). The rationales for these strategies are (1) clients often behave differently across situations as a function of contingencies and contexts associated with each situation; (2) multiple measures across time help capture the dynamic nature of behavior and functional relations; and (3) informants differ in their source of information about a client and data from each informant may include unique sources of measurement error. Overall, these assessment strategies help reduce the effect of measurement error from any single information source.

The emphasis on multimodal assessment recognizes that different response modes (e.g., behavioral, physiological, cognitive) may demonstrate different time courses, may vary in their responsiveness to hypothesized causal variables, and may differ in their response to a therapeutic intervention. For example, combat veterans treated with exposure techniques (e.g., imaginal exposure, systematic desensitization) for posttraumatic stress disorder often report reduced nightmares and intrusive thoughts; however, little or no change may occur in other modes of responding. Thus, changes in one mode may not necessarily be accompanied by commensurate changes in another mode if the modes are controlled or maintained by different variables.

The emphasis on environmental variables means that behavioral assessment emphasizes a social-systems view of behavior problems—client behavior problems can best be understood by taking into consideration medical, family, work, cultural, religious, and other social systems. For example, a case formulation of a child with aggressive behavior problems may need to take into account contextual cues that evoke hitting and other aversive behaviors. However, a comprehensive case formulation might also include consideration of the quality of parenting practices or whether the educational setting is structured in a way that positively facilitates a teacher's ability to manage the child's aggressive behaviors. A successful intervention to reduce the aggressive behaviors of such a child might involve family therapy and intervention within the structure of the classroom in addition to traditional behavior management strategies.

B. Behavior Problems, Levels of Analysis, and Behavioral Dimensions

Often, the initial task of the behavioral assessor is to identify and specify the client's behavior problems, most often on the basis of client self-report or the report of a

referral source (e.g., a teacher, counselor). To guide initial intervention foci, behavior problems are ordered in terms of importance. In many cases, consultation with the client will facilitate selection of the most important target behaviors. However, when the client is not able to provide meaningful information about the relative importance of behavior problems (e.g., clients with cognitive limitations), behaviors that are dangerous to the client or to others are often selected as the first intervention target.

The level of specificity of a behavior problem refers to the number of elements or component behaviors that are subsumed by the variable label. Behavior problems characterized by low specificity are molar in their construction and subsume one or more behavioral facets. For example, the diagnostic construct major depression is a molar level construct that includes several observable, and more specific, behavior facets such as changes in eating and sleep patterns and low rates of pleasurable activities. Behavior problems with greater specificity have fewer clinically important facets, require less inference for observation, and often are more amenable to behavioral assessment methods and measurement.

Measurement of behavior implies measurement of one or more dimensions of behavior. A behavioral dimension is a property of an event, or series of events, that can be quantified. The dimension most often modified in a behavioral treatment program is rate, or the frequency of behavior per unit of time. For example, although the ultimate goal of an overweight client might be to lose weight, the immediate goal may be to decrease daily high caloric snacking and increase the frequency of daily exercise. Treating a child with autism often means decreasing the rate of self-injurious behaviors while increasing development and frequency of self-help skills. Behavioral marital therapy might include decreasing the rate of negative or sarcastic remarks while increasing the rate of proactive verbal communication and problem-solving.

Other dimensions often measured in behavioral assessment include (1) the magnitude or intensity of the behavior (e.g., decreasing the intensity of a fear or anxiety response); (2) the duration of the behavior (e.g., decreasing perseveration on a task, increasing time studying, increasing time in the presence of a feared stimulus); (3) the latency of behavioral responses (e.g., decreasing response time to a stimulus); (4) interresponse time (e.g., the time between two instances of a response; for example, the time between two instances of a child's disruptive behavior in a classroom); and (5) qualitative aspects including the physical features of the behavior or its topography (e.g., the types of errors

a child with a stuttering problem makes) and acceptability (e.g., whether the behavior is appropriate in a given social context, whether the behavior is compatible with societal expectations or laws, or the client's own moral standards). An important task of the behavioral assessor is to identify which of the above response dimensions is the most appropriate dimension to modify and to design an assessment plan that facilitates accurate measurement of that dimension.

Finally, responses must be recorded in some way using a reliable and accurate data coding system. The most common recording systems include paper-and-pencil forms, electromechanical devices, audio and video recording, and computerized data entry. Data collected during self-monitoring is often recorded in a journal or self-monitoring diary. Psychophysiological data are frequently recorded using a polygraph machine. Even with highly standardized assessment methods, reliability and accuracy of recording should not be assumed. Reliable and accurate measurement of behavior is as much dependent on the definition and level of specificity of the variable being measured as it is on the methods by which the behavior is recorded.

V. METHODS OF BEHAVIORAL ASSESSMENT

A distinctive feature of the behavioral assessment paradigm is the variety of assessment methods available to the behavioral assessor. Table 2 provides a listing of common behavioral assessment methods. We now introduce each behavioral assessment method, discuss examples of the behavioral assessment method drawn from the empirical literature, and review factors that affect the validity of inferences that are derived from each behavioral assessment method.

A. Behavioral Observation

1. Naturalistic Behavioral Observation

Naturalistic behavioral observation is a behavioral assessment method in which an individual is observed in his or her natural environment (e.g., home, school, work), usually in a context that is most associated with a problem behavior. Typically, observations are made on a predetermined schedule by one or more observers. A time sampling interval is determined *a priori* (e.g., 20-second periods, 5-minute periods) and the observer records the occurrences of the target behavior and/or other relevant events during the interval. Multiple observers are often used and percentage agreement or

TABLE 2
Behavioral Assessment Methods

Method	Types and descriptions	Instruments and measurement devices
Behavioral observation	Naturalistic behavioral observation involves measurement of overt behavior in the individual's natural environment. <i>Example:</i> Observe a child's behavior in a classroom or at home. Analogue behavioral observation involves the measurement of a client's overt behavior in a contrived situation that is analogous to situations the client is likely to encounter in his or her environment. <i>Example:</i> Code marital interactions during a marital therapy session.	Child Behavior Checklist Direct Observation Form; Revised Edition of the School Observation Coding System; Marital Interaction Coding System.
Behavioral rating scales	Completed by individuals who are either familiar with a client's behavior or have the opportunity to directly observe a client's behavior. <i>Example:</i> Have a parent and teacher complete a child behavior checklist.	Child Behavior Checklist; Motivation Assessment Scale.
Self-monitoring	Systematic self-observation and recording of parameters (e.g., frequency, intensity) of targeted behaviors, environmental events, cognitions, and/or mood states. <i>Example:</i> Have a client diagnosed with anorexia nervosa complete an eating diary after each meal.	Self-monitoring forms are usually individually tailored to an individual's target behavior problem(s).
Psychophysiological assessment	Measurement of physiological and motoric components of behavior problems using a variety of measurement devices, especially electromyographic, EEG, cardiovascular, and electrodermal measures. <i>Example:</i> Record heart rate, galvanic skin response, and blood pressure of trauma survivor while the client listens to a script recounting the traumatic event.	Polygraphs, heart rate monitors, amplifiers are available through several commercial companies.
Self-report	Behavioral Interview: A structured or semistructured interview that assesses dimensions of a client's behavior, behavior–environment interactions, behavioral contexts, and the functional relation of the behavior(s) with other controlling variables. <i>Example:</i> Interview inmates in a residential drug treatment facility using the Drug Lifestyle Screening Interview (see Walters, 1994). Behavioral Questionnaire: A measurement instrument completed by the client, or individuals that know the client well, that assesses (1) behavioral dimensions and (2) functional relations of behaviors with cognitions, emotional states, and other controlling variables. <i>Example:</i> Have a client complete the State and Trait Food Cravings Questionnaire to identify conditions under which food cravings occur and the cues that elicit cravings.	Functional Analysis Interview Form; Drug Lifestyle Screening Interview; Alcohol Use Inventory Motivation Assessment Scale; State and Trait Food Cravings Questionnaire

other statistics are calculated (e.g., kappa) to ensure reliable data recording.

Naturalistic behavioral observation has been used as an assessment method to assess a wide array of behaviors. For example, Gulley and Northrup in 1997 observed two

children diagnosed with attention deficit–hyperactivity disorder (ADHD) in their classrooms and systematically varied each child's daily dose of methylphenidate (MPH). By observing multiple, operationally specific behaviors over time (e.g., social behavior, disruptive behavior,

efficiency at solving math problems, responses to comprehension problems), they were able to show the dosage level of MPH that was associated with the greatest improvement across behaviors. Teacher ratings corresponded with the academic, behavioral, and social measures for one participant, but not the other, suggesting that teacher ratings were not necessarily sensitive to changes in behavior as a function of medication dose.

Data collected using naturalistic behavioral observation can be affected by both participant-related and observer-related error variance. On the participant side, reactivity to the assessment method can change the rate of a participant's behavior and make it less likely that observed behavior reflects behavior as it naturally occurs in the environment. Reactivity effects are discussed in more detail at the end of this section.

Observer-related error variance can affect the accuracy of observations in a potentially endless number of ways. For example, the degree of observer training can affect observer reliability and accuracy. Cumbersome recording forms or poorly operationalized behaviors can lead to unreliable coding. Raters can "drift" in their ratings if their understanding or application of coding rules decays over time. Other observer-related factors include observer attentional lapses during recording intervals, contamination of data if an observer is aware of another observer's recordings, errors in time-sampling parameters (e.g., frequency and duration of the time-sampling parameters are incongruent with the dimensions of the observed behavior), behavioral sampling errors (e.g., an important behavior is not included in the behavioral coding system), and observer knowledge of patient status. Frequent accuracy checks of observer ratings should be made by an independent auditor to ensure that observer agreement indices do not fall below an acceptable level (e.g., .80). If the accuracy of an observer's ratings is below the criterion, retraining should be initiated.

The validity of inferences drawn from naturalistic observation also depends on the choice of observation setting. As a general rule, observation should occur in situations where the problem behavior is most likely to occur. Because the dimensions of behavior often vary across situations and contexts, selecting the most relevant naturalistic setting for observation is an important decision.

How the data are aggregated and displayed can have a significant bearing on the validity of inferences as well. Naturalistic behavioral observation data may provide useful information when data are aggregated across many minutes but not in shorter intervals, and vice versa. In addition, how the data are interpreted af-

fects the validity of inferences that are made. A common interpretive strategy for observational data is to graph data and intuitively interpret the results. O'Brien in 1995 showed, however, that individuals using intuitive estimation methods often underestimate the magnitude of highly correlated variables and overestimate the magnitude of weakly correlated variables.

2. Analogue Behavioral Observation

Analogue behavioral observation is a behavioral assessment method in which a clinician observes a client's behavior in a contrived environment (e.g., a waiting room, play room, clinical setting) to assess variables hypothesized to influence behavior. Although analogue assessment is a direct measure of behavior, the target behavior is observed outside of the individual's natural environment. A special section of the journal *Psychological Assessment* (Vol. 13, No. 1) is devoted to a discussion of analogue behavior observation.

There are several classes of analogue behavioral assessment. Each class includes many different instruments for measuring behavior. A role-play is an analogue behavioral assessment class in which a client performs one or more behaviors in a contrived social situation. An experimental functional analysis is a structured observation session in which clients are observed while variables hypothesized to control or maintain a target behavior are systematically introduced and withdrawn. Family and marital interaction tasks is a class of analogue behavioral assessment in which members of a familial unit interact with one another on a task specified by the assessor that is relevant to the family or couple. Behavioral avoidance tests are often used to assess a person's response to a feared stimulus by measuring proximity to the stimulus (e.g., how close, in feet, a person with a snake phobia can come to a snake in a glass cage) or other approach behavior.

Other analogue behavioral observation techniques include enactment analogues, in which the individual is observed performing a newly acquired skill; contrived situation tests, in which a novel situation is presented to an individual to determine whether the individual can apply newly learned skills; think-aloud procedures, in which a person reports his or her thoughts during performance of a behavior; and response generation tasks, in which an individual engages in, or generates, one or more response options to a stimulus event. Variants of analogue behavioral observation have been used to assess a wide array of behavioral problems and phenomena. Hundreds of studies have employed the technique to assess marital interactions, child behavior

problems, adult social functioning, and countless other behavioral disorders.

The utility of the analogue observation in helping the clinician generate hypotheses about functional relations depends on the degree to which the analogue context includes the elements that affect the behavior problem in the natural environment. For example, McGlynn and Rose in 1998 observed that anxious patients usually fear stimulus classes, rather than a single stimulus, and that one analogue session would be unlikely to include the myriad of feared stimuli present in the client's natural environment. Analogue behavioral observation is most likely to be a cost-effective alternative to naturalistic behavioral observation when the targeted behavior(s) occurs with high frequency in the analogue situation and is not reliably or accurately measured using other less costly assessment methods (e.g., questionnaires, rating scales).

Analogue observation sessions are more likely to provide important information regarding functional relations than behavioral rates. For example, couples may exhibit a higher frequency of negative comments toward one another during an initial assessment interview than they would at home where they could more easily avoid their spouse or partner. Alternatively, behaviors that occur only in private contexts may not occur at all in an analogue situation (e.g., battering, verbal threats). Researchers have long noted that partial-interval recording in analogue settings underestimates high rate responding, does not produce valid estimates of behaviors of short durations, and can misrepresent temporal relationships between behaviors and events.

The novelty of the assessment environment may make it more likely that irrelevant behaviors, rather than the target behavior, are observed. For example, a child who is defiant toward his parents may be stimulated by unfamiliar objects and toys in an observation room and may not interact with a parent as a result. Nonetheless, role-play activities may still permit observation of related variables and their dimensions (e.g., tone of voice, eye contact, frequency of reflective statements made by each partner).

All forms of analogue behavioral assessment require a coding or rating system in which the assessor quantifies a dimension of behavior. For example, Heyman and Vivian in 1993 developed the Rapid Marital Interaction Coding System (RMICS) to facilitate analogue observation of marital communication styles. In 2001 Heyman and colleagues found that observation periods as brief as 15 minutes were sufficient to obtain stable estimates of most RMICS codes in maritally distressed couples. However, in happily married couples, some variables

and behaviors (e.g., dysphoric affect, withdrawal) were observed too infrequently to be reliably coded in brief laboratory interactions.

Analogue behavioral assessment methods and their respective coding systems have generally not been subjected to the type of psychometric rigor common for other psychometric instruments. For example, reports of analogue assessment methods often do not include information about (1) the goals of the analogue assessment, (2) the specific behaviors, functional relations, constructs, and facets to be measured, (3) the response modes and dimensions to be measured, (4) the methods of data collection, (5) how the specific scenarios, situations, and instructions might affect client behavior, or (6) a discussion about how dimensions of individual differences (e.g., sex, religion, age, ethnicity, sexual orientation) might influence responses. One of the major difficulties in evaluating the usefulness of analogue assessment, especially in the assessment of child behavior problems, is the lack of standardization demonstrated by most available measures.

Closely related to standardization is the issue of reliability, or consistency of measurement. The reliability of analogue behavioral observation coding systems is generally not well studied. For example, one researcher concluded that only 20% of published marital communication studies included reliability information for the constructs that were studied. Another researcher concluded that no test-retest reliability data are available for parent-directed-play coding systems or free-play behavior coding systems.

Additionally, the external validity of most analogue assessment measures has not been well investigated. External validity, in the analogue context, is the degree to which behavior observed in the analogue setting is representative of the client's behavior in his or her natural environment. Norton and Hope in 2001 concluded that the evidence concerning the external validity of role-play methods is "equivocal" and data on the external validity of other analogue assessment classes are either insufficient or absent.

B. Behavioral Rating Scales and Behavioral Checklists

A behavioral rating scale is an assessment instrument completed by a clinician or a third party (e.g., significant other, teacher, parent, peer) that includes items that assess one or more targeted client behaviors. A behavioral checklist is similar to a behavioral rating scale but often includes fewer items and may include dichotomously scored response options. Many behavior

rating scales and behavioral checklists have been standardized using a normative sample of individuals and aggregate raw data into standardized scale scores or global scores.

Behavioral rating scales are frequently divided into two classifications: narrow band behavior rating scales and broad band behavior rating scales. Narrow band behavior rating scales include items that sample from a small number of domains and are not intended to be global measures of an individual's behavior. Broad band behavior rating scales usually include more items, sample from a wider spectrum of behaviors, and are often used to screen for more than one disorder or behavioral syndrome.

For example, behavioral checklists and behavioral rating scales are the most popular methods of gathering information in assessing ADHD. Narrow band measures include the 55-item Social Skills Rating System, which divides item content into three narrow domains: problem behaviors, social skills, and academic competence. Another narrow band instrument is the Disruptive Behavior Rating Scale (DRS). The DRS includes item content covering oppositional defiant disorder, ADHD, and conduct disorder. Broad band behavioral rating scales include the Child Behavior Checklist (CBCL) and the Conners Parent and Teacher Rating Scales. Both the CBCL and the Conners Scales provide several scale scores and include versions for parents, teachers, and youths to complete. The popularity of these behavioral assessment methods can be attributed to their cost-efficiency, ability to quantify the opinions of important persons in a client's life, and their ease of administration. In addition, the most widely used instruments (e.g., the CBCL) rest on an extensive foundation of empirical literature that testifies to their reliability and validity.

Although behavioral rating scales and behavioral questionnaires are popular, it should be emphasized that they are indirect measures of behavior. As indirect measures, data collected using behavioral rating scales and behavioral checklists reflect a rater's retrospective impression of a client's behavior rather than an objective recording of the rate at which behavior occurs, as with naturalistic behavioral observation methods. Consequently, all behavioral rating scales and behavioral checklists are subject to rater bias regardless of the rigor with which the instrument is designed. Although indirect observation of behavior can be useful in behavioral assessment, its limitations need to be understood by the behavioral assessor.

In addition to being indirect measures of behavior, behavior rating scales and behavioral checklists rarely provide information pertaining to the functional relations of variables. Most behavior rating scales and behavioral checklists include items that measure topographical behavioral dimensions rather than functional relations. To some degree, the contextual variability of behavior can be addressed by having multiple informants complete the instrument provided each informant observes the client in different contexts (e.g., having a parent and a teacher complete the same rating scale). A thorough functional assessment, however, requires greater attention be paid to other variables that may be maintaining the behavior (e.g., the type of reinforcement received for an oppositional behavior; whether the problem behavior results in avoidance of an aversive event or situation).

C. Psychophysiological Assessment

Psychophysiological assessment involves recording and quantifying various physiological responses in controlled conditions using electromechanical equipment (e.g., electromyography, electroencephalography, electrodermal activity, respiratory activity, electrocardiography). Which response or response system is measured depends on the purpose of the assessment. Psychophysiological measurement has been used to assess autonomic balance (e.g., heart rate, diastolic blood pressure, salivation), habituation to environmental stimuli, reactivity to traumatic imagery, orientation response, and other physiological systems.

Frequently, the behavioral assessor is not so much interested in the behavior measured by the equipment as what may be inferred from the behavior. For example, a large literature exists with regard to the psychophysiological measurement of responses to anxiety-eliciting stimuli. Keane and co-workers in 1998 showed that male military veterans with posttraumatic stress disorder (PTSD) exhibited greater changes in psychophysiological responding (i.e., increased heart rate, skin conductance, systolic and diastolic blood pressure) when presented a series of trauma-related cues than did veterans without PTSD. Other studies have found increased physiological responsivity in females with PTSD and increased heart rate responses to startling tones in individuals with PTSD.

Selection of the eliciting stimulus, or stimuli, and the response modes to monitor during a psychophysiological assessment are important considerations, especially when investigating responses to trauma-related cues.

For example, research has consistently shown that individuals are more physiologically reactive to scripts detailing their own personal experiences than to standardized scripts detailing either neutral scenes or traumatic situations. Synchronous responding to stimuli across physiological modes has not, however, been generally observed. For example, Blanchard, Hickling, Taylor, Loos, and Gerardi in 1994 found that heart rate and electrodermal activity, but not systolic or diastolic blood pressure, were responsive to audiotaped scripts describing a motor vehicle accident the participant survived.

All of these studies demonstrate how psychophysiological assessment can be used to identify behavioral differences in individuals, provide criterion-related validity for psychiatric diagnoses, and can be used as a clinical marker of client change since clinical improvement has been associated with changes in physiological indices. However, psychophysiological assessment is often cumbersome, expensive, and, depending on the client and his or her problems, may not provide information that sheds light on the functional relations of variables operating in a client's life. In addition, psychophysiological information does not inherently possess greater validity or is more objective than other behavioral assessment methods. Data from a psychophysiological assessment require interpretation in the context of convergent evidence from other assessment methods (e.g., a behavioral interview, analogue behavioral observation) in order for the information to be clinically meaningful.

D. Self-Monitoring

Sometimes neither naturalistic nor analogue behavioral observation methods are feasible. For example, a behavior may occur only in private (e.g., vomiting in a client diagnosed with bulimia nervosa), may not be directly observable (e.g., negative self-statements), may occur in contexts that cannot be easily observed in the natural environment (e.g., problematic interactions with a work superior), or may not be easily replicable in an analogue assessment context (e.g., group social gatherings). In these situations, clients may be asked to self-monitor their own behavior. Self-monitoring refers to any assessment method in which clients record observations of their own behavior to a recording form. While most self-monitoring studies have reported methodologies in which the client records data on a predetermined schedule (e.g., hourly, daily, when an event occurs), recent research has explored the use of electronic pagers,

wrist terminals, ambulatory measurement devices, and handheld computers to signal, and sometimes record, client behavior.

Most self-monitoring recording instruments are designed to maximize the chance of observing a functional relation between a behavior and an extrinsic variable. A common self-monitoring record is an A-B-C log. An A-B-C log is a serial record of the antecedent events (A) that occur prior to the behavior (B) and the consequences (C) or events that follow the behavior. A-B-C logs are useful in identifying environmental events that are functionally related with a problem behavior. Variants of the A-B-C log are the basis of most self-monitoring recording forms. For example, daily food records have been used by researchers studying clients diagnosed with bulimia nervosa. Daily food records typically provide space for the client to record the time of a meal, the food and liquid that was consumed, where the food was eaten, the type of eating event (e.g., meal, snack, binge, purge), and the circumstances surrounding the food intake. Some researchers have used a daily obsessional thought record to assess obsessions, mood, and other cognitive variables. Other recording formats include paper-and-pencil diaries and computerized diaries.

The accuracy of self-monitoring data can be affected by several factors. For example, one difficulty in having HIV-positive males self-monitor sexual behavior is that the activity of self-monitoring may affect rates of sexual behavior (i.e., reactivity to the assessment method). In addition, clients who are unlikely to comply with self-monitoring instructional sets should be assessed by other means. Eating disorders researchers have pointed out that clients with anorexia pose significant challenges for a self-monitoring assessment methodology. Clients with anorexia may distort their reports of caloric intake in order to mislead therapists and avoid negative consequences from family and friends. Thus, the validity of self-monitoring data may be affected by the type of eating disorder and the context of the monitoring. Clients who restrict their intake, and are keeping food diaries for themselves, are likely to be accurate in their recording. However, if the recording is in a treatment context, accurate recordings are less likely to occur because of the constellation of influences that could affect the client's report. Other variables that are known to affect the accuracy of self-monitoring data include the number of behaviors to be monitored, social desirability, demand characteristics, the length of the recording period, the client's awareness of accuracy

checks, availability heuristics, the client's emotional state when making a recording, and degree to which the client was trained in self-monitoring.

The wisdom of using self-monitoring techniques with children has also been questioned. Shapiro and Cole in 1999 concluded that children can be reliable monitors of their own behavior but that the technique frequently leads to reactive effects that can change the rate of behavior. Peterson and Tremblay in 1999 concluded that self-monitoring in children is likely to be inaccurate if the behavior is contrary to medical advice, when a behavior is supposed to occur but the child deliberately fails to perform it, when the behavior is socially inappropriate or embarrassing, when the child is not motivated to self-monitor behavior, or when the child may have difficulty monitoring the behavior (e.g., thumbsucking).

Several strategies may enhance both the accuracy of collected data and the probability of client compliance. For example, researchers recommend scheduling accuracy checks, selecting target behaviors that are not difficult to code and record (e.g., self-monitored motoric responses as opposed to verbal responses), training participants in self-monitoring, contracting with individuals, providing reinforcement contingent on accurate recording, providing a recording device that is unobtrusive, limiting the number of behaviors to be monitored, and selecting behaviors that have a positive rather than negative emotional valence.

E. Self-Report Instruments

1. Behavioral Interviews

A behavioral interview is a set of structured or semi-structured queries designed to elicit responses regarding (1) one or more overt target behaviors, (2) behavior–environment interactions, (3) the most relevant behavioral dimensions, and (4) relations of the behavior(s) with hypothesized maintaining variables. Behavioral interviews differ from traditional clinical interviews in that they are structured, focus on overt behavior and behavior–environment interactions, are sensitive to situational sources of behavioral variance, focus on current rather than historical behaviors and determinants, and define behavior at a molecular rather than molar level.

Behavioral interviews are sometimes cumbersome and time consuming to administer. However, the recent development of behaviorally oriented computerized assessment applications has made efficient collection of behaviorally relevant data less problematic. For exam-

ple, Albert Farrell has developed a computer program that helps both clinicians and clients assess client behavior problems and monitor treatment progress. Farrell's program has become a seamless part of the assessment procedures of a university clinic.

2. Behavioral Questionnaires

A behavioral questionnaire is a series of questions, often in Likert-type format, that include item content designed to assess the functional relations of extrinsic variables with a target behavior. In contrast to traditional clinical questionnaires, behavioral questionnaires usually include questions that assess antecedent events, the effects of the behavior problem, and acquire data on one or more behavioral dimensions. For example, Cepeda-Bineto, Gleaves, Williams, and Erath in 2000 designed a food cravings questionnaire with items that assess cues that trigger food cravings, positive reinforcement that comes from eating, relief from negative states as a result of eating, physiological states associated with hunger, and emotions surrounding food cravings and eating.

3. Issues in the Use of Self-Report Instruments

Behavioral assessors have historically been somewhat skeptical of the inferences made from self-report data. Objections include the role that client biases, memory errors, and other factors might play in degrading the accuracy of self-reports. However, some behavioral problems are difficult to observe directly and the client's self-report may be the only source of information concerning the dimensions of the target behavior. For example, Sobell, Toneatto, and Sobell in 1994 concluded that self-reports are a valuable, cost-efficient, and reasonable source of information when assessing patients with substance abuse problems. However, they issued the caveat that inaccurate self-reports are most likely to occur when (1) individuals may violate social conventions or the law by admitting to engaging in a behavior or (2) individuals are unable to provide accurate self-reports (e.g., a demented patient, a very young child).

Although behavioral questionnaires may be inexpensive to administer, have face validity for patients, and are easily scored, behavior therapists should be cautious when making inferences from instruments that are not developed from a behavioral framework. Traditional clinical questionnaires often yield global or aggregate scores that are insensitive to the conditional nature of behavior, the functional relation of behavior to antecedent events and consequences, and the variability of behavior across situations and contexts. In addition, variables are often defined at a molar level that is not

sensitive to variability of component behavioral facets. Many individuals exhibit discordance across response modes (i.e., behavioral, physiological, cognitive) while most self-report questionnaires produce scale or global scores that imply uniform responding.

Inferences drawn from questionnaire data are also attenuated by the fact that self-report and observer ratings often only modestly agree. For example, some researchers have reported significant mean differences between self- and peer-reported interpersonal problems. In one study reported in 1999, Handwerk, Larzelere, Soper, and Friman had parents of 238 troubled children complete the CBCL and the children complete the Youth Self-Report (YSR), the self-report version of the CBCL. They found that parental ratings of the frequency and intensity of their child's problem behaviors were over a standard deviation higher than the self-reports made by the children. The discrepancies were apparent across all scales, and in the same direction (i.e., parents > children) regardless of age, sex, site, and parent informant. These results suggest a lack of agreement of parent and child's appraisals of the child's behavior. Another implication is that the estimated severity of a child's behavior will depend on whether a clinician places more weight on a child's self-report or a parent's rating of the child's behavior. The assumption that responses to a questionnaire or behavioral interview accurately reflect dimensions of client behavior is generally not warranted. Inferences based on questionnaire and interview results should be cross-checked against data collected via other methods.

VI. FACTORS AFFECTING INFERENCES MADE FROM BEHAVIORAL ASSESSMENT DATA

All behavioral assessment methods include variance that is attributable to the behavior being measured and variance that is due to measurement error. The validity of clinical inferences can be affected by the content validity of an instrument, reactivity of individuals to the assessment process, and the degree of accuracy in measurement.

A. Content Validity

Content validity refers to the degree to which elements of an assessment instrument are relevant to and representative of the targeted construct. With regard to behavioral assessment, content validity refers to whether

the methods and instruments chosen for conducting the assessment capture all important aspects of client functioning. For example, in assessing a client complaining of depression, the inferences derived from the assessment would be limited to the degree that the assessor failed to assess the component facets of depression and the various modes of responding. A strategy that focused solely on identifying cognitions surrounding depressive symptoms might not identify important behavioral patterns (e.g., lack of activity) that contribute to the client's low mood. Thus, assessment strategies that incorporate multiple methods of information gathering across multiple modes of responding are likely to minimize error variance associated with any one assessment method.

B. Reactivity

Reactivity refers to changes in behavior that occur in a person who is being observed as a function of the assessment process. Reactivity effects can occur in all behavioral assessment methods and can lead to behavioral increases or decreases depending on the behavior that is being observed. Reactivity effects are often associated with the duration of observation, the amount of change in the environment associated with the observation, the identity of the observers, the amount of instructions provided subjects, the goals of assessment, and the methods of data reporting. Korotitsch and Nelson-Gray in 1999 suggested that variables affecting self-monitoring reactivity include the valence of the target behavior (desirable behaviors tend to increase in frequency), motivation for change, the topography of the target, the schedule of recording, concurrent response requirements, the timing of recording, goal-setting feedback and reinforcement, and the nature of the recording device. Reactivity may be mitigated or eliminated by allowing participants to habituate to the changes introduced to their environment because of the assessment procedure. For example, if a video recorder is introduced to a classroom, allowing the camera to be present for a few days before beginning measurements may allow children to habituate to its presence.

Emerging technological innovations can also minimize reactivity effects in some situations. For example, Boyce and Geller in 2001 reported a study in which the experimenters observed automobile driving behaviors by utilizing several hidden cameras strategically placed in a moving automobile. The cameras were the size of a pinhead and recorded what the driver saw on the road during a 45-minute drive, the driver's face,

the location of the driver's hands, and road markings on the highway. The four video channels were funneled to a quad-multiplexer that integrated the camera views and time stamped the videotape record. The video images were later coded in 15-second intervals for safe driving techniques (e.g., correct turn signal use, maintaining a safe following distance from another vehicle). The results showed that older participants engaged in less risky driving behaviors than younger participants. In addition, male drivers did not take more risks than female drivers, leading the authors to suggest that previous research suggesting greater risk-taking behavior by males may be an artifact of the self-report methods that were used.

C. Accuracy

Although many definitions of accuracy have been proposed in the behavioral literature, accuracy refers to the extent to which data collected during a behavioral assessment approximates the true state of nature. In behavioral assessment, accuracy is relevant to both the recording (i.e., data coding) and the reporting (i.e., interviewee responses) of behavior.

Accuracy may be attenuated in several ways. Researchers have long noted that accuracy of self-monitoring data can be affected by the response mode that is monitored (i.e., cognitive, motor, or physiological behavior). Low-frequency, overt motor behaviors appear to be more accurately recorded than high-frequency, verbal behaviors for most individuals.

Accuracy can also be affected by recorder bias. Recorder bias may result from a potentially endless number of factors: inattention, carelessness, poor training, errors in selection of intervals during which behavior is recorded, technical difficulties, and so forth. When multiple raters observe behavior, calculating the degree to which any one rater agrees with the other raters can help identify raters who may be systematically biasing their observations and, hence, their data.

Accuracy of reporting can fluctuate over time as a function of a variety of respondent variables. For example, Carr, Langdon, and Yarbrough in 1999 concluded that the accuracy of clients self-report is subject to (1) biased or inaccurate recall of behavioral occurrences and (2) the changing functions of behavior. In addition, modifying a client's recognition and understanding of a problem behavior may affect both rates of responding and the client's estimates of behavioral rates. For example, a client may not initially be aware of the environmental cues that reliably precede a panic attack (e.g.,

being in a public place). However, a functional analysis may make the client aware of a relationship between the behavior and the context and make it more likely that the client is able to cope with previously anxiety-eliciting situations. As a result, the client may experience a decrease in frequency of panic attacks.

VII. CLINICAL CASE FORMULATION

Ultimately, behavioral assessment must inform treatment planning and increase the probability that maximally efficacious treatments are implemented. The importance of developing a clinical case formulation based on assessment results has been recognized by workers endorsing diverse models of psychopathology. However, integration of assessment tools from diverse, and sometimes incompatible, theoretical models has not been successful.

Increasingly, clinical case formulation is being viewed by behavior therapists as a crucial contribution to successful treatment outcome. Recent volumes on clinical case formulation highlight the prominent role case formulation plays in treatment planning. However, appreciation for the importance of clinical case formulation in the behavioral paradigm is a relatively recent phenomenon. Behavioral models of clinical case formulation have focused on the identification of antecedent conditions and behavioral effects that maintain the target problem. Clinical case formulations have spanned a wide array of disorders and behaviors including transient tic disorder, delusional speech in schizophrenia, trichotillomania, obsessive-compulsive disorder, developmental disabilities, chronic cough, and borderline personality disorder.

However, the necessity of conducting a clinical case formulation, while intuitively appealing, remains a subject of some debate. Studies confirming the utility of an *a priori* case formulation are difficult to design for several reasons because numerous intervening variables that are extraneous to the case formulation can affect a client's behavior (e.g., client-therapist rapport, quality of treatment delivery, duration of the client's presenting problems, frequency and strength of the client's responses, response class parameters of the client's behavioral repertoire). Nonetheless, some authors have suggested that treatment outcome is more related to the accuracy of the clinical case formulation than to intervention strategies. For example, Persons, Curtis, and Silberschatz in 1991 proposed the formulation hypothesis, which suggested that successful treatment outcomes depends on the accuracy of the initial

case formulation, thereby elevating the role of clinical case formulation to a level on a par with, and even superior to, treatment delivery. Objections to the formulation hypothesis include the observations that (1) treatment outcome is affected by a wide variety of factors extrinsic to the therapeutic context, and (2) clients sometimes improve in the absence of a formal clinical case formulation.

A. The Cognitive-Behavioral Case Formulation Model

Jacqueline Persons and her colleagues have developed a cognitive-behavioral case formulation model (CB) that focuses on the identification of overt behaviors and the underlying cognitive mechanisms hypothesized to control the behaviors. The therapist works with the client to create a behavior problems list, a list of specific beliefs about himself or herself that may affect the client's behavior problems, and a list of external events and situations that activate core beliefs. From these data, a set of working hypotheses are developed regarding the functional relations of problem behaviors and maintaining variables. Causal mechanisms in CB are often presumed to be underlying cognitions and are assessed using a multiple-choice questionnaire.

Persons and her associates have found that clinicians trained in the CB show moderate agreement in their lists of clients' overt problems. Doctoral-level training, clinical formulation training, experience in cognitive-behavior therapy, and greater psychotherapy experience have been associated with better agreement in problem identification but not in identifying schemas that may be influencing the client's behavior.

B. A Problem-Solving Approach to Clinical Case Formulation

Whereas the model described by Persons and her colleagues emphasizes the identification of core schemas that underlie behavioral problems, Arthur and Christine Nezu have conceptualized assessment and therapy as a problem-solving process composed of the following components:

1. *Problem orientation*: The clinician conceptualizes the client's problem as multiply determined by psychological, biological, and social influences.
2. *Problem definition and formulation*: The clinician assesses the behavioral problem across multiple response modes (e.g., behavioral, cognitive, affective,

physiological) and contexts, considers historical and developmental information, and gathers data from standardized measures, behavioral observation, and psychophysiological measures.

3. *Generation of alternatives*: The clinician considers different treatment options and creates a list of possible target variables, solutions, and interventions.
4. *Decision making*: The clinician evaluates the clinical utility of each treatment and selects the one that is likely to be most effective for the client.
5. *Solution implementation and verification*: The clinician works with the client using the selected treatment option and assesses outcome.

A visual summary of the case formulation is provided by means of a clinical pathogenesis map. The map is a flow diagram summarizing the relationship between stressful events, historical factors, contemporaneous events, and behavior problems.

C. Functional Analytic Clinical Case Modeling

Another case formulation model has been developed by Stephen Haynes and his colleagues. A functional analytic clinical case model (FACCM) is a means of schematically representing a functional analysis² using vector graphic diagrams, as discussed by Haynes, Leisen, and Blaine in 1997. FACCM variables include original causal variables, causal variables, moderating variables, client behavior problems, and effects of client problems. Original causal variables are variables that affect client behavior, either directly or through their effects on other causal variables, and are not modifiable (e.g., events that happened in the past, medical conditions). Causal variables are variables that affect the client's problems and are presumed to be modifiable. Client problems are behaviors or cognitions exhibited by the client that are evoked or maintained by causal variables. Finally, the effects of client problems are events or processes that follow, and may be consequences of, client problems. In addition to identifying the above variables, FACCMs communicate the hypothesized strength of each variable in the model,

² The definition of the term "functional analysis" varies within behavioral psychology and across disciplines that use behavioral principles. In applied behavior analysis, the term refers to the systematic manipulation of variables to estimate functional relations. We use Haynes and O'Brien's more broad use of the term in 1990 to refer to the identification of "important, controllable, causal and noncausal functional relations applicable to specified behaviors in the individual."

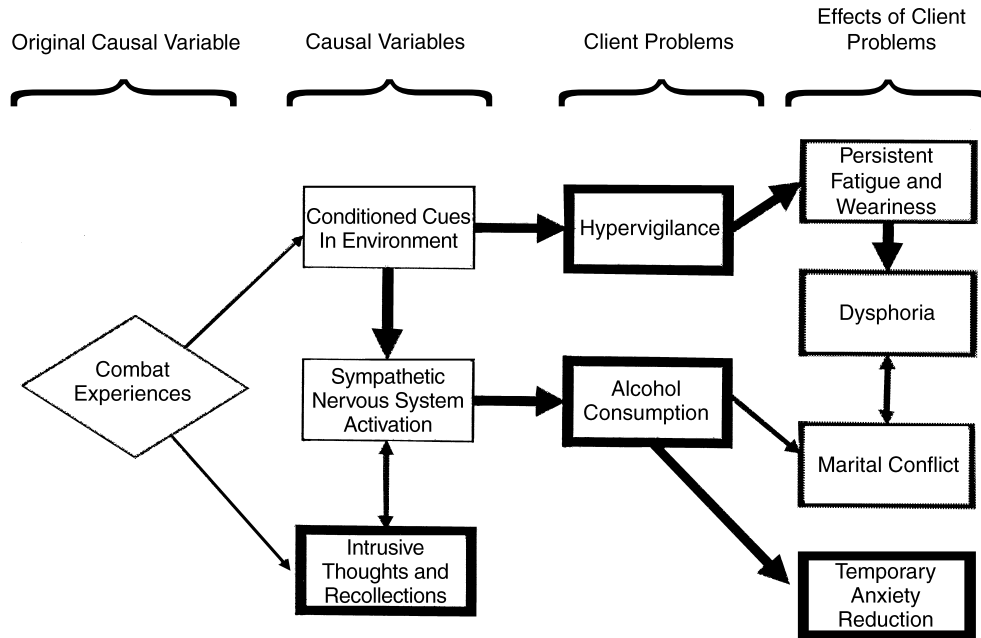

FIGURE 2 A functional analytic clinical case model (FACCM) of a Vietnam war veteran’s drinking behavior and hypervigilance. *Note.* Using the example of the war veteran provided in the article, an FACCM can show both respondent and operant conditioning at work. An original causal variable, the combat experience, is paired with a variety of innocuous stimuli (smells, sounds, etc.) that will later remind the veteran of his combat experiences through respondent conditioning and generalization. The trauma of the combat experience leads to intrusive thoughts and recollections long after the veteran returns from the combat theater. Both environmental cues and the intrusive thoughts and recollections have the potential to elicit sympathetic nervous system activation (e.g., increased heart rate, respiration). Sympathetic nervous system activation can also reciprocally elicit intrusive thoughts and recollections (e.g., an increase in heart rate through exercise can trigger a combat memory). The main client behavior problems thus involve alcohol consumption, which has the effect of temporary anxiety reduction and is maintained through negative reinforcement, and hypervigilance of environmental stimuli (i.e., conditioned cues in the environment). Sustained hypervigilance has the effect of creating a persistent sense of fatigue and weariness. In tandem with marital conflict caused by excessive alcohol consumption, the fatigue resulting from the client’s hypervigilance contributes to another effect, dysphoria.

the modifiability of causal variables, the strength and causal direction of relationships between variables, and the importance of each behavior problem. A computer program developed by Haynes, Richard, and O’Brien in 2000 conducts a path analysis that takes into account all variable relationships in an FACCM and rank orders the effect of each causal variable on the model.

FACCMs are usually specific to a context and are not assumed to be equally valid for individuals with topographically similar target behaviors. FACCMs are dynamic in that they are expected to change as more assessment information becomes available and the variables affecting a target behavior change. Figure 2 is an

example of an FACCM for a Vietnam war veteran addressing client behavior problems of excessive alcohol consumption and hypervigilance.

D. Commentary

The three models described by Persons, Nezu and Nezu, and Haynes provide frameworks by which clinicians can assess and understand functional relations in a clinical case. The models provide a systematic, generalized way of thinking about functional relations rather than suggesting causal mechanisms for a specific behavior or any of its dimensions. In this way, clinical

case formulation models can be thought of as templates that guide conceptualization of functional relations across disorders.

An interesting question for future research involves the degree to which the various clinical case formulation models lead clinicians to hypothesize different functional relations in the same client. In addition, researchers have yet to determine conclusively whether clinical case formulation models enhance treatment outcome and which models, if any, are more likely to produce incremental treatment gains.

VIII. COMPUTERS AND BEHAVIORAL ASSESSMENT

In the future, behavioral assessment will be increasingly augmented by the use of computer technology. Already, researchers have developed computer programs that help the behavioral assessor efficiently collect, store, and analyze data. Programs are now available that ease data collection and analysis across all the major methods of behavioral assessment. For example, software for event recording has replaced earlier electromechanical devices and paper-pencil recording formats. Tapp, Wehby, and Ellis in 1995 developed the Multiple Option Observation System for Experimental Studies (or MOOSES). The software eases event-based recording, interaction-based recording, duration recording, and interval recording of observed behavior. The software is also capable of several types of data analysis (e.g., interobserver agreement, sequential analysis, duration of events within behavioral states). Similarly, Noldus in 1991 reported the development of an early MS-DOS-based coding system called The Observer, and a subsequent multimedia revision, that allow researchers to construct complex coding templates and code behavioral responses as they occurred. Other computerized observational coding systems are available to behavioral researchers and have been extensively reviewed in the literature.

Self-monitoring software has also been developed for handheld devices. An advantage of handheld devices is that they promote assessment of momentary states in the natural environment. Recent research has found that assessment of momentary states may yield results that are significantly different from participant's retrospective ratings of their behavior and skills. For example, some researchers have reported that retrospective self-report measures of coping skills were very poor predictors of how well individuals actually cope in stressful situations.

Several clinically applicable handheld software programs have been described in the literature in recent years. Newman, Kenardy, Herman, and Barr Taylor in 1996 used a Casio PB-1000 handheld computer to prompt patients with panic four times per day to report anxiety levels and occurrence of panic attacks. During the client's office visit, data were uploaded to a desktop computer, stored in a database, and then analyzed. Reports were generated that summarized client responses to the computer. Others have recently reported using handheld devices to record frequency of smoking behavior, measure reaction time during a prolonged, simulated submarine crisis, measure stress reactions in the natural environment, and assess obsessive-compulsive, fibromyalgia, and dementia symptoms.

The extent to which handheld devices will be successfully incorporated into the clinical practice depends on cost-effectiveness, technological, and psychometric issues. With regard to cost-effectiveness, handheld devices may be prohibitively expensive for clinicians to use with clients given that the devices are at higher risk for being lost, not returned, or damaged. In addition, software that is robust enough to be generalized to a wide array of behavior problems is not currently available for handheld devices.³ Even if the software was readily available, efficient methods for conducting data analyses and incorporating results into treatment planning have yet to be developed. Additionally, the technological learning curve may dissuade some clinicians from using these devices at all. From a psychometric standpoint, the effect collecting data using a handheld device has on client behavior (e.g., reactivity effects) is not well understood. Despite these considerations, however, computer and handheld technology should continue to play an important role in the evolution of behavioral assessment.

IX. SUMMARY

Behavioral assessment emphasizes the measurement of variables that are highly specific and require low

³ However, the tools for developing such software are readily available. For instance, Microsoft offers copies of Embedded Visual Basic 3.0 free of charge through its Web site. The software allows developers to create user interfaces for a number of handheld and palm-top devices and debug the software in an emulated mode on a desktop computer platform. Data saved in an Embedded Visual Basic application can be downloaded to Microsoft Access for analysis. In order to run Embedded Visual Basic 3.0, users should have the Windows NT 4.0 or Windows 2000 operating systems installed on their development computers.

levels of inference, over multiple assessment periods, across multiple methods and modes of responding. The behavioral assessment paradigm is closely tied to behavioral principles first elucidated almost 100 years ago. The vitality of behavioral assessment and behavior therapy is evidenced by the exponential growth of journals devoted to their study.

The behavioral assessor may choose from a variety of assessment methods (e.g., naturalistic behavioral observation, analogue behavioral observation, psychophysiological measurement, behavioral rating scales, self-monitoring, behavioral interviews, and behavioral questionnaires). The ultimate goal of behavioral assessment is to facilitate clinician hypotheses about client functioning and develop a clinical case formulation that will suggest the most efficacious treatment intervention. Several behavioral and cognitive-behavioral researchers have developed clinical case formulation models in recent years and the importance of these models in focusing treatment planning continues to increase. With the development of sophisticated handheld and desktop computer applications that ease data collection and analysis, the family of behavioral assessment methods should continue to evolve as the most useful way to assess the relationship and importance of variables operating in a client's life.

GLOSSARY

- antecedents** Events, environmental circumstances, thoughts, behaviors, statements, emotions just prior to the onset of the behaviors targeted for change.
- consequences** Events, internal or external, that immediately follow the targeted behavior(s).
- punishment** Any consequence, internal or external, that decreases the likelihood that a targeted behavior will occur in the future.
- reinforcement** Any consequence, internal or external, that increases the likelihood of a targeted behavior occurring in the future.
- single case design** Applying scientific methods to a clinical case utilizing an $n = 1$.

Case formulation is a process in which a therapist collects information regarding the presenting concerns of a therapy client, describes the client and how a problem(s) came about, and summarizes what the primary problem is as well as what skills and resources the client brings to therapy. The ultimate purpose of case

formulation is to suggest how to proceed in making alterations in the individual's behavior with the intent of creating solutions to the presenting problem(s). Behavioral case formulation utilizes behavioral and learning theories in this process, emphasizing observable behaviors and environmental factors that influence the initiation, alteration, or maintenance of problematic and more useful behaviors. This article outlines the basic processes involved in case formulation from a behavioral perspective.

I. DESCRIPTION OF BEHAVIORAL CASE FORMULATION

Behavioral case formulation is a process in which therapists seek to describe clients, their strengths and resources, stressors, and current concerns in the context of specific, observable, and measurable indicators. Behavioral case formulation has been described as testable hypotheses that connect presenting problems to one another, explains why the problems have developed, and provides predictions of the patients' behavior based on those hypotheses. Other descriptions include references to scientific or empirical methods applied to clinical cases or to considering each case as a minipsychological experiment. An interesting example of this approach is the single case design in which empirical methods are used in the case formulation and treatment of a single individual.

The behavioral emphasis on applying scientific methods assumes several things: (1) behavior may be understood in scientific terms, (2) behavior is sufficiently predictable that we may draw inferences based on earlier behavioral patterns to predict future behavior, (3) behavior may be internal or external, but observable in some fashion by the client and others, (4) behavior is strongly although not exclusively influenced by the environment, (5) all clients present with existing skill sets, resources, and useful observations that can be utilized during behavioral therapy, and (6) we can further alter behavior patterns systematically through the application of scientific and learning principles. The first step of behavioral case formulation is an observation period during which the therapist and client jointly begin collecting information about the presenting concerns of the client. During this phase of treatment the client and clinician identify the target problem(s), including intensity, severity, duration, and the contexts (who is present and what happens just before during and after the problem) in which the problem(s) occurs. Target difficulties in behavioral therapy may be (1) behavioral excesses, occurring more than is desirable in a given context (2) behavioral deficits, not occurring as frequently as desirable in a given context, (3) skills deficits, for example coping or problem-solving skills deficits, or (4) behavioral anomalies, such as behaviors that are inappropriate for any person at any age in any context.

Gathering this information can be accomplished through direct clinical observation, interviews, self-report instruments, self-monitoring, and other assessment methods.

Direct clinical observation is theoretically the most accurate method of data collection. Observation allows the clinician–scientist to witness and therefore evaluate firsthand the relevant external environmental factors and make hypotheses about what would result in the desired change. In application, however, direct observation is neither very practical nor particularly objective. First, as stated earlier, target behaviors may be internal and not directly observable by the clinician. When this is the case, extra time must be taken by the clinician and client to jointly identify external signs of the internal experience so that they may develop observable criteria for success. Second, human behavior patterns change when a person is aware of being observed and covert observation presents such significant ethical concerns as to render it inappropriate in most circumstances. In addition, even well trained observers show bias, seeing what is expected. However, even with its potential pitfalls, direct observation may provide the most valuable information in the case of child behavior analysis.

Interviewing is the most common method of gathering relevant clinical information. The clinical interview may be unstructured, structured, or semistructured. Unstructured interviews offer a great deal of flexibility for the client to discuss personal concerns in the order that makes the most sense and may assist in developing rapport. The cost of that flexibility, however, may be a loss of salient information, timeliness, objectivity, and reliability across interviews. Structured interviews offer greater detail and the likelihood of a thorough and consistent assessment at the cost of rapport and flexibility. Semistructured interviews such as the SCID-I (Structured Clinical Interview for the *DSM IV*) appear to offer the best of both worlds with increased reliability and predictable production of clinically useful data.

Assessment instruments may also be helpful in the data-gathering phase of behavioral case formulation. “Objective” standardized self-report instruments usually require clients to make quantitative or forced qualitative responses to specific questions. These standardized assessment instruments are helpful in balancing some of the subjectivity common to interviewing methods. They allow for the questions to be asked consistently at each administration, scores can be compared to other administrations (if test-retest reliability is sufficiently high) and to other clients’ scores or “normal” population scores. They are also quite practical, making repeated information collection inexpensive (over time) and fairly quick relative to obtaining the same information through interview. For example, a common depression questionnaire may take as little as 5–10 min for the average adult to complete when the interview needed to ask the same questions may easily require 20–30 min to complete. Although standardized instruments as a group often have much better test-retest reliability and interrater reliability than interviewing methods, there are a number of disadvantages to the use of standardized questionnaires. Clients often state that they do not prefer to complete the instruments on a frequent basis. Because of this, clients may answer questions in a habitual pattern rather than answering each question uniquely. Validity (the extent to which a questionnaire measures what it is intended to measure) is also a concern as questionnaires cannot anticipate the way individuals will express themselves or explain their experiences. It is a common occurrence in clinical practice to have clients scratch out items or choose not to answer items on an assessment instrument because it does not directly pertain to their experience. This requires further time from the clinician to ask for the relevant information in interview format, thereby reducing the initial utility of the instrument. It is noteworthy that several authors have found that the

clinician's effectiveness in treatment as well as the client's willingness to complete outcome assessment measures may be enhanced when the instruments are immediately scored and the client and clinician get rapid feedback about the results.

Self-observation or self-monitoring may be an effective option to direct clinical observation. As discussed earlier, humans are natural scientists and with some coaching, most clients can become excellent observers of their own behavior. Some theorists have reasoned that this process may be therapeutic in and of itself, increasing the likelihood of follow-through on therapy assignments and resolution of nontargeted problems before they need to become the focus of therapy. Examples of common self-monitoring tasks include the client noting the intensity, frequency, duration, context, and so on of the target behavior(s) such as intensity of depressive feelings on a 1–10 scale, frequency of crying spells, duration of time spent sleeping in bed, and contextual information (antecedents and consequences) of pain behaviors. As with other methods, self-monitoring or self-observation may be biased, may be simply inaccurate, may have numerous omissions of important data, and may include erroneous information. Practically speaking, if the client does not want to fill the observation sheets out on a regular basis, the information will not be particularly useful. Utility of self-monitoring tasks may be enhanced by reinforcement of the behaviors required to fill them out, by directly using the information brought in (no matter how much is available or unavailable), and by refining the self-monitoring forms to emphasize that which is most salient to the client at that time.

Regardless of which methods are used, the emphasis of the initial data sort includes

1. A description of who the client is in behavioral terms
2. What this person's concerns—problems are from their perspective
3. What is the person ready and willing to work on first
4. What personal or environmental strengths and resources are available
5. What the person's most effective learning strategy is
6. What strategies to remedy the problem have already been attempted (with an emphasis on that which has been successful under some circumstances)
7. A detailed accounting of an example of the problem behavior—behavior chain
8. The antecedents to the problem behavior(s)
9. The consequences to the problem behavior
10. The reinforcing properties of the environment
11. The functional relationships between the environment and behavior
12. How have these developed
13. How have they persisted
14. What in the environment can produce change now
15. What change has been produced in the past
16. A detailed accounting of how change occurred in the past
17. A detailed accounting of the exceptions to the problem
18. Identification of the antecedents and consequences of the exceptions to the problem
19. Identification of significant life events
20. Identification of family history of presenting concerns
21. Information about client's medical condition
22. Information about any substance use including prescribed medications, over-the-counter medications, illegal drugs, or herbal supplements.

Together, these indicators are used to formulate the hypothesis about the problem, how it formed, how it is maintained, and how it may be resolved.

This formulation becomes the foundational underpinning of a course of behavioral treatment and is updated through continuous assessment in the course of treatment refining the hypotheses over time. It is of note that discussing the context in which the problem occurs (or when exceptions to the problem occur) is a prime opportunity to utilize the expertise of the client and to create rapport through positive reinforcement of the client's efforts and differential reinforcement of scientific thinking processes. As humans are natural scientists and hypothesis testers, the client is likely to have formed hypotheses in attempting to remedy the problem prior to seeking external help. In fact, the client may already know "how" to fix the problem but is having difficulty implementing the solution or may have had success fixing the problem in certain contexts but not others. An expert clinician will partner with the client from the beginning of the information gathering or observation phase. It is also important to note here that the information gathered should include hypotheses about the potential effect of making a change in that person's behavior or environment. For example, will changing the target behavior(s) result in reinforcement from the environment or, instead, punishment or loss of previous reinforcement? Will making a change elicit a significant desirable or undesirable response from the environment resulting in a likelihood of short and unsustainable therapeutic gains? The ecology of the

change is an essential part of the hypothesis to be tested in the modification phase of behavioral case formulation.

Now that the target behaviors have been observed, discussed, reported, or otherwise recorded, and hypotheses have been formed about how they began, have been maintained, and how they can be modified, the modification phase begins. The therapist at this point may find that seemingly clear terms are not operationalized sufficiently to proceed. In this case, the clinician and client can refine their terms and make certain that the focus is on the observable, specific, and measurable. Specific behaviors rather than labels or traits are the hallmark of a behavioral approach such that external signs of internal experience are defined as well. Although diagnoses are required by most third-party payers and many institutions as an aspect of treatment planning, there is little agreement as to their clinical utility in behavioral case formulation. Because it is often required, it is recommended that the client and clinician partner in the diagnostic process finding the best-fitting category. It may be necessary to discuss the purpose of a diagnosis (for most clinicians it appears to be for communication with other professionals and for payment structures) and to work toward the least severe and most inclusive diagnostic category possible, minimizing the negative stigma associated with diagnoses.

Together the client and clinician devise a modification methodology, based on the clinician's expertise and skills and client's readiness and willingness to engage in specific, observable, and measurable behavior change. This phase involves clarifying which specific behaviors will be targeted in which order, which methods will be used to observe the change, and how the clinician and client will measure the amount of change. They will further establish a timeline for the testing of the hypotheses (i.e., treatment phase of eight sessions over 8 weeks) and agree on what exact interventions will be implemented (i.e., exposure, relaxation procedure, self-reinforcement schedule). How the changes will be implemented and how the changes and effort will be monitored are particularly important parts of this phase. It is common to utilize the previously chosen observation methodologies with modifications to reduce the amount of time required. For example, a pre- and posttest battery of methods may be proposed with a simple rating system and utilization of one short standardized instrument at each session. Applying scientific principles, the methodology is updated throughout the formulation, and the hypotheses are revised and then sequentially tested. As the clinician and client obtain more relevant data, they gain greater specificity of modification method.

II. THEORETICAL BASES OF BEHAVIORAL CASE FORMULATION

Behaviorists contend that all behavior is understood in context, and that all behavior is systematically variable. Behavioral therapists contend that although individuals vary from one another in their response to similar environmental stimuli, they will frequently develop their own idiosyncratic behavior patterns that can be defined, observed, and measured. These patterns are the focus of behavioral theory and of behavioral therapies. The basic theoretical framework is that effective clinical intervention is dependent on an accurate understanding of the factors that initiate and maintain behavior(s). The factors that initiate and maintain behaviors include antecedents and consequences. Antecedents are the events that immediately precede the targeted behaviors. Like the target behaviors, they can be overt or covert. They are not considered causal but, instead, are said to mitigate the likelihood of a behavior occurring. This relationship with the targeted behavior is strengthened in conjunction with consequences. Consequences are events that immediately follow the targeted behavior(s). These are also overt or covert and can either increase or decrease the likelihood of a behavior occurring. When an increase in a consequence increases the likelihood of a behavior occurring again it is termed positive reinforcement. When the decrease in an unpleasant consequence increases the likelihood of a particular behavior, it is called negative reinforcement. Negative consequences reducing the likelihood of a particular behavior are called punishment. An increase in a negative consequence that reduces the likelihood of a particular behavior is termed positive punishment. A decrease in a consequence that reduces the likelihood of a particular behavior is called negative punishment. In practical terms, different types of punishment are often grouped together and may also be referred to as "mitigating factors." Behavior therapists assert that antecedents and consequences govern both normal and abnormal behavior.

These basic principles yield the following theoretical explanations of undesirable behavior:

1. The excessive use of punishment or aversive stimuli can produce behavioral anomalies, emotional disturbance, and "traumatic" conditioning
2. Inadequate opportunities for learning may result in an inadequate repertoire of skills
3. Reinforcement of inappropriate behavior may result in behavioral excesses, behavioral deficits, or behavioral anomalies

4. Failure to reinforce appropriate behavior may result in behavioral excesses, behavioral deficits, or behavioral anomalies
5. Lack of models or poor models may result in an individual failing to develop a functional behavioral repertoire
6. Poor discrimination skills may result in failure to discriminate between situational variables determining what behavior is appropriate or inappropriate
7. Inadequate self-reinforcement may result in an individual seeking an excess of external reinforcement, social skills deficits, or insufficient emotion regulation

These hypotheses for abnormal behavior reinforce the basic theoretical construct that stimulus–response chains can be identified for any given behavior or set of behaviors. It is of note that early behavioral theorists used a strict definition of behavior that included only that which is externally observable. More recent theorists such as David Barlow and Aaron Beck suggest that internal, or covert, behaviors are governable by the same principles as overt behaviors and therefore equally malleable by the application of learning principles. Current theorists continue to emphasize that the key is in targeting specific, observable, and measurable behaviors; identifying what initiates and reinforces behavior; and then making systematic adjustments (behavior therapy methods) to the behavior chain to create the desirable result.

III. EMPIRICAL BASES FOR BEHAVIORAL CASE FORMULATION

Behavior therapy and its constituent methodologies have been extensively studied, and are, at present, “a favored child” among therapies. One reason for this is that behavioral case formulation requires specificity, the utilization of hypothesis formation, and systematic hypothesis testing. Behavioral methodologies are the clinical equivalent to scientific methodologies and, as such, lend themselves to empirical study. It is said that behavioral methods are studied more than any other therapies. The most recent findings suggest that behavioral and cognitive-behavioral methods consistently produce positive therapeutic results, are easily individualized to the needs of the client, and are, by design, replicable. Behavioral methodologies have been proven to be more effective than medications for most anxiety problems. Studies also show that behavioral methods are more effective with depressive disorders than any other therapy modality and

are recommended as the treatment of choice in conjunction with medication therapy for a number of depressive disorders. Behavioral methods have also been proven effective for externalizing behavior disorders, anger management problems, learning difficulties, social skills deficits, coping skills deficits, pain management, compliance issues in medical treatments, and sleep problems.

IV. SUMMARY

Behavioral case formulation is a method by which a clinician–scientist seeks to understand and then summarize the concerns and strengths of a therapy client. It has long been considered the scientific method applied to therapy. It is a process by which therapists systematically investigate targeted behaviors, form hypotheses about how the targeted behaviors came about, and hypothesize about how they are maintained. The hypotheses form the basis for treatment in which the clinician and client jointly alter individual factors in the internal or external environment (testing the hypotheses) and make observations about the results. Based on these observations, the methodology continues to be modified until the desired result is achieved. Clients are often taught the basic methods involved so that they can maximize the benefit from the process and generalize what they learn to other areas of their life.

treatment acceptability The degree to which the consultee approves of a particular treatment plan.

treatment integrity The degree to which a particular treatment plan is implemented as intended.

GLOSSARY

baseline The period during which behavior is observed before any treatment is implemented.

developmental consultation A form of behavioral consultation that involves sequential, planned treatment of a large number of behavior problems, frequently related to a major psychological disorder or dysfunction.

operant learning A behavioral theory which holds that behaviors are learned by the consequences (reinforcement or punishment) associated with them.

problem-centered consultation A form of behavioral consultation that involves treatment of a small number of specific behavior problems.

punishment Any consequence of a behavior that decreases the frequency of the behavior.

reinforcement Any consequence of a behavior that increases the frequency of the behavior; loosely synonymous with the common term *reward*. Positive reinforcement involves providing something desirable to the individual, while negative reinforcement involves removing something undesirable from the individual's environment. Both positive and negative reinforcement have the function of increasing the frequency of the behavior they follow.

I. DESCRIPTION OF TREATMENT

A. Overview and Fundamental Characteristics

Behavioral consultation is a treatment modality that involves at least three individuals: the client, the consultee, and the consultant. The client is typically a child who is exhibiting some sort of behavior problem and needs psychological services. The consultee is typically a caregiver for the client, usually a parent or teacher, but it could be a peer. The consultant is a mental health professional, trained in a variety of treatment practices and techniques. Through the consultation process, the consultant and consultee work together to address the challenging behaviors displayed by the client. The consultation process also can be used to increase the skills and social competencies of the client.

Each individual has specific roles and responsibilities in the consultation process. The consultant works with the consultee to elicit a clear description of the behavior problem(s) and goals, examine possible explanations for the behavior, develop a plan for treatment, and formulate a method for evaluating the effectiveness of the treatment. The consultee implements the treatment with

the client and collects data that are used to evaluate treatment efficacy. After the treatment has been implemented for a sufficient period of time to permit evaluation, the consultant and consultee together decide whether to maintain, modify, or discontinue the treatment program. It must be emphasized that the treatment is typically implemented by the consultee in this process, although in some cases the consultant and consultee may share this role. This strategy distinguishes consultation from traditional psychotherapy, where the treatment is administered directly by the mental health professional (the therapist). For this reason, consultation is considered an indirect mode of service delivery.

Consultation is also a problem-solving process. In fact, the traditional term behavioral consultation is now usually replaced by the term “problem-solving consultation.” Very specific, carefully defined problems are targeted for treatment. In most cases, the process of consultation focuses on remediating a few targeted behavior problems, rather than addressing more general concerns about the client. This type of consultation is called problem-centered consultation. A second type of consultation, called developmental consultation, can be invoked to deal with a wider array of client problems, including comprehensive assessment and treatment of major disorders. Developmental consultation involves repeated application of the same steps used in problem-centered consultation; problems are addressed in sequence to produce broad improvements in client functioning. Ultimately, the goals of both types of consultation are twofold: to attain an acceptable level of client behavior, and to teach the consultee a process for handling other behavior problems exhibited by other children. The first goal is accomplished by implementation of a treatment plan designed for the identified client. The second goal is accomplished by having the consultee participate in every stage of the consultation process, and in so doing develop their skills and understanding of how to approach children’s challenging behaviors.

Five stages of the consultation process have been identified: initiation of a consulting relationship, problem identification, problem analysis, plan implementation, and plan evaluation. In textbook cases, problem identification, problem analysis, and plan evaluation are readily accomplished through single interviews of approximately one hour each between the consultant and consultee. Initiating a consulting relationship typically occurs at the same time as the problem identification interview. Plan implementation is the lengthiest

part of the process and is usually carried out by the consultee during the consultee’s day-to-day interactions with the client in the natural setting.

B. Initiation of a Consulting Relationship

Successful initiation of the consulting relationship is crucial to the success of the treatment process. It is important for consultants to use positive interpersonal skills in their interactions with consultees. Some characteristics that appear to enhance the relationship between the consultant and consultee include active listening by the consultant and consultant acceptance of the consultee’s perspective through nonjudgmental statements, openness, nondefensiveness, and flexibility.

In traditional behavior consultation, the establishment of a collaborative relationship between the consultant and consultee during the initiation stage is viewed as essential to the ultimate success of the consultation process. Each participant contributes his or her own knowledge and expertise to the case. The consultant brings professional knowledge of treatment procedures (e.g., behavioral principles) and the consultative process. The consultee brings knowledge of the client and the problems that the client is exhibiting. The consultant’s and consultee’s knowledge bases are combined through the consultation process to achieve effective problem resolution.

It is important during the initiation stage for the consultee to attain a clear understanding of the stages of the consultation process, and to identify the roles and responsibilities of each participant at each stage. In this way, appropriate focus will be maintained through the process, allowing for organized development, implementation, and evaluation of a treatment plan. To assist the consultee in understanding the consultation process, it is essential for the consultant to review and discuss the stages of the process—and the roles and responsibilities of each person at each stage—during the initiation of the consultation relationship.

C. Problem Identification

The second stage of the consultation process is known as problem identification. The primary goal of this stage is for the consultant to elicit a clear description of the client’s problem behavior and/or social or academic difficulties. In consultation, a behavior problem is defined as a discrepancy between the actual and desired behavior level. Thus, it is very important to arrive

at a clear understanding of both the client's current behavior and the desired behavior level. Often, however, descriptions initially provided by consultees are vague and incomplete. For instance, a teacher may say, "Billy has problems getting along with peers." Although this description gives some general information about the area of concern, it does not provide specific information essential for understanding the problem and planning a treatment. At this point, the consultant needs to elicit such particulars. This specific information is usually obtained by asking the "W" questions—such as who, what, where and when the behavior occurs. For instance, the consultant might ask, "what does Billy do when he is having trouble getting along with peers," and "when does this behavior occur?" Answers to these specific questions help the consultant and consultee obtain a clear picture of the problem situation, which will later be used to develop an appropriate treatment. For instance, Billy's problems could range from failing to initiate conversations with peers to physically attacking peers when they invite him to play. Knowing the precise nature of Billy's behavior problem is essential for developing an appropriate treatment. The most desirable descriptions of problem behaviors in consultation are those that refer only to the observable aspects of the behavior, are unambiguous, and fully specify all aspects of the behavior—thereby distinguishing the problem behavior from other behaviors that are not of concern. Such clear descriptions are called operational definitions.

Sometimes, in the course of problem identification, more than one behavior is of concern to the consultee in more than one situation. If the list of problem behaviors is relatively short, problem-centered consultation is generally the most appropriate treatment modality. If the list is long, developmental consultation may be the best option. In either case, the therapeutic process works best when only one or two behaviors are chosen for treatment at a time. Thus, the consultant must elicit from the consultee a prioritized list of concerns that will be targeted for treatment. In problem-centered consultation, the consultant and consultee focus their immediate efforts on the top one or two concerns on the list. After those issues have been satisfactorily addressed through consultation, the process may be used again to address the next one or two concerns on the list (provided they have not changed in the meanwhile). For developmental consultation, the consultant must help the consultee recognize at the outset that numerous iterations of the consultation process will be necessary to address the various problem behaviors dis-

played by the client. These behaviors are addressed in a planned sequence, designed to most effectively produce broad improvements in client functioning.

By the conclusion of the problem identification stage, the consultant and consultee should have an understanding of the "ABCs" of the highest priority problem behavior(s). The "A" refers to the antecedent conditions that regularly come before the behavior occurs; the "B" refers to a clear description of the behavior itself; and the "C" refers to the consequences that follow the client's behavior. All of this information is necessary for a full understanding of the problem to be addressed and in planning a treatment to remediate the problem(s).

Another important part of the problem identification process, which can be completed only after the ABCs of the behavior are understood, is to decide on the specific goal(s) for the treatment. Goals are typically expressed as desired increases or reductions in the frequency, duration, or severity of identified behaviors. Setting specific goals helps the consultant and consultee focus on the most important problems and ensures that these behaviors are addressed in the remainder of the consultation process. Equally as important, goal setting is essential for determining the success of the treatment(s) applied.

The last step of problem identification involves establishing a baseline for the problem behavior(s). The baseline refers to the level of the behavior before treatment is started. In textbook cases, the consultee agrees to record the occurrence of the problem behavior for a representative period of time following the problem identification interview—perhaps two weeks. In practice, if the behavior problem is severe, it may be necessary to rely on retrospective records and to proceed immediately to the problem analysis stage. In either case, it will be important to have the most accurate information possible regarding the occurrence of the problem behavior before treatment is begun, so that any changes in behavior level with treatment can be measured and the effectiveness of the treatment can be evaluated accurately.

The importance of thorough problem identification in the consultation process can hardly be overemphasized. Without successful problem identification, the behavior of concern remains partly unknown. It will be very difficult to design an effective treatment, and any treatment attempted will likely be applied in inappropriate situations. Thus, the problematic behavior will not be addressed consistently (if at all), and change is unlikely to occur. Moreover, if the behavior is not

clearly identified, it will be impossible to monitor accurately any changes in the behavior, and the effect of the treatment cannot be accurately evaluated. Research in the field has shown that clear problem identification is a major factor closely associated with successful treatment outcomes in consultation.

D. Problem Analysis

Problem analysis is the third stage of the consultation process. In this stage, the consultant and consultee work to identify particular antecedents and consequences that may be influencing the problem behavior. The process of identifying the relevant connections between antecedents, behaviors, and consequences is known as “functional assessment” because the function performed by each factor is evaluated. Once the functional assessment is completed, a treatment plan may be formulated. The plan may involve changing relevant antecedents to the problem behavior, consequences of the problem behavior, or both. If the plan involves changes in consequences, contingencies that reinforce the behavior problem are removed. In addition, new contingencies are instituted to reinforce alternative, positive behaviors (e.g., prosocial skills and social competencies). Usually, the new contingencies involve providing the client with some type of reward for displaying the alternative, positive behavior. In practice, it may be wise to identify a number of rewards that clients would find motivating, and either to rotate the rewards periodically or to allow clients to choose a reward for which they will work. Both strategies have the advantage of preventing clients from becoming satiated with a single type of reward; the latter strategy also allows clients to select the most motivating reward and encourages them to “buy into” the treatment process by participating actively in its application. It should be stressed that well-designed treatments emphasize use of reinforcement to increase appropriate behavior, rather than punishment to decrease problem behaviors. In this way, clients receive positive feedback about their performance, which may have the additional benefits of enhancing self-esteem, increasing willingness to cooperate in the treatment, improving rapport with the caregiver (the consultee), and preventing defiant behavior.

Another strategy frequently used in treatment design is removing or altering antecedents that may trigger the problem behavior. This technique can be a very easy and effective means of changing client behavior, for it may prevent the problem behavior from ever getting started. For example, telling a young girl that she has to

wash up for dinner in two minutes, rather than that she has to quit playing immediately, may be sufficient to prevent a temper tantrum. The first strategy allows the child to finish the current activity and includes a promise of a generally pleasurable event (dinner), whereas the second strategy signals only the immediate end to playtime. In some cases, removal or significant alteration of antecedents may not be feasible. For instance, a young child may always have to get into the car to be taken to school, even if getting into the car for school triggers a temper tantrum. Nonetheless, in those cases where antecedents can be removed or substantially altered, rapid improvements in client behavior may occur with minimal consultee effort during plan implementation.

Another strategy that may be helpful in plan design is for the consultant and consultee to select an established treatment technique that “matches” the problem or concern, based on empirical research supporting the match. Increasingly, a number of behavior therapy procedures have been shown to work effectively with children when implemented by mediators.

The last step in problem analysis is to set initial goals for clients. It is usually too much to expect the client to obtain the final, desired goal level right away. To facilitate client success during the early stages of the treatment, initial goals that are attainable by the client must be set. Generally, these goals will be well short of the ultimate desired behavior level and may represent a very modest improvement in behavior over baseline level. Nonetheless, such intermediate goals must be used. If attainable goals are set, the client will begin to experience success, and will be rewarded and reinforced for appropriate behavior. This success will result in performance of appropriate behavior at the initial goal level. Once this step is achieved, the goal may be raised in another increment that is attainable by the client. This process is repeated as necessary until the desired end behavior level is attained.

E. Plan Implementation

Plan implementation is the next stage of the consultation process. It is the only stage that is generally the sole or primary responsibility of the consultee. Typically, the teacher or parent carries out the treatment by changing the antecedents and consequences in the natural setting (usually home or school) as planned, so that problem behavior is no longer reinforced, and positive, alternative behaviors are rewarded. If the treatment has been designed appropriately for the client,

the problem behaviors will begin to decrease and positive behaviors will increase.

During this stage, it is critical that the client's behavior level is closely monitored. The consultee must make periodic records of the client's behavior. This monitoring is essential for determining the success of the treatment during the plan evaluation stage. The consultant and consultee should hold brief but regular meetings during the treatment process to discuss and evaluate client progress. Once the client achieves the initial goal, successively higher goals are set. In an ideal situation, the client will show continuous improvement and meet each successive goal.

If the client consistently fails to attain a certain goal level, the consultant and consultee must determine the reason for failure. One possibility that always should be considered is that the goal level was too high. If this appears to be the case, the treatment may be continued by returning to the last behavior level that the client successfully achieved, and then increasing the goal level in smaller increments than previously attempted.

Another possibility that always should be considered is that the design of the treatment was flawed. For instance, it is possible that the consultant and consultee did not correctly identify all the reinforcing consequences of the behavior problem during the functional assessment. In this case, the client still may be receiving sufficient reinforcement to continue the problem behavior, despite the changes made. Thus, the treatment must be re-designed to remove the remaining reinforcing contingencies. It also is possible that the rewards instituted for positive alternative behaviors were not sufficiently motivating. In this situation, new rewards must be identified that are sufficiently attractive to change the client's existing behavior pattern.

A treatment may also fail because it is not implemented as intended. In technical terms, the treatment may lack integrity. A wide variety of factors may be responsible for consultee failure to make the planned changes. Some common reasons include lack of time, improper understanding of the precise changes that need to be made, or interference from outside sources. If it appears that the consultee did not carry out the treatment as planned, the consultant and consultee should carefully review the difficulties that arose and should make appropriate modifications to the plan. In extreme cases, the whole treatment plan may need to be reformulated. It is a fundamental principle of behavior consultation that treatments must be implemented as intended to produce the desired positive effects.

Once the causes of failure have been identified and a revised plan has been formulated, the implementation phase begins again, usually starting at the last goal level successfully achieved by the client. Although one may hope that treatments always will succeed on the first round of implementation, often several rounds are necessary to attain the ultimate desired goal. Design and implementation of treatments is a complex process, and participants should anticipate a certain degree of frustration and backtracking in a significant proportion of cases.

F. Plan Evaluation

Plan evaluation, the final stage of the consultation process, occurs at the end of a somewhat lengthy course of treatment—either at the end of a time limit set by the consultant and consultee for the consultation process, or when it appears that the client has attained maximum benefit from the treatment program. The consultant and consultee together review the client's progress. Data collected by the consultee are essential for assessment of client progress. Generally, case study methods using an AB design are applied to evaluate progress. In AB designs, the "A" refers to the baseline period before the treatment was started, and the "B" refers to the treatment phase after the treatment plan was implemented. The level of the problem behavior in these two phases is compared to determine client progress. Ideally, if data have been collected by the consultee over a period of weeks during both the baseline and treatment stages, it may be graphed for easy visualization of trends.

Figure 1 displays a sample graph for a treatment designed to reduce a child's problem behavior of calling out answers in class. The problem behavior was at a relatively high and fairly constant level during the baseline phase. It then fell to progressively lower levels through the month following treatment implementation. At the time of the last data recording, the behavior had reached the desired goal of only once or twice per day.

An important decision that must be made during the plan evaluation interview is whether to maintain, modify, or terminate the treatment. If it appears that the client is making significant progress but has not yet achieved the ultimate goal, the usual choice is to maintain the treatment and continue the consultation process. If it appears that the client has not achieved the ultimate goal and is making little progress toward it, two options are available: (1) the treatment may be

FIGURE 1 Sample graph showing baseline and treatment phases of a successful treatment for calling out answers. Baseline refers to data collected before the treatment was implemented. Treatment refers to data collected after the treatment was implemented.

substantially modified, or (2) consultation may be terminated and other treatment modalities pursued. If, on the other hand, the client has achieved the target goal, it may be appropriate to terminate the program. Generally, the most desirable outcome of consultation is for the client to continue at the newly achieved behavior level without special support. In the ideal case, there will be naturally occurring, positive consequences for appropriate behavior—such as parent and teacher approval, academic success, or maintenance of good peer relationships—which do not involve specially designed contingencies and will continue to reinforce the client's new behavior in the absence of special rewards. In practice, however, abruptly terminating the treatment may result in the return of the problem behavior, especially in cases that did not involve teaching the client new skills. One recommended solution to this dilemma is gradually fading out the treatment. For example, the client continues to receive reinforcement for maintaining appropriate behavior, but the amount or—more commonly—frequency of reinforcement is gradually decreased. In this way, the importance of the rein-

forcers associated with the treatment is gradually decreased, allowing the natural, positive consequences of appropriate behavior to become more salient to the client. Also, the client learns to perform the desired behavior for fewer special rewards. Eventually, the special support becomes unimportant, and the client will continue to perform the desired behavior without it.

To this point, the focus of consultation has been on improving client behavior. In the plan evaluation stage, however, it is also important for the consultant to help the consultee recognize and generalize the skills they have learned and used through the consultation process. At least two types of generalization may occur. The consultant should help the consultee realize that similar treatments might work with other clients with similar problems. In addition, the consultant should help the consultee realize that they can apply the same problem-solving steps used in consultation to many kinds of behavior problems displayed by different clients—either on their own or through additional work with a consultant, if necessary. Thus, plan evaluation not only serves the needs of the client

in the current case, but also prepares the consultee to achieve greater success in handling future behavior problems with other children.

II. THEORETICAL BASES

As the name implies, behavioral consultation historically has been associated most strongly with behavioral schools of psychology. The theory underlying traditional behavioral consultation involves direct adaptation of behavioral principles, particularly principles of operant learning. Generally, it is assumed that inappropriate behavior is learned and maintained by reinforcement received for performing the behavior. Two types of reinforcement may be distinguished. Positive reinforcement occurs when the client obtains some desired object. The desired objects may be tangible, such as food or toys, or intangible, such as attention. Negative reinforcement occurs when something undesirable is removed from the environment as a result of inappropriate client behavior. For instance, children may be excused from doing chores, or from solving math problems, if they have a temper tantrum. It is important to distinguish negative reinforcement from punishment, which is the application of some undesirable consequence for inappropriate behavior.

Drawing on operant principles, the treatment strategy most commonly adopted in behavioral consultation is to modify the reinforcing contingencies which occur in the client's environment. The reinforcing contingencies associated with the problem behavior are removed, as far as possible. Reinforcing contingencies are added for alternative, positive behaviors. The end result is that clients will learn the alternative, positive behavior because there is no longer any gain associated with the problem behavior, and they may obtain new reinforcement by behaving appropriately.

Operant learning theory also recognizes that behaviors are triggered by antecedent conditions. The individual may learn that a particular behavior is reinforced only under specific conditions—that is, when certain antecedents are present. (Providing reinforcement under only specific conditions is known as “differential reinforcement.”) For instance, a child may learn that dawdling is negatively reinforced when the teacher says it's time to do math, but not when the teacher says it's time for recess. Thus, the child performs the behavior when—and only when—those antecedents are present. This principle leads to another strategy that is often used in consultation: changing of antecedents, or

“stimulus control.” Those antecedents that trigger the behavior are removed from the environment. Conversely, antecedents that trigger appropriate behaviors may be added to the client's environment. For instance, a child may be allowed to play only with “good” friends with whom he or she behaves appropriately.

One intriguing implication of traditional behavioral theory applied to consultation is that if the process is pursued properly, it must eventually meet with success. If clients do not initially terminate their inappropriate behavior and replace it with the desired positive behavior, it is because the contingencies involved in learning and maintaining the behaviors were not adequately addressed in the initial treatment plan. It is possible that all the contingencies maintaining the problem behavior were not removed, or the rewards for alternative positive behavior were not sufficiently desirable to the client. In either case, the plan may be reformulated, and the treatment may be attempted again. In theory, it is always possible to remove the contingencies associated with the problem behavior and to institute sufficiently reinforcing contingencies to support the alternative positive behavior. The only difficulties (which may be considerable) lie in the practical aspects of correctly identifying and removing all the reinforcing contingencies for the problem behavior, and providing sufficiently reinforcing contingencies for the positive behavior.

A number of additions and elaborations have been made to these fundamentals of behavior theory applied to consultation. One important addition is the concept of the extinction burst. Observations of clients who have been treated using behavioral methods indicate that when the treatment is first put into effect, the occurrence of the problem behavior actually may increase. This phenomenon may be particularly evident if the treatment plan calls for ignoring the problem behavior rather than giving the client attention for it. In such cases, almost all clients initially attempt to obtain their usual reinforcement by increasing the severity or duration of the problem behavior. This “extinction burst” occurs because the client has not yet broken the old associations between the behavior problem and its reinforcing contingencies, or has not made the new associations between the alternative positive behavior and its reinforcing contingencies. In practice, the consultee must simply continue to carry out the treatment plan, despite the temporary increase in the client's problem behavior. If the consultee continues with the plan, and the plan adequately addresses reinforcing contingencies for the

old and new behaviors, the extinction burst will soon fade, and the problem behavior will be replaced.

In recent years, several expansions have been made that go beyond application of traditional behavioral principles to the practice of consultation. It has been recognized that changing the contingencies associated with various behaviors may not be sufficient to cause clients to improve their behavior. Clients may not possess the skills necessary to perform any positive, alternative behaviors to the problem behavior. In this case, even if clients are motivated to change, it may be impossible for them to alter their behavior because they do not know what else to do. The remedy in these situations is to provide the client with skill training. Skill training serves to teach clients what positive, alternative behaviors they should perform, and how they should carry out those behaviors in practice. At times, skill training can be a lengthy process, especially for clients with significant cognitive or emotional challenges.

In a similar vein, it has been recognized that consultees also may need training in methods of providing the appropriate consequences agreed upon during plan design. Sometimes consultees are unfamiliar with the techniques of providing positive reinforcement to clients. For instance, consultees may need training and practice in providing specific verbal praise for positive client behaviors. Conversely, consultees may lack skill in promptly and calmly enforcing consequences for inappropriate behavior, such as making the child go to his or her room after a single warning.

There also has been interest recently in incorporating additional forms of treatment with those derived from traditional behavioral principles. For instance, literature on effective teaching is replete with techniques for teachers to maximize their instructional effectiveness. Strategies drawn from this body of literature may facilitate improved client behavior in the classroom and may be incorporated into consultation treatments. These strategies typically bear some relation to behavioral antecedents and consequents, but do not derive from traditional behavior theory.

Another important movement is to include empirically supported treatments in the consultation program. A number of mediator-based treatments have been found to be effective with certain types of behavior problems. There is a growing body of empirical literature documenting appropriate matches between particular treatments and specific behavior problems. A recent focus in consultation is selecting treatments that have been shown to match particular behavior prob-

lems. These treatment procedures are often derived from diverse theoretical orientations, including behavior therapy.

In current work in problem-solving consultation, treatments drawn from various branches of psychology other than traditional behavior theory have been incorporated into what has been traditional behavioral consultation. For instance, cognitive techniques in which the client stops or alters the thought processes that lead to inappropriate behavior have been used in the treatment programs. In future work, the fundamental stages of consultation—initiation of the relationship, problem identification, problem analysis, treatment application, and plan evaluation—may continue to provide a framework for the consultative process, while treatment design is expanded to incorporate additional techniques from nonbehavioral schools of psychology.

In sum, it is clear that traditional behavioral consultation is strongly grounded in traditional behavior theory, particularly theories of operant learning. Fundamental principles of operant learning continue to guide the practice of behavioral consultation. Nonetheless, the field of behavior consultation is clearly evolving to incorporate new advances in psychology, as already witnessed by the inclusion of empirically supported treatments and skill training approaches for both clients and consultees.

III. APPLICATIONS AND EXCLUSIONS

One of the great strengths of behavioral consultation is its range of applicability. In theory, behavior consultation can be used with any client with any identifiable behavior problem. Moreover, as long as appropriate reinforcing contingencies can be addressed, appropriate skill training is supplied to the client and consultee, and the treatment is faithfully applied by the consultee, a successful outcome is anticipated. In this sense, behavior consultation represents an especially promising treatment delivery option.

Another great advantage of behavioral consultation derives from the indirect nature of the process. As emphasized earlier, the consultee is primarily responsible for administering the treatment to the client, which is the most time-consuming phase of the process. Thus, consultation can be an extremely efficient means of service delivery from the standpoint of consumption of professional consultant time and resources. A psychologist may be able to work on several consultation cases

in the same time that would be required to conduct a single direct treatment.

There are also considerable advantages to treatment by having the consultee act as the primary treatment agent. Because the consultee is typically a caregiver for the client, the consultee usually spends substantial periods of time with the client on most days. Thus, the client can receive continuous and ongoing treatment. In addition, the treatment usually takes place in the natural setting, where the problem behavior actually occurs. This context permits immediate, on-the-spot application of the strategies developed in the treatment plan. Finally, because the consultee can readily observe the client's behavior in the natural setting, the consultee can collect extensive data on client behavior, which permits thorough evaluation of plan effectiveness.

It is clear that behavioral consultation has a wide range of applicability and offers a means to efficiently use both consultant and consultee resources. Nonetheless, there are certain challenges that must be faced in the process. One of these challenges has already been discussed: it can be difficult to identify correctly and change all the relevant antecedents and consequences for the behavior problem, and to provide sufficiently motivating rewards for performance of alternative, desirable behaviors.

Two other challenges that can disrupt the consultation process deserve special mention. The first is the problem of treatment acceptability, which refers to consultee willingness to implement the treatment. If the consultee is very willing to implement the treatment, it has a high degree of acceptability; if the consultee is not willing to implement the treatment, it has a low degree of acceptability. Research has indicated that treatments with a high degree of acceptability are more likely to be implemented by the consultee. Treatments with a low degree of acceptability probably will not be implemented by the consultee and will provide no benefit to the client. The issue facing the consultant is how to facilitate the design of treatments with a high degree of acceptability.

A number of factors that influence acceptability have been identified. Time required for the treatment appears to be a major factor. Treatments that require less time are preferred over those that require more time. Other important concerns include whether the treatment is positive or negative (i.e., emphasizes rewards for good behavior vs. punishment for bad behavior), the complexity of the treatment, and fairness to other children in the setting. In general, it appears that positive treatments are more acceptable than negative ones,

more complex treatments are more acceptable for more severe problems, and treatments are more acceptable if they are perceived as fair to all children in the setting. The most critical point to remember, however, is that the treatment must be acceptable to the particular consultee who will administer the treatment to the client. Thus, the personal perspective and concerns of the consultee must be taken into account during treatment planning; otherwise, no treatment will occur, and the problem will persist. It is important for the consultant to ask the consultee during the planning phase whether he or she finds the treatment acceptable. If the consultee indicates that the treatment is not acceptable, it must be modified before any attempt at implementation is made.

The issue of acceptability must be distinguished from another challenge associated with consultation: the problem of treatment integrity. Treatment integrity refers to whether the treatment is implemented as planned. Unlike the issue of acceptability, integrity does not involve consultee attitude toward the treatment, or consultee intention. Treatment integrity refers to what actually happens during the plan implementation stage. If the treatment is implemented as intended, it has a high degree of integrity. If it is not implemented as intended, it has a low degree of integrity. Treatment integrity represents a considerable challenge to the efficacy of consultation. In one study, only half the consultees who verbally agreed to implement a treatment actually carried the plan through to completion.

A number of factors affect treatment integrity. Some of the factors are identical to those that influence treatment acceptability. Time involved appears to be the major determinant of both integrity and acceptability. Treatments that require large amounts of consultee time typically have a low degree of integrity, as well as a low level of acceptability. Other important factors related to integrity include the complexity of the treatment, the number of treatment agents, and the perceived effectiveness of the treatment. In general, it appears that more complex treatments have lower integrity. Adding to the number of treatment agents also seems to lower integrity, while obtaining information that supports the effectiveness of the treatment increases integrity. The most important point, however, is that the consultant needs to work with the consultee to identify possible detractors to treatment integrity for the specific plan under consideration. The consultant also needs to develop ways to overcome those obstacles before any attempt is made to implement the plan.

The upshot of these considerations is that although consultation has a nearly unlimited range of applicability in theory, there are critical practical considerations that may interfere with its use in any real-world case. It is vital that consultants be aware of issues of treatment acceptability and integrity, and work with consultees to develop treatments that are highly acceptable and likely to possess a high degree of integrity. These issues may be addressed while planning the treatment by talking openly with consultees about whether the treatment is acceptable to them and problem solving about obstacles that may interfere with implementation (i.e., reduce treatment integrity). If issues of acceptability and integrity can be resolved, there is a good chance that the plan will be carried out faithfully, and the client will receive ongoing treatment for the behavior problem, when and where it occurs.

IV. EMPIRICAL STUDIES

A number of studies have been conducted to document the effectiveness of consultation. Several different variables have been examined to evaluate separate aspects of the consultation process.

As previously discussed, the two main goals of behavioral consultation are improving the client's behavior and enhancing the consultee's knowledge and ability to handle children's challenging behaviors. From reviews of studies reported in the literature, it appears that in most cases, some or all aspects of the client's behavior improve significantly with behavioral consultation. It also appears that in most cases, some or all aspects of consultee knowledge and ability improve significantly with consultation. Additional research has revealed that most teachers who have participated in consultation cases believe that their own professional skills have improved as a result of consultation. Moreover, teachers in schools with consultants tend to view children's behavior problems as less severe than teachers in schools without consultants. Referral rates among teachers who have participated in consultation drop rapidly after four to five years, suggesting that these teachers may gain the confidence and ability to handle children's behavior problems on their own. Notably, teachers and administrators rate consultation as one of the most important services provided by school psychologists, and school psychologists rate consultation as one of their most preferred professional activities.

These findings suggest that consultation is a very beneficial and highly regarded treatment modality. In-

terestingly, however, most of the research on the effectiveness of consultation was completed in the late 1970s or early 1980s, rendering the results somewhat dated. In addition, some of the outcome research appears to suffer from certain methodological shortcomings. In fact, recent commentaries have noted that solid evidence is lacking for certain supposed positive results of behavioral consultation, such as the ability of consultees to apply the skills they have learned to other cases. In addition, there is contradictory evidence on other points, such as the need for equality in the relationship between the consultant and consultee. In sum, although the preponderance of existing evidence indicates that behavioral consultation is an effective and desirable treatment modality, further studies are needed to evaluate the efficacy of traditional consultation strategies and methods.

V. CASE ILLUSTRATION

To describe the elements of behavioral consultation, we will consider the hypothetical, somewhat ideal case of "Jimmy." Jimmy is a third grade student. His teacher, Ms. Thompson, has reported that Jimmy often "acts out" in class and that his behavior is disruptive to other students. Jimmy often spends so much time acting out that he completes very little of his work. She believes that Jimmy has attention deficit hyperactivity disorder (ADHD), and has asked the school psychologist what can be done about Jimmy's behavior.

To successfully initiate the consulting relationship, it is important for the school psychologist to begin by listening to Ms. Thompson's concerns about Jimmy. One of the first steps that the psychologist needs to take after hearing Ms. Thompson's account of the situation is to discuss the nature of the consultative process, the stages of consultation, and the roles and responsibilities of each participant at each stage. Ms. Thompson appears to believe that the psychologist will either work directly with Jimmy to "cure" his disorder or will provide her with a "quick fix" solution that will promptly eliminate the behavior problem. Such beliefs can be common among consultees who have not participated in the consultation process before and do not understand the indirect nature of service delivery. The consultant must make clear that he and Ms. Thompson will collaborate on developing a treatment to improve Jimmy's behavior, which Ms. Thompson will implement in the classroom. Contrary to traditional, direct service models, that consultant probably will not conduct individual therapy

with Jimmy, nor will he simply give a one-step solution to Ms. Thompson. The consultant needs to describe the stages of the consultation process (e.g., problem identification, problem analysis, plan implementation, and plan evaluation) so that Ms. Thompson is aware that she and the consultant will work together, and that a certain amount of time and effort will be required before Jimmy's behavior can be effectively treated. The consultant also needs to emphasize that he brings professional training in behavior principles to the relationship, while Ms. Thompson contributes her knowledge of Jimmy, her classroom expertise, and her knowledge of effective instructional techniques. Thus, the consultant can work with Ms. Thompson to identify behaviors for treatment, develop a treatment plan, and monitor treatment effectiveness. Ms. Thompson, however, will implement the plan in the classroom setting and will act as the primary agent of change.

Once Ms. Thompson understands the nature and stages of consultation, problem identification may be started. Ms. Thompson's early statements that Jimmy "acts out" give some indication of the type of behavior problem but do not describe the behavior in a clear way. The consultant begins by asking Ms. Thompson to describe exactly what Jimmy does when he "acts out." Ms. Thompson reports that Jimmy will rock in his chair, fidget, play with items from his desk, get out of his seat, and wander around the room.

The consultant pursues further description of the behavior by asking how often Jimmy displays these behaviors, how long they go on for, and how severe they are. Ms. Thompson replies that the behaviors seem to occur in streaks of 15 to 30 minutes, occurring two or three times per day. The behaviors are sufficiently severe that Jimmy only gets about one-quarter of his work done, and other students have complained to Ms. Thompson that they cannot concentrate when Jimmy is acting up.

The consultant now has a reasonably clear picture of Jimmy's problem behaviors. In the consultant's professional knowledge, Ms. Thompson's concerns about Jimmy fall into the category of "academic-engaged" behavior. At this point, however, there is no information that might indicate what triggers Jimmy's "nonengaged" behavior or what reinforces its occurrence. The consultant proceeds to ask important "W" questions: when the behaviors occur, in what setting they occur, who is present when they occur, and what happens after Jimmy performs the behaviors.

Ms. Thompson reports that Jimmy's challenging behaviors seem to occur when the class begins new seat-

work assignments. Knowing that there are different types of seatwork, the consultant asks for additional clarification about what types of seatwork assignments Jimmy is doing when the behavior occurs. Also, there are typically more than two or three periods of seatwork per day in most third grade classes, so it seems that something else must be triggering Jimmy's behavior in certain situations. Ms. Thompson indicates, however, that she is not aware of any particular work types associated with the behavior at the moment. Moreover, the setting (Ms. Thompson's classroom) and the people present are consistently the same.

The consultant now turns to what happens once Jimmy begins to display the nonengaged behaviors. Ms. Thompson reports that she attempts to direct Jimmy to sit still and do his work. She indicates that she gives verbal directions, or verbal reprimands, or stands next to him until he settles down and starts working. The consultant asks how Jimmy responds to these attempts to make him work. Ms. Thompson indicates that Jimmy may start his work but soon begins some other nonengaged behavior. The consultant asks if any other treatments have been tried with Jimmy, and Ms. Thompson indicates not.

The consultant now has a fairly clear understanding of the antecedents, behavior, and consequences regarding Jimmy's behavior problem, as far as Ms. Thompson can describe them during this interview. The antecedent appears to be starting seatwork assignments. The behavior includes a variety of nonengaged activities, such as rocking in the chair, rummaging through his desk, fidgeting, and getting out of his seat. The consequences seem to be that Jimmy receives a fair amount of attention from Ms. Thompson and does not do much of his work.

The consultant and Ms. Thompson discuss goals for Jimmy. Ms. Thompson at first indicates that she wants Jimmy to work like the other children in her class. The consultant pursues further clarification of her statement in order to obtain a specific description (e.g., an operational definition) of the desired behavior. In operational terms, Ms. Thompson wishes to increase Jimmy's on-task behavior to the same level as that of the other students, and to increase his work completion to the same level as other students, although she cannot describe more specifically what levels of on-task behavior and work completion she desires at the moment.

Finally, the consultant requests that Ms. Thompson record data on Jimmy's behavior for a two-week period. Ms. Thompson is understandably impatient to begin treatment, so the consultant explains the importance of

obtaining baseline data for treatment evaluation. With this understanding of the significance of behavior observation, Ms. Thompson agrees.

The consultant knows that in most circumstances, the most informative type of data to have on academic behavior is the amount of time spent working on academic tasks, relative to the amount of time spent off-task. The consultant suggests that Ms. Thompson observe Jimmy during representative seatwork assignments and record the amount of time he is engaged in academic work. Ms. Thompson indicates, however, that she does not think she has time to make such detailed observations. The consultant, aware that Ms. Thompson is unlikely to carry out any procedure that requires too much time, discusses with her alternative strategies for data collection. They agree that she will go over Jimmy's seatwork assignments, and they note the amount of work completed. Although this technique does not directly address the problem of engaged behavior, it certainly addresses the problem of work completion. Moreover, work completion is likely correlated with Jimmy's on-task behavior, so this technique represents a reasonable compromise for data collection.

The consultant also realizes that the current understanding of antecedents for Jimmy's behavior is incomplete, as is the current understanding of the desired behavior level. The consultant asks Ms. Thompson to make further notes of when Jimmy's behavior occurs (including time of day and specific seatwork tasks), as well as to note the level of work completion by other children in the class, so that a specific goal for Jimmy may be formulated. Ms. Thompson agrees.

The problem identification interview is now concluded. Ms. Thompson's willingness to collect behavior observations indicates that good rapport has been established between the consultant and consultee. A generally clear description of the ABCs of the behavior has been obtained; where vagaries remain, the consultant has arranged for Ms. Thompson to collect additional relevant information. The availability of baseline data will ensure accurate assessment of treatment effectiveness, at least with respect to work completion. Because only two specific behavior problems have been identified, problem-centered consultation appears to represent a more appropriate treatment modality for Jimmy than developmental consultation at the present time.

The consultant and Ms. Thompson meet two weeks later for the problem analysis interview, after Ms. Thompson has collected the baseline data. The interview begins with a review of the data collected. Com-

plete data for the entire consultation period are displayed in Figure 2; at the time of the problem analysis interview, only the data in the "baseline" region of the graph actually would be available. The data generally confirm Ms. Thompson's initial reports that Jimmy completes only about one-fourth of his work. With respect to the times of occurrence, Ms. Thompson reports that Jimmy's behavior occurs at various times of the day. Hence, time does not appear to be an important factor in determining Jimmy's behavior. Ms. Thompson notes, however, that Jimmy's behavior occurs whenever the seatwork assignments involve writing. The consultant realizes that this is an important additional specification to the antecedent conditions for Jimmy's problem behavior.

Ms. Thompson also reports the level of work completion among other children in her class whom she regards as good students. These children completed approximately 90% of their seatwork.

The consultant and consultee now conduct a functional assessment of the conditions that trigger and maintain Jimmy's behavior. Considering what has been learned about the ABCs of Jimmy's behavior, they hypothesize that Jimmy's behavior is related to working on writing assignments. They hypothesize further that his off-task behavior is both positively and negatively reinforced. It is negatively reinforced in that he is able to avoid doing writing assignments, which he dislikes. It is positively reinforced in that he receives considerable attention from Ms. Thompson when he engages in these behaviors.

Using this information, the consultant and consultee now work to formulate a treatment plan. They decide on a plan that involves several components. Ms. Thompson will no longer pay attention to Jimmy when he displays off-task behavior. Instead, she will provide praise to Jimmy when he is appropriately engaged in his seatwork. In addition, Jimmy will earn rewards for work completion involving writing. He will be awarded stickers for completing a specified amount of his work. When he earns five stickers, he also will receive a prize from Ms. Thompson's selection of rewards that she uses with her class on special occasions. Jimmy will be allowed to pick the reward he wants to work for in advance. Ms. Thompson indicates that the treatment plan is very acceptable to her, and she does not anticipate significant difficulties with implementation—indicating that treatment integrity is likely to be high.

This treatment plan has a number of desirable features. It is a "positive" plan, in the sense that Jimmy has

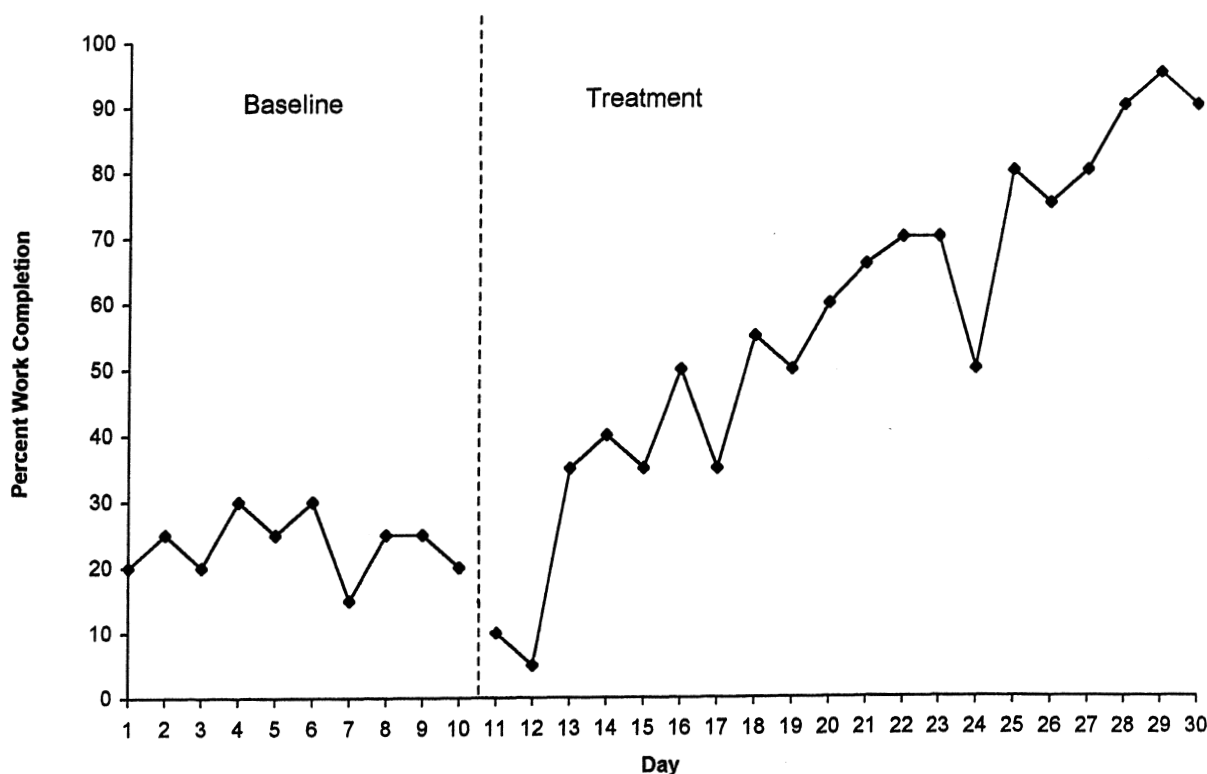

FIGURE 2 Jimmy's work completion.

the opportunity to earn rewards rather than working to avoid punishment. It is also positive in that desirable, positive behaviors (staying engaged and achieving work completion), which are alternatives to Jimmy's problem behaviors, are specified. It is easily implemented because the rewards are easy to give; providing verbal praise as the desired behavior is occurring requires little effort and can be very motivating. In fact, the use of verbal praise seems especially promising in this case, since there is already evidence that Jimmy is motivated by teacher attention. It is also easy for Ms. Thompson to check Jimmy's work completion; indeed, this task is one she performs on an informal basis for all students. Giving stickers is an easy, commonly utilized procedure, and using rewards that are already available and in use in Ms. Thompson's classroom is a straightforward matter. Allowing Jimmy to pick rewards in advance helps to ensure that he will find something motivating to work for and will have a clear awareness of what he can gain by behaving appropriately. Also, allowing Jimmy to pick from a selection of rewards helps to ensure that he will not burn out or "satiated" on one particular reward. All of these factors contribute to the

high degree of acceptability, and anticipated integrity, of the treatment.

The final step in problem analysis is to determine goals for Jimmy. Ms. Thompson has decided that she wants Jimmy to attain 90% work completion on writing seatwork, like other good students do. She believes that Jimmy's off-task behavior will decrease as his work production increases; therefore, she wants to focus on increasing his work completion. The consultant agrees that this approach is a reasonable one and is supported by research. Now the consultant and Ms. Thompson must determine an attainable initial goal. Because Jimmy is completing only about one-fourth of his writing seatwork at the present, it is too much to expect that he will achieve full work completion immediately. Instead, the consultant and Ms. Thompson agree that an initial goal of one-third of the work is reasonable. Jimmy will receive a sticker every day when he completes one-third of his work. Once this goal has been consistently attained, it will be raised to half his work, then two thirds, three quarters, and finally 90% of his work. In addition, Ms. Thompson will praise Jimmy when she notices him on task.

At the conclusion of the interview, Ms. Thompson agrees to start the treatment at the beginning of the following week. She will continue to collect data on work completion as during baseline, so that baseline and treatment stages may be compared. The consultant and Ms. Thompson agree to meet briefly twice per week to review Jimmy's progress and to determine whether changes are needed in the treatment plan.

Ms. Thompson proceeds to implement the treatment. She explains the new reward system to Jimmy, and she allows him to pick a reward to work for during the first week.

Data from the first two days, as depicted in Figure 2, show an immediate decrease in Jimmy's work completion. Ms. Thompson also reports that Jimmy's nonengaged behavior increased considerably during this time. This increase in problematic behavior, and the corresponding decrease in work production, is probably an extinction burst, which the psychologist anticipates. Although Ms. Thompson is initially discouraged by this worsening in Jimmy's behavior, the psychologist explains the phenomenon to her and encourages her to continue the treatment.

On the third day there is a sudden improvement in Jimmy's behavior, and he earns his first sticker for completing one-third of his work. He is learning that he will no longer receive attention for his inappropriate behavior and that positive consequences are now associated with engaged behavior and work completion. As a result, his on-task behavior and work completion increase significantly. Ms. Thompson and the consultant, however, decide to maintain the same goal until Jimmy has earned stickers for three days in row, to ensure that he has firmly associated his new behavior with success. After earning three stickers in a row, the goal is raised to completing one-half of his seatwork.

Over the next few weeks, Jimmy attains higher and higher behavior goals. Goals are raised after Jimmy earns stickers for three days in a row. As the goals are slowly raised, his behavior improves to meet them. Full data on Jimmy's work completion are displayed in Figure 2. Occasionally, Jimmy has off days when he does not earn stickers (such as Days 17 and 24), but the treatment program is continued as planned because he is able to achieve his goals fairly regularly. If some point had been reached where Jimmy consistently failed to achieve his goal, the consultant and Ms. Thompson would have met to discuss possible causes for the difficulty and develop appropriate modifications to the treatment plan.

After the fourth week, the consultant and Ms. Thompson meet for the plan evaluation interview. They review the data collected through treatment, and they conclude that Jimmy has attained the desired behavior level determined during the problem identification interview. Ms. Thompson, however, wonders whether suddenly discontinuing the treatment program will bring a return of the problem behavior. The consultant applauds Ms. Thompson's awareness of the potential danger of abruptly terminating the treatment procedure. He indicates that it is usually best to use some sort of fading procedure in which the frequency of rewards is gradually decreased while Jimmy continues the appropriate behavior. In this way, Jimmy's appropriate behavior becomes less dependent on special reward contingencies. The consultant and Ms. Thompson decide to require two days of 90% work completion to earn stickers, then three days, and finally up to one week. If he maintains appropriate behavior at that point, it seems likely that Jimmy will no longer require special rewards for the behavior, and the treatment program will be ended.

In the plan evaluation interview, the consultant also asks Ms. Thompson whether she believes similar treatments might work with other children. Ms. Thompson indicates that she believes so and is able to name other situations where she would use similar methods. The consultant also asks if Ms. Thompson believes she could use the problem-solving steps they have used in consultation to address other challenging behaviors displayed by other children. Ms. Thompson expresses confidence in her ability to do so. The consultant and Ms. Thompson agree that Ms. Thompson is capable of finishing the fading portion of the treatment without additional consultant input. At this point, the consultative relationship may be ended, because it appears that both client and consultee have achieved maximum benefit.

It is important to note what has not been addressed through the consultation process. Ms. Thompson's initial impression, that Jimmy suffers from ADHD, was not addressed because a short list of only two specific related behavior problems (nonengaged behavior and failure to complete work) was generated. These behaviors were adequately treated through the problem-centered consultation process, and Ms. Thompson reports no other concerns about Jimmy. Thus, there seems to be no need to pursue developmental consultation to address wide-ranging ADHD issues at this time. If Ms. Thompson's list of concerns about Jimmy had included a wider variety of problems which appeared, in the

consultant's professional knowledge, to be related to ADHD, a developmental consultation approach might have been used to address issues of broad psychological dysfunction.

VI. SUMMARY

Behavioral consultation represents a unique form of therapy with many positive features. Because it is an indirect form of service delivery, the professional time and resources of the consultant can be used with particular efficiency. The knowledge and skills of the consultant and consultee are combined through the consultative process to design the best treatment possible. Because consultation has a very specific, problem-solving focus, the most problematic behaviors exhibited by the client are given full attention. In addition, solid grounding in behavioral principles and treatments supported in the empirical literature ensures that a wide range of sound treatment strategies are available. Focusing on the specific behavior exhibited by a single client, however, permits individualized treatment. Moreover, implementation of the treatment by a caregiver in the natural setting promotes the success of the treatment. The focus on a specific behavior also permits extensive data collection and thorough evaluation of treatment effectiveness. Finally, by involving the consultee in the entire process, the consultee learns principles of problem resolution, which may be applied to the challenging behaviors exhibited by other children.

Consultation brings its own challenges as well. It can be difficult to accurately identify all the antecedent and consequent conditions that contribute to the behavior problem. Conducting a thorough and labor-intensive functional assessment increases the chance that all relevant conditions will be correctly identified on the first attempt, but participants must recognize that in some

cases, initial problem analysis may not yield all relevant information. Without such knowledge, it can be difficult to design effective treatments. In addition, problems of treatment acceptability and treatment integrity must be addressed. Because the consultee is the primary treatment provider, the treatment plan must meet with the consultee's approval and must be sufficiently easy to implement in practice in the natural setting. It is well known that consultees often balk at the time, effort, or other interfering factors associated with otherwise potentially useful treatments. Thus, consultants must work diligently to see that the consultee's perspective and situation are taken into account through the consultation process. With appropriate consultant skill and effort, however, great benefits may accrue to both the client and the consultee through the process of behavioral consultation.

GLOSSARY

behavioral contract A verbal or written agreement that specifies contingencies of behavior between two or more persons or parties for a specified duration.

reward A desired action or product that is provided to an individual contingent on adequate performance of a target behavior.

target behavior An action that is the focus of change in a contingency contract.

Behavioral contracting, or contingency management, is a therapeutic tool used by mental health practitioners to facilitate a desired change in identified unacceptable behaviors. The following sections underscore the basic tenets of contingency contracting, including its conceptual framework, methodology, and application.

I. OVERVIEW OF CONTINGENCY CONTRACTING

A behavioral contract is a verbal or written agreement that specifies the relationship of behavior between two or more persons for a specified duration. The behavioral contract is typically initiated by mental health professionals in therapeutic settings as a means of motivating patients to initiate and maintain desired behavior. In utilizing behavioral contracting, it is assumed that the patient has the abilities to perform the behaviors that are specified in the contract. There are two general methods of contracting, quid pro quo, and good faith.¹ In the quid pro quo method, a contingency is established between two or more individuals such that the performance of a specified behavior by one participant is contingent on the performance of a specified behavior by the other participant. For instance, if a married couple is dissatisfied with the cleanliness of their kitchen, a husband might agree to dry and put the dishes in the cabinet if the wife agrees to wash the dishes. This method of contracting is best utilized when there is equal status among its participants (e.g., married couple, friends).

In a good faith contract, significant others of the patient agree to provide the patient with a desired product or action (i.e., reward), but only on the patient's

¹ Some consider the good faith contract a quid pro quo arrangement.

successful completion of the respective target behavior. Significant others are usually persons who are of higher authority status than the patient (e.g., parent, employer, supervisor). An example of this method of contracting would be a parent permitting his bed-wetting 6 year old to view television from 5 to 7 p.m. if the child evidences continence during the preceding night.

Although verbal contracts may be implemented when contingencies are unsophisticated, the terms of a behavioral contract are usually specified in a written record. It is common to have all involved parties, and ideally, a neutral witness (e.g., therapist), acknowledge their support of the contract by signing the document. It is also customary to include an ongoing record of the performance of target behavior, and provision of agreed on consequences. This behavioral exchange is reviewed regularly so that target behaviors are accurately monitored, and earned consequences are provided in a timely manner. To strengthen the contingency relationship specified in the contract, some contracts specify that tokens (e.g., small chips) be provided to patients immediately after the target behavior is performed. These tokens may be exchanged at a later time for specified rewards. This "token economy" system is particularly effective with children, psychotic individuals, or those persons who evidence dementia or mental retardation, because these individuals sometimes experience problems with their memory and often evince difficulties delaying their gratification. Point systems are similar in that the performance of each target behavior is assigned a point value, and each reward requires the exchange of a specified number of points. For instance, an adolescent male might earn three points for washing the car, and later exchange these three points to obtain a ride to the park from his parent.

II. DEVELOPING THE BEHAVIORAL CONTRACT

Five stages are involved in establishing a behavioral contract: (1) identifying the target behaviors, (2) identifying the rewards, (3) negotiating the contingency plan, (4) establishing and role playing the monitoring process, and (5) and ongoing review of the behavioral exchange. The following sections underscore generic applications involved in the implementation of a good faith contract following these stages.

A. Identification of Target Behaviors

Identified patients are usually the individuals who are expected to improve their behavior, as these indi-

viduals are the persons who seek treatment for their problems, or are brought to treatment because their problems negatively affect themselves or others. Target behaviors are usually elicited from friends or family members of the patient, or from external sources (e.g., staff member, therapist, behavior problem checklist). However, when patients are insightful of their problem behavior, they should be involved in generating their own target behaviors, particularly when they are motivated to improve their behavior.

Target behaviors may be identified during clinical interviews (e.g., "What chores would you like your son to do more often?"), or "which lists" (e.g., "List the three most important things you would like your husband to do, ideally."). It is imperative that target behaviors are well defined, because vaguely defined behaviors are susceptible to misinterpretation and disagreement among participants. For instance, a father's initial request to have his son "take the trash to the street curb regularly" might be further specified in the contract to include the specific actions desired, when and where the actions would need to be performed, and for how long (e.g., "Bring the contents of all waste baskets in the house to the end of the driveway every Friday at 7 a.m. for 6 months."). Along a similar vein, participants must be able to monitor target behaviors so that appropriate consequences may be provided. Indeed, if a mother is incapable of recognizing her daughter's use of illicit drugs, drug use should not be targeted in the behavioral contract. Rather, the contract should include target behaviors that are more identifiable, and that have been associated with the girl's use of illicit drugs (e.g., coming home immediately after work in the evening, attending classes at school).

Of course, the patient must be capable of performing the target behavior. If not, the patient must be taught to perform the behavior, or the behavior must be modified or excluded from contractual consideration. For instance, if a child is incapable of studying 2 consecutive hours due to problems associated with inattention, study time may be distributed across several occasions (e.g., four study periods of 30-min duration, with each study period being separated by 1 hr of playtime). As an alternative, overall study time could be reduced initially and later increased gradually as study skills improved. Last, the behavioral contract should include only those target behaviors that are expected to be functional, or reinforcing, to the patient after the contract is discontinued.

B. Identification of Rewards

Rewards are provided to patients after target behaviors are adequately performed, and it is imperative that

the patient strongly desires the rewards that are specified for use in the contract. As with the elicitation of target behaviors, potential rewards may be obtained from significant others of the patient, the patient, or external sources. The patient is relied on as the primary source of rewards, as this individual must ultimately decide if the reward will provide sufficient external motivation to perform the target behaviors that are specified in the behavioral contract. Rewards are typically elicited from patients during clinical interviews, or from the administration of reinforcer menus (a list of age-appropriate rewards), and wish lists (i.e., "If you could make three wishes, what would you wish for?"). In generating potential rewards, a significant other may be instructed to specify what the patient has been observed to do in the patient's free time so that access to these activities can be made contingent on performance of target behaviors. However, it is more common to simply ask the significant other what the patient would probably like as rewards. As might be expected, the patient must confirm potential rewards that are generated from significant others or external sources. This allows the patient to determine all rewards that are utilized in the contract and also provides the patient an opportunity to enhance each reward (e.g., use of mother's car on the weekdays may not be desired, although use of the car during the weekend may be extremely desired). The relative strength of rewards is often determined by instructing the patient to rate the desirability of each potential reward, utilizing a Likert-type scale (e.g., 0 = *not desired at all*, 6 = *extremely desired*).

When significant others are responsible for the contingent provision of rewards, the rewards must be under the control of the significant other. If the patient did not earn the reward as specified in the contract, the significant other must have the ability to restrict the patient from experiencing the reward. Similarly, if the patient has earned the reward, the significant other must provide the reward in a timely manner, and as delineated in the contract. Indeed, compliance with contingencies set forth in the behavioral contract assists in establishing trust between all involved parties.

C. Negotiating the Contingency Plan

Once target behaviors and rewards are identified, a contingency plan is negotiated with the mental health professional assuming the role of an arbitrator. In this process, the mental health professional reviews the identified target behaviors and rewards with the patient only and instructs the patient to determine a fair contingency plan. The patient's initial contingency plan is

brought to the significant other for approval, or modification. If changes are desired by the significant other, modifications are performed, and the revised plan is presented to the patient for approval, or modification. Contingency plans go back and forth in this manner until a plan is mutually adopted by both parties. At any time in the aforementioned negotiation process, a therapist may bring both parties together to expedite compromise. If the patient refuses to participate in the negotiation process, or if the patient is incapable of participating in the negotiation process, the significant other solely determines the contingency plan.

D. Establishing and Role Playing the Monitoring Process

After the contingency plan is adopted, the monitoring process is established and practiced. The patient and significant other agree to get together at a mutually satisfactory time to review, and record, all target behaviors that were performed during that day, including rewards that were earned and provided. This meeting time is usually anchored to a fairly reliable event (e.g., immediately prior to retiring for the evening) and occurs daily at a convenient location in the patient's residence.

It is very important that the behavioral exchange process is role played prior to its implementation in the patient's environment. The role-play process is best initiated as soon as the contract contingencies are established during the initial session. The behavioral exchange process consists of reviewing the monitoring of target behaviors, and the provision of earned rewards. In this endeavor, the mental health professional initially models the role of the significant other in reviewing the contingency contract (i.e., simulates the role of a significant other in initiating the review of the behavioral contingencies at home). In addition to demonstrating the review process, modeling helps to determine if target behaviors are too difficult, or if problems are likely to occur in the contract. In modeling the role of the significant other, the mental health professional reviews the list of target behaviors and descriptively praises the patient for having performed target behaviors that day. The completion and/or noncompletion of target behaviors are recorded, and the patient is provided rewards that were earned that day. Modeling continues until all target behaviors are reviewed, and there is no confusion among the participants. The patient and significant other are then asked to role play the contingency review for the same day. Feedback is given by the mental health professional during this role play to assist the monitoring and behavioral exchange

process. Last, participants are instructed to review the contract in the patient's environment on a daily basis until the next intervention session.

E. Ongoing Review of the Behavioral Exchange

Future intervention sessions focus on praising the patient for the performance of outstanding target behaviors, ensuring that the contract is implemented fairly, and modifying the contract, as needed. The mental health professional attempts to determine if the significant other monitored targeted behaviors adequately, and if rewards were provided as specified in the contract. The mental health professional also determines that no unearned rewards were obtained by the patient. The most frequently occurring modifications to the contract involve the addition and deletion of target behaviors, and the addition of rewards.

III. THEORY

Behavioral contracting owes much of its theoretical underpinnings to the tenets of B.F. Skinner's operant conditioning. Indeed, it has been established that if a given behavior increases in frequency consequent to the application of a stimulus, the stimulus is deemed a positive reinforcer. Thus, in behavioral contracting there is an attempt to modify the patient's environment such that the patient's positive reinforcers will only be available on successful completion of target behaviors. If the target behaviors are truly functional to the patient, the contingent rewards may be gradually eliminated as the patient begins to experience naturally occurring reinforcers. For example, the frequency of a child's completed homework assignments may increase consequent to the child's receipt of a dime per each completed assignment. However, the child's homework may continue to be performed long after the dime is discontinued because natural reinforcers for the completion of homework would probably begin to occur within the duration of the contract (e.g., praise from teacher and parents, respect from other students, personal pride, school awards). Moreover, on practicing homework repeatedly, this behavior may become habitual, and an expected way of acting. As Aaron Beck's self-regulation theory posits, the child would identify himself as an individual who regularly performs homework well. If behaviors occurred that were inconsistent with this child's homework completion, the child

would be inclined to regulate his behavior to be consistent with his beliefs (i.e., an individual who performs homework well).

IV. APPLICATIONS AND EXCLUSIONS

As mentioned earlier, behavioral contracting may be utilized by therapists, psychologists, and other mental health professionals to facilitate improvement in the behaviors of their patients. Persons entering into the contract are usually the identified patient, and those who are interested in the patient's welfare (i.e., staff members, teachers, family members, friends, employers). Behavioral contracting procedures are appropriate across ethnicity and gender, and usually are appropriate for children who are 3 or more years of age, or the developmental equivalent. Contracting procedures may be implemented in a variety of settings, including medical and psychiatric hospitals, outpatient mental health clinics, residential drug rehabilitation centers, schools, camps, and detention centers.

A self-monitoring contract, may be implemented when significant others are unavailable, and the patient is motivated to contingently reinforce her/himself only for the performance of target behaviors. However, this type of contracting suffers from inherent problems, most notably the patient's lack of objectivity in monitoring target behaviors, and failure to comply with contingencies due to forgetting and lack of willpower. Therefore, behavioral contracting is best utilized when significant others are available to monitor target behaviors, and enforce the agreed on contingencies.

V. CASE ILLUSTRATION

The following case illustration, the details of which were obtained from a study conducted by the first author, underscores the importance of utilizing contingency contracting as a motivational tool. Karen, a 12-year-old, Hispanic female, presented to an outpatient psychology clinic with a 5-month history of eating only stage II baby food and frozen yogurt. She complained that her throat was too constricted to swallow solid foods. The onset of her refusal to eat solid foods occurred after she choked on a piece of steak. She was reported to be 106 pounds at that time (i.e., the 50th percentile in weight for a girl her age). During the initial assessment session, Karen weighed 85.5 lbs., and

appeared to be losing about .5 lb. per week. A psychological examination revealed that Karen evidenced conversion disorder. This disorder is indicated when the individual believes deficits in voluntary motor or sensory functioning are present that suggest a neurological or medical condition. However, the symptoms have no identifiable organic etiology.

The first four intervention sessions focused on encouraging Karen to eat solid foods, encouraging family support, and encouraging her to eat foods of increasing viscosity during the intervention sessions. Karen was taught to focus on relaxing her throat muscles during meals. The aforementioned interventions resulted in an initial increase of about 1.5 lbs. However, after only 1 week of intervention, she refused to attempt new foods and evidenced no further gains in her weight for 3 weeks.

In an effort to reinstate her motivation to attempt lumpier foods, and consequently gain more weight, the therapist added contingency contracting to the intervention plan. Specifically, if Karen gained 1 lb. per week, and continued to attempt foods with greater viscosity, she maintained "green status." Green status meant that she would receive one therapy session per week instead of two sessions, eat home meals in a room of her choice instead of being restricted to the dining room, be able to make long distance phone calls to her brother to report treatment gains, be able to leave the dinner table as soon as her meal was consumed instead of being restricted to the table for about 40 min, and be able to go to the grocery store with her mother to choose her favorite foods. She was provided a bonus opportunity that included a plane ticket to visit her out-of-state brother if she gained 5 lbs. Her parents also planned surprise celebration activities with Karen and bought her new clothes, when she was on green status. If she failed to gain 1 lb. per week, she was put on "red status," which meant that Karen did not have an opportunity to earn the preceding rewards.

Contingency contracting resulted in her attempts to eat with foods of greater viscosity, and immediate and sustained weight gain (i.e., approximately 1 lb. per week during 6 weeks of contingency contracting). At the 10-month follow-up assessment, she reportedly weighed 100 lbs. an increase of 14 lbs. since contingency contracting was implemented. During the follow-up interview, Karen's mother revealed that Karen was eating a

variety of nutritious foods fairly regularly, although she was described by her mother as a "light eater."

VI. SUMMARY

A behavioral contract is a verbal or written agreement that specifies the relationship of behavior between two or more persons for a specified duration. The behavioral contract is most often initiated by mental health professionals in therapeutic settings to motivate patients to perform desired behaviors. In quid pro quo contracting, the performance of a specified behavior by one participant is contingent on the performance of a specified behavior by the other participant. Good faith contracting requires a participant to provide rewards to another participant for the completion of target behaviors. Establishing a behavioral contract involves identification of target behaviors and rewards, negotiating a contingency plan, establishing and role playing the monitoring process, and conducting an ongoing review of the behavioral exchange.

in vivo exposure Systematically confronting “real life” feared situations, conducted repeatedly in a graded fashion.

subjective units of distress A rating scale used by the therapist and group members to record and communicate degree of distress anticipated or experienced during exposure tasks. The scale ranges from 0 (no fear or distress) to 100 (extreme fear or distress).

GLOSSARY

automatic thoughts The content of one’s stream of consciousness, consisting of thoughts or images that may be positive (e.g., “I can deal with this situation”) or negative (“I’m a loser”).

cognitive distortions Distortions in the way information is processed such as the tendency to exaggerate the aversiveness of unpleasant events (catastrophizing) or the tendency to classify events in black and white categories (e.g., “success” vs. “failure”). Cognitive distortions can arise from dysfunctional beliefs.

diaphragmatic breathing Paced breathing exercises used in panic control treatment to counter hyperventilation and physiologic hyperarousal.

dysfunctional beliefs Basic assumptions the person holds about the self, world, or future (e.g., “I am fundamentally flawed,” “The world is a dangerous place,” “My life will never improve”). Such assumptions are considered to be dysfunctional if they impair the person’s life or give rise to emotional problems.

interoceptive exposure Systematically confronting feared bodily sensations (e.g., accelerated heart rate) that serve as interoceptive fear cues.

I. DESCRIPTION OF TREATMENT

Behavioral group therapy (BGT) is an effective, efficient psychotherapy that has been successfully adapted to treat a wide variety of psychological disorders, and occasionally to address psychosocial aspects of physical ailments (e.g., irritable bowel syndrome). BGT shares some characteristics with other forms of group psychotherapy and is not simply a didactic, classroom-style approach to skills acquisition. At the same time, it is also a unique group therapy in several respects. The content is structured, both within and across sessions. Compared to group therapy in general, the design of BGT is specific toward the target problem, even in some of the more “generic” forms of BGT that tackle groups of problems. BGT is multimodal in nature whereby a package of treatment components is assembled to address the multidimensional nature of most forms of psychopathology. Finally, the number of sessions is generally fixed and the duration of treatment is measured in weeks rather than months. BGT uses closed groups of medium size (e.g., 6 to 8 individuals),

and is often preceded by one-on-one interviews with prospective group members and one of the therapists in order to establish diagnoses and assess suitability for group therapy. Following formal treatment, a more informal group open to “graduates” of the BGT program is often useful to provide booster sessions for those who require it.

There are important advantages to offering behavior therapy in a group setting. The first reason is efficiency. More people can be helped with less therapist time, although it can require more administrative coordination and scheduling. In the case of relatively homogeneous groups that are organized around the primary disorder, there comes the reassuring sense of common, shared experience for many individuals. Perhaps the most important advantage of the group format is that the role of the therapist can be systematically decentralized and instead a self-help approach is encouraged. Group members can act as supportive coaches in reviewing and engaging in exposure exercises, and can work together in cognitive restructuring. Group cohesion and a self-help orientation can promote self-reliance and ultimately self-efficacy and mastery. Accordingly, terms like “program” may be preferable to “therapy,” and “group member” may be preferable to “patient.”

The next section provides a theoretical overview of BGT. Immediately following this overview we present two case illustrations of BGT. The first involves a protocol for panic disorder with agoraphobia, and serves to highlight different types of exposure techniques in BGT. The second BGT protocol has more cognitive components and is designed to treat generalized social phobia. The chapter concludes with a brief discussion of applications and exclusions for BGT, along with a summary of the current empirical knowledge base.

II. THEORETICAL BASES

BGT is based on contemporary conditioning and cognitive theories of emotional disturbance. Current conditioning models assume that emotional reactions can be learned in multiple ways, including classical conditioning, transmission of information from one person to another, and observing other people react emotionally to stimuli. Classical conditioning, as conceived in contemporary models, is a process of learning to associate a stimulus with a particular outcome. In other words, it is a process whereby the person develops expectations about the consequences of a particular stimulus. The experience of being mauled by a

dog can lead the person to associate dogs with harm. This expectancy thereby gives rise to fear and avoidance of dogs.

Contemporary cognitive theories of emotional disturbance have their origins in the pioneering work of Aaron Beck and Albert Ellis. These models posit that emotional problems are not directly caused by aversive events, but are the result of the person's beliefs about the event. Thus, a given event (e.g., a canceled visit from one's mother-in-law) could elicit any number of emotional responses (e.g., disappointment, joy, annoyance) depending on the person's interpretation of the event. Cognitive theories propose that dysfunctional beliefs are prime sources of emotional disorders. A person who held the belief that “My world must always be predictable” would become distressed at the mother-in-law's canceled visit. In comparison, a person who believed that “You have to expect the unexpected” may react with mild disappointment.

Dysfunctional beliefs give rise to automatic thoughts, which form part of the person's stream of consciousness. A person who believed that “I am a failure as a person” might have a stream of negative automatic thoughts such as “Nobody likes me,” “What's the point in trying,” and “I'll never succeed.” Such thoughts arise when particular life events occur that are relevant to the person's dysfunctional beliefs. A person who believed that “My worth depends on my ability to be a good mother” might not become terribly upset if she lost her job, but would become profoundly despondent if somebody criticized her child-rearing practices. Thus, emotional problems arise when particular life events interact with particular dysfunctional beliefs.

Dysfunctional beliefs also give rise to a variety of cognitive distortions, which are aberrations in the processing of information. A person who believed that “People are always trying to exploit me” would be concerned about being taken advantage of, and therefore vigilant for such occurrences. As a result, the person would tend to overlook the altruistic acts of others. This is an example of overfocusing on the negatives. Other examples of cognitive distortions are shown in Table 1. Cognitive restructuring exercises, as described elsewhere in this chapter, are used to replace dysfunctional cognitions (thoughts, beliefs, and distorted information processing) with more adaptive forms of thinking.

How do cognitive and conditioning theories fit together? It might seem that these are two completely different ways of conceptualizing emotional problems. However, the two theories are quite compatible, and

TABLE 1
Examples of Cognitive Distortions

<i>Distortion</i>	<i>Description</i>
All-or-nothing thinking	Classifying events in black and white categories; e.g., regarding some as either “good” or “bad”; appraising your performance as either “perfect” or “a complete failure.”
Overfocusing on negatives	Focusing on negative events to the exclusion of positive events; e.g., focusing on all the times that you have failed, and ignoring the times you succeeded.
Catastrophizing	Exaggerating the aversiveness of unpleasant events; e.g., regarding your anxiety as “excruciating and never ending” rather than “unpleasant and short-lived.”
Demandingness	Imposing rigid rules and demands on oneself or others; e.g., “people <i>should</i> take care of me”; “I <i>must</i> be a success at my career.”
Personalization	Taking personal responsibility for events where there is insufficient evidence that you were responsible; e.g., when a friend fails to phone, you interpret this as due to some personal failing (“I’m boring to talk to”) instead of considering the other possibilities (“She didn’t call because she had a migraine”).

have been synthesized in the emotional processing model (developed by Edna Foa and Michael Kozak). According to this model, emotions are represented in networks (structures) stored in long-term memory. Consider, for example, the network underlying a person’s social phobia. The network contains stimulus information (e.g., authority figures, oneself as a social object), response information (e.g., representations of one trembling, sweating, blushing, and fleeing), and meaning information (e.g., concepts such as “danger” and “threatening”). The elements of information are linked together. For our social phobic, “authority figures” is linked to “threatening” (a stimulus-meaning link); “self” is linked to “weak and ineffectual” (another stimulus-meaning link); “authority figures” is linked to “blush, trembling, and flee” (stimulus-response link); and “threatening” is linked to “fear” (meaning-response link). Thus, each emotional network consists of an interconnected matrix of stimulus, response, and meaning information. Stimulus-response links can be acquired by conditioning or other forms of learning, and stimulus-meaning or response-meaning links can represent dysfunctional beliefs (e.g., “Authority figures are threatening”). In this way the emotional networks combine elements of conditioning and cognitive theories.

Networks are activated by incoming stimuli that match its stimulus, response, or meaning information. Activation of the network evokes emotion and associated responses such as escape or avoidance. Networks underlying emotional problems are modified by, first, activating the network (via presenting the person with relevant stimuli) and then by incorporating corrective

information. This is known as emotional processing. Exposure exercises and cognitive restructuring techniques are both methods of modifying networks underlying emotional problems. Skills training (e.g., assertiveness training) is another way of modifying the networks. As a result of emotional processing, links are changed and meaning information is modified. For example, the stimulus-meaning link might change from “authority figures are threatening” to “authority figures are generally benign.” In summary, the interventions used in BGT aim to modify the patient’s emotional networks so that the latter become more adaptive.

III. CASE ILLUSTRATIONS

A. Panic Disorder with Agoraphobia

Panic disorder with agoraphobia (PDA) is characterized by sudden, intense episodes of anxiety (panic attacks) that often occur unexpectedly. The attacks are usually associated with feelings of impending doom and are composed of physical symptoms (e.g., shortness of breath, dizziness, racing heart) along with catastrophic thoughts (e.g., thoughts that one is dying, going crazy, or losing control). Agoraphobia frequently accompanies panic disorder and is defined as a fear of being in places where escape may be difficult or help not forthcoming in the event of a panic attack. Situations that are either avoided or require the presence of a trusted companion include public transportation, being in crowds or lineups, and traveling long distances.

From a cognitive behavioral perspective, panic attacks are viewed as arising from catastrophic misinterpretations of bodily sensations, and phobic avoidance is seen as a conditioned response. BGT for PDA is composed of several modules delivered over 10 sessions and the protocol is a group adaptation of the individual treatment developed by David Barlow and colleagues. Because of space limitations, and to avoid redundancy with other chapters, we will highlight group adaptations rather than cognitive-behavior principles and techniques in general.

Session 1: The introductory session involves setting group members at ease. Some members may have difficulty being in a group setting or in not sitting next to the doorway. A brief explanation of a Subjective Units of Distress scale (SUDS) can give everyone a common meter to express their anxiety at that time, and there is often a relief that the high state anxiety is not an isolated experience. The scale ranges from 0 (no fear or distress) to 100 (extreme fear or distress). Following the introduction of therapists and some brief group rules about the importance of confidentiality, attendance, and homework assignments, a brief introduction and history from each group member is sought (e.g., location of first panic attack, treatment history). Listening to others' histories can be reassuring for many group participants, but some may become distressed for fear of "picking up" new variants of catastrophic "what if?" thoughts, and this can be addressed from a cognitive perspective. An effort is made to have every group member make at least some contribution, and this is true throughout the sessions. Group members are provided a schedule and overview of coming sessions. Using a blackboard or easel, more detailed descriptions of panic attacks are then solicited from group members. The attacks are broken down into component physical symptoms and associated cognitions. An informative exercise is to ask individuals about the worst thing that has happened during an attack, so that they can see that worst-case feared outcomes (e.g., loss of consciousness) are in fact extremely rare. Situations that people avoid are then listed (e.g., strenuous exercise, public transportation). Safety nets (e.g., availability of cellular phone) are also included. Using the information now listed the therapist can suggest thematic links between internal sensations, associated thoughts or interpretations and the role of escape, control, and phobic avoidance. In short, the cognitive behavioral model and rationale can be presented using the information provided by group members as illustration. At the end of the session SUDS ratings are again elicited from group members. In most cases there will have been a decrease over

the 2 hours and this can be used as an example of *in vivo* exposure "in action." Homework consists of a self-directed, behavioral approach test to get an estimate of baseline functioning. This involves assignments where participants are asked to enter feared situations (e.g., travel five blocks by bus) and rate their peak SUDS levels during the exercise.

Session 2: This session contains much of the corrective psychoeducational information about panic (e.g., nature of fear and fight/flight response). Sensitivity to anxiety and other physical sensations and the process of catastrophic misinterpretation in panic attacks is included. Information about the role of escape, avoidance, and the maintenance of fear then follows, with the message that "what is learned can be unlearned." Wherever feasible, group members are called on to provide examples of the various components. Realistic goals are then discussed and targets identified. Homework consists of self-directed exposure of a mildly feared situation with the instruction to remain in the situation until anxiety has noticeably decreased. An example of diary construction is reviewed in order to record the situation, time, SUDS, and thoughts experienced during exposure tasks.

Session 3: Exposure exercises are reviewed for each group member. The theme of this session is the rationale and implementation of exposure. This might begin with drawing a graph showing gradual reduction of anxiety with repeated exposure exercises of sufficient duration. Implementation includes detailed construction of a hierarchy of feared situations in collaboration with group members. Handouts on techniques for coping with anxiety and panic are provided and reviewed. Examples of helpful coping self-statements are provided and also solicited from group members. The importance of graded, self-directed exposure is emphasized and at least three exposure exercises per week are encouraged. The involvement of spouse, significant other, or friend as a "coach" may be discussed. Finally, goals are set for the therapist-assisted exposure session in Session 4.

Session 4: This session involves therapist-assisted *in vivo* exposure. If two therapists are present the group is divided according to the theme of the situational exposure and it is certainly easier to implement group exposure if a co-therapist or assistant is available. However, a situation such as a shopping mall provides a number of different exposure opportunities that can accommodate most group members (e.g., escalators, elevators, lineups, heights). In addition to providing support, the therapist can work with individuals to identify and challenge "hot cognitions" (i.e., those occurring in the moment) and to

observe and correct problematic breathing (e.g., holding breath). Exposure to situations that can be followed up with self-directed exposure is encouraged.

Session 5: *In vivo* exposure tasks from Session 4 and from homework exercises are reviewed, and group members are called on to participate in solving problems that may arise (e.g., modification of exposure tasks, additional coping techniques). The remainder of the session is devoted to (1) interoceptive exposure, which involves confronting internal feared sensations and (2) exploring the nature of effective and ineffective breathing patterns, which include diaphragmatic, paced breathing and hyperventilation, respectively. A group approach to these behavioral techniques is particularly helpful because of the support of other group members, the ability to create a shared common experience, and the opportunity to solicit and to provide feedback from individuals other than the therapist. Similar to *in vivo* exposure, a repeated graded approach is utilized in interoceptive exposure. Of the various interoceptive exposure exercises, voluntary hyperventilation (with therapist participation) is one that is particularly appropriate to a group setting. Education and practice of diaphragmatic, paced breathing is conducted toward the end of the session. Most individuals find it to be a relaxing exercise, and they are asked to rehearse this coping skill to effectively acquire it for their antipanic arsenal. Homework exercises are outlined.

Session 6: It is roughly the halfway point in the course of treatment and considerable time is taken to check in with each group member to review progress and problem-solve as a group where necessary. If time permits, further interoceptive tasks can be conducted (e.g., spinning in a chair to induce dizziness). The session concludes with outlining self-directed exposure exercises and planning the next therapist-assisted exposure session.

Session 7: By this time, there is generally good group cohesion and many group members can help each other as coaches. For example, traveling on a crowded bus might prove challenging to some members whereas a shopping mall destination may prove challenging to others.

Session 8: Following a review of homework exercises, the session begins with progressive muscle relaxation. An audiotape is used and is available to group members. A taped version also allows the therapist(s) to participate alongside other group members. Relaxation strategies, including the paced breathing exercises, are reviewed. General and specific changes in attitudes and thinking styles are reviewed, especially in the context

of challenging catastrophic interpretation of internal sensations. Thoughts and concerns about future group termination are discussed. The session concludes with outlining self-directed exposure exercises and planning the last therapist-assisted exposure session.

Session 9: The last *in vivo* session is more of a group exposure rather than a therapist-assisted exposure, and an attempt is made to keep therapist contact to a minimum. Subgroups might also be formed. For many individuals the goal is to encounter a very challenging event, often something that has been discussed for some time and also something that is entertaining (e.g., going to an amusement park, seeing a movie in a large theatre).

Session 10: The final session usually begins with a group discussion about the previous week's exposure session, and this allows a progression into a more general discussion about gains that have been made in the past several weeks. Remaining challenges and strategies for overcoming them are discussed. The importance of continued self-directed exposure in achieving long-term goals is highlighted. Members can provide feedback to each other on gains observed while in group and during group exposure sessions. Relapse prevention strategies are discussed. Self-help support groups for "graduates" of cognitive behavioral programs may be available. Appropriate self-help books for more general issues are recommended. Often the group concludes with coffee and doughnuts and this adds to the positive, "graduation" ambience.

B. Generalized Social Phobia

Generalized social phobia (GSP) is a common and disabling disorder that affects many areas of a person's life. Situations commonly avoided include presentations to small or large groups, being observed while eating or drinking, and many forms of social interaction (e.g., initiating a conversation). Dysfunctional attitudes and extreme negative thinking appear to play an important role in the etiology and maintenance of the disorder. Phobic avoidance is a major feature of GSP and so exposure therapy is indicated. However, because of the way that people with GSP interpret their social interactions, even seemingly successful social encounters can be perceived as failures through a critical dissection or "postmortem" ruminative process. Accordingly, cognitive restructuring is an important component of treatment. Behavioral group therapy for social phobia was pioneered by Richard Heimberg and colleagues and is arguably the nonpharmacologic treatment of choice for this condition. Because of the psychological complexity of GSP

this cognitive approach is more intensive, and requires more therapist skill and experience, than BGT for PDA. Groups are smaller (e.g., six members) and of longer duration (12 sessions). Within-session exposure sessions (role playing) accompanied by cognitive strategies are a major focus of the therapy. Individuals with severe social deficits are more appropriate for behavioral social skills training. Some individuals will have high levels of criticism toward others in addition to self-criticism, and their interpersonal style may be inappropriate for this type of group approach. Prior to the formal group treatment, one or two individual sessions with each member is conducted in order to explain the cognitive behavioral model and rationale, and to help alleviate anticipatory anxiety surrounding group therapy.

Session 1: The introduction and orientation is similar to BGT for PDA except that the state anxiety in the group is generally much higher. The therapist therefore takes a “go slow” approach and acknowledges the demands of the situation. Often the subjective, internal experience of anxiety will be disproportionately greater than outward, observable signs of anxiety, and it is useful to point this out. It helps address automatic thoughts such as “Everyone looks so calm and I’m falling apart—I’m not ready to be in a group,” and also encourages group members to look at each other and make eye contact. These types of exercises can be done in a sensitive and humorous way and helps set group members at ease so that they are able to process the information provided. The therapist can also provide his or her own SUDS level, which is generally far above 0, and this can serve to highlight the adaptive functions of moderate anxiety. Individual experiences of symptoms, cognitions, and situations avoided are elicited, and again an attempt is made to call on every group member. The rationale for both cognitive and behavioral treatment components is reviewed using the specific examples provided by group members. As a cognitive exercise, members are asked to verbalize their negative automatic thoughts about the group program (e.g., “This may work for others, but it will never work for me”). A structured diary to record automatic thoughts is reviewed and distributed.

Session 2: After a brief review of CBT theory from the previous week, the diaries are discussed. Considerable time may be spent with each group member to begin the difficult process of identifying the nature and extent of negative thinking. Fears of negative evaluation may be linked to extreme self-criticism. Some group members may become tearful or may temporarily leave the room. When it becomes appropriate, the thoughts

surrounding this experience should be reviewed and other group members can be called on to provide their thoughts and feelings to counter the automatic thoughts of the individual who became upset. Subsequently, other group members can be called on to elicit their own negative automatic thoughts (e.g., “Oh God, I should be doing something to help”). Compared to BGT for PDA, this group program spends more time in the present on within-group issues. More therapist effort is required to build group cohesion. Group members can be informed that it is important to identify all negative thinking before attempting to change it and that is a painful exercise at first. A list of cognitive distortions is provided and is reviewed using examples provided by group members.

Session 3: Diaries of automatic thoughts and associated cognitive distortions are reviewed. While the therapist might help each member uncover additional automatic thoughts, other group members can be called on to help identify appropriate cognitive distortions. Considerable time may still be required for each group member. The remainder of the session is devoted to the rationale and principles of exposure.

Session 4: Cognitively, the group now moves toward challenging the automatic thoughts once they are identified through a variety of cognitive restructuring techniques. This process will likely have already begun for some members following the awareness of cognitive restructuring. The goal is to challenge (e.g., “Do I know for certain that X will happen”), rather than to “replace” negative thinking. Behaviorally, exposure is now more formally incorporated in the construction of fear hierarchies for each member.

Session 5: Self-directed exposure assignments from the hierarchy are reviewed. Several “lessons” (information and skills acquisition) are presented. These lessons are brief (15 to 20 minutes) modules that are partly didactic and occasionally involve role playing on the part of the therapist (ideally two therapists can role play social interactions). The first lesson is on the role of fear of negative evaluation and its consequences (e.g., heightened self-focused attention) in social phobia. Cognitively, the challenging of automatic thoughts means that they are no longer uncritically accepted as valid, and members are now encouraged to generate reasonable (rational) responses to the automatic thoughts. An effort is made to make these responses reality-based with the recognition that they will likely not “feel” right at first and that this shift takes time. Group members are encouraged to generate additional possible reasonable responses for each other when weekly diaries are

reviewed. Exposure homework assignments are developed for implementation during the following week.

Sessions 6 through 9: The format of these sessions is to begin with a lesson. The remaining themes include effective conversation, perfectionism, anticipatory anxiety, assertiveness, and control. These exercises can involve the participation of group members. For example, the lesson on conversation begins by having the therapist allow a long silence. This “pregnant pause” is then used to elicit individuals’ reactions and automatic thoughts around initiating and maintaining conversation. The remainder of each group session is devoted to cognitive restructuring. The process evolves from identifying and challenging automatic thoughts to understanding underlying dysfunctional belief systems. Self-directed exposure is continued based on the situations listed in the hierarchies.

Sessions 9 through 11: The bulk of these sessions is composed of *in vivo* exposures or “role-plays.” The goal is to have two role-plays for each group member over the course of treatment. Role-plays will have been discussed with group members as early as the individual, pregroup interviews. Because it is a taxing exercise for many individuals it is reserved until the second half of the group therapy protocol. The simulated exposures are designed to be as realistic as possible and can include social interactions (e.g., initiating conversation at a party) and formal presentations (e.g., delivering a retirement speech). Props are used (e.g., drinking glasses) and furniture arranged to enhance realism. Immediately prior to the exposure the therapist meets with the central role-play member and rehearses the situation, assists in identifying all automatic thoughts, and gauges the SUDS rating of the anticipatory anxiety. Immediately following the exposure, a debriefing session occurs with all group members to discuss the role-play. Automatic thoughts are reviewed as well as the success of various methods of challenging them. The debriefing is very much a group exercise, because members can provide direct feedback to automatic thoughts (e.g., “Everyone can see how badly my hand is shaking—they think I am weak”). Unlike most social situations, the debriefing following the role-play allows all group members to find out what others were thinking, the strengths and shortcomings of their performance, how noticeable their anxiety was, and so forth. This type of feedback, especially because it is not coming solely from the therapist, can provide powerful evidence to counter the postmortem rumination that can occur after seemingly successful social encounters.

Session 12: The final session reviews the gains that each participant has made. Members are asked to reflect

on how their perceptions of being in a group environment has changed from being a form of *in vivo* exposure to being in a safe place. Members can provide feedback to each other on changes observed over the course of the program. Remaining challenges are identified and necessary steps to achieve long-term goals are outlined. Most members have had significant social anxiety since adolescence or “as long as they can remember,” and they can be reminded that the realistic goal of the group was “to launch, rather than to cure.” Relapse prevention, support groups, and appropriate self-help books are also discussed. An informal period with coffee and doughnuts often concludes the group and serves both as a final group exposure and as a positive, “graduation” experience.

IV. APPLICATIONS AND EXCLUSIONS

Almost any behavioral therapy that is used in an individual (one-to-one) format can be implemented as a group therapy. Examples include behavioral treatments for mood disorders, anxiety disorders, eating disorders, and substance-use disorders. Group size, session duration, and session frequency can be adapted to fit the specific needs and resources of a given treatment setting. Groups typically consist of 8 to 10 patients and 1 to 2 therapists. Group sessions are typically 2 to 2.5 hours, and last from 10 to 14 weeks.

BGT can be either generic or problem-specific. Generic groups impart general skills, such as social skills training or cognitive restructuring techniques. Such groups can therefore contain patients with a variety of different problems. A group might consist of a mix of patients with mood and anxiety disorders. Generic groups are most effective when they impart skills relevant to all group members. Cognitive restructuring, for example, would be useful for most people with emotional disorders. Other interventions, such as exposure exercises, are useful for only some patients (e.g., those with phobias) and therefore are used sparingly in a generic group treatment.

Problem-specific programs treat more homogeneous groups of patients. Examples of panic disorder and social phobia programs were described earlier. Other examples include protocols specifically for depressed patients, and protocols specific for patients with bulimia nervosa. There has been little research on whether generic or specific programs are most effective. Patients with emotional disorders are likely to

have more than one problem. A patient with posttraumatic stress disorder, for instance, is also likely to have a comorbid mood disorder. These patients would benefit from a generic program, which teaches skills relevant to each of the person's problems. However, generic programs are not always sufficient. Sometimes it is important for the patient to receive specific treatment, focusing on his or her main problem.

There are several factors to bear in mind when deciding whether or not a patient is suitable for group rather than individual therapy. Patient preference and therapist resources are important considerations. For many treatment programs, the problem of long waiting lists has been addressed by conducting most treatment in groups, thereby increasing the number of patients that can be treated at a given time. Patients desiring individual treatment may have to wait longer for a therapist to become available. Group composition is another important consideration in selecting participants. Ideally, groups contain patients with approximately the same level of impairment. Patients who are functioning either at a much higher or much lower level than other group members may feel alienated from the group, and the interventions may not be optimal for the patient's problems. To illustrate, consider a group program for major depression, which would consist of behavioral exercises (distraction training, mastery and pleasure exercises) and cognitive restructuring. Patients with moderate depression tend to benefit from each of these interventions. Patients with severe depression are most likely to benefit from behavioral exercises. Accordingly, a patient with severe depression would not benefit from the interventions used in a group consisting mostly of patients with moderate depression. Such a patient would be best treated either individually or in a group of patients who are all severely depressed.

A related consideration in selecting group versus individual treatment concerns the interpersonal style of the patient. Patients who are very hostile or suspicious may prove to be too disruptive for inclusion in group therapy. For the most part, however, most patients suitable for individual therapy can be effectively treated in group therapy.

V. EMPIRICAL STUDIES

Few studies have directly compared the efficacy of group versus individual treatments. More often, these formats have been compared in meta-analyses, which are statistical methods for combining data from large

numbers of outcome studies in order to evaluate the efficacy of various interventions. Research has revealed few differences between the efficacy of group versus individual protocols for treating specific disorders. The formats have been found to be equally effective for a variety of disorders, including social phobia, posttraumatic stress disorder, panic disorder, and other disorders. Thus, the average patient benefits as much from group as from individual therapy. Finally, although particular patients may benefit more from one format than another, research has revealed few ways of reliably identifying these patients. An important area for further research in CBT in general is the identification of individual differences in suitability for these treatment modalities.

VI. SUMMARY

BGT is an effective treatment strategy that can be applied to a number of different conditions and context. It is a structured approach that contains both generic and specific modules, depending on the nature of the target condition. Most forms of BGT include both exposure and cognitive restructuring. Homework exercises and review of activities outside of group are an important feature. BGT is a relatively short-term treatment and the number of sessions is fixed. An important goal is to impart effective coping skills and to promote self-efficacy. BGT is also an approach that transports well—in many instances it can be effectively delivered by paraprofessionals outside of specialty clinics.

GLOSSARY

exchange theory The quality of social relationships is influenced by the interdependence of reinforcement and the reward–cost ratio of behaviors exchanged in these relationships.

social learning theory Interpersonal behavior is determined by controlling variables in the social environment and by individuals' cognitive-perceptual processes that are used to interpret these behaviors.

Behavioral marital therapy (BMT) is a well-known and empirically validated psychoeducational approach to the assessment and treatment of marital distress. BMT originated in the late 1960s and has evolved into a comprehensive and systematic therapeutic approach that features multimethod assessment procedures and at least two primary intervention components: communication and problem-solving training and behavioral exchange techniques. Although focus on interpersonal behavior

change is a hallmark of the approach, developments over the past decade have incorporated the evaluation and modification of cognitive and affective variables that may serve to mediate marital dysfunction.

I. DESCRIPTION OF TREATMENT

Since its inception in the late 1960s, behavioral marital therapy (BMT) has incorporated a multimethod assessment approach to the conceptualization and treatment of distressed marriages, followed by interventions inspired primarily by the tenets of social learning theory. The approach has been subjected to rigorous empirical investigations and, as a result, it has evolved over three decades to include not only behavioral variables, but also the investigation and incorporation of cognitive and affective variables. Moreover, the name of the approach itself, traditionally called behavioral marital therapy, has given way to behavioral couples therapy in many settings. The idea is that, in practice, the approach can be applied as effectively to treat nonmarital relationships (e.g., heterosexual couples living together, same-sex relationships, any adult dyad attempting to establish and maintain an intimate relationship), as well as to treat married couples.

A. Assessment

BMT has a fairly distinct tradition of beginning the couple evaluation process by employing three or four

different methods of gathering information to understand the problems and strengths of a given relationship and to plan various interventions to accomplish the therapeutic goals. First, there are a series of semi-structured clinical interviews, typically 2 to 3 sessions, which often include separate meetings with each partner as well as meeting the couple in a conjoint format. In general, the objectives of these so-called assessment interviews are to (1) screen clients for the appropriateness of couple therapy, (2) determine the nature and course of events related to partners' presenting complaints, (3) determine the goals and objectives of the partners for couple therapy, (4) establish an effective therapeutic relationship, and (5) orient the couple to the therapist's orientation and approach to treatment.

Each partner has one or more reasons for initiating couple therapy. Typically, in the first meeting, the therapist will help the partners to develop a problem list, which indicates each person's perception of the various problems in the relationship. Problems can be categorized into matters of content and process. Problematic content areas often include finances, sex, dealing with in-laws, raising children, struggling with partners' annoying personality traits or mental illnesses, or coping with specific stresses that adversely impact the marriage, such as unemployment, major physical illnesses, or other traumatic events external to the couple relationship. Process concerns have to do with *how* the couple interacts. Typical complaints include ineffective ways of communicating with one another and discord regarding how they attempt to solve problems and manage marital conflicts.

It is also important during the evaluation stage to ascertain the partners' respective goals and expectations for couple therapy. For example, are they both committed to the relationship or is one partner planning separation or divorce? Are the identified problems negotiable for both partners? Are their goals and expectations realistic given partners' levels of competence and motivation? Before making a viable treatment plan, all these interpersonal competence and motivational issues must be considered. Finally, the initial interviews allow for the therapist to establish a therapeutic relationship with the couple. The therapist must gain sufficient credibility and trust and offer hope that the partners' pain, suffering, dissatisfaction, and distress can be addressed effectively. If this step is not accomplished, likely the couple will not continue with therapy. One way to aid in the accomplishment of this preliminary bonding is to explain in advance the purpose and value of the various evaluation and intervention procedures. What is expected from the

clients? What are the role and responsibilities of the therapist? How will information be gathered and what is the prognosis for resolving their problems? An open discussion about what will be done and why is another hallmark of the BMT approach.

A second fairly unique assessment procedure used in BMT to gather diagnostic information about the couple is the administration of various questionnaires and inventories to learn about specific strengths and problem areas. The discussion of specific measures is beyond the scope of this article. Suffice it to say that there exist several standardized measures that are designed to assess one or more of the following variables: global relationship satisfaction; communication skills and deficits; areas of change requested by the partners; types of conflict; intensity levels of conflict and styles of conflict resolution; partners' cognitions, expectations, and beliefs about the relationship that may be causing problems; sexual function and dissatisfaction; participation in pleasurable events and rewarding social activities; and steps toward divorce. BMT practitioners typically ask the couple to complete a selected set of these instruments either before or at the very beginning of the evaluation process. Often feedback and interpretation of the results are given to the couple regarding their responses.

The third assessment procedure that is routinely associated with the practice of BMT is observation and analysis of a sample of *in vivo* marital conflict interaction. That is, couples are helped to identify an existing issue about which they have disagreement; they are asked to spend 10 to 15 minutes in the session talking together in a demonstration of just how they go about attempting to resolve an existing marital conflict. The therapist may or may not leave the room to less obtrusively observe and/or to videotape the communication sample for later review and analysis. The conflict resolution communication sample provides unique and important information regarding the level of problem-solving skill the couple possesses to resolve relationship conflicts and the extent to which improvement in these processes will become treatment goals.

In many programs associated with BMT, a fourth assessment procedure involves asking partners to collect data about events and interactions that occur in their home environments. In an attempt to obtain reliable information about the baseline (i.e., before treatment) frequency of certain events (e.g., arguments per week in which either partner loses one's temper), partners may be asked to observe and count the frequency of these events. Accordingly, later when treatment interventions are introduced, partners may again be asked

to count these events to determine if improvement has occurred. Some BMT programs gather these data as part of the assessment stage; others may postpone this so-called spouse observation procedure until the formal intervention stage of treatment.

In conclusion, the multimethod assessment procedures employed by BMT practitioners provide both converging and diverging types of information that are used in a systematic manner to conceptualize relationship dysfunction (and relationship strengths) and to formulate a treatment plan (i.e., interventions).

B. Interventions

From its inception, the traditional interventions associated with BMT have included communication and problem-solving skills training and behavioral exchange techniques. Over the years, in many empirical studies, both interventions have been shown to be highly correlated with marital satisfaction. Although “communication problem” is probably the number one complaint of couples seeking therapy and most therapy approaches work on improving communication between partners in some manner, the hallmark of BMT has been direct training in skill acquisition. The therapist is likely to employ a basic communication training manual, such as *We Can Work It Out*, written by Clifford Notarius and Howard Markman in 1993. Throughout the course of treatment, the therapist employs any number of the following types of interventions to help couples modify their patterns of miscommunication and to acquire improved problem-solving skills: didactic instruction, behavioral rehearsal, coaching and feedback about practicing the skills, videotape feedback, and regular homework assignments to support generalization of the new skills into the home environment. Often, the couple learns to improve basic expressive and listening skills first and then is taught how to apply these skills progressively to the various problems in their relationship. Thus, a second phase of communication training emphasizes skills related to problem-solving and conflict management. Typically, some variation of the universal problem-solving model is taught, which includes five remedial steps that are designed to modify the couple’s maladaptive interaction patterns: agenda building, mutual definition of the problem, brainstorming, implementing the solution, and evaluation or modification of the initial plan.

Usually concurrent with the communication and problem-solving interventions is the introduction of behavioral exchange techniques. Based on the principles of social learning theory and exchange theory, emphasis is

placed on helping partners to define and instigate increases in positive behaviors and to reduce negative behaviors that are exchanged by partners in their home environment. A technique called contingency contracting may be employed, where partners enter into written behavioral contracts to increase or decrease certain targeted behaviors. If the behavioral goal is accomplished, a reward for the individual or couple may be earned; if failure to perform the agreed-on behavior occurs, a punishment may be invoked. More recently, using a bank account analogy, practitioners of BMT have helped distressed couples to reduce or eliminate what either partner might experience as withdrawals from the relationship bank account (e.g., criticisms, starting arguments, inconsiderate or disliked behaviors) and to make positive deposits into the relationship account (e.g., initiate quality activities together, increase caring behaviors or other behaviors that partners find pleasing). Over the course of couple therapy, a systematic approach is employed whereby at first the easiest changes are made, followed by work on the more difficult areas of partner interaction and compatibility. Unlike the communication and problem-solving interventions, which take place largely within the therapy sessions, behavioral exchange assignments are carried out in the couples’ home environments. Much emphasis is placed on developing homework assignments that are likely to be successful and that achieve the couples’ desired goals.

As a therapeutic approach, BMT also is known for applying the same two basic interventions described above to specific areas of interaction with which distressed couples often have to contend. For example, several sessions may be devoted to systematically enhancing communication about and designing home-based behavioral interventions for parent training, sexual dysfunction, financial management, and mild cases of domestic violence. BMT also has been effectively applied as a concurrent or secondary treatment to manage partner’s individual problems, especially when these problems adversely affect the relationship or the quality of the relationship causes or exacerbates these individual problems. Examples of individual problems often treated, in part, with BMT include anger management, depression and anxiety management, and substance abuse.

Finally, during the past decade, in particular, many clinical investigators have developed models of couple therapy that have expanded the traditional BMT approach to incorporate the identification and modification of important cognitive and affective variables. That is, part of the communication and problem-solving training

that is done during BMT may well include helping partners to recognize and alter certain maladaptive cognitions that interfere with the well-being of the relationship. For example, if partners have unrealistic expectations or beliefs about their partners or the relationship, or if they have certain biases, prejudices, or make faulty attributions, then these cognitive variables may appropriately be targets of therapeutic intervention. Partners can be taught to recognize these beliefs or persistent themes both in the treatment sessions and at home, to determine their accuracy and influence on the relationship, and to make modifications if appropriate. Similarly, it is recognized that affective variables (i.e., feeling reactions) often developed over time within the individual partners may be playing important roles in causing or maintaining relationship distress. Primarily within therapy sessions, partners can be helped to explore the origins of certain negative, disruptive, or intimacy-inhibiting feelings. For example, fears of rejection or abandonment, avoidance of conflict, and anger outbursts that occur out of proportion to the present situation are all feeling states that can serve to influence the relationship negatively. Clients may be helped to consider the possibility of learning how to understand and manage these types of feelings more constructively.

In summary, over three decades of development, BMT has offered a psychoeducational, behaviorally oriented approach to the assessment and treatment of couple distress that has been expanded to include interventions targeting maladaptive behaviors, cognitions, and affective variables and instigating positive changes in these modes of function for the betterment of the couple relationship.

II. THEORETICAL BASES

BMT has generally been defined as the application of social learning theory and behavioral exchange principles to the treatment of marital distress. During the past decade, BMT has expanded to include an analysis of cognitive and affective variables that influence or control behavior. Social learning theory posits that interpersonal behavior is determined by a combination of variables related to what happens in an individual's social environment and to one's cognitions and perceptions about these events. Accordingly, as regards marital interaction and satisfaction, the social or interpersonal environment is a primary determinant. If these theories suggest that behavior is a function of its antecedents and consequences and that the perceived quality of a relationship is primarily a function of the behaviors exchanged be-

tween partners, then interventions designed to promote rewarding (i.e., positively perceived) behaviors and to reduce or eliminate punishing (i.e., negatively perceived) behaviors would help improve partners' satisfaction with the marriage.

Cognitive and perceptual processes have been theorized to mediate between overt behavioral exchanges. Partners' personal interpretations or attributions regarding the occurrence and/or meaning of the behaviors can be critical regarding their value in the relationship. For example, if a wife has a desperate fear and prevailing belief that her husband does not love her, it may be that otherwise positive behaviors emitted by the husband will not be appropriately recognized by her. Moreover, if his intended positive value is not received, she may even criticize or discredit him for offering the behavior. Additionally, affect as experienced by the partners is theorized to play an important role in controlling both functional and dysfunctional processes in intimate relationships. For example, if the husband was neglected emotionally as a child, he may have learned to experience a disproportionate negative emotional response when his wife attempts to be more independent and self-sustaining than is comfortable for him. Helping both partners to discover and to understand this emotional connection between his family-of-origin upbringing and their marital events may facilitate attitudinal and/or behavioral changes that can help to improve the situation.

Taking principles of social learning theory toward a theory of therapeutic change in couple therapy means assessing which attitudes, behaviors, and related problems constitute the complaints and target variables for intervention. The goal is to increase the rewarding and to decrease the punishing behaviors exchanged between partners and to identify and improve the nature of any cognitive and affective mediating variables that may influence the occurrence and interpretation of these behaviors.

III. APPLICATIONS AND EXCLUSIONS

Generally speaking, BMT is most appropriately considered when couple distress is the primary problem or when certain nonrelationship factors have caused significant relationship distress, and the couple, as a unit, needs therapeutic attention. There are no known restrictions in the application of BMT to diverse ethnic, racial, national, age, gender, or socioeconomic groups. However, regarding couple-specific features, BMT is thought to be most effective when the partners possess

the abilities to collaborate toward mutual objectives of change, to offer support and accommodation to one another while addressing the problems at hand, and, when necessary, to compromise with one another in resolving their defined problems. When these criteria are met, a combined emphasis on behavior exchange and communication/problem-solving interventions has been quite effective. In comparison, because BMT is fundamentally change-oriented, the approach may be less effective when the couple's level of relationship distress is very high, one or both partners' commitment to the marriage is low, the issues in conflict are unlikely to change, the couple is invested in maintaining traditional sex roles, or the couple is unable or unwilling to collaborate, accommodate, or compromise with one another. In these cases, while couple therapy may be indicated, an approach less focused on behavior change probably would be more effective (e.g., integrative behavioral couple therapy, emotion-focused couple therapy, insight-oriented couple therapy).

Of course, in terms of exclusions, there are a number of situations where couple therapy, in general, is not the treatment of choice—at least initially. If either partner's level of individual psychopathology is too severe to be managed or treated in conjoint therapy, alternative treatments should be considered (e.g., hospital inpatient milieu, individual or group psychotherapy, and/or pharmacotherapy). For example, certain personality disorders (i.e., antisocial personality disorder, ASPD) may include a predisposition and learning history regarding the use of physical violence to gain or maintain control of someone. Cases featuring domestic violence and including individuals with ASPD often are not appropriate for BMT. Similarly, therapists may encounter other instances of major individual psychopathology where BMT is excluded, at least as the primary treatment of choice, such as active psychoses, disabling disorders of depression, anxiety, or substance abuse. In such cases, the individual problems should be treated in lieu of BMT. If and when the individual problems are treated and they are improved at least to the point where a relationship focus is appropriate in therapy, then BMT may well be indicated as a concurrent or secondary treatment approach.

IV. EMPIRICAL STUDIES

In a review of the empirical literature on BMT in 1998, Donald Baucom and his associates indicated that over two dozen well-controlled studies have been performed evaluating the efficacy and effectiveness of

BMT. BMT is the most widely evaluated form of marital treatment. For the past three decades, many direct studies and several meta-analytic investigations of multiple studies have confirmed that BMT, as an integrated approach, is a statistically and clinically efficacious treatment when compared to waiting list control groups and nonspecific treatment or placebo control groups. In general, the research has not found the specific components of BMT (i.e., behavioral exchange vs. communication/problem-solving training) to be differentially effective, nor has BMT been demonstrably more or less effective than other marital therapy approaches to which it has been compared directly.

Regarding the impact of BMT on couples' lives, reviews of multiple studies suggested that based on various relationship assessment scores obtained pre- and posttreatment, 56 to 66% of the couples treated with BMT improved significantly and 35 to 54% reported that their levels of marital satisfaction changed from the clinically distressed to the nondistressed scoring ranges. Follow-up outcome data from these studies suggest that most couples maintain these gains for 6 months to a year, with some relapse indicated 2 to 4 years following treatment. Finally, given the limited data available, it appears that over 90% of couples treated with BMT find the approach worthwhile and would recommend it to a friend in need; the couple dropout rate for couples entering BMT has been estimated at only 6%. In conclusion, in many empirical studies completed over 30 years of investigation, BMT has been shown to be a valid, efficacious, and effective treatment for marital distress.

V. CASE ILLUSTRATION

A. Intake Session and Inventory Assessments

A friend referred Cindy and Bob to the clinic. They were in their early thirties, had been married for 6 years, and had two daughters, aged 2 and 4. It was the second marriage for Bob, a boiler repairman and mechanical engineer, and the first for Cindy, who was occupied as a housewife and mother. During the initial clinical interview the co-therapist team asked about presenting complaints and the precipitating event leading to the initiation of therapy. When asked, "Why are you seeking help now?" Bob said that he had recently admitted to having an affair with a young woman he had met during his rather extensive car racing activities. Bob claimed that since the birth of their second

child Cindy's role had become almost exclusively one of mothering instead of being a wife (i.e., a loving sexual partner). With their relationship and sex life faltering, Bob became more involved with car racing activities, met an attractive, seductive girl, and succumbed to the affair over a period of several months. Beset with guilt and the frustration regarding spouses' increasingly incompatible roles, however, he finally told Cindy about the affair.

Cindy, claiming that management of the young children and house required a huge amount of her time, asserted that Bob did not appreciate her responsibilities. He was very unhelpful with these tasks and, while spending less and less time at home, he became more and more demanding and resentful about their lack of sexual activity. Cindy, in a fairly unemotional presentation, indicated that she felt hurt, angry, and abused regarding the affair. Nevertheless, the decision to seek professional help was primarily Bob's in that he wanted to "make or break" the marriage in order to relieve his ambivalence and frustration.

To summarize the content of the first session, the presenting complaints from Bob were inability as yet to emotionally divorce himself from his lover, lack of affection and sex from Cindy, Cindy's tendency to spend more money than they had, and Cindy's excessive attention to children and house. Current relationship strengths that Bob noted were their ability to be effective, loving parents and a basic caring and love for one another. Cindy cited the major problem areas as Bob's general lack of commitment to her and the family, the quantity and quality of sexual interaction, and a desire for a reduction in the one or two nights each week and most of every other full weekend that Bob devoted to racing. Strengths noted by Cindy were their mutual caring for one another, good senses of humor, and being good parents. At the end of the initial session an agreement was made to complete the marriage evaluation process. A marital relationship assessment battery was distributed and the baseline results, obtained within 1 week, are listed in Table 1. The posttherapy scores also are tabulated for later reference.

Very briefly, the pretherapy data in Table 1 indicated that both partners are distressed and dissatisfied with the relationship, Bob significantly more than Cindy (Inventory #1). Bob has seriously entertained the idea of separation and divorce and has initiated certain discussions outside the relationship; Cindy has taken significantly fewer steps toward divorce (Inventory #2). In terms of self-attributions of self-esteem, psychological tension and anxiety, and physical symptoms (Inventory #3), Bob

TABLE 1
Marital Relationship Assessment Battery:
Pre- and Posttherapy Scores

Inventory	Pretherapy		Posttherapy	
	Bob	Cindy	Bob	Cindy
1. Locke-Wallace MAS	47	85	104	116
2. Marital Status Inventory	7	3	7	3
3. Self-Description Inventory				
Self-esteem	6.4	4.3	6.1	5.6
Psychological distress	1.4	3.4	1.8	2.4
Physical symptoms	0.4	1.2	0.5	0.8
4. Areas of Change Questionnaire	16	10	9	4
5. Response to Conflict Scale				
Self-appraisal	2.8	1.0	1.9	0.7
Spouse appraisal	1.4	3.1	1.2	2.1
6. Inventory of Rewarding Activities				
Proportion of activities alone	55%	25%	27%	15%
With spouse only	12%	28%	31%	35%
With spouse and other adults	13%	18%	14%	14%
With family	2%	21%	17%	20%
With other adults, not spouse	18%	8%	11%	12%
Time distribution				
Working	24%	5%	24%	10%
Sleeping	25%	33%	28%	35%
Rewarding activities	32%	9%	22%	21%
Neutral or nonrewarding	20%	52%	26%	34%
7. Sexual Activity				
Worry about sex (0-8 scale)	0	5	2	3
Frequency of intercourse (Past month)	3	7	8	9
Want spouse to initiate sex (-3 to +3)	3	-1	2	0

Note: While quantitative inventories are an important part of BMT, detailed description of the inventories is beyond the scope of this article. Briefly, however, Inventory (Inv.) #1 measures global marital satisfaction; a score of 100 discriminates happy from unhappy couples. Inv. #2 measures steps toward divorce, range 0-14, a score of 4 or greater indicates significant risk. Inv. #3 measures the three named variables regarding individual function; range is 0-8. Inv. #4 measures conflict potential in domestic activities; happy couples average 7 total and unhappy 28 total for husband plus wife scores. Inv. #5 measures spouses' perceptions of maladaptive conflict responses, 0-8 scale; happy couples average 1.35 per person, unhappy couples average 2.77. Inv. #6 measures proportion of rewarding activities each partner engages in, in five social formats. Happy couples endorse a balance of activities across all formats, including about 35% activities with spouse only. Inv. #7 measures various aspects of sexuality: worry, frequency, and initiative.

demonstrated a pattern that strongly suggested denial and minimization of the negative aspects of these dimensions. Generally, such a pattern suggests one is likely to deny or rationalize one's own contribution to marital difficulties and to emphasize the faults of one's partner. In contrast, Cindy's results suggested mild-moderately-low self-esteem, psychological distress, and physical symptoms. The Areas of Change Questionnaire scores (Inventory #4), which total 26 for the couple, fell within the range for distressed couples. Bob's potential conflict score was higher than Cindy's, reflecting his withdrawal from the domestic environment. The Response to Conflict Scale (Inventory #5) indicated that both partners viewed Cindy's responses to conflict as within the normal range, whereas they perceived Bob as responding in a more intense and maladaptive fashion. The Inventory of Rewarding Activities (Inventory #6) can be interpreted in several ways. The gross indicators are, however, that during the past month, Bob has engaged in a majority of elective activities alone and a relatively high proportion with other adults, excluding his spouse. His profile suggested relative deficiencies in elective activities with spouse and family. This pattern was largely the consequence of Bob's long-term withdrawal from the family and his increased outside activities with his racing friends. Cindy's proportions of elective activities were more generally appropriate for a satisfied marriage. Regarding time distribution, in a typical 168-hour week, note that Bob slept an average of only 6 hours a night. He also claimed a solid proportion of rewarding activities. In stark contrast to Bob and consistent with other available data, Cindy indicated very little rewarding time and an overwhelming amount of neutral or nonrewarding activities: 78% of her waking hours! Finally, data about sexual activity (Inventory #7) confirmed that sex was a major problem area. Whereas Bob characteristically denied that sex was a personal concern, he nevertheless indicated a low monthly frequency and called for significantly more initiation by Cindy. In contrast, Cindy did admit to worrying about sex, indicated a desire for Bob to initiate requests less frequently, and reported a higher monthly frequency. In summary, the inventories documented the level and nature of marital dysfunction in many areas. For this couple, there was certainly sufficient self-reported distress to warrant marital therapy.

B. Communication Sample

The 10-minute videotaped communication sample was obtained at the outset of the second evaluation ses-

sion. The conflict issue selected for problem-solving was Bob's involvement in car racing activities. Here is a representative sample of their interaction.

Bob: What is it about my racing?

Cindy: It's just that you spend so much time at it. Last night you worked on the car, tonight you have a meeting and then you will be gone all weekend.

B: Yes, but this is an important race and then there won't be another one until Long Beach. [3 weeks later.] Besides you're invited to come.

C: I know, but I am not able to manage those kids all day by myself and at night you would rather party anyway than be with us. Last time you said you would be home by six and you got home at midnight.

B: I know. I already told you I'm sorry about that? We get so wired all day that it's hard to leave without having a few beers and winding down. What's wrong with that?

C: Nothing! I want you to have a good time, but you promised you would come home early. And when you come home that late you are too tired the next day to do anything with us.

B: [Said with disgust.] Well, maybe I should quit racing, but it's the only fun thing I do!

C: [With resignation.] No ... you need an outlet, but the kids and I need some time with you too.

At this point, the pattern was set. The remainder of the discussion went similarly round and round. This couple is conflict-avoidant. Little direct anger was expressed throughout the interaction; however, they concurred during debriefing that they probably would not have carried on such a discussion at all at home. As it was, they spent most of their time describing the problem and summarizing their own positions. There was minimal evidence of understanding one another, expression of feelings, or problem solution statements. Unlike many couples, however, they did manage to stay on the topic, they shared the talk time, and they demonstrated fair-to-good nonverbal sending and listening skills. Unfortunately, their natural pattern at home was to withdraw from potential conflict discussions even before reaching the level of wheel-spinning problem description evident in the observed sample.

C. Treatment Goals and Interventions

By the end of the evaluation period, good rapport had been established between therapists and clients, there was a consensus on the problems and goals of therapy, and a treatment contract was set for 10 sessions. Goals

and intervention methods are indicated in Table 2 in the tentative order of sequence.

D. Treatment Progress

At the outset both Bob and Cindy seemed motivated to improve their marriage. While admitting to some emotional ambivalence about being with wife versus lover, Bob indicated that he wanted to stay with the family and make the marriage more rewarding. He had terminated contacts with his lover. Bob and Cindy made very good early progress. In fact, with only an average amount of direction, encouragement, repeated assignments, and reinforcement by the therapists, they did quite well through the beginning stage of therapy and part way through the middle stage.

The difficulties arose when goal 7 (in Table 2) was broached through explicit focus on treatment goal 8. Treatment session number six had ended with an assignment extending goal 2 into sexual interaction. The therapists designed the assignment carefully so it would be successful. On a given day, Bob agreed to come home by 5 P.M., to shower, and to help Cindy feed and bed the kids by 8 P.M. That would leave about 3 hours for them to have a nice, jointly prepared dinner, to relax for awhile, and then to engage in a pleasurable sexual encounter. The therapists suspected that if major resistance were going to emerge, it would be associated with movement toward increased intimacy (i.e., confronting the risk of rejection) through a sexually oriented assignment. Their concerns were well founded. Possibly giving off mixed signals, after dinner the two combined to fail the assignment. Bob started to watch the news on TV waiting for Cindy to initiate the romance; she thought he was too comfortable and not interested in having sex and got involved in a different activity. During the therapy session, exploration of cognitions and feelings indicated that Cindy was still a little unsure of herself as a competent sexual partner and thus was reluctant to initiate affectionate interaction. At the same time, she became aware of lingering, if unexpressed, resentment about Bob's affair. She wanted to be given special attention and to be seduced. In Bob's case, he was still vulnerable to their old interaction pattern and his self-defeating thinking style: "If Cindy really cares about me, knowing that I want sex and affection, she will initiate it; I'm tired of always having to be the initiator." In addition, Bob admitted that although he had no contact with his girlfriend, he still occasionally experienced strong feelings for her. The therapists pointed out that such expectations and

TABLE 2
Treatment Plan for Bob and Cindy

Goals	Interventions
1. Establish collaborative set	Persuasion and didactic instruction in systems thinking; homework assignments that require and reward couple collaboration; therapist reinforcement for teamwork
2. Increase contact time for Bob and Cindy; Bob and family	Negotiation, structured homework assignments, e.g., caring activities, mutually rewarding couple and family activities
3. Increase couple communication	Basic communication skills training in session; graded assignments at home—assigned reading, discussion, and exercises.
4. Increase Cindy's independent rewarding activities	Negotiated resource allocation, e.g., money for babysitters; homework assignments
5. Increase problem-solving and conflict-resolution skills	In-session training in problem solving and conflict-management skills; structured homework
6. Resolve financial management issues	Apply problem-solving skills; establish budget
7. Increase Bob's father role and decrease his "sex-deprived, errant husband" role; increase Cindy's wife role and decrease her "overburdened mother-housewife" role	Systematic assignments above that foster one role over the other; therapist reinforcement of role shifts; techniques of dealing with blocks to progress
8. Increase quality of sexual interaction	Graded assignments, e.g., caring activities; structured exercises, e.g., sensate focusing; communication skills about sexual interaction
9. Resolve Bob's ambivalence concerning wife versus lover	A planned and eventual consequence of all the above

mixed emotions were likely to be self and relationship defeating, particularly when left nonverbal (i.e., as hidden agenda). The remainder of the session was devoted to the careful design of another romantic evening together with encouragement to explicitly discuss their ongoing expectations and feelings.

Over the final few sessions, with much more open communication, they were able to reconstruct a better sex life. The therapeutic emphasis was on mutual responsibility for initiation of and response to sexual behaviors. Bob learned that in exchange for less frequency (e.g., two to three rather than five encounters per week) that quality could be improved in terms of Cindy's responsiveness, enthusiasm, and active participation. Moreover, with modest decreases in Bob's working late and racing activities, there was increased contact time available for the full gamut of family and relationship business. This included sex and affection sometimes initiated by Cindy.

E. Posttherapy Assessment and Follow-Up

The posttreatment communication sample reflected increased collaboration and assertiveness during conflict resolution by both partners. The Marital Relationship Assessment Battery posttherapy results are presented in Table 1. These data suggested significant improvements in many of the relationship indicators. At 6-week follow-up, both partners claimed that they had maintained the improvement in marital satisfaction.

VI. SUMMARY

Behavioral marital therapy consists of fairly distinct assessment and intervention phases. First, a multi-method assessment of the behavioral problems and strengths of the distressed relationship is accomplished through the use of semistructured clinical interviews, standardized marital inventories, observed samples of problem-solving conflict resolution in the clinic, and possibly information derived from spouse observation in the home environment. Based on the results for a given couple, a treatment plan is devised that typically

includes at least two major interventions designed to improve presenting complaints: communication and problem-solving training and behavioral exchange assignments. In this context, couples learn how to improve the ratio of pleasing-to-displeasing behaviors, how to be more open and effective in communicating about important relationship issues, and how to more effectively solve problems and manage their marital conflicts. The primary focus is on applying interpersonal behavior change technology. However, partners' cognitions and affective states also are considered and may be targeted for intervention. After a typically brief course of therapy (i.e., 12 to 20 sessions), posttherapy assessments are repeated and one or more follow-up sessions are planned to assess and to help maintain gains made in treatment.

convey information and provide direction to clients in the context of making behavioral changes. This article will provide a detailed description of instructions for behavioral therapy and a review of theory and empirical studies pertaining to the manner in which instructions are provided by behavior therapists.

GLOSSARY

antecedent variable An environmental stimulus that cues a particular behavioral response, including both emotional or physiological responses (e.g., sadness, fear, panic) and instrumental responses (e.g., escape in response to a feared stimulus). An antecedent event for a spider phobic would be seeing a spider.

consequent variable Reinforcement or punishment that follows a particular behavioral response (e.g., praise, approval, attention, monetary reward, removal of privilege).

modeling Learning that occurs from the observation of others and observation of the consequences of another's behavior, as well as any imitative change in behavior that follows.

psychoeducation Educational materials designed to explain the manner in which psychological phenomena occur and to provide a rationale for specific treatment approaches.

role-playing Acting out ways of handling real-life situations for the purpose of modifying maladaptive ways of responding and replacing them with more adaptive ones, or for learning and practicing a newly acquired skill. Also referred to as behavioral rehearsal.

Instructions for behavioral therapy encompass a variety of methods that behavior therapists employ to

I. DESCRIPTION OF TREATMENT

In behavioral therapy, instructions to clients tend to be specific, structured, and directive. Behavior therapists maintain a focus on specific problems, as opposed to underlying causes or traits, and assess the antecedents, consequences, and maintaining factors for behavior. Although goals for treatment are often developed in collaboration with clients, behavior therapists take primary responsibility for the direction of therapy sessions, establishing the agenda and structuring the session. Instructions are conveyed through psychoeducation, direct feedback, homework assignments, and specific techniques.

A. Psychoeducation

Behavior therapists provide information that is designed to educate clients about therapeutic processes, including conceptualization of the target problem, procedures to be used, effectiveness of a given procedure, likelihood of change, and the respective roles of therapist and client in achieving behavioral change.

In educating clients about the conceptualization of a problem, behavior therapists provide explanations of presenting symptoms from a learning theory perspective, focusing on factors that serve to maintain problem behaviors. Concrete examples are often provided, and clients are encouraged to think of prior learning experiences that illustrate specific concepts. For instance, in explaining factors that often serve to maintain a fear of public speaking, the therapist may ask the client to recall past experiences with public speaking in order to identify maladaptive cognitions (e.g., “I am making a fool of myself”) and behaviors (e.g., talking quickly, leaving the situation in order to avoid speaking) that were present.

Behavior therapists rely on the empirical literature to guide treatment choices and provide explanations of the rationale for treatment. In addition to providing verbal explanations of a problem’s causes and subsequent rationale for treatment, clients are often provided with educational materials in written form, and asked to read the materials as homework assignments. The ultimate goal of educating clients about the conceptualization of the problem and treatment procedures is to arrive at a consensus regarding the treatment plan and implementation.

Considerable attention has been devoted to the study of a client’s expectations of change and the roles of client and therapist in bringing about change. In general, behavior therapists attempt to understand the client’s expectations of therapy, to correct misperceptions, to educate clients about the rationale for selecting certain procedures, and to motivate clients to have positive expectations for change.

B. Direct Feedback

Behavior therapists provide instructions through direct feedback. Target behaviors are assessed on an ongoing basis and feedback is provided regularly throughout treatment. In-session observations provide a sample of behavior and may indicate progress toward specific goals. Specific suggestions are made regarding behavioral changes. For example, in working with an individual with depressed mood, a behavior therapist may provide feedback that decreased activity and withdrawal from others are contributing to the client’s depression. Therefore, behavioral activation strategies may be recommended, and in collaboration with the client, a specific plan established for ways to increase activity level.

C. Homework Assignments

Behavior therapists incorporate homework assignments in treatment in order to bring about change and encourage generalization of behaviors to environmental contexts outside of the therapy session. Examples of homework assignments include practicing a relaxation exercise two times per day, engaging in daily *in vivo* exposure practices, and completing a writing assignment. Specific instructions are provided regarding how to complete homework assignments. The parameters for assignments may include the duration and frequency of tasks, how to structure the environment, and efforts to anticipate factors that may interfere with successful completion of the assignment. Often, monitoring forms are provided so that clients can record the occurrence of specific behaviors between sessions, as well as provide documentation of completed exercises. For example, clients may be asked to monitor daily mood and anxiety levels using a 10-point scale or to record cognitions that occurred in the context of specific tasks.

D. Specific Techniques

Behavioral therapists provide instructions through a variety of methods. Throughout treatment, teaching, modeling, and role-playing may be used to instruct clients in how to engage in particular behaviors. The following three techniques are often combined in a single session.

1. Didactic Teaching

Behavior therapy relies on didactic teaching to explain behavioral concepts and to instruct clients in how to complete exercises. Individuals are often presented with psychoeducational materials in both verbal and written formats, with the aim of informing them of the various factors that are maintaining maladaptive behaviors. For instance, in presenting information regarding diaphragmatic breathing to individuals with a history of panic attacks, behavior therapists may provide a description of the physiology of panic, followed by an explanation of how certain cognitive and behavioral responses, such as hyperventilation, serve to maintain and increase physiological responses. The therapist may then proceed to explain the rationale for diaphragmatic breathing and demonstrate this technique in session.

2. Modeling

Therapists employ modeling to demonstrate appropriate performance of certain behaviors. With

modeling instructions may be presented both verbally and visually. Although it is possible to utilize a videotaped or imagined model, often the therapist serves as the model in session, demonstrating a specific technique, then asking the client to imitate the behavior. Using diaphragmatic breathing as an example, the therapist may first describe the procedure, ask the client to watch while the technique is demonstrated, and then have the client perform the procedure. Feedback is then given to clients regarding their performance. Specific criteria are often established for the client to ensure the procedure is being performed properly. For instance, in behavior therapy designed to improve the interaction between parent and child, parents are instructed to demonstrate a certain number of descriptive statements and praises in an allotted time frame.

3. Role-Playing

Role-playing is employed in behavior therapy to modify maladaptive responses and replace them with new responses. Role-playing may also be used to instruct clients in how to perform a newly acquired behavior or to engage in a behavior in a given context. Therefore, role-playing is an example of behavioral rehearsal in that behaviors are repeatedly acted out until they become part of the individual's behavioral repertoire. This type of instruction is most commonly applied with interpersonal difficulties, especially when problems are associated with assertiveness or social skills.

Role-playing allows the therapist to teach a behavior, to observe the client performing the behavior, and to have the client perform the behavior in the presence of stimulus cues that are likely to be present in real-life situations. For example, a therapist may demonstrate ways of responding assertively to a controlling and demanding spouse. The client may then anticipate certain reactions the spouse may have and the therapist can role-play these reactions so as to provide a closer approximation to real-life circumstances.

II. THEORETICAL BASES

Behavioral therapy represents an approach that is empirically based and strongly rooted in learning theory. The direct and structured manner in which instructions are provided in behavioral therapy reflects a scientific approach. Therapists develop a hypothesis about factors that are maintaining maladaptive behav-

ior, select a method of modifying the behavior, provide instruction in how to achieve behavioral change, monitor progress toward the stated goal, and ensure that behavioral change generalizes to appropriate contexts. Progress toward specific goals is assessed systematically over the course of therapy through monitoring exercises, observations of behavior in session, and information gathered from collateral sources, if pertinent.

III. EMPIRICAL STUDIES

There is a paucity of empirical investigations that have directly addressed the manner in which *instructions* per se are given in behavioral therapy. The closest approximation comes from studies that have evaluated nonspecific treatment effects, referred to as "placebo" effects, in evaluating the effectiveness of behavioral therapy in comparison to more traditional forms of psychotherapy. Nonspecific effects refer to those factors associated with the conduct, rather than content, of psychotherapy: the relationship between the therapist and client, expectations for improvement in the context of a helping relationship, a rationale that establishes the expectation of change, and procedures that involve the interaction of the therapist and client.

Hans Eysenck's work, spanning more than 40 years, has examined the placebo effect as it relates to the evaluation of psychotherapy outcomes. Eysenck has summarized research on psychotherapy effectiveness and concluded that behavior therapy, in comparison to traditional psychotherapies (e.g., psychodynamic, client-centered, Gestalt, rational-emotive), has evidenced greater effect sizes, over and above that which can be attributed to placebo. In current psychotherapy outcome research, there is an effort to differentiate active treatment components from nonspecific effects, holding nonspecific aspects constant across treatment conditions.

IV. SUMMARY

Instructions for behavioral therapy encompass a variety of methods and techniques that behavior therapists employ to provide direction to clients in order to achieve behavioral changes. Behavior therapists maintain a directive stance, establish a specific agenda for therapy sessions, and structure the course of therapy

toward the achievement of specific treatment goals. Behavior therapists utilize psychoeducation, direct feedback, homework assignments, and specific techniques, such as modeling and role-playing, to convey specific concepts and to assist clients in achieving behavioral change.

treatment effect size A statistic that reflects the average amount of difference (expressed as a fraction of the pooled standard deviation) observed between a treated and untreated group of patients.

GLOSSARY

cognitive-behavioral insomnia therapy A multifaceted treatment approach designed both to reduce dysfunctional beliefs about sleep and correct sleep-disruptive habits.

insomnia A form of sleep disturbance characterized by difficulty initiating or maintaining sleep or by chronically poor sleep quality. Accompanying the nocturnal sleep difficulty are daytime complaints (e.g., fatigue, poor concentration) and, at times, more serious signs (e.g., poor work performance, compromised social functioning) of dysfunction.

paradoxical intention A treatment strategy in which an individual is instructed to purposefully engage in a feared activity in order to reduce performance anxiety that confounds associated goal-directed behavior.

relaxation therapies A group of behavioral treatments that involve formal exercises, which when practiced repeatedly, lead to increased ability to lower psychological and physiological levels of arousal.

sleep restriction A behavioral strategy in which time in bed at night is restricted in order to encourage a more consolidated sleep pattern.

stimulus control A structured behavioral regimen designed to disassociate a problem behavior or conditioned autonomic response from a specific environmental setting.

Insomnia is a highly prevalent and significant health concern resulting from varied causes. Often misconceptions about sleep and myriad sleep-disruptive habits serve important roles in perpetuating this type of sleep problem. In such cases, behavioral therapies designed specifically to address these perpetuating factors are often required to eradicate the observed sleep difficulties. This chapter briefly describes insomnia, considers the cognitive and behavioral anomalies that contribute to this condition, and reviews the most commonly employed behavioral insomnia therapies.

I. NATURE AND SIGNIFICANCE OF INSOMNIA

Insomnia, characterized by difficulty initiating, maintaining, or obtaining qualitatively satisfying sleep is a widespread health complaint. Like the common cold, most individuals have experienced at least transient bouts of nocturnal sleep difficulty due either to an impending stressful (e.g., final exam) or exciting (e.g., a long-awaited vacation trip) event or due to

acute medical or environmental factors. However, slightly over one-third of the adult population complains of recurring, intermittent sleep difficulties whereas 9 to 10% endure chronic, unrelenting insomnia problems. Although many health care professionals as well as the lay public may minimize its significance, insomnia may have notable short- and long-term consequences. At a minimum, insomnia results in daytime fatigue, decreased mood, and general malaise. In more protracted cases it may cause impaired occupational and social functioning. In addition, there is substantial evidence that insomnia dramatically increases risks for medical complaints, alcohol and drug abuse, and serious psychiatric illnesses. Moreover, insomnia alone contributes to increased health costs and utilization among affected individuals and, in turn, escalates health care costs for society in general. Indeed, insomnia sufferers may collectively spend well over \$285 million per year for prescription sleeping pills whereas the projected annual direct, treatment-related costs of insomnia to the U.S. population may be as high as \$92.5 billion. Thus, chronic insomnia represents a significant public health problem that warrants early detection and treatment.

II. THEORETICAL BASIS FOR BEHAVIORAL INSOMNIA THERAPIES

As might be surmised by the above discussion, sleeping pills remain the most popular treatment for those chronic insomnia sufferers who report sleep complaints to their physicians. Indeed, as many as 50% of those patients who complain of insomnia to their physicians are treated with sedative hypnotics or sedating antidepressant medications to address such complaints. Although these agents may be useful in the management of transient insomnia, they generally fail to provide long-term relief for those with more chronic sleep disturbances. Patients who use hypnotics on a long-term basis often suffer such unwanted effects as drug tolerance, dependence, hang-over, short-term memory loss, and a gradual return of their sleep problems. Side effects may be particularly problematic among elderly hypnotic users who are at increased risk for toxic drug interactions and serious falls resulting from oversedation. Although some recently developed sleeping pills hold the promise of reduced side effects, all currently available sleep

medications represent only symptomatic treatments that fail to address the underlying factors sustaining insomnia. Thus, even the most recently developed sleeping pills often provide little lasting relief for those with chronic sleep disturbances.

Insomnia, as a symptom, often heralds underlying psychiatric, medical, or substance abuse disorders that require treatment before the sleep disturbance can be resolved. Nonetheless, effective and enduring insomnia treatment in many cases requires additional strategies designed to reestablish normal functioning of the human biologic sleep system. According to the 1988 theory of Wilse Webb, normal sleep functioning is regulated by homeostatic mechanisms that respond to increasing periods of wakefulness by increasing the propensity to sleep, circadian mechanisms that regulate the timing of sleep onset and offset, and environmental and behavioral factors that may serve to facilitate or inhibit the sleep process. Assuming adequate functioning of the homeostatic and circadian systems as well as sleep-conducive environmental/behavioral conditions, normal, subjectively satisfying sleep results. However, disruption of normal homeostatic or circadian functioning and/or disruptive environmental/behavioral conditions may contribute to sleep disturbances.

For many insomnia sufferers, normal sleep/wake functioning becomes chronically disrupted through the development of poor sleep habits and conditioned emotional responses that either interfere with normal homeostatic or circadian processes or serve as environmental/behavioral inhibitors to sleep. For example, daytime napping or spending extra time in bed in pursuit of elusive, unpredictable sleep may interfere with normal homeostatic sleep-controlling mechanisms and serve to reduce sleep drive on the ensuing night. Alternately, the habit of remaining in bed well beyond the normal rising time following a poor night's sleep may disrupt the circadian sleep-wake rhythm and make the subsequent night's sleep more difficult. Additionally, the repeated association of the bed with unsuccessful sleep attempts may eventually result in a conditioned arousal in the home sleeping environment. Finally, failure to discontinue mentally demanding work and allot sufficient wind down time before bed may make subsequent sleep initiation very difficult. Because any of these factors may contribute to and perpetuate sleep difficulty, behavioral/psychological interventions that correct these anomalies are often required to eradicate the chronic sleep difficulty.

III. DESCRIPTION OF BEHAVIORAL INSOMNIA THERAPIES

Formal applications of behavioral interventions to insomnia were first reported in the 1950s but such treatments did not gain much popularity until the 1970s. Over the past 30 years, various behavioral insomnia therapies have been developed, tested, and, at times, modified. The nature and specific focus of these treatments has varied significantly in that some are composed of fairly formalized “exercises” designed primarily to address sleep-related performance anxiety and excessive bedtime arousal, whereas others include fairly regimented behavioral prescriptions designed to eliminate sleep-disruptive habits. The following discussion provides brief descriptions of the most commonly employed behavioral insomnia therapies.

A. Relaxation Therapies

Since the late 1950s a host of formal relaxation therapies including progressive muscle relaxation training, autogenic training, imagery training, biofeedback, and hypnosis have all been used to treat insomnia. Common to these approaches is their focus on such factors as performance anxiety and bedtime arousal, which often perpetuate sleep difficulties. Regardless of the specific relaxation strategy employed, treatment entails teaching the insomnia sufferer a formal exercise or set of exercises designed to reduce anxiety and arousal at bedtime so that sleep initiation is facilitated. Typically multiple weekly or biweekly treatment sessions are required to teach relaxation skills that the patient is encouraged to practice at home in order to gain mastery and facility with self-relaxation. The goal of all such treatments is that of assisting the insomnia sufferer in achieving sufficient relaxation skills so that insomnia resulting from sleep-related performance anxiety and bedtime arousal can be minimized or eliminated.

B. Stimulus Control

This approach, introduced by Richard Bootzin in 1972, is based on the assumption that both the timing (bedtime) and setting (bed/bedroom) associated with repeated unsuccessful sleep attempts, over time, become conditioned cues that perpetuate insomnia. As a result, the goal of this treatment is that of reassociating the bed and bedroom with successful sleep attempts. Stimulus control achieves this endpoint by curtailing sleep-incompatible activities in the bed and bedroom

and by enforcing a consistent sleep-wake schedule. In practice, stimulus control requires instructing the insomnia sufferer to (1) go to bed only when sleepy; (2) establish a standard wake-up time; (3) get out of bed whenever awake for more than 15 to 20 minutes; (4) avoid reading, watching TV, eating, worrying, and other sleep-incompatible behaviors in the bed and bedroom; and (5) refrain from daytime napping. From a theoretical perspective, it is probable that strict adherence to this regimen not only corrects aberrant, sleep-disruptive conditioning, but it also likely reestablishes a normal sleep drive and sleep-wake rhythm. From a practical viewpoint, this treatment has appeal since it is easily understood and usually can be administered in one visit. However, follow-up visits are usually conducted to ensure compliance and achieve optimal success.

C. Paradoxical Intention

As the name implies this treatment strategy employs a form of reverse psychology to address sleep difficulties. Designed mainly to address the excessive performance anxiety that contributes to sleep onset difficulties, this treatment instructs the insomnia sufferer to remain awake as long as possible after retiring to bed. In essence, the insomnia sufferer is placed in the paradoxical position of having to perform the activity of not sleeping when in bed. If the individual complies and genuinely tries to remain awake in bed, performance anxiety over not sleeping is alleviated and sleep becomes less difficult to initiate. Like the other treatments, an initial visit to provide treatment instructions and follow-up sessions to support the patient and ensure compliance are usually recommended when administering this intervention.

D. Sleep Restriction

Sleep restriction therapy (SRT) is a behavioral insomnia therapy wherein sleep improvements are achieved primarily by limiting or restricting the time allotted for sleep each night so that the time spent in bed closely matches the individual's actual sleep requirement. The treatment, first introduced by Arthur Spielman and colleagues in 1987, grew out of the observation that many insomnia sufferers spend excessive time in bed each night in efforts to obtain their elusive sleep. Indeed, many such patients may experience excessive time awake each night simply *because* they are allotting far too much time for sleep. Typically this treatment begins by having the insomnia sufferer maintain a sleep log on

which a record of each night's sleep is kept. After the insomnia sufferer has maintained a sleep record for 2 to 3 weeks, the average total sleep time (ATST) is calculated from the information recorded. Subsequently an initial time-in-bed (TIB) prescription may either be set at the ATST or at a value equal to the ATST plus an amount of time that is deemed to represent normal nocturnal wakefulness. However, unless there is persuasive evidence to suggest the individual has an unusually low sleep requirement, the initial TIB prescription is seldom set below 5 hours per night. Subsequently, the TIB prescription is increased by 15 to 20 minute increments following weeks the insomnia sufferer, on average, is sleeping greater than 85 or 90% of the TIB and continues to report daytime sleepiness. Conversely TIB is usually reduced by similar increments following weeks wherein the individual, on average, sleeps less than 80% of the time spent in bed. Since TIB adjustments are usually necessary, SRT typically entails an initial visit to introduce treatment instructions and follow-up visits to alter TIB prescriptions.

E. Cognitive Therapy

Underlying and supporting insomnia sufferers' performance anxiety and sleep-disruptive habits are a host of dysfunctional beliefs and attitudes about sleep. Beliefs that sleep is unpredictable and uncontrollable or that one must obtain 8 hours of sleep at night to function each day can add to anxiety about sleep and, in turn, interfere with the sleep process. Furthermore, insufficient knowledge about how one should respond to a night of poor sleep may lead to practices such as daytime napping or "sleeping in," which disrupt the ensuing night's sleep. Given increasing recognition of these types of sleep-related misconceptions, therapeutic strategies that specifically target these cognitions may be useful in insomnia treatment. Hence, cognitive therapy designed to correct these dysfunctional beliefs, either through formalized patient education modules or via the cognitive restructuring method similar to that commonly used in cognitive therapy with clinically depressed individuals, is often employed in the treatment of insomnia sufferers. Once again, usually multiple sessions of such treatments are provided in clinical applications of these cognitive therapies.

F. Cognitive-Behavioral Therapy

This treatment strategy might best be regarded as a second-generation behavioral insomnia treatment that

evolved from the above described strategies. Cognitive-behavioral insomnia therapy or CBT typically consists of one of the cognitive therapy strategies used in combination with both stimulus control and sleep restriction therapies. One presumed advantage of this treatment is that it includes treatment components that address the range of cognitive and behavioral mechanisms that perpetuate insomnia. As a result, this treatment should be more universally effective across insomnia sufferers regardless of their presenting complaint (i.e., sleep onset complaints vs. sleep maintenance difficulty). Admittedly, CBT is a multicomponent and seemingly more complex treatment than those previously described. Nonetheless, in practice, this intervention usually requires no more therapist or patient treatment time than do the less complex first-generation treatments reviewed above. Often CBT's cognitive therapy and behavioral instructions can be provided in no more than eight sessions, but some CBT models utilize as few as 2 to 4 sessions in their clinical applications. However, most current CBT proponents employ multiple treatment sessions to provide those they treat sufficient support and follow-up.

IV. EMPIRICAL STUDIES

Since their emergence, the behavioral insomnia therapies have been studied extensively. Indeed, well over 100 published studies have tested one or more of these treatments. A critical review of this voluminous literature is a daunting task and well beyond the scope of this chapter. Fortunately, in 1995 Douglas Murtagh and Kenneth Greenwood conducted a critical review of this literature in order to determine the general and relative effectiveness of the various behavioral insomnia therapies. In this review, they employed special statistical procedures to estimate treatment effects sizes for the behavioral insomnia therapies in general and for each treatment considered individually. As used in these analyses, the term treatment effect size reflected the average amount of difference (expressed as a fraction of the pooled standard deviation) observed between treated and untreated insomnia sufferers. Hence, a hypothetical effect size of 0.5, expressed in such terms, would indicate that treated individuals, on average, showed a half standard deviation improvement greater than those who were not treated. In clinical treatment studies, effect sizes in the 0.2 range are considered small, those in the 0.5 range are considered medium, and those 0.8 or greater are considered large.

FIGURE 1 Short-term and long-term treatment effects for the behavioral insomnia therapies. [Adapted from Edinger, J., & Wohlgemuth, W. K. (1999). *Sleep Med. Rev.*, 3, 1–18, by permission of W. B. Saunders.]

Figure 1 shows the treatment effect sizes reported by Murtagh and Greenwood for the behavioral insomnia therapies in general. This figure shows both the short-term (i.e., at the conclusion of treatment) and long-term (i.e., at follow-up) effect sizes for the behavioral insomnia therapies, considered collectively, for a number of subjective (sleep log) measures including sleep onset latency, number of nocturnal awakenings, total sleep time, and subjective sleep quality. It should be noted that all of the treatment effect sizes shown are in the medium to high ranges. Furthermore, these data indicate that patients treated with the behavioral insomnia therapies tend to appreciate additional improvements through extended follow-up periods, which averaged 8 months in length for the studies Murtagh and Greenwood considered. Such findings are particularly encouraging inasmuch as the behavioral treatments are devoid of the previously mentioned side effects and lack of long-term effectiveness noted with many sleeping pills.

When comparing the behavioral insomnia therapies with each other, Murtagh and Greenwood noted that stimulus control therapy produced larger treatment effect sizes than did the other treatments particularly on measures reflecting difficulty falling asleep, the number of nocturnal awakenings noted, and overall perceived sleep quality. Relaxation therapies and treatment combinations that usually included stimulus control and relaxation techniques produced the largest improvements in nocturnal sleep time. It should be noted, however, that the studies considered in this critical review included highly screened and selected insomnia sufferers

who generally had no accompanying medical or psychiatric illnesses. As a result, the effectiveness of these treatments in applied clinical settings with more “real world” patients remains questionable. Furthermore, most of these studies focused on sleep onset problems and excluded individuals who solely or primarily complained of sleep maintenance difficulties. This is particularly unfortunate because insomnia sufferers with sleep maintenance complaints far outnumber those who solely complain of a difficulty falling asleep. Finally, the relatively newer CBT approaches were not considered in this review because only in the last few years have well-controlled studies of this approach been reported. Hence, the findings reported by Murtagh and Greenwood leave several important questions about the behavioral insomnia therapies unanswered.

Over the past 5 years an increasing number of studies conducted to test CBT approaches have been published. This growing literature has shown that CBT is a promising insomnia treatment for a various types of insomnia sufferers. Specifically, these studies have shown that CBT produces clinically significant sleep improvements among those who suffer from either sleep onset or sleep maintenance difficulties. Furthermore, studies have shown that this modality is effective among insomnia patients who additionally suffer from significant sleep-confounding medical (e.g., chronic pain syndromes) and significant psychiatric (e.g., depression) disorders. Moreover, some very recent research has shown that paraprofessionals can be trained to administer effectively these treatments in “real world”

primary care settings. Finally, results of these studies generally show moderate to high treatment effect sizes across a variety of outcome measures. Although far from conclusive, these findings suggest that CBT is a promising behavioral insomnia therapy that likely represents an advancement over the first-generation therapies from whence it evolved.

V. SUMMARY

Chronic insomnia is a fairly prevalent and significant health concern that often is perpetuated by dysfunctional beliefs about sleep, heightened anxiety, and a host of sleep-disruptive compensatory practices. Whereas sleeping pills are often prescribed for this condition, such treatment may be encumbered with side effects and usually fails to address the psychological and behavioral anomalies sustaining the sleep problems. In contrast, the behavioral insomnia therapies are each specifically designed to address one or more of these perpetuating mechanisms. Research has shown that first-generation behavioral insomnia therapies such as stimulus control and relaxation training are moderately to highly effective particularly for ameliorating sleep onset difficulties with highly screened and perhaps clinically skewed samples. However, recent studies suggest that a multifaceted cognitive-behavioral therapy, which targets both dysfunctional sleep-related beliefs and sleep-disruptive habits, appears effective for sleep onset and sleep-maintenance insomnia. Furthermore, very recent studies suggest that this treatment is effective in applied clinical settings. These results are encouraging and suggest that behav-

ioral insomnia therapy has a deserving and important niche in the management of those insomnia sufferers who seek treatment.

GLOSSARY

classical conditioning Pavlovian or respondent conditioning that involves pairing a neutral stimulus with a stimulus that elicits an unconditioned response to yield a conditioned response to the neutral stimulus.

follow-up A specific point in time (e.g., 3 month follow-up), after which treatment has been terminated, when the researcher evaluates the stability of the results of the treatment intervention.

genotype genetic site for a particular characteristic.

kg of weight (1) = 2.2046 pounds.

meta-analysis A statistical technique in which the findings from a number of studies are combined to determine whether significant trends emerge.

reinforcement Contingent positive and negative events that follow a behavior and serve to increase the likelihood that a behavior will be repeated in the future.

resistance training Weight-lifting.

self-monitoring Keeping records of daily food intake and physical activity.

shaping The process of gradually learning a complex behavior by breaking the behavior into smaller parts and learning the components in succession.

stimulus control A technique used to limit or decrease the number of environmental cues that are associated with eating.

very low calorie diets (VLCDs) Dietary prescription in which daily caloric intake is limited to less than 800 kcal.

The behavioral treatment of obesity focuses on altering lifestyle by modifying one's eating habits and physical activity in order to achieve weight loss. The goal of this treatment is to achieve a negative energy balance, which is achieved via burning more energy than is consumed by eating. This article will present an overview of the behavioral treatment of obesity including a description of treatment, the theoretical bases underlying treatment, the applications and exclusions of treatment, the empirical studies investigating the efficacy of treatment, and a case illustration demonstrating the treatment approach.

I. DESCRIPTION OF TREATMENT

A. Basic Philosophy of Treatment

As described in the next section, lifestyle behavior modification for obesity is based on changing eating habits and physical activity to yield negative energy balance, that is, burning more energy than is consumed via eating. During the initial phase of treatment (approximately 26 weeks), weight loss occurs at a rate of approximately 1 to 2 lb. (.5 to 1 kg) per week and

gradually tapers to a weight plateau. After this first phase, the goal of treatment is weight maintenance, where the person learns to balance energy intake and energy expenditure. This section describes the primary components of lifestyle behavior modification during these two phases of treatment.

B. Components of Behavioral Weight Loss Interventions

1. Self-Monitoring

A central feature of behavioral weight loss interventions is self-monitoring of eating and exercise habits. Self-monitoring generally involves recording food intake and intentional efforts to increase physical activity. This monitoring should occur at the time of each behavioral event, that is, at each meal or snack or immediately after a bout of exercise. Self-monitoring also generally involves recording (1) environmental events associated with eating and exercise (e.g., place and time of day), (2) cognitive and emotional reactions (e.g., eating in response to stress), and (3) hunger ratings before and after eating. Self-monitoring serves several purposes: (1) enhanced awareness of habits, patterns of behavior, and amount of food eaten at meals and snacks, (2) record of behavior that can be used to evaluate progress and to set goals for reinforcement, and (3) dietary record that can be analyzed for the adequacy of the person's nutritional intake across time.

2. Stimulus Control

Stimulus control procedures are designed to alter the relationship between antecedent stimuli and eating and exercise habits. Commonly used stimulus control procedures are (1) eating at the same time and place at each meal, (2) slowing eating by putting utensils down between bites, (3) eating on small plates, (4) resisting the urge to have seconds, (5) eating while seated, (6) leaving a small amount of food on one's plate, (7) serving small portions of food, and (8) exercising at the same time each day. These procedures serve several functions: (1) extinction of the conditioned association between certain environmental events and unhealthy eating or exercise habits, (2) conditioning of a three meal/day eating pattern that is associated with specific environmental cues, (3) slowing the pace of eating, and (4) developing a consistent pattern of physical activity that becomes habitual.

3. Reinforcement/Shaping

As noted in the next section, the natural consequences of eating (e.g., the good taste of food and reduction of hunger) facilitate the development of overeating habits,

whereas the natural consequences of exercise (e.g., fatigue and muscle soreness) facilitate the development of a sedentary lifestyle. Furthermore, as a person gains weight, the natural consequences of exercise become even more aversive, resulting in less physical activity as obesity increases. Finally, the natural consequences of eating and exercise make conditioning of these habits highly probable. Unfortunately, alteration of the natural consequences of eating is essentially impossible without pharmacological or surgical intervention. On a more positive note, the development of healthy physical activity habits makes some of the natural consequences of exercise less aversive over time. Nevertheless, because these natural consequences are so difficult to modify, behavioral programs have typically tried to modify other reinforcers (e.g., social reinforcement or monetary rewards for behavior change).

The principle of shaping is generally employed when reinforcement contingencies are formulated. Shaping refers to setting small, but reasonable goals at first, and then gradually making them more challenging over the course of treatment.

4. Goal Setting

Behavioral weight control programs are generally very "goal oriented." Typically, the person will set a weight goal, a calorie goal, and an exercise goal. Also, individualized goals are usually established. These goals might include such things as cessation of eating certain types of foods (e.g., soft drinks), walking up stairs instead of using elevators, or modification of snacks (e.g., eating fruit instead of ice cream). As a general rule, the person is instructed to monitor success and failure in making these behavioral changes and this information is reviewed in each therapy session.

5. Behavioral Contracting

To enhance the person's motivation for achieving these goals, a procedure called behavioral contracting is often used. Behavioral contracting involves clearly specifying behavioral goals in terms of frequency, duration, or intensity (e.g., "I agree to walk at least 30 minutes per day for at least five days per week"). A behavioral contract generally includes some type of reinforcement contingency for successful attainment of the goal (e.g., "if I meet my exercise goal for this week, I will reward myself by purchasing a copy of my favorite magazine").

6. Meal Planning

Goals related to nutrient intake may take many forms (e.g., calories, fat grams, or dietary exchanges). In general, research has shown that explicit meal plans are

most effective for compliance. An explicit meal plan might include an actual menu to be followed each day. The use of portion-controlled foods that are prepackaged for use in diets can be quite useful for persons who have difficulty following a more general meal plan. Ideally, a dietitian should manage this aspect of the program.

7. Modification of Physical Activity

Programs to increase physical activity generally include increasing exercise and decreasing sedentary behavior. Research has found that aerobic exercise is the most effective form of exercise prescription and that compliance is best when the exercise program is incorporated into their normal lifestyle.

8. Problem-Solving

Formal training in problem-solving is a common component of most behavioral weight control programs. This type of training involves assisting the person to (1) identify problems that are obstacles to successful weight management; (2) define the problem in objective behavioral terms; (3) brainstorm about potential solutions to the problem; (4) conduct a cost/benefit analysis for each solution; (5) select a solution and develop a plan of action; and (6) evaluate the success or failure of the plan of action and revise it, based on this evaluation. This component of treatment is often useful in modifying obstacles that negatively impact compliance with the basic behavioral weight management program.

9. Social Support

Enhancement of social support for behavior change has been found to be a very important factor in successful weight management. Social support may be derived from a spouse, family member, or friends. In the treatment of childhood or adolescent obesity, involvement of the parents in the therapy program has been found to be very useful. Enhancement of social support is best accomplished by inviting family members and friends to attend some of the therapy sessions. In these sessions, support persons learn to reinforce healthy behavior change and are discouraged from engaging in actions that sabotage progress toward behavior change.

C. Components of Behavioral Weight Maintenance Programs

1. Relapse Prevention

Returning to old, unhealthy habits is a primary cause of relapse and regain of weight that has been lost. Relapse prevention programs generally assist in the identification of situations that place the person at risk for

returning to old, unhealthy habits and to develop specific plans to manage these high-risk situations. For example, parties might be a high-risk situation for overeating. The person might develop a plan of action that involves healthy eating before going to the party to reduce hunger and standing or sitting in areas that are away from tempting foods. Relapse prevention programs also often include a discussion of the distinction between lapses and relapse. People often engage in “all-or-nothing” thinking so that when they deviate from the behavioral prescriptions of the program, they feel as though they have failed, resulting in loss of motivation and returning to old habits.

2. Booster Treatment

Booster treatment generally involves periodic therapeutic contact during the period of weight maintenance. This therapeutic contact may take many forms, including face-to-face sessions, scheduled telephone calls, or asynchronous internet exchanges. Because obesity is now viewed as a chronic illness, most experts believe that some type of booster treatment may be needed over the course of an entire lifetime, if weight loss is to be successfully maintained.

3. Tool-Box Approach

In recent years, there has been a growing trend toward individually tailoring treatment. To accomplish individualized treatment plans, the weight management therapist needs a “tool box” with many therapeutic “tools.” For example, during the weight maintenance phase, the tools might include special programs to manage the holiday season or periodic portion-controlled diets to lose 5 to 10 pounds that have been regained.

II. THEORETICAL BASES

There is a significant genetic component to the development of obesity, and it is generally believed that some interaction of genetics and environment may predispose selected persons to gain weight. For example, one genotype may predispose someone who consumes a diet high in fat to become obese. Another genotype may predispose someone who consumes a high carbohydrate diet to become obese. The focus of a behavioral intervention incorporates modification of eating behaviors and physical activity to yield energy imbalance. Figure 1 illustrates the relationship between body weight and changes in energy intake and energy expenditure.

When the energy consumed exceeds the amount of energy burned, the long-term result is excess body

FIGURE 1 Body weight as a function of energy intake and energy expenditure.

weight caused by storage of “extra” energy in body fat stores. The primary source of energy consumption is the food (and beverages) that individuals consume. Energy expenditure, or the energy that individuals “burn” is derived from several sources: (1) physical activity (about 25%), (2) basal metabolic rate (about 70%), and (3) the thermic effect of food (about 5%). Metabolic rate and thermic properties of food are not easily altered by behavior. However, certain drugs can increase (or decrease) these metabolic responses. Therefore, behavioral weight loss programs generally focus on the modification of eating behavior and energy expenditure that results from increased physical activity.

The term positive reinforcement refers to environmental events that increase the likelihood that a behavior will be repeated. The reinforcing properties of eating may include the taste and pleasurable sensations associated with eating food, a feeling of wellness associated with eating or with physiological sensations of satiety. In general, individuals are likely to engage in a behaviors in order to achieve short-term, immediate reinforcement. As such, individuals who are highly motivated by the immediate consequences of eating may be prone to overeat. Conversely, the short-term consequences of physical ac-

tivity may be somewhat unpleasant for some individuals; physical exercise may be associated with fatigue, muscle soreness, and boredom. When trying to motivate change of these habits, it is important to emphasize the long-term consequences of healthy eating and physical activity. The long-term consequences of healthy eating are weight loss and improved health; the long-term consequences of physical activity include increased energy, weight loss, and general health improvements. Indeed, once individuals engage in a regular physical activity regimen, it is likely that the short-term consequences of exercise will become rewarding (i.e., muscle soreness diminishes, and individuals may experience improved mood following exercise).

Classical conditioning refers to the set of circumstances by which cues in an individual's environment become associated with a particular behavior. When an environmental stimulus is repeatedly paired with a behavior, the stimulus itself becomes a “trigger” to elicit a behavioral reaction. In the case of eating behavior, many aspects of the environment may become associated with hunger sensations and with eating. The smell or sight of food may become conditioned stimuli to eating and therefore trigger hunger sensations. This association is

conditioned because the smell and sight of food are repeatedly paired with eating behavior. However, additional stimuli, when paired with eating, may become associated with feelings of hunger. For example, if an individual habitually eats while watching television, then hunger sensations can be elicited by watching TV (independently of physiological hunger). It is important to distinguish between physiological and psychological hunger. Physiological hunger refers to the physical process by which the body signals a need to eat. Psychological hunger refers to the perception of hunger, which may be independent of energy depletion. Psychological hunger is often the result of classical conditioning. For example, after repeatedly eating while watching TV, the television may become a conditioned stimulus for "hunger." In essence, television watching will elicit hunger sensations. In response to this type of conditioning, stimulus control procedures are implemented to limit the cues or stimuli in an individual's environment that are associated with eating.

Obesity is not a psychiatric disorder. However, it has been estimated that as many as 10 to 25% of individuals seeking obesity treatment engage in binge eating behavior. It is important to note, however, that not all obese individuals binge eat. As defined by the *American Psychiatric Association Diagnostic and Statistical Manual for Mental Disorders, 4th Edition*, binge eating occurs when one consumes an amount of food that is significantly larger than normal in a discrete period of time. During binge episodes, individuals report feelings of loss of control over their eating. Research indicates that binge eating frequently arises in response to dietary restraint; as individuals engage in strict dietary restriction, they experience strong physiological hunger, which then leads them to binge eat. Further, individuals with rigid rules about the kinds of foods they will allow themselves to eat may engage in binge eating once they have broken a rule about eating. Binge eating may also arise in response to negative emotions; because eating is a pleasurable activity for most people, the binge episode may serve to ease the negative mood. However, binge eating is frequently followed by feelings of extreme guilt and other negative emotions, which may therefore perpetuate the cycle of binge eating.

III. APPLICATIONS AND EXCLUSIONS

In general, behavioral weight control therapies should be matched to the individual. Because of the lifestyle be-

havior change required by the program, an individual's motivation for treatment and willingness to implement the behavioral changes required must be assessed. For example, certain individuals may not be willing to take medication or may be resistant to particular aspects of a behavioral program. Treatment effectiveness will be contingent upon the client's willingness and ability to engage in all aspects of the weight loss regimen.

Cultural issues may also influence a client's willingness and motivation to lose weight. For example, the stigma of obesity varies across cultures. Women, more than men, are likely to attempt weight loss for appearance reasons. Men are more likely to enter into obesity treatment programs when they believe that their overweight status has deleterious health effects. African Americans are less likely to experience social pressures to lose weight and may therefore be less motivated to seek treatment. For some people, it may be beneficial, therefore, to emphasize the health-related benefits of weight loss rather than the appearance-based reasons for weight loss.

In addition, an individual's physical health must be considered when prescribing caloric restriction and a physical activity regimen. A physician should be consulted to assess the safety of caloric restriction. Likewise, a dietitian or nutritionist should be consulted in formulating dietary recommendations. Individuals with Type II diabetes or cardiovascular disease may require special diets and medical monitoring throughout the course of any weight loss program. Further, overweight individuals may experience knee or other joint problems; in such cases physical activity may be limited. Consultation with a medical doctor, physical therapist, and/or exercise physiologist is indicated in such cases.

It is also important to consider the psychological sequelae of obesity. In American culture, there is a stigma associated with obesity. The "obesity stereotype" is that people who are overweight tend to be less socially competent, lazier, and less intelligent than normal weight individuals. In addition, most obese people have experienced various forms of discrimination and teasing about their weight. As a result, obese people often suffer from low self-esteem and may be very concerned about their body shape. In addition, many individuals may have attempted unsuccessfully to lose weight in the past, or they may have lost weight only to regain it later. A pattern of unsuccessful weight loss attempts frequently leads to frustration and lowered self-esteem. It is important that clinicians remain sensitive to these issues when treating obesity.

Finally, it is important to identify individuals with eating disorders. The most common type of eating disorder

associated with obesity is binge eating disorder. Binge eating disorder is characterized by recurrent episodes of binge eating in which the individual consumes large amounts of food and perceives a loss of control over eating. Unlike the pattern of behavior observed in bulimia nervosa, binge eating episodes in binge eating disorder do not occur with compensatory behaviors to prevent weight gain (e.g., fasting, purging, exercise). Binge eating disorder occurs in less than 2% of obese people, although binge eating as a behavioral symptom is much more common (10% to 25%). Other problems that are often observed include bulimia nervosa, nonpurging type and preoccupation with body size and shape, as the source of all of the person's problems. When such problems are identified, the treatment strategy should incorporate a component to reduce the frequency of binge episodes and overconcern with body size and shape. In addition, clinicians should carefully monitor the emergence of other eating disorder symptoms that may emerge over the course of treatment.

IV. EMPIRICAL STUDIES

A. Early Studies (1967–1990)

Behavioral methods for the treatment of obesity were first applied over 30 years ago. In 1967, Richard B. Stuart was among the first to describe the application of learning principles to the treatment of obesity. His first behavioral program successfully treated eight overweight women, who attained an average weight loss of 17 kg over a 12-month period. It was Stuart's early success story that sparked researchers' interest in this approach to the treatment of obesity.

The research studies that followed in the 1970s were modeled on Stuart's behavioral weight control program; however, there were some notable differences in the application of the treatment protocol. In Stuart's program, he used an individualized approach, tailoring the program to fit the needs of the individual patient. Treatment sessions took place three times per week for the first 4 to 5 weeks, then less frequently as treatment progressed. The studies of the 1970s that followed Stuart's early studies moved in a different direction. These studies delivered treatment to small groups of 6 to 10 persons and usually met once per week for 12 to 16 weeks. As noted by Don A. Williamson and Lori A. Perri, in 1996, this approach to behavioral weight loss treatment resulted in less impressive results (average weight loss of about 4 to 5 kg).

Since the 1970s behavioral treatment programs for obesity have been intensified in terms of length and aggressiveness, yielding average weight losses of about 8.5 kg. However these weight losses usually occur in the short term and are not maintained in the long term, after treatment ends. Most persons who receive behavioral weight control regain much of the weight that was lost, although the regain of weight usually takes about 5 years. On average, most people reach their maximum point of weight loss about 6 months after the initiation of treatment. After treatment ends, weight regain ensues, and over a period of time, persons gradually regain the weight that was lost over the 6 months of treatment.

B. Intensive Lifestyle Behavior Modification (1990–2000)

1. Increased Duration of Treatment

After the trend of regaining weight was noted, behavioral researchers in the 1990s tried to identify more effective long-term strategies. One strategy was to increase the length of treatment. Treatment length increased from an average of 8 weeks in 1974 to an average of 21 weeks by the 1990s. Comparable increases in weight loss have occurred with increases in treatment duration. In 1974 the average weight loss associated with the 8-week treatment protocol was 3.8 kg, and in 1990, the average weight loss associated with a 21-week treatment protocol was 8.5 kg. In 2000, Robert W. Jeffery and colleagues estimated that average weight losses in behavioral treatment studies have increased by approximately 75% between 1974 and 1994, and that this approximate doubling of average weight loss has occurred in conjunction with the approximate doubling of treatment duration in the last 20 years. In 1989, M. Perri, A. Nezu, E. Patti, and K. McCann reported that treating participants for 40 weeks as opposed to 20 weeks was associated with more weight loss. In a review of this research in 1998, Perri concluded that extended contact with participants yielded better weight loss. Therefore, longer duration of treatment has been consistently associated with greater weight loss.

2. Very Low Calorie Diets and Meal Planning

One way of improving weight loss is to incorporate a very low calorie diet (VLCD), defined as less than 800 kcal/day, into the treatment protocol. Most behavioral

weight control programs have used low calorie diets (LCD), which usually consist of approximately 1200 to 1500 kcal/day. Thomas A. Wadden and Albert J. Stunkard's initial study, which was conducted in 1986, and studies that followed, consistently found that a VLCD combined with behavior therapy was more successful than a LCD combined with behavior therapy, in producing more initial weight loss (in the short term); however, this initial weight loss did not improve long-term outcome. Williamson and Perrin reported on the results of several studies, which used VLCDs in addition to behavior therapy. They noted that the addition of behavior therapy to a VLCD, in the active treatment phase, did not yield weight loss above that usually associated with VLCDs alone; however, the addition of behavior therapy did seem to slow the rate of weight regain.

In addition to VLCDs, diets that are more structured have also been emphasized. According to Rena Wing, food provision (actually providing the persons with the appropriate food) was effective in improving the amount of initial weight loss in one study, but was no more effective in the long term than was a condition that had a standard calorie goal of 1000 to 1500 kcal/day. Subsequent studies have found that the most important component of food provision is the provision of structured meal plans and grocery lists (not the provision of food, *per se*), which appear to exert their effects by assisting people in selecting healthy foods, and by creating a regular meal pattern (i.e., breakfast, lunch, dinner).

3. Exercise

Unlike the dietary approaches mentioned above, increased attention to exercise has been related not only to enhanced short-term weight loss, but also long-term weight loss. In fact, the benefit of exercise has been particularly effective in the long term. Recent research has focused on type of exercise that may produce the best weight losses. In 1995, R.E. Anderson and colleagues found no differences in treatment programs using aerobic exercise, resistance training (weight lifting), or the combination of aerobic exercise and resistance training (although all yielded significant weight losses). In 1985, Leonard Epstein and colleagues reported that lifestyle exercise (e.g., using stairs instead of an elevator), produced somewhat more weight loss in children than did aerobic exercise, although both of these types of exercise promoted far better weight maintenance than did calisthenics. Similarly, in 1995, these researchers found that children who were taught to decrease sedentary activities had greater decreases in percent

overweight than the group that was taught to increase aerobic exercise. Kelly D. Brownell and Thomas A. Wadden, in 1992, speculated that exercise may be beneficial in the long term for physiological or psychological reasons. It is possible that exercise is effective in the long term because it increases lean body mass, elevates metabolic rates, or decreases appetite. With regard to the psychological effects of activity, the authors noted that even the smallest amounts of exercise (e.g., parking further away from a store) can have positive effects on mood and self-efficacy.

4. Social Support

Enhancement of social support has been tested as a means of improving long-term weight loss. The most common way to enhance social support has been to include spouses or significant others in the treatment process. A 1990 meta-analysis revealed that there are both short-term and long-term benefits to including spouses in obesity treatment. In 1999, Wing and Jeffery found similar results with the inclusion of friends in the treatment process, revealing that persons who entered treatment with friends had better success at maintaining weight losses 6 months after a 4-month behavioral treatment program.

5. Increased Therapist Contact During the Maintenance Phase

Obesity researchers have tested the impact of increasing therapist contact during the weight maintenance phase, as a means of facilitating long-term success. In 1984, Perri and colleagues found that the addition of posttreatment therapist contact via the telephone and mail significantly enhanced maintenance of weight loss for a group that received behavior therapy plus relapse prevention training. In the same year, Perri reported similar results with the use of booster sessions to enhance maintenance of weight loss. In 1989, Perri and colleagues reported that women in a behavioral weight control program that received 1 year of additional contact (biweekly treatment contacts of various sorts), maintained their weight losses better than the group of women who received no contact during the maintenance phase. In recent years the internet has been employed as a means of increasing therapist contact to improve long-term weight maintenance, and preliminary results of this approach are encouraging.

6. Relapse Prevention

Relapse prevention components have been tested as one means of achieving better long-term weight

maintenance. In 1996, Williamson and Perrin concluded that development of the skills to respond immediately to overeating or to a small weight gain is useful to prevent relapse. In 1995, Rita G. Drapkin, Rena R. Wing, and Shaul Shiffman reported that those subjects who were able to generate more coping responses to hypothetical high-risk situations were most successful in weight management.

7. Secondary Prevention

Secondary prevention of obesity, aimed at children, appears to be a promising approach for the treatment of obesity. In 1990, Leonard H. Epstein and colleagues found that when comparing a therapy program attended by both child and parent (in which both were reinforced for weight loss and behavior change), the children lost more weight than those children who attended a child only program, without a parent (in which only the child was reinforced for behavior change), or a nonspecific control treatment (which reinforced families for their attendance). At 5- and 10-year follow-ups, the children in the child and parent treatment program had significant decreases in overweight when compared to the nonspecific control group, and the children in the child only group were midway between these two groups. These findings suggest that early interventions with overweight children may be a useful method of preventing chronic obesity in adulthood. Because obese children are 6.3 times more likely to be overweight adults than are nonobese children, Wing has advocated secondary prevention targeting obese children as an important public health initiative.

8. Pharmacotherapy

Drug therapy has been used in conjunction with behavior therapy to improve weight loss and maintenance. Currently, there are three medications that can be used for short-term weight loss. These are (1) phentermine, (2) the combination of caffeine and ephedrine, and (3) phenylpropanolamine. In terms of long-term weight loss, Michael Weintraub, in 1992, conducted a 3-year trial of fenfluramine and phentermine ("fen-phen"). Although this drug combination appeared to be very promising and attracted widespread attention, "fen-phen" was found to be associated with heart valve damage in a substantial number of its users, and was abruptly taken off of the market in 1997. Despite this health scare, the enthusiasm for the possibility of new long-term drugs to aid in weight loss has not been lost. The Food and Drug Administration has now approved two weight loss medications for long-term use. In 1996,

sibutramine (Meridia), a serotonin reuptake inhibitor, was approved and in 1999, orlistat (Xenical), a medication that inhibits digestion of dietary fat, was approved. Jeffery and colleagues assert that most weight control medications to date have shown maximum efficacy when combined with behavior modification programs. However, in general, the addition of behavior therapy does not seem to prevent the regaining of weight after medication is withdrawn. Thus, current research evidence indicates that neither medication, behavior therapy, nor the combination of the two "cures" obesity. Instead, this research suggests that obesity is best conceptualized as a chronic medical condition that requires continuous management.

9. Chronic Disease Concept

In 1998, the Obesity Education Initiative Expert Panel (of the National Institutes of Health) reported that obesity is now recognized as a chronic disorder that requires continuous care. Today, behavioral weight control therapies conceptualize the treatment of obesity in terms of a chronic disease. Behavioral weight control therapies for obesity are clearly effective treatments for weight loss, but like all other treatments for obesity (with the possible exception of surgery), behavior therapy does not lead to long-term maintenance of weight loss, after weight loss treatment is terminated, but behavior therapy plays many important roles in the management of obesity: (1) behavior therapy may be useful when used in a stepped care approach for the moderately obese, who have not been successful at losing weight without the help of a professional, (2) behavior therapy could be used with persons who are withdrawing from pharmacotherapy and who may benefit from behavior therapy in an effort to maintain weight loss, and (3) behavior therapy may be useful for persons who are able to maintain weight loss, by establishing behavior therapy support groups to provide social and therapeutic support for the long term. In order for such an approach to be effective, major centers would need to establish long-term counseling programs and make them available at little or no cost to obese patients. By using this public health approach, obesity could be addressed in an ongoing manner as a chronic illness, as opposed to an acute disease.

V. CASE ILLUSTRATION

Brian was a 20-year-old Caucasian male who weighed 323 lb. with a height of 6 ft 2 in. Brian had

been overweight since childhood. His identity was highly connected to being obese. For example, he delivered pizzas and took great pride in consuming multiple pizzas if they could not be delivered. His friends were amazed at his appetite and ability to consume very large quantities of food. He was enrolled in college, but was on the verge of flunking out of school at the time of the referral. He reported eating binges, but they were atypical in that they were not secretive and he did not experience guilt or negative feelings following the binges. He had never seriously attempted dieting to lose weight and he was very sedentary, but in generally good health other than his rather significant obesity. His family was intact, with a mother, father, and older brother, who had experienced problems related to substance abuse.

Brian was seen in individual therapy for over 2 years. Family therapy was also incorporated into the treatment plan. Treatment followed the protocol described by Williamson and colleagues in 1996. Initially Brian was seen once per week in individual therapy and the frequency of therapy sessions was gradually faded to bi-weekly and then once per month over the course of the first year. He was seen about once per month during the second year of therapy. All components of the behavioral management program (described earlier) were used in Brian's therapy program, including self-monitoring, stimulus control procedures, reinforcement/shaping, goal setting, behavioral contracting, problem-solving, meal planning, modification of physical activity, relapse prevention, and enhancement of social support. Toolbox approaches were used to individualize treatment. Behavioral therapy for binge eating was used to modify skipping meals and cognitive approaches were used to modify beliefs about the "benefits" of binge eating. Also, family therapy was used to alter the communication patterns of the family. Brian's parents and brother talked about Brian in terms of being the obese son with the big appetite. They gave him considerable attention for his "huge appetite" and mildly scolded him for engaging in dietary restraint. Family therapy was devoted to reverse the behaviors to which the family members attended so that they reinforced efforts to control eating. They learned to help Brian eat three healthy meals per day and did not attend to eating binges.

At first, Brian struggled with the behavioral weight management program. Over the course of the first 3 months, he lost only 4 pounds, primarily because he continued to engage in binge eating. However, from months 3 through 6, he was more successful and lost an additional 36 pounds. During the next 6 months, he

began to substantially increase physical activity. He began running and lifting weights. During this 6-month period, he lost 40 more pounds. Over the second year, Brian consolidated most of the behavioral changes that he had made and continued to increase his physical activity. He eventually lost 100 pounds and weighed between 220 and 225 pounds. He graduated with a bachelor's degree in finance and eventually enlisted in the military. He is now a career officer in the military and has successfully maintained his weight loss for the past 10 years. He is married and has two children. He reports that he occasionally has urges to binge, but can control the urges with effort to direct his attention away from eating and by focusing upon engaging in exercise. He never developed symptoms indicative of an eating disorder although he clearly emphasizes the importance of exercise as a means of managing his body weight.

VI. SUMMARY

Behavioral weight control therapies involve two primary phases: (1) weight loss, and (2) weight maintenance. During the period of weight loss, energy intake via eating is reduced and energy expenditure due to physical activity is increased. A variety of therapeutic techniques are used to modify these habits. During the period of weight maintenance therapy, the person learns to match energy intake (eating habits) with energy expenditure (exercise). Research has found that long-term therapeutic support is often required for long-term weight maintenance.

GLOSSARY

cognitive-behavior therapy This therapy involves a set of principles and techniques that stress the reciprocal relationship between thoughts and feelings. Its underpinnings rest on experimental psychology, particularly social learning theory. Most normal and abnormal behaviors are considered to be maintained and modified by environmental events. In treatment, the emphasis is primarily on current determinants of behavior. Direct problem solving is an integral part of this form of therapy.

modeling Basically, modeling consists of learning by observation. For example, a client may accompany the therapist to a store to observe the assertive return of faulty merchandise. Therapists may perform several target behaviors, which the client imitates and then adopts into his or her own repertoire.

role-playing There are many settings in which acting the part of another person for educational or therapeutic purposes proves helpful. For example, employees may be trained, via role-playing, to handle problems with customers, to present an impressive sales pitch, to learn how best to interact with their superiors or subordinates, and so forth. In therapy, clients may rehearse ways to cope with stress and family conflicts.

self-efficacy People estimate and judge their own capabilities of organizing and executing various courses of action. Their behaviors will be heavily influenced by whether or not they perceive themselves as capable of attaining specific goals. In many situations, to successfully accomplish a desired outcome, a person needs to be convinced of his or her effectiveness, strength, or power to do so.

social learning theory A point of view that explains simple and complex behaviors by combining data derived from conditioning with known facts of cognitive mediation. Thus, there is emphasis on overt learning (e.g., habits), vicarious learning, and symbolic activity (e.g., language) to account for the development, maintenance, and modification of behavior.

social skills training Social skill is a construct that includes a broad array of interpersonal competencies including assertiveness, warmth, empathy, conversational facility, perceptiveness, good listening skills, and clarity of verbal expression. In therapy, where a deficit in any of the aforementioned factors is behind a client's distress, he or she will be trained (via role-playing, modeling, and didactic instruction) to try to remedy the situation.

I. DESCRIPTION OF TREATMENT

A. Definition

The term behavior rehearsal is used to describe a specific procedure that aims to replace deficient or inadequate social or interpersonal responses by efficient and effective behavior patterns. The patient or client

achieves this by practicing the desired forms of behavior under the direction of a therapist. Thus, before asking for a raise, an employee might be advised to rehearse exactly what to say and how to say it.

Cognitive-behavior therapy emphasizes that psychological problems may stem from misinformation (faulty reasoning, dysfunctional beliefs, erroneous ideas) and missing information (skill deficits, gaps in knowledge). Clients who do not know how to behave appropriately and effectively in specific situations must be taught the necessary skills. The therapist responds much like the director in a movie who coaches a character actor to master a role. Thus, take for example a man who is at a loss for words when receiving unfair criticism from his employer. Typically, the therapist will commence by playing the part of the employer, while the client endeavors to respond appropriately. The enactment is usually audiotaped or videotaped so that the client may analyze the playback. The client then assumes the role of his employer, while the therapist models an appropriate response to the criticism. Again, recorded playbacks may be reviewed. Special attention is paid to expressive elements (speech content, as well as paralinguistic factors such as voice, pace, pitch, and tone). In addition, nonverbal behavior is scrutinized, especially eye contact and facial expression. The client enacts the role again and again until he and the therapist are satisfied with his performance. At this stage, the client is encouraged to test his skills in the actual situation.

A brief account of an actual case history may clarify the foregoing:

A 32-year-old architect had consulted several therapists for help with his feelings of depression and anxiety. They discussed his childhood, interpreted his dreams, and one of his doctors prescribed antidepressant medication—all to no avail. The client had become aware of cognitive-behavior therapy and decided to consult a psychologist who was well versed in this approach.

During the first session, it became clear that his problems had developed soon after he became a fully fledged architect and started looking for a job. Although his grades in school had been excellent, he never obtained employment that matched or utilized his abilities. He was usually hired by small firms on a temporary basis and was given work to do that was beneath him. He had applied to many distinguished organizations, went on interviews, but was never hired.

What methods should be used to help this frustrated and unhappy man? Is there any evidence that his problems could best be resolved by delving into his past, in-

terpreting his dreams, or simply encouraging him to ventilate his dissatisfactions? The answer is "No." Regrettably, many therapists still believe in and adhere to these old-fashioned methods. Yet modern psychotherapy has come to regard the best treatment process as a form of education, where clients are trained to remedy gaps in their repertoires.

Therefore, after giving the architect some psychological tests and studying a detailed life history inventory that he had filled out—thereby obtaining an overview of his past and present functioning—the therapist was able to select a treatment strategy that made the most sense. One factor stood out. The client's communication style was extremely unimpressive. He mumbled, swallowed his words, spoke too softly, and made little eye contact—none of which inspired much confidence or respect. Given his unfortunate style and demeanor, it seemed likely that prospective employers would not be impressed. Thus, "behavior rehearsal" was administered.

Therapist and client role-played job interviews. The therapist pretended that he was a potential employer, and the client discussed his credentials and answered questions. A tape recorder was switched on. In listening to some five minutes of the simulated interview, it was evident that the client had undersold himself and had come across poorly. The therapist then switched roles—he was now the architect, and he demonstrated how the client could emphasize his excellent training and occupational strengths, make eye contact, project his voice, and speak clearly. Over four hour-long sessions that took place over two weeks, the therapist and client rehearsed different interviews, stressing nonverbal aspects such as eye contact, firm handshakes, and good posture, and they practiced exactly what the architect would say and how he would sound. Not surprisingly, the client then went on a real job interview and gained employment with a highly prestigious company at a salary that was indeed commensurate with his abilities. He no longer complained of depression or anxiety. At a followup interview a year later he described himself as "generally more confident" and said he was "doing extremely well."

II. THEORETICAL BASES

We have already alluded to the social learning theory paradigm as the base on which behavior rehearsal rests. In 1958, Joseph Wolpe, one of the pioneers of behavior therapy, borrowed the term psychodrama to describe role-playing scenarios that were used to encourage

unassertive clients to stand up for their rights. He emphasized that unlike Moreno's original psychodrama, it did not consist of encouraging clients to act out their underlying attitudes in relationships. Instead, with the therapist playing the role of someone to whom the client ordinarily reacted with excessive anxiety, he or she was directed to behave in a new, usually assertive manner. Wolpe's assumption was that this outward display of new (assertive) behavior would reciprocally inhibit the anxiety. He stressed that when the client is able to deal successfully with the "play" situations in the office, it is a steppingstone toward dealing with the real-life situation. Instead of calling this process "psychodrama," I pointed out that the play-acting of prescribed behavior might better be called behavior rehearsal, and this became the accepted term.

In a book that Wolpe and I co-authored in 1966, the following statement appears:

Where the patient's reaction pattern is considered deficient or inappropriate, he is required to re-enact the incident while the therapist plays the role of the other person(s). The therapist may then switch roles and act the part of the patient, sometimes presenting a deliberately over-dramatized picture of assertion, thus affording the patient an opportunity for learning adaptive responses by imitation.

This perspective opened the door for behavior rehearsal to be construed as a process of social influence that transcended the reciprocal inhibition explanation that new behaviors control the underlying anxiety. It tied behavior rehearsal to the vast literature on role-playing, and it went beyond a focus on assertive training to the much broader realm of social skills training.

Today, self-efficacy as propounded by Albert Bandura may be the theoretical base that most aptly accounts for the value of behavior rehearsal. Before venturing into any course of action, a person first needs to feel capable of achieving success. Entering a situation unprepared, unrehearsed, and feeling unskilled is unlikely to yield a successful outcome. Individuals' beliefs about their own degree of efficacy will determine whether they feel optimistic or pessimistic, what courses of action to pursue, how much effort to expend in trying to achieve specific goals, and the degree of perseverance likely to be displayed in the face of impediments. Many studies have confirmed the significant role of perceived self-efficacy in human adaptation, coping, and change. These findings extend far beyond the consulting room or the clinic and include educational systems, business organizations, athletic teams, and even the power plays in

urban neighborhoods with violent crime. In the clinical arena, it is not surprising that when clients are trained, rehearsed, coached, instructed, and guided towards a desired achievement or end, their sense of self-efficacy increases dramatically.

III. EMPIRICAL STUDIES

Behavior rehearsal is part of the general field of social skills training and a variety of role-playing techniques that have been developed. As already mentioned, the method has been widely used and includes areas that fall outside the clinical or psychotherapeutic arena. Thus, reports abound in which it has been applied to employees in business and industry (e.g., for handling problems with customers). Behavior rehearsal has been used extensively in helping people deal with stress in family conflicts. For example, it has been applied to marital situations where the partners' distress is a function of poor communication styles. The case has even been made for regarding the entire enterprise of psychotherapy in terms of skills training.

Many years ago (1966) I conducted a study in which behavior rehearsal was compared to nondirective therapy and advice in effecting behavior change. Clients with response deficits in assertiveness and other interpersonal transactions were randomly assigned to receive specific role-playing and behavior rehearsal procedures, they were treated via nondirective person-centered (Rogerian) reflection, or they were given advice on how to deal with their difficult situations.

If, for instance, a client complained that he felt resentful of his older brother's plans to admit their aged father to a nursing home without first discussing the matter with him, the person-centered therapy might have proceeded as follows:

Therapist: So you are angry and perhaps hurt that you were not consulted in the matter.

Client: Right. Frankly, I know of a far better facility, and I wish he had shown me the courtesy and respect of discussing it with me.

Therapist: You feel disrespected.

Client: Yes I do. It's as if my opinions do not count. I'm informed about it when the matter is fait accompli.

Therapist: So it was too late for you to provide potentially helpful information.

Client: Correct. I think I should share my feelings about this with my brother. But I'm not sure how to go about it.

Therapist: You don't quite know what to say to him.

Client: I want to get my point across without making unnecessary waves.

Therapist: You're not quite sure how to go about it.

A client in the advice-receiving mode would be managed more or less as follows:

Therapist: I think it would be good for you to get it off your chest and tell him how you feel about it.

Client: I agree, but I wonder how I can do it without causing needless resentment:

Therapist: Well, when you bring up the topic, don't put him down, don't chastise him. Discuss your own feelings. Use "I feel" messages and not "You are" messages. Do you know what I mean by this?

Client: I think so.

Therapist: Well, in essence, do not say to him "You are wrong for not having discussed it with me." Rather say, "I feel hurt that I was left out of it."

Client: But how should I bring up the subject?

Therapist: You can always say something like, "I want to chat with you about the way I feel about the nursing home dad is in."

Client: Okay. I guess I could then say that Greenacres is a much better place for the elderly.

Therapist: Right. And then you could say that you wish he had discussed the matter with you before making a final decision.

Client: Sounds good to me.

Therapist: So when will you talk to him about it?

Client: Probably this week.

Therapist: Good. The sooner the better because it is playing on your mind.

The behavior rehearsal procedure would have been conducted along the following lines:

Therapist: Let's pretend that I'm your brother. I'll switch on the tape recorder, and we can have a little dialogue and then listen to it.

Client: Fine.

Therapist: Okay. Why don't you start?

Client: Actually, I'm not quite sure how to start the conversation.

Therapist: How about saying, "I want to discuss the nursing home dad is in?"

Client: (role-playing) There's something I need to talk to you about. I've been treated as if I'm chicken liver. You didn't even ask me for my opinion about which nursing home would be best for dad.

Therapist: Let's stop a moment. You have launched an attack. Let's just listen to that brief playback on the recorder. Don't you agree that it will put your brother on the defensive?

(Client and therapist review the brief opening salvo.)

Client: I see what you mean.

Therapist: Let me be you now, and let's put on the recorder again. (role-playing) I feel hurt and put down that I was never asked for any input re dad's future.

Client: I didn't think of asking you because you have never shown much interest in the matter. All I knew was that you'd prefer dad to be within commuting distance from us.

Therapist: (no longer role-playing) Is this what he'd say to you?

Client: Yes. I'm pretty sure of it.

Therapist: All right. How would you respond?

Client: I'd probably say, "That's garbage! I'm just as interested in dad as you are."

Therapist: You are still on the attack.

Client: Well, that's what I'm afraid of. I'm so mad at him. I'd probably just blow up.

Therapist: Then let me be you now. (role-playing) I'm very concerned about dad's comfort and his welfare. I want the best for him. I think there are far better facilities.

Client: Don't be such a jerk. How come you are suddenly such an expert on nursing homes?

Therapist: Let's not miss the point. All I am saying is that I feel entitled to be involved in the family decision making, and I am also asking if several places had been looked into.

Client: (no longer role-playing) I see what you're doing. You are simply sticking to the issues.

Therapist: Exactly. Now let's start from the beginning. Talk to your brother.

Client: (role-playing) I want to share some feelings with you about dad and the nursing home situation. In the first place, I am bothered that I was not consulted, and second, I wonder if he is now in the best vicinity around here.

Therapist: That's much better. But you were looking down at your feet. Try to look him in the eye. Now let's go over the entire conversation and see if you can avoid launching an attack.

It is perhaps not surprising that, at the following therapy session, clients who received behavior rehearsal are far more inclined to report having confronted the issue than those who received advice or nondirective therapy. When conducted in groups, behavior rehearsal is often even more robust. Role-playing in a group is apt to be more authentic. For example, a man who is awkward about asking women out on a date is more likely to benefit when role-playing in a group with an attractive woman than when the male therapist plays this particular role. Peer pressure in a group and the wider range of feedback available also tend to augment positive outcomes.

IV. SUMMARY

Social skills training is one of the important aspects of social learning approaches to clinical problems. The implication is that many people fail in their interpersonal dealings because they have response deficits—they do not know how best to approach others, how to make assertive rather than aggressive responses, and how to express their feelings in an adaptive manner. Coaching, training, and modeling are integral aspects of the specially focused role-playing procedures called behavior rehearsal. This technique has been widely applied within and outside clinical situations to include business organizations, athletic teams, and educational settings. When used in a group, behavior rehearsal tends to be especially effective.

GLOSSARY

applied behavior analysis Uses techniques derived from operant conditioning to modify behaviors of personal and social importance based on the notion that behavior is a function of its consequences.

behavior Behavior is what organisms do. With humans, behavior includes public or overt actions (e.g., walking, talking) and covert actions such as thinking, feeling, emoting, remembering, problem solving, self-observing, and the like. Some behavior therapists define behavior narrowly in terms of observable overt actions, whereas others consider all overt and covert actions as behavior.

behavior analysis An integrated basic and applied branch of psychology concerned with the prediction and control (influence) of behavior via identification and manipulation of consequences that follow behavior. This view is grounded in the philosophy of science known as radical behaviorism. The applied branch of behavior analysis is often used synonymously with behavior modification, and terms such as applied behavior analysis. Clinical behavior analysis is a newer branch of behavior analysis most closely affiliated with outpatient psychotherapy.

behaviorism A conceptual framework that is grounded in a unique view of human behavior and mental life: a frame-

work that underlies a science of behavior, not the science itself. Behavioral science comprises findings, principles, laws, and theories resulting from behavioral research, whereas behaviorism entails the philosophy, ideology, assumptions, and values implicit in a science of behavior. Behavior therapy is part of behaviorism but is not synonymous with it.

behavior modification Set of procedures (e.g., contingency management, time out, positive reinforcement) that are derived largely, but not exclusively, from behavior analysis, operant learning principles, and theory.

behavior theory Refers to overarching conceptualizations of human behavior grounded in basic behavioral science and principles of learning. There are many behavior theories that more or less share this basic set of features.

behavior therapy Comprises the systematic application of operant and respondent learning principles and contemporary learning theory for the purposes of scientific understanding and the alleviation of human suffering in therapy. This approach values objectivity and demands that rigorous empirical standards of proof be applied to treatment development and ongoing evaluation of psychosocial treatment outcomes.

cognitive-behavior therapy A branch of behavior therapy that considers cognition as something other than behavior and therefore requires a unique conceptual system and procedures to account for it. Cognition is said to mediate or cause other behavior, and faulty cognitive processes are believed to contribute to the etiology, maintenance, and treatment of abnormal behavior. Traditional behavior therapists, who hold to the monistic assumption that cognition is behavior, regard the hyphenated term cognitive-behavioral as a redundancy.

contextualism A philosophical world view, most affiliated with the writings of Stephen Pepper and philosophy of sci-

ence known as radical behaviorism, that takes as its root metaphor the actions of the whole organism in its context.

epistemology A branch of philosophy concerned with the nature and origins of knowledge (e.g., what is known or knowable). Though behavior therapists are not generally committed to any single epistemological theory, they do generally adhere to an empiricist epistemology.

mechanism A philosophical position that adopts as its root metaphor the machine and the parts that drive its operation. Mechanists uphold that the whole can be derived from the sum of its parts, and that discovery of the parts (e.g., thought, emotion, overt behavior) and the relations among parts are critical to explaining human behavior. Mechanists generally uphold a correspondence-based truth criterion and are generally nomothetic in their reasoning.

methodological behaviorism A normative theory about the scientific conduct of psychology and claims that psychology should concern itself with the observable behavior of organisms (human and nonhuman animals), not mental events such as thoughts, feelings, and other similar private constructions. The reason is that private events fail to meet the criterion of public agreement. In this view, reference to mental events adds nothing to explaining the variables controlling behavior. Mental events are private entities that, given the necessary publicity of science, do not form proper objects of empirical study. Methodological behaviorism is at the core of John B. Watson's (1878–1958) behaviorism, *not* Burrhus F. (B. F.) Skinner's (1904–1990) radical behaviorism.

monism A philosophical position that stipulates that what one observes and talks about is a real and physical world—one world of substance existing in space or time. Monism is at the core of behaviorism and a behavioristic world view and is reflected in the thesis that behavior (thoughts, physiological events, overt actions) is one stuff (i.e., physical) and situated in relation to a real physical world in space and/or time: a view that is the antithesis of Cartesian dualism, but not synonymous with reductionism.

pragmatism A view, espoused originally by Charles Pierce and later developed by William James, that focuses attention on practical goals and outcomes, or making a difference. The general pragmatist notion is that “a difference must make a difference to be a difference.”

radical behaviorism A philosophy of science associated with the writings of B. F. Skinner and the activities of those operating within the basic and applied branches of behavior analysis. Radical behaviorism is a contextualistic, monistic, functionalistic, wholistic, and pragmatic philosophy of science: one that rejects the truth by agreement criterion of methodological behaviorism and considers events taking place in the private world within the skin. Private events are not called unobservable and are not dismissed as subjective but are to be interpreted and explained using the same scientific terms used to explain all other behavior. This is what is “radical” about radical behaviorism.

scientist–practitioner model Originated out of the 1949 conference in Boulder, Colorado. The model stipulated a framework for training clinical psychologists such that clinical psychologists should be (a) producers of scientific knowledge, (b) consumers of scientific knowledge, and (c) evaluators of knowledge via data-driven outcomes assessment in their work with those they serve.

social learning theory A theory, developed by Albert Bandura, proposing that the influence of environmental events on the acquisition and regulation of behavior is largely determined by cognitive processes. Expectancies and vicarious learning play a central role, and the person is viewed as an agent and an object of environmental influences.

vicarious learning Stipulates that humans can learn simply by observing others, and that such learning does not require positive or negative reinforcement.

Behavior therapy comprises a set of activities involving the systematic application of operant and respondent learning principles and contemporary behavior theory for the purposes of scientific understanding and the alleviation and prevention of human suffering. This should not be taken to mean that there is unanimity of voice among those calling themselves behavior therapists with regard to this view of behavior therapy. Long-standing disagreements exist over the very definition of behavior therapy, including the range of acceptable intervention methods and explanatory concepts that fall within its purview. Yet, the distinguishing foundational tenets of behavior therapy, remain rooted in behaviorism, learning principles, and behavior theory, and the science-based application of such principles, coupled with a strong empirical foundation, in therapy. Though not all behavior therapists ascribe to this view (in fact, many do not), those that do are practicing behavior therapy consistent with the original intent of the term.

Nowadays, the science and practice of behavior therapy are often equated with a range of intervention techniques (called behavioral, cognitive-behavioral, and sometimes cognitive only) aimed at modifying and changing problematic human behavior and fostering development of more adaptive functional behaviors. To be sure, an impressive array of empirically supported psychosocial intervention technologies emanated from the behavior therapy movement, and many such technologies now dominate the psychotherapy scene as treatments of choice for a wide range of problems. One could argue that practitioners from other psychotherapeutic orientations who employ such

interventions are, in fact, practicing behavior therapy. Yet, behavior therapy is more than the mere application of behavioral intervention technology, more than using an experimental approach, more than taking an empirical approach in working with clients, and certainly more than a focal interest in behavior. Indeed, this small set of intellectual commitments is shared somewhat by psychologists of varying persuasions, and particularly those that ascribe to the scientist–practitioner model. As is outlined, behavior therapy comprises a shared set of working conceptual assumptions and values that help frame answers to basic research and applied questions and ultimately is what behavior therapists do when attempting to alleviate an increasingly wide range of human suffering in individuals, couples, groups, organizations, communities, and so on. This approach is most uniquely and closely aligned philosophically, conceptually, and methodologically with behaviorism and an experimental approach to solving basic and applied problems rooted in principles of learning and behavior theory; hence the name “behavior” therapy is most aptly used to distinguish this approach to science and practice from other approaches that are data based and empirically driven but neither philosophically nor conceptually rooted in behaviorism and behavior theory. Our intent here is to elucidate the conceptual assumptions and behavioral values that are somewhat unique to the behavior therapy movement and to show how such conceptual assumptions guide the science and practice of behavior therapy. We begin with an overview of the evolution of behavior therapy as a unique approach to psychological science and practice.

I. BRIEF HISTORY OF THE CONCEPTUAL EVOLUTION OF BEHAVIOR THERAPY

Behavior therapy was conceived in a psychotherapeutic climate that was more than ready for it, but not quite ready to embrace it. At the time of behavior therapy’s formal inception in the early 1950s, the mental health care scene was largely dominated by psychiatrists, many of whom were trained in medicine first, and second in classic psychoanalysis, or what was the then dominant Freudian or neo-Freudian psychoanalytic framework. Treatment focused largely on unearthing unconscious processes believed to be the real reasons for psychopathology and suffering. Therapy was long term, often taking years not weeks, and the disease model of the etiology, diagnosis, and treatment of psychological

disorders served as the prevailing conceptual framework. Psychiatrists ruled the roost with regard to mental health care, and psychologists often played second fiddle to them. Persons in psychotherapy often devoted considerable time and resources to delve into their pasts to uncover unconscious and hidden conflicts believed to underlie their problems, with the hope that, in the hands of a skilled psychoanalyst, they would achieve insight (i.e., making the unconscious conflicts consciously accessible), and ultimately a cathartic cure. Treatment was also driven more by hunch and clinical intuition than by science and data. Empirical accountability, or treatment decisions supported and guided by data, was virtually nonexistent. Public mistrust about psychotherapy, including social stigma about mental disorders, was at an all time high. Something had to change, and the early behavior therapy pioneers were poised to offer an alternative approach that would forever revolutionize mental health care.

A. Early Developments and Precursors

Various theories and procedures common to contemporary behavior therapy were described before behavior therapy, or even psychology, was established as a scientific and professional discipline. For instance, in first-century Rome, Pliny the Elder placed spiders in the glasses of alcohol abusers to cure them of their addictions. Today, that technique is referred to as a form of aversive counterconditioning. A procedure similar to imaginal desensitization was outlined in 1644 by Sir Kenelm Digby and involved the association of aversive imagery with pleasing circumstances. John Locke in 1693 described in vivid detail a procedure for the treatment of an animal phobia that we would now call *in vivo* exposure therapy. In the 18th century, the “Wild Boy of Aveyron” received an intervention that many would currently view as comprising positive reinforcement and modeling procedures. In his 1890 book, *Principles of Psychology*, William James described a case of a child who had become extremely fearful following an experience of being burned by a candle and, in so doing, showed a remarkable conceptual grasp of conditioning before conditioning had been formally introduced within American psychology. A point system or token economy, or what many would identify as an operant procedure, was implemented by Alexander Manconchi in the 1800s to prompt inmates at the Royal British penal colony to obey prison rules. As Isaac Marks noted in his 1981 text, *Cure and Care of Neuroses*, even Freud

and his followers periodically affirmed the role of exposure in treatment of fears and phobias, and other procedures, from diverse areas such as Chinese medicine, Zen Buddhism, Morita therapy, folk practices of aboriginal tribes in Malaysia, and psychotherapy practices resemble what many would call behavioral interventions. Though these and other examples are certainly of historic interest, none appears to have influenced the development of behavior therapy directly (if at all). The more direct antecedents of the behavior therapy originated from a confluence of factors occurring within early-20th-century psychology.

B. The Beginnings of a Behavioral Revolution within Psychology

Psychology in the early part of the 20th century was struggling with its own identity as a science. Psychology prior to 1913 was considered a science of mental life, and the chief method of studying mental life and experience was introspection. Introspection and its variants represented an attempt to systematically unearth the contents, structures, and functions of consciousness via complex and often convoluted methods of teaching research participants to accurately observe and report on their own private experiences. Introspectionism, as it came to be called, was essentially a doctrine that upheld that the hidden world of private mental life mattered and that consciousness was a worthy topic of psychology that distinguished it from other sciences as a science in its own right.

That all changed in 1913, with the publication of the first of two lectures John B. Watson delivered before the Columbia University Psychological Seminary, titled *Psychology as the Behaviorist Views It*. In the first of these lectures, which appeared in *Psychological Review* and became well known as the “behaviorist manifesto,” Watson argued forcefully against consciousness as psychology’s subject matter and introspection as psychology’s method of choice. Instead, he maintained that psychology is and should be a purely objective experimental branch of natural science, whose theoretical goal is the prediction and control of behavior. In so doing, Watson tried to provide a coherent rationale to legitimize behavioral methods that had been in use since the 1870s with animals and humans and to redefine psychology’s subject matter as observable behavior, not mind, with its chief methods being direct observation and measurement of behavior. In effect, Watson maintained that one could understand the mind by understanding relations between antecedent environmen-

tal stimuli (S) and reflexive or elicited behavioral responses (R); a view now familiar to many as an early form of stimulus–response, or S–R psychology.

John B. Watson’s relatively short career in psychology and as an academic was indeed influential, and he can be credited for bringing the work of Russian physiologist Ivan Pavlov, and particularly Pavlov’s work on the conditioned reflex, to American psychology and proselytizing its theoretical and applied importance. Indeed, by the early 1920s, Watson and his wife Rosalie Rayner had demonstrated the acquisition of conditioned fear of a white rat in the now-classic case study of Little Albert, and the subsequent generalization of such fear to other white furry objects. This demonstration was derived from conditioning procedures set forth originally by Ivan Pavlov: procedures that came to be known as Pavlovian or classical conditioning in the United States and abroad. By 1924, Mary Cover Jones went on to demonstrate how fears could be treated via social imitation (now known as modeling) and exposure to a feared stimulus without anticipated negative consequences: a procedure that extends basic knowledge of Pavlovian classical conditioning principles, such as extinction via nonreinforced exposure, to the applied realm. With this successful demonstration, the seeds of what would become behavior therapy were planted. Though it took about 25 years for Watson’s ideas and those of his followers to catch on, by the early 1930s, Watsonian behaviorism—sometimes referred to as methodological behaviorism—and its variants had taken center stage within American psychology. Psychology had ceased to be the science of consciousness and had become the science of behavior *sine qua non* observable behavior.

C. Post-Watson Era of the 1930s and 1940s: Enter the Neobehaviorists

Few of Watson’s ideas had survived intact in the 1930s, and many of his neobehaviorist contemporaries began to take psychology and behaviorism in new and quite different directions. Psychology as a science of behavior was retained during this period, and behaviorism flourished in academic departments around the United States. New theories of learning and conditioning revolved around major neobehaviorist figureheads, such as Clark Hull, Edwin Guthrie, Edward Thorndike, B. F. Skinner, and Edward Tolman. Each of these individuals, in turn, laid the conceptual and scientific groundwork for what would later become behavior therapy.

At the peak of his career Clark Hull was one of the, if not the, most influential behaviorists in the world and devoted most of his life to developing a sophisticated behavioral theory of adaptive behavior. His interest in mechanical devices and mathematics would become a metaphor for how to conceptualize the nature of human behavior and mental life. Like the other neobehaviorists to follow, Hull viewed consciousness as phenomena in need of explanation, not as explanatory devices in their own right. Indeed, Hull's behaviorism emerged from his view that Watsonian behaviorism was crude and seriously flawed. Hull gave close attention to Ivan Pavlov's work and saw in it a way to study conditioning as a means to achieve his goal of an experimental science of thought processes conceived as mental habits. Just as a machine operates according to relations among parts, Hull deduced that human behavior functions similarly via relations among habits that are established through associative conditioning processes. Indeed, Hull's thinking about human behavior as "machine-like" was a direct outgrowth of his interest in mechanical devices, and machine design became a model of theoretical structure to explain the human machine. Logic and deductive thinking were the cornerstones of Hull's psychology, and hierarchical theory building in terms of conditioned habits and habit chains the model of human action. Hull's theoretical system eventually collapsed under its own weight, but Hullian notions would play a large role in the conceptual thinking of early behavior therapists, particularly Hull's focus on precision and scientific rigor, rejection of subjectivity, conceptualization of Pavlovian conditioning in terms of habit formation and mediation, and use of the hypothetico-deductive method. Though Hull's emphasis on logic did not have any real import in the thinking of behavior therapists, his mechanistic view of psychological science and human behavior did. As we see shortly, mechanism is very much part of contemporary behavior therapy.

Edward Tolman is similarly important for his purposive behaviorism: a brand of behaviorism that was explicitly cognitive from the start and, in many respects, is the precursor of modern cognitive theory and the cognitive-behavioral movement within behavior therapy. Tolman identified himself as a behaviorist, eschewed introspection, downplayed Pavlov's reflexology, opposed the behaviorism of John B. Watson, outright rejected Thorndike's connectionism, and openly embraced Gestalt psychology and contextualism as a philosophy. In his 1932 classic, *Purposive Behavior in Animals and Men*, Tolman disputed the mechanistic pic-

ture of behavior presented by many versions of behaviorism and insisted that behavior is inherently purposive and cognitive, with purpose and cognition being part of the contextual behavioral whole as manifest in behavior, not as mentalistic entities apart from behavior. In this work Tolman foreshadowed the concept of what would be known as the intervening variable: a concept that represents an attempt to legitimize talk and inferences about cognitions, purposes, and the like by anchoring such inferences in terms of observable antecedent and consequent events. Eventually Tolman would move his thinking in the direction that knowledge about the world is mediated by cognitive representations of that world, and that purposes and cognitions would have to be assigned a hypothetical rather than observed status. Tolman adumbrated what would become a major source of conceptual disagreement in behavior therapy, with some behavior therapists emphasizing the causal status of cognition, while others maintaining that cognitions are not causes of behavior, but merely more behaviors in need of explanation.

Last, while the neo-behaviorists Edward C. Tolman and Clark L. Hull were vying for ascendancy within experimental psychology, a young student of animal behavior, B. F. Skinner was at work articulating the philosophy and science of a new brand of behaviorism that would forever revolutionize psychology and behavior therapy. Unlike his behaviorist contemporaries, Skinner argued that most animal and human learning is shaped and maintained by consequences following behavior; that behavior is both elicited (in a Pavlovian sense) and emitted (in an operant consequential learning sense) and must be understood in relation to environmental contextual variables; and that behavior is what organisms do, including thinking, feeling, emoting, problem solving, and what are traditionally referred to as cognitions. For Skinner, the skin was merely an arbitrary boundary between public and private events: a boundary that presented a particular challenge for a scientific account of private life, but not for the philosophy of that science. Indeed, unlike John B. Watson, Skinner's radical behaviorism was radical precisely because he maintained that a science of behavior must provide an adequate account of events occurring within the skin (e.g., cognitions, emotions) in a manner consistent with other known laws and principles used to account for other behavior (both private and publically observable). What Skinner rejected was the use of mentalistic lay terminology (e.g., anxiety, fear, creativity, joy) and hypothetical constructs as explanations in a science of behavior, not the very real phenomena to which such

terms may refer. In his 1938 book, *The Behavior of Organisms*, Skinner outlined the beginnings of this new research program with laboratory animals: a program that emphasized the scientific goals of prediction and control (one goal, not two) of behavior via intensive experimentation with individual organisms across time. This program, in turn, eventuated in what came to be known as operant psychology, or the field of basic and applied behavior analysis. It would be almost a decade later before Skinner's ideas would take hold in behavior therapy, and when they did, they were compartmentalized as falling under the aegis of behavior modification and applied behavior analysis.

By the end of the 1940s, behaviorism had reached its zenith within American academic psychology and was, in many respects, poised for a precipitous decline two decades later with the rise in popularity of cognitive theory and cognitive experimental psychology in the 1960s. Before such a decline would take place, behaviorism and behavioral thinking would first revolutionize the face of applied clinical psychology as an alternative to psychoanalysis. That revolution, became known as behavior therapy.

D. 1950s: The Dawn of Behavior Therapy across Three Continents

Behavior therapy emerged on the psychotherapeutic scene in the early 1950s as an applied extension of experimental psychology, which was still predominantly behavioristic in its approach. Applied psychology, on the other hand, was dominated largely by psychiatrists, and a disease model of psychopathology and human suffering. According to this model, abnormal behavior was considered symptomatic of an underlying mental illness, or a psychic disturbance or personality conflict similar to a medical disease. Clinical psychology, as a profession, was a newcomer having only been recognized formally in 1949 in the years shortly following World War II. Though early clinical psychologists, trained as they were within the scientist-practitioner model set forth by the delegation at the 1949 Conference in Boulder, Colorado, were poised to establish behaviorism in mental health care, and hence what came to be known as behavior therapy, they did not. Newly trained clinical psychologists during this period, though trained as scientists within the predominant experimental and behavioristic mold, turned to the then-dominant Freudian and neo-Freudian conceptual framework for their clinical inspiration as practitioners. Indeed, there was no real viable competing alterna-

tive framework for the practice of clinical psychology. Though Andrew Salter's 1949 book, *Conditioned Reflex Therapy*, describing human neurosis in Pavlovian conditioning terms had just come on the scene, and John Dollard and Neil Miller offered a compelling behavioral translation of Freudian concepts in 1950, neither text seemed to have any appreciable impact in producing a behavioral applied psychology anchored in behavioral science. In fact, Dollard and Miller's efforts to bring Freudian concepts in line with conditioning principles was predicated on the tenuous assumption that classic Freudian psychoanalysis was, indeed, efficacious as a treatment for psychological problems. This assumption, of course, was just that, an assumption without any hard data to support it. As controversy mounted regarding the efficacy of psychotherapy in general, many began to seek out alternatives. One such alternative that was about to emerge as a dominant player was behavior therapy.

Behavior therapy was established through the tenacious and somewhat independent efforts for several pioneers, including Joseph Wolpe and his student Arnold Lazarus in South Africa, the experimental and clinical work of Monty B. Shapiro and Hans J. Eysenck at the Maudsley Hospital in London, England, and efforts of Andrew Salter, O. R. Lindsley, and B. F. Skinner in the United States. All shared an interest in the extrapolation of experimental findings and principles from laboratory research with animals to explain human behavior, and predominantly—with the exception of Lindsley and Skinner—the acquisition and elimination of neurotic anxiety. The early pioneers shared a sense of unity, common purpose, and a revolutionary passion for the science itself and what the science could offer individuals, groups, and society at large. Most of the early founding members had one foot planted in the basic experimental science and one in the clinic and moved between both nimbly and with grace. The early behavior therapists understood behaviorism, behavior theory, behavior principles, and how to put them to use creatively to achieve practical purposes in therapy. Behavior therapy was, in many respects, considered the applied application of behavioral science, much as engineering represents the applied extension of physics. Early behavior therapy entailed a behavioral core: a core that was reflected in a rigorous scientific approach aimed at developing a science of human behavior and use of that knowledge to achieve practical therapeutic goals. Armed with only a handful of powerful theoretical ideas and treatment techniques, Wolpe, Lazarus, Eysenck, and Skinner, along with a few colleagues and students

(e.g., Cyril Franks, Andrew Salter, Stanley Rachman, Leo Reyna) took on the psychoanalytic and psychiatric establishment at universities and in applied clinical settings across three continents. In so doing, the pioneers of the behavior therapy grounded psychotherapy squarely in the context of behavioral science.

Two highly influential books also appeared during this time that helped to establish behavior therapy as a unique approach to the understanding and amelioration of human suffering in psychotherapy: namely Joseph Wolpe's (1953) *Psychotherapy by Reciprocal Inhibition*, and B. F. Skinner's (1958) *Science and Human Behavior*. Skinner's 1958 text showed how the principles of reinforcement and punishment could be put to practical use in understanding and modifying otherwise complex human behavior in and outside of therapy. Though Skinner was not a behavior therapist, he was tenacious throughout his long life in showing how the principles derived from basic behavioral science had broad practical relevance. Wolpe's 1953 book, on the other hand, offered a more narrow conceptualization of human neurosis in terms of Pavlovian and Hullian learning principles coupled with a dash of neurobiology, while also introducing new therapy techniques derived from such experimentally derived principles (i.e., systematic desensitization, assertion training), and impressive outcome data to back them up. To this day, Wolpe's carefully documented program of treatment development, a program that included his own basic laboratory research with cats and clinical outcome data on more than 100 individual cases, remains the largest single-case replication series in the history of psychology.

In the ensuing years, data supporting the efficacy of behavior therapy began to mount at a rapid rate. Soon others increasingly joined the behavioral inner circle and rallied together to promote a rigorous experimental epistemology with regard to treatment development and analysis of therapeutic processes and outcomes, and against what was perceived as a conceptually rich, but practically useless, psychoanalytic approach to psychotherapy and behavior change. Behavior therapy began to grow and with that growth came concern about the nature and meaning of the term *behavior therapy*: a term first coined in 1953 by Ogden Lindsley, B. F. Skinner, and Harry Solomon in a monograph describing the application of operant procedures in a psychiatric hospital setting. By 1958, Arnold Lazarus offered an explicit definition of behavior therapy as *the application of objective, laboratory-derived therapeutic techniques to the treatment of neurotic patients*. One year later, Hans Eysenck would define behavior therapy more broadly as

the application of modern learning theory to the treatment of psychiatric disorders. The definition of what constitutes behavior therapy would continue to undergo substantial revision in the decades to follow such that the conceptual foundations of behavior therapy—rooted in behaviorism, learning theory, and principles of learning—would be replaced by the more general affiliation of behavior therapy with psychological science, empiricism, a data-driven approach to treatment, and a specific brand of therapy or therapeutic techniques. The dissolution of behavior therapy's behavioristic conceptual core began in earnest in the 1960s, and in many respects, has not recovered since.

E. The 1960s and Beyond: Behavior Therapy Comes of Age and Grows a Belly

By the 1960s, the behavioral revolution in mental health care was on its way to being won, and behavior therapy was considered a viable alternative framework to the prevailing psychiatric medical model of human suffering. Two behavior therapy journals, *Behaviour Research and Therapy* and *The Journal of Applied Behavior Analysis*, were established, and several highly influential anthologies outlining the fundamentals of this approach appeared, including Hans Eysenck's *Behavior Therapy and the Neuroses* and his later book *Experiments in Behavior Therapy*, and Leonard P. Ullmann and Leonard Krasner's *Case Studies in Behavior Modification*, and an edited volume by Cyril Franks titled *Behavior Therapy: Appraisal and Status*. Behavior therapy underwent substantial growth during the tumultuous 1960s, and with that growth came increasing diversification, internal dissent, and self-critical evaluation. It was the decade, as Cyril Franks recently put it, of oversimplification with regard to behavior theory and behavioral principles, grandiose claims regarding the effectiveness of behavior therapy, and intolerance from within and from without.

In 1966, the founders of behavior therapy established a professional organization, first named Association for Advancement of Behavior Therapies (plural), and later modified in 1968 to reflect the singular Association for Advancement of Behavior Therapy. The name change occurred, in part, to convey the sense that behavior therapy was primarily a conceptual approach to science and practice, not a collection of professionals united by an interest in behavior change technologies. Most behavior therapists shared a common, though by no means uniform, learning-theory orientation and interest in a general behavioral approach. Yet, many were attracted to

the promise of behavior therapy mostly for its pragmatic approach and its empiricism, particular as applied to treatment development and implementation, and data-driven therapy outcomes assessment. Behaviorism, as the conceptual core of behavior therapy, was gradually replaced by more pluralistic views, and behavior therapy came to be defined within much broader sociopsychological models. Such models emphasized empiricism and altering a person's behavior *directly* through the application of *general* psychological principles, not necessarily behavioral learning principles. Early behavioral approaches, grounded as they were in behavioristic thinking and animal research, were increasingly viewed as too narrow and simplistic to account for complex human behavior. Particularly controversial was the capacity of behaviorism and behavior theory to account for the role of cognition in relation to problematic behavior seen in outpatient clinics with highly verbal adults. This controversy was never satisfactorily resolved and came to a head with the 1969 publication of Albert Bandura's highly influential text, *Principles of Behavior Modification*. In that text, Bandura outlined his social learning theory approach, emphasizing the importance of vicarious learning, cognitive mediation, and the self-regulatory function of human behavior. Ironically, social learning and cognition were always part of post-Watsonian behaviorism and early behavior therapy, and particularly the writings of B. F. Skinner and Arthur Staats. Yet, the behavioral conception of cognition as behavior to be explained in terms of principles of learning was seen as limited; a view that persists to this day.

By the mid-1960s, behavior therapy had grown a belly and the song, bell, and hammer of the early days were replaced by increasing pluralism, numerous heterogeneous treatment procedures with different theoretical rationales, and open debate about the conceptual basis and methodological requirements of behavior therapy. Without a common enemy, behavior therapists began to fight battles with themselves about the very nature of behavior therapy and what constituted an adequate definition. Such criticisms, and even outright dissent, reached as far as the halls of Congress and state and local governments, resulting in withdrawal of research funding, forced abandonment of treatment programs, and legislation that otherwise banned some techniques used routinely by behavior therapists on the grounds that they violated the rights of patients and others. It turned out that much of the criticism was due, in large part, to public misunderstanding about behavior therapy, including poor understanding about behaviorism on the part of those calling themselves behavior thera-

pists. Indeed, during this period, it was common for behavior therapy to be wrongly associated with sterilization programs applied to black persons with retardation, insulin shock therapy applied to psychotic patients in institutionalized settings and without their consent, the use of coercive procedures such as punishment or shock to control behavior, and general charges of manipulation and dehumanization. Even within psychology, behavior therapy was often viewed as mechanistic, in an inhumane coldhearted sense. Behavior therapists were likewise increasingly guilty of misunderstanding and misapplication of behaviorism, behavior theory, and behavioral principles in the applied arena. Most often this would take the form of simplistic and rigid extrapolations of behavioral learning principles from animal research to explain interesting and important facets of human behavior (e.g., thinking, emotion). The result of attempts to squeeze such principles into an analysis of problematic human behavior (e.g., cognition, emotion, self-control) was often met with frustration and frank failure. The same sort of misaligned extrapolation occurred with regard to behavioral theories in the context of psychotherapy, and often with similar poor results. Such difficulties served, in part, to foster the cause of the more ecumenical strands of behavior therapy that were increasingly becoming more popular, particularly Albert Bandura's social learning approach, Arnold Lazarus's multimodal therapy, Aron Beck's cognitive therapy, and eventually the perspective known as cognitive-behavior therapy.

By the mid 1970s and throughout the ensuing two decades, behavior therapy's behavioristic conceptual core had eroded, and few behavior therapists turned to behavioral thinking for their clinical inspiration. The unbridled enthusiasm of the late 1950s and 1960s was replaced by a more cautious optimism and concern by some that behavior therapy had lost its behavioristic conceptual moorings and, in so doing, had become indistinguishable from the rest of applied empirical psychology. Clinical scientists and practitioners were increasingly drawn to behavior therapy for its empiricism, not for its behaviorism. Cognitive conceptualizations and cognitive-behavior therapy became the rule, and behavioristic behavior therapy the increasing exception. Behavior therapists began to incorporate empirical methods and concepts from experimental and social psychology, and psychological science more generally. Treatment development and implementation proliferated, numerous doctoral-level behavior therapy training programs were now well established. Behavior therapists' identity as empiricists disappeared as other

approaches to therapy began to participate in clinical trials. It gradually became apparent that empiricism could be exported to any approach, not just behavior therapy. Behavior therapists were left without a unique theoretical legacy, and gradually behavior therapy and cognitive-behavior therapy became one of many strands in mainstream clinical psychology: an approach without an overarching theory and one far removed from the behaviorism from which it initially emerged. In many respects, behavior therapy had become nothing more than the personification of the conceptually neutral scientist-practitioner model of clinical psychology.

F. Contemporary Behavior Therapy Nearing the Age of Fifty

Behavior therapy in the year 2001 looks quite different from the behavior therapy of the 1950s. Behavior therapists have long since won the fight for legitimacy in the mental health care arena; the success of behavior therapies for a wide range of problems is well established. Behavior therapies are in vogue, and behavior therapists have few real adversaries. Armed with data in hand, behavior therapists are leading the charge to demonstrate that psychosocial interventions work to alleviate a broad range of human suffering. Randomized clinical trials, efficacy, effectiveness, manualized treatments, dissemination, treatment outcomes assessment, accountability, time efficiency, cost containment, treatment quality and integrity, and managed care are now common buzz words. There are relatively few behavior therapists with one foot planted in basic behavioral science and the other foot in the clinic. Few of those calling themselves behavior therapists are thoroughly familiar with behaviorism and contemporary principles of learning from behavioral science, and even fewer look to behavior theory and behavioral principles for clinical inspiration. Ironically, it is precisely this approach that paved the way for behavior therapy's early successes: one that contemporary behavior therapy seems to have lost sight of, particularly judging the need for the thematic title—*Bridging the Gap from Science to Clinical Practice*—of the 1994 annual meeting of the Association for Advancement of Behavior Therapy. Most behavior therapists identify themselves loosely as cognitive-behavior therapists and do not see use of this hyphenated term as a conceptual redundancy. Novel treatment innovations are few and far between, and the modus operandi is to transport existing treatments almost whole cloth (e.g., relaxation training) to diagnostically dissimilar clinical conditions and test for their

efficacy within large-scale randomized clinical trials. In many ways, behavior therapists have suffered from their own inadequate training in philosophy of science and have become radical empiricists, logical positivists, and, to use B. F. Skinner's terminology, methodological behaviorists. In doing so, behavior therapists have fallen into the trap of mechanistic thinking, of dualism, and of deemphasizing the importance of behavior principles and behavior theory. Behavior therapy's treatment technologies are now finding their way into the hands of nonbehavioral practitioners who, by virtue of their training, have little affiliation with behavior therapy, behavior principles that drive the treatment technology, and behaviorism. Though dissemination is an important and potentially beneficial development, it also illustrates that one need not be trained behaviorally to use a behavioral intervention successfully. Interest in the conceptual foundations of behavior therapy, and the practice of conceptually driven behavior therapy is, for the most part, seen as irrelevant for the successful implementation of behavioral intervention technologies. What it means to be a behavior therapist is now, more than ever, anyone's guess.

II. CONCEPTUAL FOUNDATIONS OF BEHAVIOR THERAPY

The conceptual foundations of behavior therapy owe much to the historic evolution of behaviorism, not in the sense of its impressive products vis-à-vis treatment interventions, but the development of a unique way of framing basic and applied problems. To use the term conceptual to describe the foundations of behavior therapy may, at first glance, appear like a contradiction. The reason has to do with the meaning of the adjective term conceptual: a term which is derived from the Latin words *conceptus* and *later concipere* that, when translated literally, means "the act of conceiving thought," or "existing or dealing with what exists only in the mind." This view, of course, was characteristic of introspectionism that dominated psychology in the late 19th and early 20th century: an approach that early behaviorists, and eventually behavior therapists, vociferously rejected. Antonyms of the word conceptual, such as practical, pragmatic, realistic, concrete, material, substantial, and tangible, more aptly describe the values shared by those calling themselves behavior therapists, or at least behavior therapists of the behavioristic stripe. Yet, use of the adjective "conceptual" in the context of behavior therapy is still useful, for it captures the

essence of behavior therapy as a loosely interconnected set of assumptions and values—ways of conceiving and understanding human behavior—that invariably influences the science and applied practice of behavior therapy. Conceptual is also useful as an acknowledgement that behavior therapy, like most branches of psychological science, is value laden, not value free. Whether we like it or not, conceptual values do play a role in how scientists and practitioners talk about behavior, what topics they deem worthy of their attention in research and therapy, the manner in which a therapist formulates a client's presenting problems in therapy, how one interprets data, and the criteria one adopts for truth and explanation, to name a few. These and other value-laden issues are at the core of all science and therapeutic practice and deserve our attention.

Gerald Zuriff, in his classic 1985 text, *Behaviorism: A Conceptual Reconstruction*, noted that behaviorism is not simply the science of behavior developed by behaviorists at the turn of the 19th century, but rather a conceptual framework underlying that science. Behaviorism is about the assumptions, values, and presuppositions implicit in a science of behavior, including applied practice. Behaviorism is certainly not a monolithic approach; there are many philosophical and conceptual strands of behaviorism. Today some behavior therapists share a strong family resemblance with behaviorism, but many more do not. In the purest sense of the term, behavior therapy refers to a conceptual view grounded in a science of behavior and principles of learning: one that values pragmatism, objectivity, prediction and control as mutually entailed scientific and practical goals, an empiricist epistemology, a monistic view of behavior, functionalism, structuralism, and either mechanism or contextualism as overarching philosophies.

The conceptual underpinnings of contemporary behavior therapy are more often implicit than explicit and are often mentioned by contemporary behavior therapists in passing as merely of historical interest only. Edwin Erwin, a philosopher by training, is the only person to have written a text devoted exclusively to the philosophical, conceptual, and moral foundations of behavior therapy, and that was in 1978. Almost a decade later, Rosemary Nelson and Steven Hayes edited a 1987 book devoted specifically to the conceptual foundations of behavioral assessment. Clarifying the conceptual foundations of behavior therapy should be of contemporary interest, if for no other reason than to understand more fully how such assumptions and values guide basic and applied activities, and more generally to dispel common misconceptions about what constitutes

practicing as a behavior therapist. Indeed, it does appear that the tide is slowly shifting back to an interest in the conceptual core of behavior therapy, as indexed by the expansive content of articles written by three generations of behavior therapists that appeared in a 1997 two-part special series of the journal *Behavior Therapy* titled "Thirty Years of Behavior Therapy: Promises Kept, Promises Unfulfilled," and a 1999 edited monograph titled *From Behavior Theory to Behavior Therapy*. Our intent in the remaining sections is to make explicit the conceptual framework driving the activities of those calling themselves behavior therapists.

A. Core Conceptual Assumptions and Values

At the time of behavior therapy's initial development, psychology was largely behavioristic, experimental psychology was primarily, though not exclusively, behavioristic, and the pioneers of behavior therapy were aligned with what was the predominant behavioristic view in American psychology; though not entirely by training (e.g., Joseph Wolpe was trained as a psychiatrist in medicine and classic psychoanalysis). The core of behavior therapy's conceptual framework emerged out of behaviorism, not independently of it, and certainly not out of thin air in reaction to classic psychoanalysis. Behavior therapy's original identity was rooted squarely in behavioral thinking; the development and creative implementation of applied treatment technology represent two of several products of that thinking. The redundancy here in this logical historic syllogism is deliberate and is meant to clarify a conceptual confusion that permeates contemporary behavior therapy. The confusion rests with the meaning of the terms behavior therapy and behavior therapist. Early on both terms referred to a behavioral way of thinking: one grounded in the belief that behavioral science (not any brand of psychological science) would develop a rich conceptual network, set of laws and principles, and powerful intervention technologies that could be put to use to explain and alleviate, with precision and scope, a wide range of human suffering. As we have seen, behavior therapy and behavior therapist have come to mean a loose association with behavioral science and a psychology of learning, and a more general affinity with experimental approach, empiricism, cognitivism, treatment technologies, and the application of findings from psychological science more generally. Behavior therapy, in effect, has become what behavior therapists do, and what behavior therapists do has come to include just

about everything that has data to back it up. Though such issues are complex and certainly deserving of more discussion, we would like to turn our attention to conceptual issues that characterize behavioral strands of behavior therapy in the original sense of the term. Such strands, in turn, can be framed within two overarching philosophical frameworks: mechanism and contextualism, respectively.

B. Mechanistic and Contextualistic Strands of Behavior Therapy

1. Mechanism

Early forms of behavioral thinking were predominantly mechanistic and reductionistic, and so too was behavior therapy. A mechanistic philosophy takes as its goal the identification of essential building blocks that compose the fundamental structure. The parts are viewed as primary from which the whole is derived. Central to this view is that the parts of the machine reflect an objective reality awaiting discovery, and that the goal of the analyses is to elucidate principles, foundational laws, and theories that can be used to categorize the parts, relations among parts, and forces that together explain the functioning of the machine. Truth is based, in large part, on correspondence between objective reality and the belief in the presumed underlying mechanisms or structures, many of which are hypothesized but not observed directly. John B. Watson's original S–R reflex thesis was mechanistic, and so too were the S–R learning theories that predominated psychology through the middle part of the 20th century. Mechanistic models, emphasizing mediational links between stimulus–response and hypothetico-deductive theorizing, were in vogue until the 1960s when they were replaced by the equally mechanistic computer simulations and information processing models from cognitive psychology.

Contemporary behavior therapy, including much of psychology, has not liberated itself entirely from mechanistic thinking, examples of which include talk of stimulus and response as immutable events with fixed properties, misunderstanding of principles of learning (e.g., considering positive reinforcement as synonymous with the delivery of M&M candy or use of verbal praise), conceptualizing conditioning preparations as equivalent with conditioning processes (e.g., viewing laboratory Pavlovian conditioning preparations as the only way to establish respondent eliciting functions: a position that we now know is incorrect), or attempts to define behavior and learning principles structurally apart from con-

text. More recent examples of such thinking in behavior therapy include the triple-response mode concept, in which abnormal behavior is conceptualized as a loosely organized system of partially independent relations between verbal-cognitive, physiological, and overt-motoric behavioral responses; symptom-focused and diagnosis-driven treatments, most of which are eliminative in nature (i.e., the symptoms are the problem, reduce or eliminate the symptoms, and thus fix the problem); and theoretical views that give causal or mediational primacy to cognitive activity as something other than behavior in explaining the origins, maintenance, and treatment of psychopathology and suffering. Added to this list would be a focus only on the topography of behavior, not its function or relation to contextual determinants; model building, and particularly models that speak of “structures” (i.e., parts) and their relations as composing explanation; and most nomothetic approaches based on aggregate groups of clients from whom inferences are made about the functioning of the human machine in the individual case. It should be noted that there is nothing inherently problematic with mechanistic thinking. The point is to recognize mechanistic thinking when one confronts it, including its assets and liabilities. Most mechanistic thinking has roots in early forms of behavioral thinking, particular the writings of John B. Watson, and the mediational neobehaviorists such as Clark Hull, Edward Tolman, Edwin Guthrie, O. B. Mower, but not B. F. Skinner.

2. Contextualism

Unlike mechanism, varieties of scientific contextualism (e.g., descriptive, functional, hermeneutic) take as their root metaphor the “act in context” or what one might think of behavior understood in and within an environmental context. It makes no sense for a contextualist to speak of parts from which the whole is derived, much as it makes no sense to speak of making love as reducible only to the actions of the genitalia, or the firing of neurons in the brain. The total unit of analysis is not reducible to mechanical collections of smaller units such as behaviors or symptoms. The unit of analysis is the whole organism in relation to its situated context: a view similar to the behavior analytic concept of the operant. What this means is that when one changes the context, one changes the organism—the event or behavioral whole—under consideration. Thus, contextualists anchor their analysis of behavior always in relation to the context and focus their interventions at the level of contextual variables that can be changed and influenced directly. Contextualists are

also inherently pragmatic and avoid claims about ultimate truth or reality. Accordingly, truth (with a small t) is judged not in any absolute sense, but rather by successful working. In other words, how well does the particular analysis help to achieve a priori practical goals? Knowledge claims, therefore, are dependent on achieving practical goals, and absolute Truth (with a capital T) held in conditional abeyance.

Modern incantations of contextualism, particularly functional contextualism, are most likely to be found within the branch of behavior therapy affiliated with the writings of B. F. Skinner and his philosophy of science known as radical behaviorism: namely applied behavior analysis and clinical behavior analysis. Contextualistic behavior therapists of the functional stripe prefer to talk about the function or purposes of behavior, rather than in terms of structures or behavioral topography only; are inherently practical and inductive in approach and method (i.e., doing what works in the most direct manner possible); eschew diagnostic thinking as a framework, but may use psychiatric diagnoses if they help achieve practical ends; are more likely to frame the analysis at the level of the individual case; and direct their interventions at changing those contextual variables of which behavior is a function. The aim of the functional contextualist is, as Tony Biglan and Steven C. Hayes noted in 1996, to develop an organized system of empirically based concepts and rules that allow behavioral phenomena to be predicted and influenced with precision, depth, and scope. Prediction and influence entail joint analytic goals: goals that are achieved when one can identify contextual variables that permit prediction of the behavior of interest, and when manipulation of such contextual features influences the nature and function of the behavior. Practically speaking, the independent variables of interest are understanding how the contextually situated actions of the therapist in therapy results in changes in the client's behavior in, and particularly outside, therapy where it really counts. Of course, the mechanistic branch of behavior therapy shares similar practical interests but adopts a different set of criteria for truth and explanation.

C. Behavior Therapy's Mixed Conceptualizations of Behavior

Two very different conceptualizations of behavior have permeated behavioral thinking. The traditional mechanistic view, owing much to John B. Watson, holds that behavior is what can be observed directly. This view, in turn, leads to a sort of dualism: behavior is what

can be seen and objectively and independently observed by others, whereas what cannot be objectively observed by others is not behavior. As an example, walking would be considered behavior, but thinking about walking would not. This view creates obvious problems, particularly when dealing with how to talk about events occurring within the skin, such as thoughts, emotions, beliefs, and the like. As we have seen, the solution offered in the 1960s was to incorporate cognitive and social learning conceptualizations to address the word beneath the skin and to restrict behavioral conceptualizations for behavior that can be observed. This solution, in turn, created its own set of problems—a sort of conceptual dualism, for now cognition and emotion were considered something other than behavior and therefore required a unique conceptual system to account for them, while behavior would still be conceptualized as overt motor acts to be explained in terms of operant and respondent learning principles. Many behavior therapists still make such somewhat erroneous distinctions: distinctions that contributed, in part, to the view that behaviorism and a science of learning are of limited conceptual value in explaining human behavior. After all, a great deal of human behavior and suffering cannot be observed directly and occurs only privately to an audience of one—the individual experiencing the private events, but this fact alone does not obviate an adequate behavioral account of such events. This is precisely the point B. F. Skinner made repeatedly throughout his writings: a point that seems to have been lost in mainstream behavior therapy.

Applied and clinical behavior analysts conceptualize behavior quite differently than do most mainstream behavior therapists. Whereas mainstream behavior therapists conceptualize behavior as divided into three separate but related parts (cognition, physiology, and overt behavior), behavior analysts consider the organism as an integrated whole; cognition is behavior, just as physiology is behavior. Behavior is what people do, but behavior is not the focal interest of behavior analysts. Unlike mainstream behavior therapists who take the behavior-as-subject-matter view (including cognition, emotion, physiology), behavior analysts operating within a contextual framework take a behavior-in-relation-to-context view. This monistic position avoids the conceptual dualism by conceptualizing all actions as behavior, including those that cannot be observed directly. It also rejects the perspective that one dependent variable (e.g., a thought) could be conceptualized as a cause of another dependent variable (e.g., another thought, overt behavior, physiology): a view that should not be taken

to mean that such private events are unimportant, however. Rather, behavior analysts prefer to talk about events occurring within the skin using the same terms used to talk about behavior that can be observed directly: namely established principles of operant and respondent learning. No new terms are invented to describe and explain private events—private events are on equal status with all other behavior to be explained and are interpreted in a manner that permits prediction and influence with scope and precision.

D. Behavior Therapy's Conception of Causation and Explanation

A behavioral conception of causation and explanation is grounded in the view that the causes of behavior reside in the determinants of behavior, not the properties of behavior. The determiners of behavior, in turn, are viewed as ultimately residing outside the behaving person. Explanation of behavior, therefore, is cast in terms of both prediction and influence over those environmental variables of which behavior is a function.

This conception of behavioral causation and explanation has been subject to its fair share of criticism. Chief among the criticisms are that this view of behavioral causation ignores the role of free will, beliefs or expectations, purposes and intentions, perception, knowledge, memories, ideas, thoughts, and feelings in guiding human action. Most psychologists, including those affiliated with strands of behavior therapy, give causal or mediational primacy to such private events in explaining human behavior, and much of the psychiatric system of diagnosis is similarly construed in terms of private events as causes of human suffering. The mechanistic core of social learning theory and other neobehavioristic and cognitive positions explains why self-efficacy and other related phenomena are considered causal. For the mechanist, structural characteristics of the behavioral system are considered behavioral mechanisms, and thus causal entities. Yet, whether such events can be construed as causes of other behavior is another matter for which there is, at present, no convincing data. Indeed, the entire field of psychology has yet to develop a technology to isolate specific private events (thought A), and not other potentially causal variables (thought B or C, physiological event F, environmental contingencies X, Y) as causes of say action Z, and there is, at present, no technology to measure directly the hypothesized private psychological processes in question. Sophisticated brain imaging technology provides a window on electrical and glucose changes in the brain, but not thoughts, feelings,

and their causal role in human action. Likewise, a person's verbal report about what they are thinking at a given moment may have nothing to do with what they were actually thinking at that moment. Indeed, we all know from commonsense social experiences that there are times when we think one thing, but say and do something quite different (e.g., a person might think "my boss is a real jerk, and then smile and with an outstretched hand say "nice to see you boss"). The issue here is not whether such private events are real and exist—they are, but whether they can be construed as causes based on available evidence and technology.

John Watson made the mistake of rejecting such events as unimportant for a behavioral science, whereas B. F. Skinner restored the importance of the inner private world in a science of behavior. Most contemporary "behavioristic" behavior therapists do not reject the very real psychological events occurring beneath the skin and acknowledge that such events can and sometimes do exert some controlling relation to other behavior, including what are loosely referred to as memories, expectancies, or feelings. What some behavior therapists do reject is talk about private events as causes, and explanations that are based solely on such events. The reasons for this rejection are pragmatic and scientific. Behavior therapists maintain that the goals of science are prediction and influence (i.e., control). The only means of achieving direct control over behavior is to manipulate environmental variables. Placing the causes, and hence explanation of, behavior inside the person puts the behavior therapist at a distinct disadvantage because there is no way to identify and influence such presumed causes directly when they are within the person. For example, saying that one thought caused another thought, an emotional response, or overt action begs the question as to what caused the first thought, how does one know, and most important what can be done about it? Contextually oriented behavior therapists resolve this issue by conceptualizing the causes of behavior as residing outside the person in the social-verbal context and direct their analyses and interventions there that, ironically, is the same context in which all therapists ultimately operate to affect clinically meaningful change.

E. Behavior Therapy's Conception of Abnormality and Human Suffering

The behavioral view of abnormal behavior is predicated on the notion that life experience gives rise to normal behavior and an adaptive range of functioning

just as life experience can produce maladaptive behavior and human suffering. To explain “normal” and “maladaptive” behavior in any absolute sense is somewhat contrary to the conceptual view of those calling themselves behavior therapists. Rather, it is maintained the similar principles of learning that result in functional behavior also can produce dysfunctional behavior. Dysfunctional and functional behavior is a matter of degree, not of kind. Maladaptive, abnormal, or dysfunctional in this sense represent complex learning, most likely attributable to deficit or inappropriate environmental contingencies. Abnormality is more than constellations of symptoms as outlined in the *Diagnostic and Statistical Manual of Mental Disorders, 4th ed.*; abnormality reflects, at the core, learning processes that are either excessive or deficit, and otherwise interfere with a person’s ability to live a full and valued life. This view of abnormal behavior has survived more or less intact and leads directly to behavior change efforts that attempt to modify deficit and inappropriate environmental contingencies that maintain and promote problems in living. The assumption that abnormal behavior is learned, and constrained somewhat by biological factors, translates into a humanistic view whereby the environment, not the person suffering, is largely at fault. The pragmatic leanings of behavior therapists further constrain the analysis to the present context in which the variables controlling problematic behavior can be identified and influenced directly, including factors controlling clients’ tendency to respond to their own responses (i.e., past memories, physical symptoms, other thoughts, or their own behaviors). This conception is also optimistic in the sense that if one learned to behave in a given way, then one can also learn to behave differently, and hence live a different life posttherapy. Therapy, therefore, is viewed as a means to construct and teach more adaptive repertoires and to deconstruct problematic behavior–environment relations that contribute to ongoing suffering.

III. THE SCIENCE AND PRACTICE OF CONCEPTUALLY DRIVEN BEHAVIOR THERAPY

Behavior therapy is both a science of behavior and a conceptually driven scientific approach to therapy and treatment development. Here the emphasis is on the word *approach*. As an approach, behavior therapy entails the values and ideals of the scientist–practitioner model, but is not synonymous with it. Though all behavior ther-

apists are, by definition, scientist–practitioners, not all scientist–practitioners are behavior therapists. Though behavior therapists tend to value rigorous empirical standards of proof and experimental methods, such features could just as easily be used by those favoring psychoanalysis, Gestalt, or humanistic approaches to therapy. Practicing in accordance with such values does not, therefore, make a psychoanalyst a behavior therapist, and use of behavioral interventions, say by a Gestalt psychologist in treating a phobia, would not necessarily mean that the Gestalt therapist is really a behavior therapist in disguise. Saying that behavior therapy draws on psychological science or social psychology for inspiration, or that it involves environmental change and social interaction, fails to disqualify just about all other data-based forms of psychotherapy that are increasingly becoming mandatory in managed behavioral health care. Thus, something more than an empirically or experimentally minded approach is needed to establish the unique identity of behavior therapy. The critical question here is what do behavior therapists do that justifies calling themselves “behavior therapists” as opposed to “psychotherapists” or simply “scientist–practitioners?” As is outlined, the main distinguishing feature is not in what behavior therapists do in research or practice, but with how they talk about what they do.

A. Behavior Therapy: True to Its Conceptual Roots

Behavior therapy is, at the core, rooted in the belief that behaviorism, and the basic branches of behavioristic science, can and do provide a coherent set of assumptions and precise sets of laws, facts, and principles with enough scope, or at least the potential for scope, to help understand and alleviate a wide range of problematic behavior and suffering. This view, of course, was characteristic of early behavior therapy, in which the pioneers set their sights on scientific understanding with at least one eye on practical utility. Initially, behavior therapists conceived of themselves as behavioral scientists investigating and applying basic learning principles to change human behavior. Those involved in treatment viewed their work as derived from basic laboratory research and behavior theory, and basic researchers saw important applied applications of their work. Behavior therapists spoke the same language as basic researchers (though not necessarily with their clients), much as physicians use a consistent set of terms derived from biology and medical science. They used the same set of terms and concepts not for dogmatic reasons, but

because it made sense to do so. Imagine that an engineer, when faced with the new challenge of designing a bridge, threw up his hands and said that “the laws of physics simply do not apply to this project,” or worse yet went about designing the bridge without regard for the new and known laws of physics. Most would say that such behavior would be foolish, and practically speaking would disconnect this engineer’s work from valuable and important knowledge derived from the science of physics. Behavior therapists go about their work in a similar fashion and interpret complex human phenomena (e.g., cognition, emotion) in a language consistent with the basic science. Such interpretations are central to initial assessment and ongoing assessment, hypothesis generation, and case formulation, selection of treatment targets, and ultimately what behavior therapists do next in attempting to ameliorate the problem(s) that a client(s) may present in therapy. Integration of the basic and applied branches of behavioral science is and remains characteristic of this work: a coherent, but far from uniform, formula that paved the way for many, if not most, of the available treatment technologies used by behavior therapists today.

At present, there is no indication that behavior therapy “true to its roots” has failed. What has happened, however, is that many behavior therapists have failed to see the conceptual richness of behaviorism and the promise of what behavioral science has to offer. For example, many behavior therapists, including nonbehavioral practitioners, would likely be surprised to learn that behavior analysts are increasingly addressing complex human phenomena such as the self, knowing, meaning, purpose, cognition, attention, emotion, verbal-regulatory processes involved in psychopathology, attributions, expectancies, and topics familiar to clinical psychologists such as transference and countertransference, resistance, suicide, anxiety, depression, and the most vexing clinical question as to how the talk that goes on between therapist and client in psychotherapy leads to clinically meaningful change outside of therapy (where it really counts). These and other developments, including new psychosocial treatment innovations for adults (e.g., functional analytic psychotherapy, acceptance and commitment therapy), have occurred because behavior therapists and clinical behavior analysts have extended new and known facts of learning systematically to address clinically important phenomena. That is, over the last two decades behavior analysts have pushed the limits of behaviorism and behavioral science and have developed a rich, coherent behavioral psychology of cognition and other

complex human phenomena and without the need for a cognitive or “other” brand of psychology. When behavior therapists think and act behaviorally, whether in laboratory, clinic, schools, organizations, they are behaving consistently with the controversial and oft misapplied Kuhnian concept of a paradigm—a disciplinary structure organized by a coherent set of basic assumptions, analogies used to clarify the basic assumptions, conventions (i.e., epistemology, methods, units of analysis), exemplars of classic works, and terminology to facilitate communication amongst its members.

B. Behavior Therapy: The Received View

According to received view, behavior therapy was never all that behavioristic to begin with, that behaviorism and behavior theory were too narrow as a basis for the conceptual development of behavior therapy, and that learning principles could only take behavior therapy so far. What was offered instead was a behavior therapy stripped of its behavioristic core: a behavior therapy that welcomed all of psychological science, and increasingly behavioral neuroscience, into its fold. The reasoning behind this move is unclear but can probably be traced to the presumed limits and failures of the behavioral paradigm and other social developments occurring during the 1960s. Whether the limits and failures were truly that, or simply reflected a lack of familiarity with behaviorism, is another matter for which we have no definitive answer. Yet, the outgrowth of the move away from a behavioral core is quite clear—many so-called behavior therapists have no unique identity and behavior therapy is but one of several growing branches of empirical science that aims to understand variables that, either in whole or in part, contribute to the etiology, maintenance, and treatment of psychological suffering. The prevailing view is that complex human behavior problems require complex solutions, many of which are outside the limits of behaviorism. The practice of behavior therapy has come to mean using the broad base of psychological science to understand and alleviate human suffering. Thus, drawing on the diverse array of psychological science for potential conceptual, empirical, and methodological solutions makes perfect sense: that is, so long as one believes that through pluralism and breadth comes clarity.

Though it is quite clear that behavior therapy has been an enormously successful experiment, it is not entirely clear that the perpetuation of increasing conceptual pluralism is responsible, let alone beneficial. The pace of novel treatment approaches, particularly those we know

not only that they work but also why they work, has slowed considerably since the late 1960s. The trend over the last decade has been to import behavioral interventions shown to be effective for one problem and to test for the efficacy for different problems, either alone or in combination with other interventions. The problem with technique-oriented interventions is that they fail to capture what is unique about behavior therapy: its methodology, its functional analytic approach, its theory, its scientific core, and its behaviorism. Behavior therapists have been retreating from their behavioral core since the early 1970s and have suffered a great deal of identity confusion as a result. In 1976, Goldfried and Davison defined behavior therapy essentially as “applied experimental psychology.” Soon, the application of any research in psychology was incorporated into the definition, and behavior therapists tended to identify themselves with scientific rigor first and foremost, and only secondarily (if at all) with developing behavior therapy as a conceptually coherent scientific paradigm. Though the behavioral core is still very much part of behavior therapy, it has been compartmentalized as relevant for specific kinds of questions, problematic behaviors, and interventions, particularly those with clear origins in a psychology of learning. This is not what the founders of the behavior therapy movement had intended behavior therapy to become: a point underscored repeatedly by Cyril Franks, and the late Joseph Wolpe, Hans Eysenck, and B. F. Skinner.

IV. SUMMARY

Though psychoanalysis was the dominant force in the first and much of the second half of the 19th century, behavior therapy appears to be poised to be the dominant player in the 21st century. Ironically, many predicted that behavior therapy would, in effect, wither away and die by the end of the 1970s. This, of course, did not happen. Behavior therapy remains a vibrant and increasing popular approach to understanding and alleviating human suffering: an approach that shares the values espoused by managed behavioral health care, namely treatment accountability, treatment quality, efficacy, time efficacy, and cost-effective care. Behavior therapy is strong, if not dominant, in academic and mental health settings in the United States, parts of Europe, and in countries such as Australia and New Zealand that never had a strong psychoanalytic tradition. If anything has died, it is this: behavior therapy’s unique conceptual identity in behaviorism and behavioral thinking.

Behaviorism has been a reference point for ideological debates in psychology since the early part of the 20th

century, and behavior therapy has taken more than a few blows on the chin for its behaviorism. Behaviorism initially emerged as a reaction against psychology’s preoccupation with consciousness and introspectionism. Behavior therapy emerged in the 1950s as a reaction against the applied incarnation of a psychology of consciousness—naming Freudian psychoanalysis and its cousins (e.g., Gestalt and Rogerian psychotherapy). This reaction was not merely empirical or experimental, it was conceptually driven, it was behavioral, it was behaviorism and behavioral science in action. Behaviorism has been on the retreat within behavior therapy since the rebellious 1960s. In its place, behavior therapists embraced cognitivism and bio-psycho-social conceptualizations. This so-called cognitive revolution was seen as an advance, for it once more legitimized speculation about consciousness and theories derived from clinical intuition and commonsense about consciousness and events occurring within the skin. Under the banner of empiricism, behavior therapy welcomed all of psychological science under its roof, and soon a new conceptual system—a cognitive system—supplanted behaviorism, and talk of behavior was relegated once more to a place outside the skin where it could be observed directly. This cognitive revolution was, in many respects, a conceptual 180-degree *revolution of the wheel* back to a level of inference, albeit highly sophisticated and data driven, that behaviorism reacted so vehemently against early on. A similar 180-degree spin occurred when behavioral thinking was relegated once again to observable behaviors. It is only recently that behavior therapists have come to terms with the view that empiricism is one part of science: a part that behavior therapy can no longer claim as its own. The other part, so often ignored in the equation, is the recognition that science and practice are fundamental human activities: activities that are influenced, to a great extent, by values. Even other so-called hard sciences are increasingly recognizing that science is inherently value laden, not value free.

A sense that behavior therapy entails a coherent set of values and conceptual assumptions has been lost for some time, leaving many behavior therapists with an increasing sense of identity confusion. Indeed, there is something intellectually dissatisfying about identifying one’s professional identity with research falling under a diagnostic label, promotion of a particular assessment device, one of several microtheories or models of psychopathology, or a new or existing treatment technology for a particular psychiatric disorder. By contrast, conceptually grounded science and practice have a certain richness about them that transcends the fads and fancies of a particular era. For these and other reasons

the wheel seems to be shifting back to an interest in behaviorism, particularly the value of a coherent conceptual identity within behavior therapy.

Some behavior therapists will no doubt disagree with grounding behavior therapy in behaviorism, behavioral talk, and the like; however, there is good reason to do so. Behaviorism is a philosophy and an ideology, a way of framing questions of scientific and practical importance. Behaviorism is not, by definition, dogmatic, nor does behavior thinking entail that one should reject by fiat all other nonbehavioral approaches to psychological science. Rather, it is the behavior of some scientists that may have made behaviorism appear that way. Behaviorism has always entailed an openness to a behavioral scientific analysis of the phenomena studied within the purview of other branches of science. A science of behavior is, at the core, an attempt to develop more effective ways of talking about human behavior and its alleviation. Behaviorism is, in many respects, a looking glass that undoubtedly influences the questions one asks, the methods one adopts, how one sees the world, the criteria one adopts for truth and explanation, how one talks about their research and applied work, and ultimately what one does as a result. This behavioral looking glass is difficult to master for it runs counter to how all of us have been socialized to talk about and explain our actions and the actions of others.

The payoff for coming to terms with behaviorism and behavioral thinking would likely be improved coherence and clarity, particularly with respect to the connectedness between the basic and applied branches of behavioral science, and ultimately a renewed sense of behavior therapy's unique identity. This is the promise of conceptually driven behavior therapy. Yet, for this promise to be realized again, behavior therapy must first resolve long-standing issues related to misunderstanding and misapplication of behaviorism and behavioral principles in clinical contexts, lack of integration and systematic extension of the concepts and findings from basic behavioral science to applied arenas with humans, including limited training in behavior theory, philosophy of science, and lack of fluency with unique technical jargon emanating from a science of behavior more generally. At present, behavior therapy is at a point of fracture over its psychological roots, its philosophy, its behaviorism, and its relation to basic behavioral science. Without a behavioral core, behavior therapy has no unique identity, and the name behavior therapist might as well be replaced with the generic term scientist-practitioner.

The immediate pragmatic question is why should behavior therapists ground themselves in behaviorism, behavior theory, and behavioral data language? Does such grounding matter in what behavior therapists do? Does behavioral thinking make a behavior therapist more effective in working with clients? Is behaviorism and behavioral thinking outdated and narrow? Such issues cut to the core of a deeper question concerning the very definition of behavior therapy itself: is it defined by its philosophical and theoretical underpinnings?; by the techniques that are typically used?; or by the attention it pays to empirical validation? The history of behavior therapy has been full of diverse opinions regarding where the *heart* of behavior therapy lies. Answers to questions such as these are no doubt complex; however, our view is that consistent and thoroughgoing behavioral thinking is not narrow, certainly not simple or outdated, and would be of value in helping behavior therapy reestablish its identity but also its historic affinity with the basic branches of behavioral science. Ironically, it was the synthesis of such domains that paved the way for behavior therapy's early successes and unique identity.

neural network Any model used to describe the neural connections that give rise to cognitive and behavioral events.

self-efficacy A cognitive structure that is associated with the perception of personal influence on the environment.

treatment manual An algorithm for administering treatment for a specified problem or problems. Usually a collection of therapeutic techniques arranged in a sequence.

GLOSSARY

behavioral assessment A systematic examination of precursors and consequences of behavior, including self-reported cognitions and psychophysiological evaluations.

behavior modification A set of procedures designed to influence behavioral change based on principles from experimental psychology.

behavior therapy The application of behavioral and cognitive interventions to alleviate emotional and behavioral disturbance.

cognitive therapy An eclectic set of approaches aimed at altering patterns of thinking and perceiving environmental and internal events to achieve behavioral and emotional change.

empirically supported treatment Any treatment or collection of techniques that has been shown effective for a specified target behavior or diagnosis. Treatment is deemed empirically supported following a predetermined number of independent investigations that demonstrate clinically significant change.

functional analysis A structured method of determining the maintaining features of any behavior. This approach involves determining antecedent events, target behavior, organismic variables, and consequences of behavior in a causal sequence.

I. OVERVIEW

Behavior therapy has become a well-developed and integrated part of mental health treatment. As a set of procedures, and as a movement within psychology, behavior therapy has undergone significant changes, not only in form but also in how practitioners view it. The purpose of this article is to provide a comprehensive understanding of the field within the limits of space constraints. Behavior therapy can be described in terms of its theoretical underpinnings and their development from inception to the present time. A summary of these events constitutes the first portion of this article. Behavior therapy can also be described in terms of its clinical approach to treating a wide spectrum of behavioral and psychological disorders. A summary of these events constitutes the second portion of this article. We seek to explicitly discuss how behavior therapy has always been defined in the spirit of manual-based treatment in that treatments must be sufficiently well described to be replicated if empirical support is to be obtained. Operationalization of intervention steps is a hallmark of behavior therapy.

II. THEORETICAL BASES

A. Definitions of Behavior Modification and Therapy

Kazdin has written the most comprehensive and authoritative history of behavior modification and behavior therapy currently available. The terms behavior therapy and behavior modification denoted differences that were perhaps once more vigorously defended than they are today. Kazdin's preface states "Behavior modification can be defined as the application of basic research and theory from experimental psychology to influence behavior for purposes of resolving personal and social problems and enhancing human functioning." This definition is theoretically inclusive as it defines behavior modification in terms of applied experimental psychology, which today encompasses cognitive psychology and cognitive neuroscience as well as operant and respondent conditioning. This definition of behavior modification is consistent with the practice of contemporary cognitive behavior therapy and therefore could be used to define both behavior modification and behavior therapy making them one and the same thing. This would erase the historical distinction between them. Behavior modification was predominantly guided by B. F. Skinner's experimental analysis of behavior, which emphasizes environment-behavior relationships. Contingencies are typically imposed on individuals and/or groups. Notable exceptions entail the use of reinforcer surveys—menus to allow individuals to select what they will work for and behavioral contracting that actively engages the client in negotiations with those who control access to reinforcers. Clinical applications tend to be in schools and institutions with children or adolescents who are developmentally delayed, delinquent, or severely mentally ill.

Behavior therapy is currently viewed as the application of cognitive-behavioral techniques to adults and children on a primarily one-to-one basis, though sometimes in groups, in both inpatient and outpatient settings. behavior therapy has been defined in several ways. Eysenck asserted that behavior therapy may be defined as the attempt to alter human behaviour and emotion in a beneficial manner according to the laws of modern learning theory Wolpe and Lazarus similarly defined behavior therapy as the application of experimentally established principles of learning. Wolpe defined behavior therapy as the use of experimentally established principles of learning for the purpose of changing unadaptive behavior. Attempts to define behavior therapy in terms of learning theory failed primarily because no single learning theory commanded

sufficient consensus. Tryon observed that clinical and experimental psychology are predicated on learning. Many facets of normal and abnormal behavioral and psychological development depend on learning. Virtually all psychological interventions by clinical and experimental psychologists, including behavior modification and therapy, presume that some new learning will occur. Developmental theories and schools of psychological interventions differ mainly in how they account for learning. Psychotherapies differ mainly in terms of what they feel clients need to learn and they best learn what they need to know. Therapies by Beck and Ellis discussed later illustrate this point. Hence, learning is at the heart of the "basic research and theory from experimental psychology" that Kazdin used to define behavior modification and that Eysenck, Wolpe, and Lazarus used to define behavior therapy. Therefore, behavior therapy and behavior modification were often used interchangeably in the early history of this approach to treatment. Tryon recommended that we recognize our common dependence on learning, which implies memory, and directly discuss our differences in how learning and memory explains behavioral and psychological disorder as well as how new learning can cause therapeutic change.

Covert conditioning constitutes a hybrid approach. Homme introduced the term *coverant* to mean "operant of the mind." Covert reinforcement, covert extinction, covert modeling, and covert sensitization soon followed. These are operant behavior modification procedures in which the behavior, antecedent stimuli, and consequent reinforcers are all imaginal and therefore purely cognitive. Martin and Peal allocated an entire chapter to this operant interpretation of cognitive behavior modification.

Finally, we note that practitioners who endorse applied behavior analysis (ABA) are primarily persuaded by Skinner's experimental analysis of behavior and therefore focus heavily on behavior-environment relationships. This has recently changed to include private events, such as the treatment protocol developed by Hayes (acceptance and commitment therapy [ACT]). The term behavior modification has primarily been used to refer to their clinical efforts. Because reinforcement contingencies can be imposed on groups of people, behavior modification has also come to connote group interventions in institutions such as hospitals, residential placements, and schools. Because systematic desensitization and related interventions are primarily provided in outpatient settings, behavior therapy has also come to refer to individual treatment. It should be noted that customized contingency management interventions are designed and implemented

FIGURE 1 Original behavioral links to environment. This figure depicts the original conceptualization of how behavior is driven by environmental consequences.

with regard to individuals in outpatient settings. This frequently entails assisting parents modify behavioral excesses or deficits displayed by their children.

B. History of Behavioral Theory

Kazdin traces the history of the theoretical foundations of behavior modification from Sechenov (1829–1905), through Pavlov (1849–1936), Bechterev (1857–1927), Watson (1878–1958), Thorndike (1874–1949), Guthrie (1886–1959), Tolman (1896–1961), Hull (1884–1952), Mowrer (1907–1982), to Skinner (1904–1990). Kazdin devotes all of Chapter 4 to Skinner, Chapter 7 to the “emergence and evolution of applied behavior analysis,” and Chapter 8 to “contemporary applied behavior analysis.” Kazdin’s Chapter 5 traces the clinical applications of work on experimental neuroses and conditioning to human behavior. Wolpe’s work on systematic desensitization beginning in South Africa and efforts by Eysenck and others in the Maudsley Group in England are chronicled. Work in the United States is also covered. Kazdin’s Chapter 9 reviews “cognitive behavior modification and self-control” before considering “ethical and legal issues” in Chapter 10. The details of these events have been omitted because they are extensive and not easily summarized except to say that the history of behavior modification therapy entails the clinical application of empirically supported methods and principles of behavior change. The primary attraction of operant and respondent conditioning by clinicians has always been that conditioning provided prescriptions for behavior change because clinicians are primarily called on to change behavior. Behavioral therapies differ from psychotherapy in general because they identify specific behaviors for change and use empirically supported treatment principles and packages to obtain these changes.

C. Behavioral Theory

Kazdin defined behavior modification therapy to include the entire theoretical basis of experimental psychology as noted earlier. Learning theories by Thorndike, Skinner, Hull, Guthrie, Estes, Tolman, and Hebb were available. However, conditioning was the primary theoretical basis for studying learning as can be seen by Kimble’s influential revision of Hilgard and Marquis’ *Conditioning and Learning*. In 1970 Kanfer and Phillip’s *Learning Foundations of Behavior Therapy* formulated a behavioral approach to clinical psychology in terms of operant conditioning. Plaud and Eifert’s book, *From Behavior Theory to Behavior Therapy*, maintains this theoretical orientation. Figure 1 presents the theoretical premise of conditioning theory. Pavlovian respondent conditioning, also known as classical conditioning, is a S–R theory in which conditional stimuli come to elicit responses similar to the responses elicited by unconditional stimuli. Skinner carefully distinguished his approach as a R–S theory in which consequent stimuli reinforced preceding behaviors. Skinner explained behavior in terms of variation and selection using the same functional argument Darwin employed to explain the origin and extinction of species. However, for present purposes it is important to emphasize that only stimuli and consequences residing in the external environment were admissible explanatory candidates in all conditioning models.

D. Operant Conditioning to Psychological Behaviorism

Behaviorism was just reviewed as a single theoretical system. Staats identified three generations of behaviorism. He ascribed the first generation of behaviorism to John B. Watson and his studies on conditioned emotional reactions. Staats associates Skinner, Hull Mac-

FIGURE 2 Psychological behaviorism. S_1 represents the original learning environment; BBR represents basic behavioral repertoires; S_2 represents the current environmental situation; B represents the behavior (including experience) and resulting learning that takes place. Adapted with permission of A.W. Staats.

Corquodale and Meehl, Spence, and Tolman with behaviorism's second generation. Staats identifies himself with behaviorism's third generation.

Staats has offered a perspective on behavioral assessment and treatment that is based on a unification of basic behavioral principles and general psychology. Unlike his predecessors, his emphasis has been on linking behaviorism with the rest of the field rather than establishing behaviorism as a separate discipline. He has called for "complementarity—not opposition." Staats outlines 11 "levels" of psychological behaviorism, essentially capturing the major experimental and applied areas of psychology. These are biological mechanisms of learning, basic learning theory, human learning principles, personality, child development, social personality, measurement, abnormal psychology, clinical psychology, educational psychology, and organizational psychology. Although not explicitly cited, efforts aimed at incorporating basic psychological science findings into behavior therapy have been undertaken in the same spirit espoused by Staats by Onken and Blaine and by Onken and Bootzin.

In determining how to best analyze human behavior and develop empirically sound interventions, Staats and associates present a diagrammatic approach to developing a functional analysis. A key component of this arrangement is the set of basic behavioral repertoires (BBR) that one develops during a lifetime and brings to treatment. The verbal-motor repertoire entails the ability to understand language and use it to regulate behavior. The verbal-image repertoire entails the ability of language to elicit a conditioned sensory response. The verbal-emotional repertoire entails the ability of language to elicit emotions. The verbal-labeling repertoire entails the person to respond verbally to external stimuli. The verbal-association repertoire entails communication, problem solving, and mathematics. The verbal-imitation repertoire entails language to govern

behavior. The verbal-writing repertoire entails language and written expression. The sensory-motor repertoire entails stimuli with action. The emotional-motivational repertoire entails affect and those factors that drive behavior. Standard psychological tests, such as IQ tests, are viewed as standardized behavioral samples. Performance on these tests quantifies specific BBRs. Hence, Staats has addressed what are usually characterized as cognitive phenomena by extending behavioral theory (see Figure 2).

According to Staats, treatment proceeds best when this illustration of initial learning situation, basic behavioral repertoires (or personality), and current contingencies operate in a continuous feedback loop. That is, intervention alters current contingencies, resulting in environmental changes, which in turn influence the BBR. In this way, assessment and treatment are inexorably linked. This approach is consistent with the original vision of behavior therapists but offers a perspective that embraces the full breadth of psychology.

Although Staats initially termed his approach paradigmatic behaviorism, Tryon maintained that his efforts were more accurately termed psychological behaviorism, and that became the title of subsequent article and the subtitle of his most recent book. Staats uses the term unified positivism to describe this approach. He endorses the general values of science including observation, measurement, and experimentation and endorses general theory construction values of empirical definition, consistency, generalizability, and parsimony but is open to and actively encourages the use of psychological constructs.

E. The Cognitive Revolution

Following a period of extensive research on basic behavioral processes, and how various forms of psychopathology may be acquired through environmental

FIGURE 3 Modified behavioral theory. In this revised view of behavior–environment relations, cognitions are considered a mediator between behavior and consequences.

circumstances (learning), many investigators became dissatisfied with conditioning theory. Increasingly, behavior therapists were persuaded that the information proffered from clients' self-report was itself an appropriate area of study and that this information might form the basis of functional assessment and intervention. That is, the way clients *think* was offered as a causative factor in behavioral and emotional problems. Heralded as a more comprehensive view of individual clients, this adjustment was intended to augment current behavioral models by accounting for cognitive styles that are introduced into clinical settings and set the occasion for the development and/or maintenance of most forms of psychopathology. This was the basis for the cognitive revolution that took hold of behavior therapy and continues to exert considerable influence today. Figure 3 depicts this modification of behavioral theory.

Prior to the more formal integration into behavior therapy that cognitive interventions enjoy today, groundwork was laid that would allow for the merging of these approaches. Notable in this regard was the work of Cautela involving coverants and covert conditioning mentioned earlier. Although originally placed in the same company as other traditional behavioral interventions (such as operant and classical conditioning), it should be noted that each element of intervention was a cognitive construction, including reinforcers, consequences, and behavior (i.e., images of behavioral events). Coverant control continues to be viewed as a behavioral rather than a cognitive treatment despite the fact that the events, antecedent stimuli, and reinforcing consequences are entirely imaginal and therefore cognitive.

It is interesting that the mainstream cognitive revolution was initiated by clinicians who were neither behavioral by training, nor experimental psychologists by

trade. Beck's cognitive therapy and Ellis's rational emotive behavior therapy each offered approaches to treatment that were essentially client centered, Socratic in method, and reliant on client self-report augured by client self-observation and verbal challenge of identified dysfunctional beliefs. These clinicians assert that the impetus for developing their approaches to treatment was as a reaction to their more traditional training in psychodynamic approaches, whereby they observed that clients spontaneously report a variety of negative thoughts that give rise to neurotic conditions. In contrast to their traditional training, each felt compelled not only by this observation, but by clinical experience that teaching clients methods for directly addressing these spontaneously reported thoughts resulted in the alleviation of emotional distress and behavior disturbance. Both approaches have been popularized and integrated into contemporary behavior therapy. Indeed, this integration appears so complete that most refer to this treatment approach as cognitive-behavioral therapy (CBT) rather than behavior therapy (BT).

1. Beck's Cognitive Therapy

Beck suggests that emotional distress is predicated upon negative automatic thoughts (NATs), which emerge from schemas. Schemas are defined as structures that organize information in a database-like form that sorts and summons information based on stimuli (either overt events or other verbalizations). In 1978 Beck and colleagues articulated this notion most prominently in the application of cognitive therapy for depression. Specifically, depressed individuals are said to possess a "negative triad" of automatic thoughts that cause negative views of the self, world, and future. Each of these domains has been characterized as a schema that is essentially negative in depressed individ-

TABLE 1
Self-monitoring Form for Client Use in Cognitive Therapy (Sample Form)

Date	Situation	Emotions	Automatic thoughts	Rational response	Outcome

uals. The principle task in cognitive therapy (CT) is to help clients systematically determine ways of challenging these thoughts, usually by evidence gathering and self-monitoring. Since the time that Beck and his colleagues described this method for treating depression, it has been extended to anxiety disorders, substance abuse, personality disorders, obsessive–compulsive disorder, eating disorders, and delusions. Beck’s approach has shown a great deal of promise in alleviating emotional distress, as well as shedding light on the interaction between therapy and medication. Specifically, it has been shown in numerous trials that cognitive therapy alone is at least as effective as antidepressant medication for depression, while also showing greater maintenance of gains following medication discontinuation. This has since become an important experimental design for use in determining the relative contribution of CBT and medication for a number of other psychological conditions such as panic disorder, obsessive–compulsive disorder, alcohol abuse, and eating disorders.

Cognitive therapy, using the approach described by Beck, involves teaching clients to become their own scientist. For example, clients are engaged in a Socratic discussion whereby the negative automatic thoughts are actively challenged. Clients are taught to identify NATs by maintaining a daily log that is structured along dimensions of situation(s), emotional response to that situation, automatic thoughts, rational response, and outcome. A sample form for client use is presented in Table 1.

The components of the strategy of monitoring events and the NATs that give rise to emotional distress are highly structured in CT. Clients are taught to identify specific situations (or imagery that occur in daydreams) that result in distressing emotional reactions. Clients are instructed in the identification of these NATs and then taught how to challenge these ideas using specific questioning of the accuracy of these ideas. They are then asked to write a rational alternative thought and the outcome from applying this alternate thought. Throughout, as a means of examining the effectiveness of the challenge, clients are also instructed to rate the degree to which they experience the emotion, as well as degree they believe both the NAT and rational alternative. Implicit in this approach is the perspective that one will not initially believe the rational alternative, but with repeated practice the underlying philosophy of the rational alternatives will begin to take hold.

In order to be effective, and for the integration of the rational alternatives to replace the NATs, Beck argues that clients must engage in personal experiments that are designed to directly challenge the accuracy of these dysfunctional thoughts. After conducting several of these experiments, practitioners applying CT seek to identify “themes” (schemas) that guide these automatic thoughts. It is at this point that the cognitive therapist begins to actively challenge the underlying theme, instruct clients to seek situations that broadly address these themes, and continue monitoring automatic thoughts as a means of identifying

other possible automatic thoughts that may arise as treatment continues. Broadly speaking, this process has been referred to as cognitive restructuring.

2. Ellis's Rational Emotive Behavior Therapy (REBT)

Ellis has described a variant of CT that is conversant with traditional operant behaviorism in that clients are taught to develop a functional analysis of their own upset emotional experience. Specifically, in the early stages of treatment, clients are instructed to identify (a)ctivating events, (b)eliefs, and (c)onsequences that surround individual events resulting in distress. After repeated practice and feedback from the therapist, clients are expected to articulate these sequences readily. Following this, clients are taught to extend this A-B-C analysis to include (D)isputation and (E)ffects of the outcome. This full sequence is then understood as a method of alleviating distress when applied repeatedly. As a means for galvanizing these effects, a number of behavioral activities are typically arranged that allow for *in vivo* challenge of irrational beliefs. For example, shame attacks are where one seeks out a situation in which the irrational belief may be directly challenged (such as announcing the time in a crowded restaurant to challenge beliefs associated with embarrassment). Another method is referred to as the rational barb, where the therapist states the irrational belief out loud to the client, and the client must rapidly arrive at a disputation (such as comments about physical appearance). Finally, rational role reversal is where the therapist enacts the role of client, and the client must identify irrational beliefs and suggest methods for disputation. These procedures are described in detail in the work of Walen, DiGiuseppe, and Dryden.

3. Distinguishing CT from REBT

It appears from the description offered here that CT and REBT have substantial overlap in conceptualization. Both involve homework designed to identify dysfunctional thinking patterns. Each is highly structured. Each approach emphasizes demonstration of the effects of *in session* disputation by *in vivo* application. However, there are some subtle differences. The first is that REBT is more reliant on specific exercises that have been packaged for challenging irrational ideas as they arise. The second is that, despite the broad similarities, most treatment trials have adhered to the format outlined by Beck, resulting in greater empirical support. Indeed, Beck has placed greater emphasis on empirical research, while frankly acknowledging similarities with

Ellis's approach. Finally, REBT emphasizes identification of particular words and styles of describing the world that may result in emotional distress. For example, Ellis has popularized some catch phrases that are liberally applied to challenge the use of particular words to describe personal emotional functioning. Ellis has suggested that people "awful-ize" to refer to the use of something being awful (rather than merely unfortunate or inconvenient). Other words specifically targeted as part of treatment are "should," "ought," and "must." Further, Ellis has encouraged people to try applying the E-prime philosophy, which specifically suggests that people avoid using the verb "to be" as it contributes to broad labeling that fosters an inability to effectively and flexibly challenge disruptive thinking patterns. In 1973 Ellis emphasizes that REBT arises from the philosophical tenets of Epictetus whereby the labeling of something as "good" or "bad" is what makes it so, and that no event is inherently good or bad.

F. Cognitive Theory Elaborations That Affect Cognitive Therapies

Although CT and REBT may rightly claim a place as mainstream components of behavior therapy, the groundswell that resulted in the widespread acceptance of these approaches had been set in motion earlier, aside from the initial "behavioral" interventions described by Cautela. Notable here is self-efficacy theory by Bandura. Self-efficacy refers to a person's belief in the extent that their actions influence the environment in ways that are advantageous. These beliefs are said to causally contribute to behavior as well as emotional experience. This is also the central position of the cognitive therapies. This assertion has led to considerable debate within the field, and is not yet resolved. The procognitive side of the argument strongly suggests that observational learning rests on an assumption that even without direct contact with contingencies higher-order organisms learn, which implies cognition. Cognitive theorists have also suggested that radical behaviorists discount cognition despite references to "private events" and that cognition represents a plausible area of investigation within the broader domain of CBT. The behavioral position suggests that cognitions (all private events) are epi-phenomena representing a higher-order class of behavior. Further, in response to the concern over mere labeling, behaviorists have argued that cognitions exist as correlates of behavior. It has been said that the move to cognitive analyses has always been part of psychological assessment but it should not occur at the cost of traditional behavioral assessment. Cognitive

FIGURE 4 Modified behavioral theory.

variables are private events and therefore are essentially unknowable by an observer because of measurement problems. Although the controversy continues regarding whether cognition represents a causal link between behavior and consequences, researchers examining treatment components for specific disorders have embraced self-efficacy. For example, in 1985 Marlatt and Gordon outlined a cognitive-behavioral theory of treatment for substance use that has gained prominence. Since that time, self-efficacy has figured prominently in several variants of cognitive-behavioral therapy for smoking, obesity, depression, anxiety disorders, and marital distress.

G. Impact of Neuroscience

LeDoux summarizes many studies that demonstrate how conditioned emotional responses are formed through activation of subcortical structures. Although he personally rejects behaviorism, his work repeatedly demonstrates the crucial importance of classical conditioning to the etiology of emotional and behavioral disorder. In short, many studies conducted in his lab, and the laboratories of other investigators, clearly demonstrate that emotional responses are formed by subcortical brain structures that respond quicker than our higher cortical centers do. This is what makes negative automatic thoughts rapid and automatic. Emotional reactions derived from traumatic experiences are retained for long periods of time after a single or few learning trials. Fortunately, higher cortical centers enable some cognitive control over these reactions. These and related supportive findings enable us to expand Figure 3

into Figure 4. The line from cognition to emotion represents this influence.

Figure 4 also illustrates that therapeutic experience with the environment, corrective emotional experiences, can modify emotional reactions. Figure 4 indicates that these therapeutic experiences (behavior–environment) relationships have both cognitive and emotional consequences. The path connecting cognition and emotion bidirectional indicating that cognitions influence emotions and emotions influence cognitions. This means that corrective emotional experiences cause people to think and feel differently that also means that cognitive changes accompany behavioral interventions. The crux of cognitive theory is that cognitive processes actively transform experience with the environment.

It can be argued that all of the interconnections in Figure 4 are causally bidirectional. This theoretical extension produces a connectionist network among thoughts, feelings, behaviors, and environmental consequences. We next consider issues related to theoretical integration and how informal and formal network theories have contributed to theoretical unification.

H. Theoretical Integration

In an effort to provide a conciliatory note on this argument, Reitman and Drabman, and Dougher point out the similarities between radical cognitivists and radical behaviorists by indicating both are interested in achieving behavior change, with fundamental differences in method to achieving that change. On the one hand, it appears that the addition of “cognitive” to behavior

therapy has led to improvement in the delivery of treatment and may even enhance treatment adherence in some cases (as in obsessive-compulsive disorder). On the other hand, others have remarked that the retreat to cognitive methods has been either premature or insufficiently informed by theory from experimental cognitive psychology. Indeed, there has been a burgeoning literature in experimental psychopathology that has examined the role of attention and memory in various conditions but has not yet “inspired any treatments”.

McNally characterized this disparity as “potentially incompatible.” On the one hand, the treatment approaches described by Beck and Ellis represent introspective approaches whereby beliefs associated with various environmental events (assumed to be central to emotional distress) are culled from direct questioning. On the other hand, experimental cognitive approaches (hereafter referred to by the more popular term information processing) rely on inferences for cognitive processes based on participants’ performance on a number of laboratory tasks. These tasks do not typically involve direct questioning. McNally indicates that although the arguments levied on both sides of this debate have been intense, there is a common theme that emerges. Specifically, both approaches at some point must rely on client report. Information processing approaches routinely rely on self-report measures for determining placement in groups (i.e., depressed, nondepressed). Likewise, clinical “belief-based” approaches rely on inferences of change based on both client report and performance during specified therapeutic tasks.

If these approaches are to be comprehensive in scope, then each must answer the question of how psychopathology develops. Efforts have been made to articulate etiology so that treatment may be informed with greater clarity. We have identified two different perspectives on this matter. First, a radical cognitive perspective supports the idea that negative (and positive) thoughts arise through discrete learning opportunities. Therefore, one has opportunities to understand emotional reactions through a lens of either rational or irrational beliefs, and these beliefs are shaped by feedback from significant others or information provided by various sources. The second (and more popular) view involves the presence of dispositional traits that set up opportunities for developing these same maladaptive patterns of thinking. There are numerous examples of how preexisting traits may predict later psychopathology such as anxiety sensitivity and panic disorder and other anxiety conditions, sociotropy-autonomy and depression, or restraint eating and eating disorders. This is not a comprehensive list of

dispositional traits that have been tied to cognitive bias or the onset of discrete forms of psychopathology. By adopting the position that one may begin with a set of characteristics that lends itself to developing psychopathology by discrete learning consequences represents an attempt on the part of researchers to be truly integrative in understanding and describing psychopathology. This is a well-established tradition in behavior theory and therapy, as advocated previously by Lazarus and Staats, among others. The presence of dispositional traits may assist in identifying schemas, according to Beck’s CT, but this has rarely been specifically articulated (except in the case of anxiety sensitivity).

The emergence of network models may enable a resolution of these theoretical differences. We first examine the emergence of informal network theories and then consider formal parallel distributed processing connectionist neural network models.

1. Informal Network Models

Lang suggested that fear can be understood as a memory network containing information about stimulus characteristics, verbal and nonverbal response tendencies, mediating visceral and somatic events (feelings), and propositions about what all these events mean under different circumstances. Each source of information can be thought of as a node. The excitatory and inhibitory connections among these nodes constitute the theoretical network that governs behavior and the psychophysiological responses to scripts read by fearful persons in Lang’s research.

Foa and Kozak expanded Lang’s network theory to include the concept of “emotional processing”, which predicts a gradual reduction in emotional responding over time given persistent activation of the fear network. Short-term habituation effects are hypothesized to change the fear network thereby resulting in long-term fear reduction. New therapeutic memories form and interact with incompatible fearful memories. Creamer, Burgess, and Pattison discuss a similar form of “network resolution processing.” Fear networks are hypothesized to vary in size, structure (interconnectedness), and accessibility .

Chemtob, Roiblat, Hamada, Carlson, and Twentyman hypothesized a 4-level cognitive schema network varying from concrete representation at Level 1 to abstract representation at Level 4. One aspect of this network influences another through “spreading activation” thereby interrelating thoughts, feelings, and actions.

The above mentioned network theories are multidimensional and interactive. They are progressive in that

FIGURE 5 S-O-R model.

they provide for flexible and complex interactions among thoughts, feelings, and actions. However, they contain few constraints and cannot be used to deduce (calculate) specific outcomes due to the absence of principles that characterize and limit network dynamics. These systems are black box and arrow models because they indicate relationships among functions and do not provide mechanism information to show why these relationships exist.

2. Formal Connectionist Network Models

Parallel distributed processing (PDP) Connectionist neural network (CNN) models are sophisticated mathematical systems that generate quantitative results when computer simulated. They have all the theoretical applicability and flexibility of the informal network models, but they have the necessary structure and constraints to enable specific theoretical predictions to be made. Specific architectures and formal learning rules systematically modify connection weights between the processing nodes in response to experience.

The common 3 layer CNN has strong similarities to a higher-order factor structural equation model (SEM). Behavior therapists have long subscribed to a 3 layered Stimulus–Organism–Response (S–O–R) model. Figure 5 renders this traditional model in terms of a 3 layered feed-forward CNN model that is equivalent to a 2nd-order factor. The bottom layer of processing nodes, frequently termed neurons, represents stimulus inputs. They are the indicators in a SEM. The second CNN layer, also called the middle or hidden layer, is composed of fewer neurons; one for each latent construct the network will need to learn. These are the latent factors in a SEM. Every input neuron is typically connected to, synapses with, every middle neuron in a CNN whereas indicators are selectively loaded on factors in a SEM. These CNN connection weights are initially set to small random values. The network decides

for itself, as a result of training, which stimuli are relevant to each latent construct by making some synapses more positive and others more negative via a learning function. Connections to irrelevant stimuli decrease toward zero. Transformation is central to the cognitive model as mentioned earlier. The middle layer transforms stimulus inputs into fewer latent constructs. Hence, these network models are cognitive models that are constructed from associative networks. The third or output CNN layer represents behavioral responses. At least one output neuron is needed to represent the presence (on) or absence (off) a target response. Multiple neurons can be used to represent more complex behavioral repertoires. Figure 4 contains two response nodes. Every middle neuron connects with every output neuron. The response layer corresponds to a higher-order factor structure in a SEM where 2nd-order factors load on 1-order factors. The CNN determines for itself which combination of latent constructs, middle neurons, enables which responses by making some synapses between responses and latent constructs more positive (excitatory) and others more negative (inhibitory) via a learning function. Irrelevant connections between 1- and 2nd-order latent constructs, between middle and output (response) neurons, are modified until they approach zero. Behavioral responses are therefore understood in terms of 2nd-order factors. The 2nd-order factors transform the 1-order factors thereby introducing a second level of transformation. More complex PDP CNN models contain additional levels and therefore perform additional transformations on prior transformations. Complex and powerful cognitive models emerge from such architectures.

These connectionist S–O–R models have been characterized as neural network learning theory (NNLT) because these brainlike PDP–CNN structures develop their functionality through learning at every developmental

step; they are trained rather than programmed. Tryon used the bidirectional associative memory model to satisfy all four of Jones and Barlow's and all five of Brewin, Dalgleish, and Joseph's explanatory requirements for a comprehensive understanding of posttraumatic stress disorder. NNLT accounts for the nonassociative as well as associative etiologies of phobias. NNLT provides a comprehensive understanding of how systematic desensitization and exposure therapies work. NNLT provides an integrated theoretical basis for multimodal behavior therapy. NNLT provides the missing theoretical link between genetics and behavior in behavior genetic explanations. NNLT resolves the cognitive-behavioral debate, synthesizes findings from human and animal research and resolves several other long-standing schisms in psychology.

H. Behavioral Assessment and Functional Analyses

Given this discussion, much has changed in behavioral theory and its application over the past 30 years. The field has witnessed growth, delineations of theoretical perspectives, and widespread applications. Indeed, the rate of change within the behavioral perspective has been so rapid that earlier writers such as Mahoney, Kazdin, and Lesswing questioned whether behavior therapy was even behavioral. This argument stemmed from earlier rebellions against the applications of techniques that assume the functional utility of private consciousness. However, as Mahoney, Kazdin, and Lesswing point out, Skinner too considered private mental activity to be of utility in determining functional relations with behavior, although he contended these were beyond our ability to empirically support.

Since the earlier growth period within behavior theory and therapy, it has been generally agreed that behavior therapy encompasses both behavior theory and cognitive theory. Indeed, the masthead of the flagship journal (*Behavior Therapy*) of the Association for Advancement of Behavior Therapy recently included cognitive sciences as part of the description of the area of study appropriate for that particular scientific forum. The masthead of *Behavior Therapy* reads as follows: "*Behavior Therapy* is an international journal devoted to the application of behavioral and cognitive sciences to clinical problems. It primarily publishes original research of an experimental/clinical nature which contributes to the theories, practices, and evaluations of behavior therapy, broadly defines." Although this change in criteria for submissions to this journal is a recent modification, there have been inherent signs that cognition has been part of behavior therapy since its early years.

1. Behavioral Assessment

Behavioral assessment represents a significant aspect of conducting behavior therapy. In the briefest sense, behavioral assessment allows practitioners to identify patterns of responses (both behavioral and emotional) that accompany specific stimulus events. These can be responses that are tied directly to the presenting problem, or may be associated indirectly, plausibly related but unacknowledged by the client, or acknowledged only after treatment has begun.

As is true of other systems of assessment, behavioral assessment encompasses both reliability of measure and validity of the evaluation. Two additional features should be highlighted here. Specifically, reliability of measurement within individuals (e.g., consistency of response) as well as ecological validity (e.g., similarity to experience outside the office) is emphasized in behavioral assessment. Given these two additional features, there have been numerous rigorously tested behavioral assessment methods developed. Notably, many instruments used in behavioral assessment are self-report questionnaires. However, behavioral assessment also includes self-monitoring (for behaviors, as well as thoughts and emotions as described earlier).

A major area of assessment for the purposes of identifying topographic as well as functional aspects of psychopathology includes activity measurement, which can include direct observation or minimally intrusive monitoring by electronic devices. Further, methods of assessment for psychophysiological response (such as heart rate, eyeblink startle, etc.) has formed an important part of assessment in behavior therapy.

Given the emphasis on empirically supported approaches to treatment, these assessment procedures are useful in two major ways. First, in providing a baseline evaluation, clinical interventions can be tailored to both specific areas of response as well as to severity level. Second, because these approaches to assessment are intended to be objective, each assessment represents an opportunity to objectively evaluate treatment progress and outcome at the level of the individual case. This has become increasingly important for practitioners given the rise of managed care and the need to demonstrate treatment efficacy to third-party payers.

2. Functional Analyses

Behavioral assessment provides an important basis for determining response areas to focus on in therapy, as well as both baseline and benchmarks for evaluating treatment progress. However, in conjunction with behavioral assessment, it is important to establish when, and under what conditions, particular problem

FIGURE 6 Classical and operant conditioning.

behaviors arise. This assessment is typically referred to as a functional analysis.

Functional analysis has its roots in earlier experimental traditions in behavior modification (described earlier). Specifically, functional analyses examine stimulus events that give rise to responses, with organismic variables intervening (the S–O–R perspective; see Figure 5). However, many theoreticians have felt that the S–O–R model fails to account for consequences of behavior. Therefore, a more complete accounting of how behavior is reinforced (and maintained) is encompassed by the inclusion of consequences at the end of the sequence (hence, S–O–R–C). Each unit of behavior is then conceptualized in these terms, and chains of these S–O–R–C analyses may be connected to represent behavior.

The goal following a complete functional analysis of any identified problem behavior is determining methods for altering contingencies to allow for the development of alternate behaviors. Further, as a functional analysis is developed, clinical interventions may be tailored that are intended to eliminate identified problem behaviors, either by extinction (nonreward or exposure), or by developing an incompatible alternate response. Therefore, the functional analysis is considered of utmost importance in behavior therapy as it sets the stage for how treatment is likely to proceed, what behaviors will be targeted, and what is likely to be utilized as reinforcement to foster change (see Figure 7).

III. EMPIRICALLY BASED APPLICATIONS

A. General Characteristics

Early in the history of behaviorally based treatment, researchers and clinicians sought interventions that

were based on sound experimental procedures and that produced observable change. Collectively known as behavior therapy, this field flourished under this banner and grew to its current status of cognitive-behavior therapy. It is then a sign of growth that at the present time, many researchers have formulated treatment manuals that are based on a collection of specific interventions, arranged in a meaningful sequence, that address specific behavior problems.

Professional ethics requires psychologists to use empirically supported treatments as well as psychometrically validated tests. The call for restricting clinical practice to empirically supported treatments did not come until after most clinicians abandoned earlier behavior modification practices of performing a functional assessment of the target problem followed by an individually tailored treatment based on extraordinarily well documented conditioning principles. Absent these two practices, cognitive therapists turned to validating multisession treatment packages for various disorders. Although this was and is a constructive practice, the earlier approach of functional assessment followed by intervention based on conditioning principles should not be overlooked as empirically informed practice. The roots of such practice are deeply ingrained in behavioral therapy, beginning with Gordon Paul's famous quote as follows: "What treatment, by whom, is most effective for this individual with that specific problem, and under what set of circumstance, and how does that come about?" Tryon republished a system of behavioral diagnosis that guides behavioral observation and interviewing to identify conditioning principles that maintain behavioral excesses or deficits and leads prescriptively to behavioral treatments based on empirically validated conditioning principles. This is in contrast to the current rush to develop treatment manuals, whereby the credo is what interventions, by

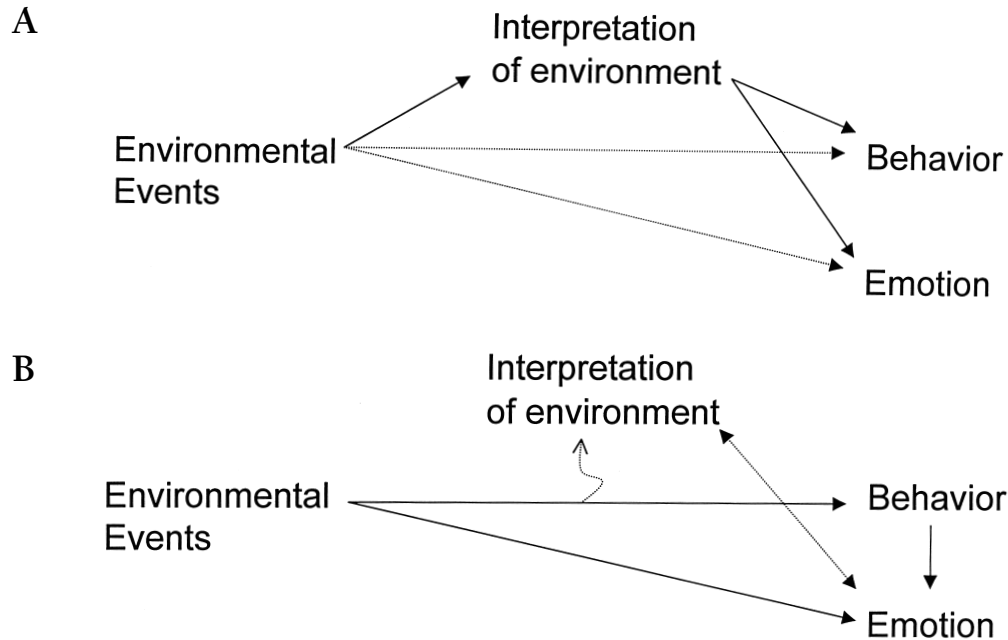

FIGURE 7 Cognitive-behavior therapy vs. Radical-behavior therapy. (A) Cognitive-behavior therapy, solid arrows indicate primary relationship emphasis. (B) Radical behavior therapy, solid arrows indicate primary relationship emphasis; double arrow indicates correlative relationship. Single arrows indicate causative relations.

which therapist, are most effective in which sequence with what diagnoses. The question of how it comes about or under what circumstances have been deemphasized in favor of packaging.

Prescriptive treatment based on known behavioral patterns has not followed such a linear trajectory from functional analysis to empirically sound intervention and back to behavior analysis. The advent of treatment manuals rests on a fundamental assumption: treatment packages have been developed around diagnoses obtained from the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. This is a surprising development in some ways, because early behavioral interventions (and current approaches based on radical behaviorism) have not endorsed psychiatric nomenclature. Instead, the emphasis has always been on developing a functional analysis of the problem behaviors (including functional assessment of cognition), and developing interventions that address these functional relations.

If this is the fundamental method of assessment and intervention then how did so many cognitive-behaviorally oriented treatment manuals develop that are centered on psychiatric diagnosis? Researchers, like most professionals, are frequently responsive to market demands. There currently exists essentially one widely used

diagnostic nomenclature in mental health settings, the *DSM*. Unlike other nomenclatures, however, the *DSM* is not a guide that allows for one to determine treatment (or a meaningful heuristic for treatment) for a given diagnosis. However, practitioners are beholden to this framework in order to communicate with other mental health practitioners, and for third-party payers. Given this state of affairs, behavior therapy researchers have sought generalities within specific disorders rather than generalities within sets of interventions aimed at typical behavior patterns. To further complicate matters, most practitioners do not readily integrate research findings into their daily practices. Therefore, it is understandable why behaviorally oriented practitioners and researchers would focus on treatment manuals as a means of integrating research findings into their practices, even if these are based upon a diagnostic scheme that runs counter to the philosophy of traditional behavior therapy.

B. Characteristics of Manualized Interventions

A wide range of psychological conditions has come to the attention of researchers wishing to develop empirically supported intervention packages. The range of disorders varies, from depression to simple phobia,

headache to childhood enuresis, sexual dysfunction to sex offenses. A detailed list of empirically supported treatment is provided by Hayes, Barlow, & Nelson-Gray in their 1999 book. Criteria have been developed for three levels of empirically supported interventions: well-established treatments, probably efficacious treatments, and experimental treatments. These criteria were developed by a task force formed by Division 12 of the American Psychological Association whose mandate was to formulate both criteria for determining efficacious treatments and to identify treatments that have been established.

The typical treatment manual that relies on cognitive-behavioral procedures is a loosely associated set of empirically sound procedures, but with little in the way of a conceptual core. Although it is not our intention to single any one manualized approach out of the larger set, one illustration of this state of affairs is dialectic behavior therapy (DBT), which has been developed specifically for borderline personality disorder. An examination of the skills manual shows that there are elements of social skills training (especially interpersonal assertiveness), mindfulness exercises, exposure for fear reduction, and cognitive disputation to name a few. This has all been neatly packaged in a user-friendly format specifically formulated for the practicing clinician. The results of this packaging have indeed been encouraging, and the popularity of this approach has been impressive. On the other hand, there is no conceptual feature that unifies these interventions, and the application for borderline personality disorder may suggest as much about the syndromal validity of the diagnosis as it does for the treatment packaging (i.e. necessary components for effectiveness).

We highlight this particular treatment as it has been shown effective with a notoriously challenging population, was developed around a specific *DSM* diagnosis where the label conveys virtually nothing about how to proceed with treatment, the actual symptoms and typical presentation of the disorder are heterogeneous, and treatment entails a conglomeration of empirically established interventions from disparate branches of behavior therapy. Further, clinicians have embraced this approach and have called for more intensive research and dismantling studies.

Some treatment manuals do follow a conceptual core, although these have been less common. There are some noteworthy examples. One is a recent manual for the cognitive treatment of pure obsessions from Freeston et al. in 1997. In this case, the functional component is that individuals with pure obsessions suffer from problems in

appraising situations for their personal responsibility, which in turn creates difficulties in determining relative risk associated with specific behavioral action. However, even in this case, there is some reliance on unrelated, noncognitive interventions such as exposure-based intervention aimed purely at fear reduction.

Treatment manuals, whether following a specific diagnosis, or designed for a more general user format (such as ACT), do offer a greater value: dissemination of effective interventions. Because most manuals no longer adhere to the "session-by-session" format, the applicability to everyday practice has been greatly increased. Other barriers to dissemination have begun to tumble as the field offers training initiatives and has developed practice guidelines for specific conditions. The necessary future directions for empirically supported treatment manuals include research into the effectiveness of components in sequence for particular conditions and "dismantling" research, where components are evaluated for the specific contribution to treatment outcome. That is, to what extent are specific components of a treatment package necessary.

IV. SUMMARY

It has been our intent to survey the literature that describes the conceptual and empirical foundations that constitute behavior therapy. This broad base of literature has grown rapidly over the past 50 years, with the greatest growth witnessed in particular over the past 20. Although the founders of the behavior therapy movement did not explicitly include cognition, this has become so fundamental to the approach that it is virtually impossible to disentangle cognitive from behavioral when discussing this approach to therapy.

A more recent trend in the empirical status of behavior therapy has been the development of empirically supported treatment manuals. These manuals, although useful for describing a template for developing an intervention for problems presented in clinical practice, may be more useful when examined as part of an empirically supported practice. That is, as clinicians we would expect a scientific process be utilized when developing a treatment plan for clients, and reliance on empirical findings to inform practice. This is consistent with the original plan described in the oft-cited Bolder model in Raimy's work in 1950. The behavioral approach to therapy embraces this position, and by promoting empirically supported practices (and not only manuals) we can come closer to implementing this model.

GLOSSARY

alarm schedule The percentage of enuretic events that trigger the urine alarm; continuous equals 100%.

anti-diuretic hormone A hormone that reduces the production of urine.

arousability The ease with which an individual can be aroused from sleep.

behavioral analysis The application of conditioning and learning principles/theory to the understanding of a behavior or response.

bell-and-pad A mechanical device incorporating a urine-sensitive pad connected to an alarm system designed to awaken the child immediately upon urine contacting the pad. Also referred to as urine alarm.

buzzer ulcers The presence of burn marks created by prolonged contact with an "active" urine alarm pad. Frequent causes include inadequate amount of urine to trigger the alarm, urine alarm apparatus too sensitive to be activated, weak batteries, alarm of insufficient intensity to arouse the child.

continence The demonstration of control over bowel and bladder activity. In the context of nocturnal enuresis generally defined as 14 or 21 consecutive nights without wetting the bed.

depth of sleep The stage of sleep as measured by electroencephalographic activity; generally 1 of 4 stages of sleep, variant stage 1 is lightest sleep and stage 4 is deepest sleep.

dry bed training (DBT) A procedure in which the child is involved in the cleaning and remaking of the bed following an enuretic episode.

desmopressin acetate (DDAVP) An anti-diuretic hormone given nasally in the treatment of nocturnal enuresis.

enuresis Wetting of the bed (nocturnal enuresis) or pants during the day (daytime enuresis) at a frequency sufficient to cause concern on the part of child and/or parents and occurring at an age by which daytime and nighttime continence is normally achieved.

full cleanliness training (FCT) A procedure that requires the child to participate in cleaning himself and his clothing following an enuretic episode. This can include taking a bath and hand washing of wet clothing. Duration of cleaning can range from 5 to 20 minutes or more.

imipramine An antidepressant that has the side effect of reducing bladder activity and therefore frequently used in the treatment of enuresis; trade name Tofranil.

intermittent alarm The programming of the urine alarm to be activated by less than 100% of wetting episodes.

overlearning A procedure frequently used in conjunction with the urine alarm that requires the child to consume enough liquid prior to bedtime to ensure at least one episode of voiding during the night.

oxybutynin An anti-cholinergic preparation that results in the relaxation of smooth muscles therefore reducing bladder contractions and activity; trade name Ditropan.

relapse The reappearance of a behavior previously altered by therapy. In the context of nocturnal enuresis relapse is usually defined as wetting the bed on one or more nights per week for 3 consecutive weeks.

retention control training (RCT) A procedure that requires the child to refrain from urinating in the presence of the

urge to do so for a progressively longer period of time; once voiding is initiated the child practices stopping and starting the stream by use of muscle control.

spontaneous remission The rate at which a behavior or response improves without systematic application of treatment.

twin-signal alarm An alarm device that presents a brief tone immediately following the enuretic event and a second tone approximately 1 minute later.

urine alarm See bell-and-pad.

I. DEVELOPMENT OF CONTINENCE

The ability to go through the night without wetting the bed, whether by postponing voiding until the morning or awakening and voiding during the night, is referred to as nocturnal (nighttime) continence. There are four stages or steps in the acquisition of mature bladder functioning necessary for nocturnal continence. These include (1) demonstrated awareness of bladder fullness (1 to 2 years); (2) ability to retain urine voluntarily (3 years); (3) capacity to start and stop the flow of urine in mid-stream (4.5 years); and (4) the ability to initiate and terminate the flow of urine at any degree of bladder fullness (approximately 5 years).

Most children achieve bladder and bowel control in a fairly systematic and reproducible fashion: (1) nocturnal bowel control; (2) daytime bowel control; (3) daytime voiding control; and (4) nighttime voiding control. In infancy voiding occurs as a result of a spinal reflex arc up to 20 times per day. This continues for the next couple of years with voluntary control of distal sphincter mechanism gradually available by the age of 3.

Enuresis is defined as the involuntary discharge of urine after the age at which bladder control should have been achieved, in most cases 5 years of age. Enuresis can occur at night (nocturnal enuresis [NE]) or daytime (diurnal enuresis), or both. NE can be further subdivided as primary (continuous), and secondary (discontinuous). The term primary NE is applied to children who have never achieved urinary continence for at least 6 continuous months. Secondary NE refers to those children who achieved dryness only to later relapse to wetting. The majority of NE cases, some 90%, are primary enuretics.

Other descriptors of NE behavior include number of wet nights per week, and number of wets per night. Some children will arouse upon wetting and others will not. A minority of children with NE are considered polysymptomatic, that is, they have coexisting urinary tract infections, dysuria (painful urination), frequency

(higher than normal episodes of voiding), and/or urgency (persistent urge to void). Children evidencing nocturnal enuresis in the absence of any other such symptoms are referred to as monosymptomatic. Approximately 10 to 20% of all 5-year-olds wet their bed at a frequency sufficient enough to be considered as NE. In most cases this involves wetting the bed one or more nights per week or at a level sufficient to cause concern on the part of the child and/or parents. Analysis of the "natural history" data suggests that approximately 15% of NE cases resolve each year such that only 2 to 4% of 12- to 14-year-olds are considered to have NE. There does not appear to be any confirmed characteristics that accurately predict which children will become dry and which will not. Some data favor those that wet less than each night, awaken in response to wetting, are motivated but not overly anxious to achieve continence, are free of comorbid psychological/behavioral problems, and live in a supportive community.

Several factors have been deemed potentially causative in NE. Included among these are small functional bladder capacity, "deep sleep," "arousal disorder," genetics, maturational delay, allergic reaction, abnormal anti-diuretic (ADH) activity, and psychological disturbance. However, detailed medical examination in most cases of NE are unrevealing for any medically related pathophysiology. Recent emphasis has been placed on maturational delay, sleep disorder, and ADH abnormality. In some cases environmental/social factors may be involved. A study by J. S. Wekke, for example, noted a higher incidence of nocturnal enuresis in special education children mainstreamed in the Dutch educational system compared to those who were not.

Genetics also play a role in NE. When both parents have had a history of enuresis there is a 77% probability that one or more of their children will be enuretic. When only one parent has a history of enuresis there is a 44% risk compared to a 20% chance of a child being enuretic when neither parent was. This possible genetic abnormality may manifest itself by a developmental delay in central nervous system functioning that could impact on the child's ability to inhibit contractions and/or maintain external sphincter contractions during the night.

It is only natural to believe that NE may be a result of disturbance in sleep. Research in this area, however, has indicated that it is unlikely that there are sleep abnormalities in enuretic patients or that enuresis begins at any particular stage of sleep. In fact, children have been noted to wet their bed in all stages of sleep although it was more likely to occur in the deeper stages. Thirty-six percent of enuretic children were found to be hard to

awaken compared to only 3.6% of nonenuretic children. The ease with which a child can be aroused appears to be a different concept and involve different mechanisms than those related to the "depth of sleep." Although "arousability and depth of sleep would appear to be related they may also exist independent of one another.

II. TREATMENT OF NOCTURNAL ENURESIS

Treatment of NE falls into two major categories, psychological and medical. By far the most common medical treatment involves the use of various medications including desmopressin acetate, imipramine, and oxybutynin. Behavioral/psychological treatments have ranged from traditional psychotherapy to the use of conditioning methodology. Probably the oldest and most researched of these procedures is the urine alarm (also referred to as bell-and-pad or moisture alarm) approach. The chapter will focus on the data related to the urine alarm in the treatment of children with NE found to be free of pathophysiologically relevant abnormalities. The data and information have been gathered from literature review and the authors' previous research and experience.

III. URINE ALARM

The potential effectiveness of an alarm device to awaken the child and prevent nighttime wetting was described by M. Pfaundler in 1904. The device was initially installed in an effort to facilitate nursing care. The concept of a urine alarm or bell-and-pad procedure was, however, popularized by Hobart Mowrer in 1938. The bell-and-pad instrumentation has been modified over the years with advanced electronics in an effort to minimize many of the early hazards such as buzzer ulcers.

The classic urine alarm is composed of a sensing device that can be activated by a small amount of urine leading to the triggering of some type of an alarm, usually auditory. The alarm, of necessity, must be of sufficient intensity to awaken the child. In some cases it may have to exceed 80 to 100 decibels. Traditionally, this device was made of two separate thin and pliable metallic-like sheaths approximately 36 inches square separated by an absorbent cloth of similar dimensions that could be placed on the bed and upon which the child would sleep. As urine was passed it was absorbed into the cloth sheeting completing a circuit and activating a battery-operated alarm.

Subsequent modifications of the urine alarm made use of a single rubber-type pad with embedded "electrodes" wherein the circuit was completed when urine bridged the gap, usually 1 to 2 inches, creating a complete circuit. The use of more sophisticated electronics has eliminated the problem of buzzer ulcers found in earlier devices. These ulcers were created when the child maintained contact with wet spots while electric current was passing through the pad.

In an effort to minimize the likelihood of the child wetting off the pad and therefore not triggering the system, sensors were developed that could be attached to the inside of the child's underwear or nighttime garment. This sensor was connected to a miniature alarm attached to the child's wrist, arm, or garment. In other instances, the sensor was embedded in a "body worn" garment. One of the more recent modifications has made use of an ultrasonic device. This device detects bladder fullness and is thus capable of awakening the child at a point of bladder contractions prior to the act of micturition. The cost and technical aspects of the system, however, may limit its general applicability.

The most common alarm or stimulus used is an auditory one. The intensity should be adjustable and sufficient to arouse the child. "Arousal conditioning" or other adjunctive therapies may be required for the "deep sleeper." A light versus auditory stimulus has been used in treating deaf children. Others have explored the use of telemetric or broadcasting arrangements to eliminate the wire running from the pad to the alarm. In some cases a vibratory or oscillatory stimulus was activated inside the nighttime garment in the hope it would awaken the child.

Other equipment issues that have been investigated included cost, sensitivity of the device, maintenance, false alarms, and durability. A ratio programmer that allows the alarm to be activated at a predetermined percentage of wetting episodes; 50% or 70% has been tried with some children. The continuous alarm, however, seems more preferable. Smaller "miniature alarms" that fit on the child's wrist can also be used. In 1970 there were no fewer than 10 different type of alarm systems available. Many of these could be obtained through commercial entities such as Montgomery Ward, Sears and Roebuck, Enuretone, etc.

A. Behavioral Analysis

A behavioral analysis of nocturnal enuresis focuses on the role of environmental conditions and appropriate learning experiences or conditioning. Treatment

emphasizes the development of bladder fullness as a discriminative cue enabling the child to inhibit voiding until the appropriate stimulus (bathroom) is present. Additionally, bladder fullness would come to be an adequate stimulus for arousal from sleep. This approach highlights the “learned” nature of the desired response (nighttime continence) and attributes the absence of the response to habit deficiencies, poor learning experiences, and lack of appropriate reinforcement contingencies.

A behavioral analysis does not ignore the potential contribution of psychological abnormalities such as childhood depression or anxiety. Rather, the behavioral analysis emphasizes the application of behavioral theory and principles of conditioning/learning to the treatment of nocturnal enuresis in place of more traditional verbal psychotherapy. The latter has not been found to be a very effective approach in treating nocturnal enuresis. In addition, behavioral analysis assumes that there is no underlying medical pathophysiology causing the nocturnal enuresis that would interfere with the use and potential effectiveness of behavioral therapies.

Some theories have been put forth to explain nocturnal enuresis and the outcome of urine alarm or bell-and-pad treatment. One such theory utilizes a classical conditioning paradigm. In this theory an event such as the urine alarm is thought to function as an unconditioned stimulus (UCS) awakening the child and reflexively inhibiting micturition or urination, the unconditioned response (UR). With repeated trials the conditioned stimulus (CS; bladder distention, detrusor muscle contraction, sphincter muscle relaxation), would produce the same inhibiting response and arouse the child (the conditioned response or CR).

Some researchers have felt that the classical conditioning paradigm did not predict the sustained dryness that is observed after treatment. They have proposed an instrumental conditioning model instead. In this model the bell or buzzer is viewed as an aversive or undesirable event that provides the basis for the development of a “conditioned avoidance response” of awakening and contracting the sphincter muscles to prevent voiding. The persistent dryness/continence that is observed following successful treatment is therefore explained in terms of the well-known resistance to extinction that is observed in conditioned avoidance responses. It is further thought that detrusor muscle relaxation and contraction of the sphincter muscles were an important part of this total response and not necessarily just the awakening of the child.

Keith Turner and his colleagues proposed a different theory. They maintained that the enuretic child’s response

during treatment was indeed an “instrumental response” but felt that the process could be more parsimoniously accounted for in terms of a punishment (passive avoidance) paradigm. They reasoned that the bell or auditory stimulus served as a type of punishment suppressing those responses, such as nocturnal voiding, that preceded or caused it.

Another behavioral approach to the problem of nocturnal enuresis has involved the use of a functional analysis. This analysis involves the application of operant conditioning principles. It views toileting and the acquisition of related behaviors such as nighttime dryness as an operant conditioning process in which social and motivational factors play an important role. The use of a functional analysis has prompted the development of therapeutic approaches that emphasize positive reinforcement for appropriate behavior, repeated rehearsal of nighttime toileting, and the application of affective negative reinforcement immediately following the enuretic event. For example, a positive reinforcement, such as a special treat, might be given for a dry night whereas wetting would result in the child having to participate in changing the wet bed.

These behavioral or conditioning approaches to nocturnal enuresis have been criticized on the basis that they overlook enuresis as a symptom of sleep or underlying problems that, even though the child may become dry at night, will probably manifest itself in some other fashion. This has frequently been referred to as a “symptom substitution theory.” Even though this theory seems to make some sense, it has not proven valid. In fact, children have been noted to be happier, less anxious, and more likely to assume responsibility therefore acting in a mature and confident fashion once the bed-wetting has been resolved. A small minority of patients have reported anxiety, bad dreams, and other emotional responses when first exposed to the bell-and-pad. However, these problem responses generally diminish as treatment continues. These emotional responses, in fact, may be likened to conditioned emotional responses or the extinction burst phenomenon frequently observed in the conditioning/learning literature.

B. General Effectiveness

In 1965 Gordon C. Young reported on 18 studies conducted between 1938 and 1964 involving 1635 children treated with the urine alarm. Success rates with the urine alarm ranged from 63 to 100%, averaging 83%. Relapse rates ranged from 9 to 52%, averaging 23%. A separate study in 1971 reported a 67% cure rate

in 83 children within 3 months of the onset of treatment but 92% at the end of 12 months. Other studies have reported up to 85% of children becoming dry in response to the urine alarm within 4 months of starting the therapy, with the majority in the first 2 months.

In a more recent review published in 1977, Daniel M. Doleys systematically evaluated the studies that were reported between 1960 and 1977. The review emphasized studies that provided (1) quantitative data, (2) between-group comparisons, (3) procedural descriptions sufficient to allow replication, and (4) follow-up data. There was total of 628 subjects. Ninety-five percent were between the ages of 4 and 15, nearly 75% were males, and the majority were primary enuretics. By applying the individual researcher's own criteria for successful treatment, which ranged from 7 to 21 consecutive dry nights, 75% of the children treated were considered successful. Treatment duration ranged from 5 weeks to 12 weeks. Forty-one percent of the children on whom follow-up data were available relapsed, the majority occurring within 6 months of treatment. Retreatment data available on 80 relapsed subjects indicated that 54 (68%) were successfully retreated.

The overall 75% success rate noted in this 1977 review was somewhat less than the 80 to 90% reported in some of the individual studies. Similarly, the 41% relapse rate was somewhat higher. Systematic reviews beyond that of 1977 continue to report success rates of approximately 70% with 20 to 30% of children relapsing. These success rates were similar when a large bell-and-pad, mini-alarm, oscillator type alarm, and alarm awakening only the child versus one awakening the child and the parents were compared. Some 60 to 80% of the children that were "cured" learned to sleep through the night while the remaining stayed dry by awakening and going to the bathroom. About 30% of the enuretic children that started treatment with the urine alarm dropped out. The vast majority of these dropouts occurred in the first few weeks of treatment.

The standard urine alarm procedure has been compared to a variety of other types of therapies. These other therapies included the use of a placebo tablet, children that received no treatment, a urine alarm that was disconnected but placed on the bed, supportive psychotherapy, advice and encouragement, and of course, "spontaneous remission." In each of these cases the urine alarm was found to be superior. There was some evidence that giving advice and encouragement helped some but a small number of children. Subjects involved in passive therapies, which were defined as instrumentation, surgery, medication, and bell-and-pad,

versus those actively involved in treatment consisting of reinforcement, reality therapy, response shaping, and sensation awareness/retention control, did not do as well; however, the difference was not statistically significant. Time to criterion and group size were not well controlled and create methodological concerns that make interpretation of the results difficult.

C. Procedure Modifications

A number of variables in the basic urine alarm protocol have been experimentally manipulated to evaluate their impact on outcome. The effect of delaying the onset of the buzzer/alarm for 3 to 5 minutes after the child wet the bed has been examined. This delay alarm group did better than a group that was not treated by the alarm but did not do as well as the no-delay group. In addition, there was a higher relapse rate in the delay group. It is therefore concluded that it is best that the alarm sound as quickly as possible after the child begins wetting the bed. It is interesting, however, to note that there was some improvement in those children when the urine alarm was placed on the bed but never activated. Factors responsible for this are frequently referred to as "nonspecific factors" and help to remind us that we may never be able to totally explain how and why a given treatment works for a specific child.

The "schedule of alarm presentation" refers to the percentage of nighttime wets that will activate the alarm system. In the traditional protocol, referred to as a "continuous" alarm, each bedwetting episode activates the alarm. A 70% variable ratio schedule indicates that "on average" 70% of the wets triggered the alarm. In some cases the percentage of wets triggering an alarm can increase or decrease during the period of treatment. In general the continuous alarm was more effective in terms of the duration of treatment and percentage of children achieving continence. The overall relapse rate, however, seemed to be somewhat less when the alarm was programmed on a more intermittent basis.

A rather unique apparatus is one that is referred to as the twin-signal apparatus. This alarm system presents a brief auditory tone at the onset of wetting and a second tone after 1 minute. The addition of the second tone is thought to help to increase the child's response to the alarm system. Although this protocol is effective there does not appear to be any distinct advantage to the twin signal alarm when compared to the one signal alarm.

Another modification to the standard urine alarm procedure involves the use of what is referred to as overlearning. In the overlearning protocol the child

consumes 32 ounces of liquids 1 hour before bedtime. This increases the likelihood that the child will have one or more wetting episodes during the night. It was believed that this would help to increase the number of “conditioning trials” during the night, which could result in a faster rate of improvement. Furthermore, consuming this amount of liquid may help the child to expand his or her control over higher levels of bladder fullness and detrusor muscular activity. In fact, when overlearning was added to the standard alarm procedure the percentage of children that became dry was comparable but the relapse rate was 13% in the overlearning group compared to 35% in the standard procedure. One research study compared the use of overlearning to a continuous versus intermittent alarm group. The percentage of children achieving continence was comparable; however, the percent of relapse was less in the overlearning group.

From a theoretical perspective these data supported the interpretation of relapse as similar to the extinction of a learned response and the intermittent schedule of alarm as a process resulting in greater resistance to extinction compared to continuous procedures. The overlearning procedure appeared to help to confirm a “generalization” hypothesis in which the conditioned awakening became associated with varying degrees of bladder fullness. The overlearning modification also produced a condition similar to “massed” practice in which trials occur more often and in closer proximity.

D. Urine Alarm Plus Medications

In the 1977 review by Daniel M. Doleys, which was referred to earlier, several medications including dexamphetamine sulfate (Dexadrine), methamphetamine hydrochloride (Methadrine), and imipramine (Tofranil) were used in the treatment of nocturnal enuresis. When dexamphetamine, methamphetamine, or imipramine was combined with the standard urine alarm protocol the duration of treatment was shorter although sometimes by a very small number of nights. However, the relapse rate was higher. In an analysis of the data, Gordon Young and Keith Turner indicated that the shorter duration of treatment was probably not clinically significant and amounted to perhaps one or two “trials.” This fact, combined with the indication of the possibility of misuse of the drugs by children in the absence of proper safeguards, resulted in the conclusion that there was little distinct advantage to adding these preparations to the urine alarm procedure.

Several new medicines have been developed since 1977. Desmopressin acetate (DDAVP) is a synthetic

analogue of arginine vasopressant (an anti-diuretic hormone.) It has very specific anti-diuretic effects with a relatively long half-life and is administered through nasal spray. DDAVP reaches its maximum plasma concentration in about 45 minutes and has a 4 to 6 hour half-life. The use of DDAVP is based on the assumption that there is a deficit in the anti-diuretic hormone in enuretic children. Some believe that there is an inadequate production of this anti-diuretic hormone during the night, thus resulting in nighttime wetting. The introduction of an anti-diuretic hormone such as DDAVP, therefore, allows for a reduction in the amount of urine permitting the child to sleep during the night without wetting.

A second newer medicine is called oxybutynin (Ditropan). Oxybutynin is an anticholinergic preparation that has direct effect on smooth muscle relaxation. This effect reduces the bladder’s ability to contract. If the bladder does not contract as much the child would then be allowed to sleep through the night uninterrupted by bladder activity.

Both DDAVP and Ditropan have been found beneficial in producing a more rapid onset of nocturnal continence. However, there is an almost 100% probability of relapse when these medicines are discontinued. They have found favor in combination with the urine alarm to help to increase motivation and compliance by prompting early success when used in the first few weeks of treatment. When used by itself, DDAVP was associated with success rates of only 42% compared to that of the urine alarm’s 78%. If used, these medicines should be gradually discontinued. Both of these medicines may be used on a periodic basis to minimize the enuretic child’s avoidance of reinforcing social activities such as overnight visits with friends, camping, and so forth.

E. Correlates of Success and Failure

As in any type of therapy it is important to identify those factors that seem to be associated with success and failure. It seems logical to assume that the acquisition of control over pelvic floor musculatures involved in the inhibition of voiding would be associated with successful treatment. Such muscular activity can be evaluated by the use of surface electromyographic studies (sEMG). In fact, children who were successfully treated for nocturnal enuresis were found to have a higher peak voltage when compared to those that failed. Furthermore, when measured prior to treatment, successful children had lower peak voltage (1.9 microvolts versus 2.7 microvolts). This observation encouraged

Arthur Housts to develop what he referred to as the "full spectrum treatment protocol." This type of treatment included a urine alarm that was worn by the child in the underwear, awakening the child during the night, the child remaining in bed until he or she is fully conscious with the alarm ringing, retention control training (Kegel exercises), and the use of overlearning, as described above. Retention control training involved the child withholding voiding during the day for progressively longer periods of time. When voiding does occur, he or she is instructed to periodically interrupt the flow of urine through the exercise of muscle control. Another component of the full spectrum treatment protocol was a parent manual explaining all aspects of treatment and an explicit behavioral contract regarding parent and child compliance. Housts reported a 75% success rate over 12 weeks of treatment with nearly 60% of the children remaining continent at 1 year.

Success rates can sometimes be increased by the use of negative reinforcement. One example is the use of a star chart. In this case a star is provided when the child awakens in response to the urine alarm and goes to the bathroom but one is lost if he or she does not awaken. Having children participate in cleaning themselves and the bed and remaking the bed following each enuretic event is another example. Such mild forms of "punishment" may enhance the child's motivation.

The use of DDAVP in conjunction with the urine alarm may help to reduce the dropout rate and therefore increase the number of children that are successfully treated. The effect of adding DDAVP to the urine alarm tends to occur in the first 3 weeks of treatment. Beyond this there appears to be no advantage over the use of the urine alarm alone. When medications such as DDAVP or imipramine are used to achieve dryness it is recommended that the urine alarm be re-instituted after 6 months while tapering the child from the medications. Success rates can also be enhanced by treating other toileting problems such as diurnal enuresis or encopresis (bowel incontinence) prior to introducing the urine alarm for nocturnal enuresis.

There appear to be a variety of factors that are associated with treatment failures. A high frequency of wetting prior to treatment and a tendency for parents to punish the child for enuretic episodes tend to correlate with failed treatment. Children that tend to display a good deal of deviant behavior and those living in a dysfunctional family environment do not do well. Maternal anxiety, failure of the child to awaken in response to the alarm, the absence of parental concern over nighttime wetting, the absence of any distress on the part of

the child over nighttime wetting, low parental education, and multiple wetting episodes during a given night have also been noted. One of the most commonly found reasons for failure is the lack of parental cooperation. A positive family history for enuresis, lack of treatment progress, and an intolerant parental attitude tended to predict early withdrawal from treatment.

Several other factors appear to have been associated with treatment failure, whether defined as early withdrawal from treatment, noncompliance of treatment procedure, or discontinuation of treatment by the professional because of a disproportionate amount of time without progress. These included elevated scores on behavior checklists indicating an abnormal level of inappropriate behaviors along with indications of general family distress. Noncompliance by parents, which tends to be highest in the first 3 weeks, unsatisfactory housing, poor maternal education, and low socioeconomic class were also noted. Parents viewing the child as withdrawn or socially incompetent and lack of parental concern seemed relevant as well.

A number of maneuvers have been found to increase the chance of success in the application of the urine alarm. These included the use of a "dummy" run with the child; allowing the child to do all the work but the parent to supervise; keeping a daily diary; no restriction of liquids; the wearing of underpants rather than pajamas to bed; the child testing the alarm prior to going to bed and rehearsing covertly or aloud the subsequent steps; overlearning; and parental praise and encouragement. In their 1998 summary of predictors of successful outcome Gretchen Gimple and colleagues noted the following: fewer wet nights pretreatment, older children, absence of daytime enuresis, parental support, and negative child perception in the absence of any significant psychiatric/psychological problem. Children with a "negative self-image" and who were exposed to parental intolerance had poor outcomes.

IV. SUMMARY AND RECOMMENDATIONS

The urine alarm has assumed and maintained a position of prominence in the treatment armamentarium for nocturnal enuresis. The apparatus generally consists of some type of sensing device activated by the presence of urine. The device is placed on the bed. The child is awakened by a bell, buzzer, or some other stimulus designed to initiate involuntary or voluntary suppression of voiding until the child reaches the

bathroom. The child then returns to bed and with parental help prepares the system by resetting the alarm and returns to sleep. In general, 70 to 90% patients become dry with a 15 to 40% relapse. Treatment duration varies from 5 to 40 weeks with a recommended continuation of treatment until 21 consecutive dry nights are accomplished. Two or more wets in 7 consecutive days have been used to determine a relapse. It is recommended that children be followed for at least 24 months following the achieving of continence even though the highest percentage of relapse occurs in the first 6 months.

The use of the urine alarm has demonstrated superiority to placebo, psychotherapy, nighttime awakening, and counseling. Medications including imipramine, amphetamine derivatives, DDAVP, and oxybutynin have contributed to increased frequency of dry nights during the early part of treatment but have not been associated with an overall increase in percentage of children that become continent. A high rate of relapse, approximately 100%, occurs upon discontinuation of the medication. Consideration needs to be given to the risk profile and cost when applying these medications.

Alarm modifications have come in various types. The devices are more sensitive and appear to have resolved concern over buzzer ulcers. Some are body worn with sensors placed in the underwear. In addition to an auditory or visual stimulus there has been the examination of a vibratory stimulus. Experimental procedures involving an ultrasonic device have been explored. The size of the alarms have been reduced because of improved technology. Treatment components for the urine alarm have

remained relatively unchanged. The addition of over-learning, the use of full cleanliness training in which the child assists in cleaning the bed, and arousal conditioning remain standard aspects of the procedure.

GLOSSARY

aversive counterconditioning A specific application of respondent conditioning that causes behavior change when a stimulus that elicits an undesired response, is consistently paired with an aversive stimulus that elicits an incompatible response. The result is that, due to such pairing, the undesired response is eventually reduced or eliminated.

cognitions A person's thoughts, beliefs, perceptions, and images.

contingency contracts Behavioral contracts between individuals who wish behavior to change (e.g., parents or teachers) and those whose behavior is to be changed (e.g., children or students).

covert assertion A behavior modification technique that causes behavior change when a person says forceful or assertive things to himself or herself (e.g., "I am brave. I am strong."), statements that often contradict the actual situation or problem.

desensitization The gradual counterconditioning of anxiety with an incompatible response such as relaxation.

modeling A behavior modification technique that causes behavior change when a person observes a behavior in one or more others and then imitates or learns that same behavior or behavior strategy.

operant conditioning A behavior modification technique that causes behavior change by building associations between certain behaviors and the consequences of those behaviors (e.g., a particular behavior is either rewarded or punished and thus increases or decreases in probability).

respondent (classical) conditioning A behavior modification technique that causes behavior change when a particular stimulus is paired or associated with a second stimulus (the unconditioned stimulus). As a result of the association, the first stimulus (the conditioned stimulus), then comes to elicit a response (the conditioned response) it did not previously elicit. Eventually, the conditioned stimulus elicits the conditioned response without the presence of the unconditioned stimulus.

semantic desensitization The process of counterconditioning the negative aspects of certain words related to unpleasant situations or a person's phobias with more pleasant images or thoughts.

Therapists and their clients alike want effective means to promote desired changes in behaviors, attitudes, and coping skills. Biblical behavior modification offers a unique way for therapists to help their Christian clients do just that. By matching behavior modification techniques to the clients' beliefs or to Biblical principles (the usual foundation for those beliefs), the therapist not only helps produce the desired changes in behavior, but also builds a relationship of trust and respect between the therapist and client. This is especially important considering the fact that many Christians avoid

seeking professional secular help because they believe, even fear, that therapists may attempt to use therapies or behavior change techniques that either ridicule and/or fail to support their religious beliefs.

I. DESCRIPTION OF TREATMENT

Biblical behavior modification, composed as it is of both theoretical and practical components from behaviorism, social learning, and cognitive science, offers a wide variety of treatments that can be especially appealing to Christians. Christians might desire, for example, to show less anger in their reactions to certain events, get rid of a slight agoraphobia in order to spend more time with fellow Christians, control a problem with alcoholism, or learn to think of others in a less critical way. In this desire to live a more Christian life (i.e., “live up to their beliefs”), Christians seek help in a variety of ways in order to change or control certain behaviors. They pray or study their Bible, talk to friends or family members, or seek counseling from a minister or a counselor/therapist (who may or may not be a Christian).

Sometimes these choices are effective and sometimes they are not, with success usually depending both on individual motivation and dedication to change and on whether or not the advice given or the action taken follows the course of proven behavior change methods. The methods and techniques of behavior therapy, especially with the Biblical applications, are designed to offer what Christians need: the ability to develop desired behaviors, discourage undesired behaviors, eliminate phobias, control addictions, and monitor thoughts and attitudes.

Therefore, with Christian clients, Biblical behavior modification can be quite effective because it is not only based on sound behavioral theory, but it also acknowledges the spiritual motivation Christians have for the behavior change. Part of its effectiveness, then, comes as a result of universal principles that cut across disciplines such as psychology and theology. However, because many think such disciplines as psychology and theology are incompatible, it is necessary to take a closer look at some philosophical controversies that are basic to the whole concept of Biblical behavior modification.

A. The Controversies: An Introduction

Those who seek good mental health, and counselors who assist those who need help in the search, are faced

with a monumental question. How do human beings learn to control their circumstances and/or behaviors—that is, promote desirable ones and eliminate undesirable ones—in order to reach life goals and live a good and happy life?

Humankind’s attempt to answer that question over the ages has given rise to major philosophical controversies over what we can and cannot control or change. In fact, these controversies have transformed themselves into many complex and interrelated questions, so many and so complex, in fact, they cannot all be discussed thoroughly here. However, to give some flavor to the overall reason for the controversies, we must take a cursory look at two of the many layers: the mind/body dilemma and the science/religion controversy.

The mind/body dilemma poses many of the questions most commonly cited, and most wrestled with, by the world’s greatest philosophers. What are we as human beings? Are we bodies with strange ethereal appendages called minds? Or are we minds (spirits) who inhabit troublesome bodies? In other words, does the body control the mind, or does the mind control the body? Do Descartes’ famous words, “I think, therefore I am,” exude truth or hide it?

Conclusions to these questions have come in all forms throughout the ages, but the latest research seems to indicate that there is no true line of demarcation. The mind and body seem so interrelated that most researchers and philosophers today acknowledge their mutual control and influence over each other. At the same time, however, scientists today are more ready to accept as true the idea that the mind (spirit) within each person represents something that is distinct from the material body. They also seem to accept that this mind, despite its unwillingness to be measured, exists as a separate entity of the person with a separate purpose: mainly, control of the body. So, the controversy continues to exist, but Christian beliefs about individual spirits seem to be more acceptable to science in today’s world than in times past.

This brings us to the science/religion controversy. Scientists have for centuries scoffed at religious beliefs, calling them subjective, superstitious, and emotion-driven. This is true, of course, in many cases, but religious people have also scoffed at science, calling it materialistic and godless, also true in many cases. Indeed, many consider science and religion mutually exclusive realms, realms that will never meet. Biblical behavior modification, however, proves that conclusion to be incorrect.

B. One Answer: Biblical Behavior Modification

During the course of these philosophical arguments over mind and body and science and religion, science developed the field of psychology to study the brains and behaviors of both animals and humans. One of the major results was the discovery of numerous facts regarding human behavior, facts that in essence became principles or tools for behavior change. For example, in the area of behaviorism, science discovered that animals and people both respond positively to rewards: Animals will push a lever for food; young students will do their homework for a star. Social learning theorists discovered we can and do learn many (maybe most) of our behaviors by imitating others. This principle is used by therapists in any number of clinical settings (e.g., teaching appropriate social skills or helping people rid themselves of phobias).

Therefore, when therapists adopt these principles to help their clients, they do not develop them “from scratch.” They, instead, adopt, adapt, and apply valid principles of human behavior to whatever setting or need they or their clients may have. As will be seen from the examples that follow, advocates of Biblical behavior modification do the same. In other words, the same principles of human behavior are inherent in Biblical teachings, and the fact that science (i.e., psychology) has now “discovered” them, helps to prove their universal and enduring nature.

II. THEORETICAL BASES

A. The Psychology: Behavior Therapy

Many people are skeptical of behavior therapies of all types because they equate them with B.F. Skinner’s behaviorism. Those who are concerned about the fact that behavior can be conditioned often consider behaviorism a type of mind control, rather than a tool to promote positive behavior change.

In part, because of such fears, modern behavior therapy tends to focus more on social learning and cognitive techniques than on conditioning behavior. However, the basic foundation of behavior therapy is still behavioristic. Therefore, in order to understand Biblical behavior modification and the examples of it that will follow, it is important to understand the concepts of behaviorism, as well as numerous other foundational principles and techniques of clinical behavior modification. Unfortunately, they cannot all be dis-

cussed, so, for the sake of clarification and brevity, they are separated below into the following broad categories: behavioral techniques, social learning techniques, and cognitive techniques.

It must be noted, however, that one of the “special” underlying premises of Biblical behavior modification is that such separation is not truly possible. In other words, just as the mind and the body are distinct, but always influence each other, so does conditioning influence social learning, which in turn, influences thoughts. Behavior modification, therefore, is a continuing interrelated circle of behaviors influencing behaviors.

1. Behavioral Techniques

a) *Respondent Conditioning* Most people know about respondent conditioning because they know about Pavlov’s dogs. That classic example shows that behavior change can occur when a particular stimulus (ringing a bell) is either coincidentally or purposely paired or associated with a second stimulus (feeding the dogs—the unconditioned stimulus). As a result of the association, the first stimulus (the bell—the conditioned stimulus), then comes to elicit a response (the salivating of the dogs—the conditioned response) it did not previously elicit. Eventually, the conditioned stimulus (the bell) elicits the conditioned response (salivation) without the presence of the unconditioned stimulus (in other words, even without the food, even when it is not time to feed the dogs). This type of conditioning is the one most often responsible for the phobias that plague so many: unreasonable fear becomes associated with an animal, place, or experience that normally would not cause that degree of fear.

Although therapists use numerous variations of respondent conditioning to effect behavior change, two forms are especially interesting. Aversive counterconditioning produces behavior change when a stimulus which elicits an undesired response is consistently paired with an aversive stimulus which elicits an incompatible response. The result is that, due to such pairing, the undesired response is eventually reduced or eliminated.

This technique is used quite often, for example, with smokers or obese clients. Smokers want to keep cigarettes from tempting them to smoke and the obese want to overcome their desire to eat too much; therefore, cigarettes and food are the stimuli that elicit the undesired response. Using aversive counterconditioning to control their behaviors, smokers might imagine cigarette smoke as fingers reaching to choke the air out of their lungs and the obese might imagine their most

tempting foods as spoiled or rotten. In other words, aversive stimuli are paired with the regular stimuli to rid them (the cigarettes, the food) of their normal “power” to influence behavior.

Desensitization is another variation of respondent conditioning often used to help clients overcome such things as the fear of public speaking or the fear of flying. After creating a hierarchy of behaviors that begins with those that cause no anxiety and ends with those that cause the most anxiety, the therapist gradually leads the client (visually and, finally, *in vivo*) through each behavior in the hierarchy. At each step the anxiety is counterconditioned with an incompatible response, such as relaxation, until the client can reach the top of the hierarchy (i.e., until the client can comfortably make a public speech or fly in an airplane). The amount of time it takes to “climb” the hierarchy varies with the person and with the situation causing the anxiety, but it usually ranges anywhere from a few hours to several months.

b) Operant Conditioning Operant conditioning, which occurs all day every day in all types of situations, causes behavior change by building in consequences to behaviors. In other words, everyone from parents and teachers to employers and spouses use it to either reward or punish particular behaviors of others and thus increase or decrease the probability of those behaviors being repeated. Operant conditioning takes many forms but the reward and/or punishment theme is common to all of them.

A specialized form of operant conditioning is contingency contracting. Contingency contracts are behavioral contracts between individuals (often parents or teachers) who wish to see changes in behavior and those (children or students) whose behavior is to be changed. The contracts, usually written out and signed by those involved, allow the rewards and punishments of various behaviors to be negotiated by both parties.

2. Social Learning Techniques

Although there are many social learning techniques and theories, the foundation principle of them all is modeling. Modeling causes behavior change when a person observes a behavior in one or more others and then imitates or learns that same behavior or behavior strategy. Parents use this technique every day as they teach their children to talk, ride a bicycle, make their beds, and use good table manners. Often, to their consternation, parents learn the true power of modeling when they see their children model their own behaviors (e.g., Mom’s disorganization or Dad’s shyness).

3. Cognitive Techniques

Cognitions are a person’s thoughts, beliefs, perceptions, and images, and many would argue that these are not behaviors because they cannot be seen or measured accurately by others. The tendency in modern behavior therapy, though, is to accept all cognitions as covert behaviors, and if accepted as such, to also consider them candidates for change through the use of behavior modification techniques. It is also important to understand that, although cognitive therapy is often classified as a separate type of approach, cognitive elements are inherent to all therapies, and, as part of the mind/body conundrum, covert behaviors (those of the mind) and overt behaviors (those of the body) have a mutual influence on each other.

Semantic desensitization, a variation of respondent conditioning, is an example of a technique with a definite cognitive component. Unlike regular desensitization, which usually counterconditions feelings of anxiety, this process counterconditions the negative aspects of certain words, words related to unpleasant situations or a person’s phobias, with more pleasant images or thoughts.

Covert assertion is a behavior modification technique that causes behavior change when a person says forceful or assertive things to himself or herself, things that often contradict the actual situation or problem. For example, a man avoiding a doctor’s appointment because of a potential health problem might repeat to himself such statements as, “I am brave. I am strong.”

B. The Theology: Judeo-Christian Teachings

Although hundreds of Judeo-Christian beliefs and teachings could be discussed to illustrate the theology of Biblical behavior modification, three major principles of Christian belief will suffice. Indeed, these three help define the interplay between behaviors (body) and belief (mind) that are so much a part of Biblical behavior modification.

1. Love

Love, one of the constants found in Christian teachings, begins with the love God has toward humankind. Christians then return that love and extend it toward others. Indeed, one of the requirements of Christian love is to reach out to others in order to show compassion and care. Therefore, Christians are expected to express love by engaging in certain types of behaviors: for example, participating in worship services, helping a friend or

neighbor in need, providing food and shelter for one's family, and so forth. In other words, one of the duties of Christians is to initiate such positive behaviors.

2. *Self-control*

The fact that God instituted laws and commands to be obeyed implies that there are both acceptable and unacceptable behaviors. Therefore, in the Judeo-Christian religions, the concept of self-control becomes an important issue. Therefore, the control of negative behaviors (usually called sins), which are in contradiction to the laws of God, becomes another important duty of Christians.

3. *Inner Peace*

Christianity, like many other religions, places a high value on a sense of inner tranquility and peace. The Christian believes there is no better way to gain that inner peace than by leading a life highlighted by two factors: love for God and others expressed by many positive behaviors and a sense of self-control that has helped eliminate undesired and negative behaviors.

C. The Focus: The Bible

When Christians have a question about what their behavior should be, they go to the Bible, which they consider the word of God, for guidance. They may go to other sources as well (e.g., ministers and counselors), but the "Good Book" is their primary source for answers. That is now the place to go for examples of Biblical behavior modification.

Although they are not always immediately evident, the Bible is replete with examples of respondent conditioning. In fact, Christians are to associate all kinds of good feelings, not only to the book itself, "his delight is in the law of the Lord..." (Psalm 1:2), but also to all the symbols and images of Christianity:

May I never boast except in the cross... (Galatians 6:14)

... for all of you who were baptized into Christ have clothed yourselves with Christ. (Galatians 3:27)

...we, who are many, are one body, for we all partake of the one loaf [communion]. (I Corinthians 10:16, 17)

Christians are also taught to associate negative feelings with certain situations, in order that the negative becomes conditioned:

Your enemy the devil prowls around like a roaring lion looking for someone to devour. (I Peter 5:8)

Watch out for false teachers. They come to you in sheep's clothing, but inwardly they are ferocious wolves. (Matthew 7:15)

With aversive counterconditioning, Biblical behavior modification offers a more specific application of respondent conditioning, one that helps Christians avoid undesired behaviors by making the association with them very aversive:

Do not join those who drink too much wine or gorge themselves on meat, for drunkards and gluttons become poor, and drowsiness clothes them in rags. (Proverbs 23:20, 21)

For the lips of an adulteress drip honey, and her speech is smoother than oil; but in the end she is bitter as gall, sharp as a double-edged sword.... (Proverbs 6:24-35)

Desensitization for the Christian is not developed in specific hierarchy form in the Bible as it is with a therapist. However, the major component of desensitization, the training in relaxation under stressful situations, is evident in many passages: "So do not fear, for I am with you..." (Isaiah 41:10); "Do not be anxious about anything." (Philippians 4:6, 7); "Let not your heart be troubled, neither let it be afraid." (John 14:27).

Operant conditioning, like respondent conditioning, is found throughout the Bible. Unlike respondent conditioning, however, examples of operant conditioning are very obvious. The following passages indicate the prevalence in scripture of the concepts of rewards and punishment for behaviors:

I praise you for remembering me... (I Corinthians 11:2)

They sow the wind and reap the whirlwind. (Hosea 8:7)

Now there is in store for me the crown of righteousness, which the Lord ... will award to me on that day... (II Timothy 4:8)

God is just: He will pay back trouble to those who trouble you and give relief to you who are troubled... (II Thessalonians 1:6-10)

In essence, the Bible exists as two major contingency contracts. The Old Testament is a contingency contract for the Jews and the New Testament is a contingency contract for Christians. In other words, the two major divisions of the Bible, contracted with two groups of people, offer a written behavior guide, complete with rewards and punishments, for each group.

Deuteronomy 28:1–64 is a lengthy, but excellent, example from the Old Testament. Examples for Christians from the New Testament, although not so lengthy, still show the contingencies of the behaviors: “If you want to enter life, obey the commandments.” (Matthew 19:17); “To those who by persistence in doing good seek glory, honor and immortality, he will give eternal life. But for those who are self-seeking and who reject the truth and follow evil, there will be wrath and anger.” (Romans 2:6–8).

The Biblical behavior modification version of modeling is also common in numerous Bible passages. The value and effectiveness of modeling is also illustrated in quite straightforward language:

These commandments that I give you today are to be upon your hearts. Impress them on your children. Talk about them when you sit at home and when you walk along the road, when you lie down and when you get up. (Deuteronomy 6:4–7)

... you shall read this law before them in their hearing so they can listen and learn... (Deuteronomy 31:10–13)

... set an example for the believers... (I Timothy 4:12)

You became imitators of us and of the Lord... And so you became a model to all the believers... (I Thessalonians 1:6–8)

Christians are taught from the time they become Christians that their thoughts, and the control of those thoughts, are important parts of their Christian life. Therefore, the cognitive portion of Biblical behavior modification has great value to them, especially if they can find ways to control the mind when it becomes unruly. Covert assertion is one method that helps in difficult emotional or physical circumstances:

I have learned to be content whatever the circumstances. (Phillippians 4:11)

I can do everything through him who gives me strength. (Phillippians 4:13)

When I am afraid, I will trust in you. In God, whose word I praise, in God I trust; I will not be afraid. What can mortal man do to me? (Psalm 56:3, 4)

Although there are many others, one last cognitive therapy to examine here is semantic desensitization, the purposeful conditioning of pleasant thoughts or images to something that is not so pleasant. Christians make use of this technique to help keep the inner peace they desire, despite what is going on in their lives.

For our light and momentary troubles are achieving for us an eternal glory... (II Corinthians 4:16–18)

For my yoke is easy and my burden is light. (Matthew 11:30)

... but we rejoice in our sufferings... (Romans 5:2, 3)

Consider it pure joy, my brothers, whenever you face trials of many kinds... (James 1:2, 3, & 12)

III. EMPIRICAL STUDIES

Many questions remain. Does Biblical behavior therapy work? And if it works, is it effective enough? Does it serve its purpose? Should a counselor consider its use with his or her Christian clients? Because there are few empirical studies on the actual application of behavior modification techniques for spiritual purposes, the answers to the above questions have to be as integrated as the approach itself.

Years of research and study have shown the practical and valuable use of respondent and operant conditioning, modeling, and cognitive therapy to effect desired behavior change. For example, counselors have gradually helped their clients rid themselves of the fear of flying; teachers have shaped their students' behaviors by rewarding those students who listen in class; advisors have modeled the proper ways to initiate a conversation; and therapists have helped clients develop cognitive techniques to gain control over irrational thoughts and feelings. Medical journals, as well as psychology journals, have examples of these same behavioral techniques being used to do such things as reduce blood pressure, overcome obesity, and control obsessive–compulsive behaviors. In other words, behavior modification therapy and its varied techniques have proven successful across the years in a wide variety of applications with a wide variety of behaviors.

Relatively recent research has also shown as fact that a person's religious/spiritual beliefs can have a profound effect on their abilities to do all the above. In fact, studies have shown that the religious person often suffers less from stress, heals faster, is less susceptible to infection, and has fewer problems with mental disorders and social maladies (such as alcoholism). The reasons are not fully apparent at this time, although some have hypothesized that the social structure and support offered by a spiritual life is beneficial. This article, of course, has argued that Biblical guides for attitudes and behaviors, used consciously or unconsciously, are based on effective universal principles. At any rate, the

field for further applied research in Biblical behavior modification is certainly ripe.

IV. SUMMARY

A. The Synthesis: Biblical Behavior Modification

In essence, Biblical behavior modification is indeed a pathway to wholeness. While respecting all the individual parts, it makes a whole out of the mind and the body, out of thoughts and behaviors. It brings together science and religion. It blends the behavior therapies into effective means and strategies to address almost any behavior problem or need. Indeed, Biblical behavior modification values and treats the whole person.

B. Conclusions

Counselors and therapists need to acknowledge the religious/spiritual beliefs of their clients, as well as become knowledgeable enough about those beliefs to match them to effective behavior change techniques. They also need to followup with further research to see how these applications can become more effective and be expanded in use for other behavior problems.

GLOSSARY

attributions Causal factors assumed to be responsible for given events-perceived causality.

bibliotherapy Requesting or advising an individual to read written material to attain hoped-for outcomes.

contingencies Associations between behavior and related cues and consequences.

dispositional attributions Characteristics of the individual.

effect size A number that summarizes the strength of effect of a given intervention.

functional analysis A demonstration of the influence of certain cues and consequences on behaviors of interest. This is sometimes confused with a “descriptive analysis” that refers to a description of assumed cues and consequences related to behaviors of interest (rather than a demonstration of their effects as in a functional analysis).

fundamental attribution error Focusing on personality attributes and overlooking environmental causes.

generalization Occurrence of behavior in situations other than those in which it was established.

imaginal therapy The client is guided through imagery regarding feared situations, thoughts, and physical reactions.

maintenance Continuation of behavior changes over time.

meta-analysis Critical review of all experimental studies regarding the effectiveness of a specific intervention in achieving hoped-for outcomes.

randomized controlled trial Random distribution of participants to an experimental group and a control group to investigate the effectiveness of an intervention.

relapse prevention Interventions designed to maintain gains in spite of lapses.

self-efficacy Expectations regarding whether we can perform given behaviors and whether these will result in given consequences.

self-management Pursuit of hoped-for goals by rearranging related cues and consequences oneself.

self-monitoring Keeping track of some behaviors, thoughts, or feelings in real-life situations.

stimulus control Influencing behavior by rearranging antecedents of behaviors.

I. INTRODUCTION

The term bibliotherapy refers to reading written material to pursue valued goals. Surveys of counselors in a variety of professions indicate that they often assign (prescribe) specific readings to clients. Self-help material is available for a wide range of aims including enhancing parenting skills, sexual pleasure, social and study skills, and decreasing substance abuse, anxiety, depression, smoking, and excess weight. Aims include providing information about a concern including its prevalence, motivating readers to address it, describing

a variety of change options, and helping readers select promising ones. The variety of aims addressed can be seen in guides to self-help resources such as those prepared by John Norcross and his colleagues. Reading has been used throughout the ages to pursue valued goals. Consider the Bible. This ancient manuscript was and is used as a guide to living and wrestling with life's problems and concerns. Steven Starker views self-help books as a modern-day oracle replacing older sources of guidance and advice. The United States has been particularly enthusiastic about the use of reading as a route to self-help; consider the attention given to the "self-made man" and, more recently, "woman." Possible benefits of bibliotherapy include attaining desired outcomes with little expenditure of time, money, and effort, and accessing accurate information about topics of interest (e.g., social anxiety, depression) and how to achieve valued outcomes (e.g., enhancing self-change skills and decreasing beliefs that hinder self-change). Another potential benefit is that we learn to rely on ourselves rather than on a therapist.

II. DESCRIPTION OF TREATMENT

Characteristics common to use of bibliotherapy in clinical practice include a request to read certain written material and instructions guiding the reader in the application of procedures described in real-life contexts. This may include self-monitoring (keeping track of particular behaviors, thoughts, or feelings in real-life situations) for assessment or to evaluate progress, as well as instructions on what to do given certain degrees of progress. Underlying assumptions on which recommendations are based are usually described and examples of applying methods given. Clinical use differs along the following dimensions: (1) extent of helper–client contact ranging from none to extensive; (2) use of individual or group format; (3) development of general versus specific skills; (4) the extent to which readers are requested to "interact" with the written material in terms of completing exercises to test their understanding of content; (5) whether bibliotherapy is used together with other methods; (6) whether access to additional written material is made contingent on reading and understanding more elementary portions; and (7) attention devoted to generalization and maintenance of positive effects. Inclusion of relapse prevention guidelines offers readers information they can review on an as-needed basis. Most programs using bibliotherapy are brief, for example 8 to 12 weeks.

Bibliotherapy materials differ in degree of attention given to helping readers to carry out an individualized assessment on which they would base selection of change methods. Some written material encourages readers to gather data (e.g., to observe and record the frequency of behaviors of interest and related circumstances). Data gathered during assessment or "self-diagnosis" are used to plan change programs. Let's say that a woman reads a self-help book in order to increase enjoyable social contacts. Possible reasons for unsatisfactory social contacts (either in frequency and/or kind) include a lack of social skills (e.g., initiating conversations), anxiety (perhaps due to fear of negative evaluation), unrealistic expectations (e.g., "I must always succeed."), poor self-management skills (e.g., in controlling anger following a rejection), and environmental obstacles (e.g., few places to meet people). Written materials differ in the extent to which guidelines help readers to identify how they can profitably change their behavior to achieve hoped-for outcomes. Common errors in searching for the causes of behavior include mistaking correlation for causation and overlooking environmental causes. To the extent to which data are informative (reduce uncertainty about how to attain valued outcomes) and assumptions about how valued outcomes can best be pursued are accurate, readers are more likely to make sound decisions regarding selection of self-change methods. Inaccurate data and assumptions may result in incorrect choices of self-change programs.

In totally self-administered bibliotherapy, the client receives or is asked to purchase material from a helper with no additional contact beyond an initial meeting. In minimal contact formats, the counselor may provide reading materials but takes a somewhat more active role such as arranging phone calls and infrequent meetings. Yet a third format consists of counselor-directed reading in a self-help book that the client obtains at the beginning of assessment followed by meetings with the helper on a regular basis. Here, written material provides a focus of discussion in relation to how this applies to the client. Last, in a counselor-directed approach, self-help books are used as a part of the counseling. In addition to reading, other formats include listening to tapes and computer-presented information. It is suggested that practitioners use books with which they are familiar, consider the length of the book as well as degree of extraneous material, and select books that are applicable to readers' concerns and reading ability. Requisites for successful use of bibliotherapy include reading skills that match the required reading level of the text.

III. THEORETICAL BASES

A basic premise is that readers can attain certain hoped-for goals by implementing material read (although, in some cases this may only be possible through relinquishing control over uncontrollable events). There is a built-in self-efficacy message, an expectation that readers can attain certain outcomes through reading and acting on what they read. The expectation is that readers will be able to successfully apply the instructions given in real life. For example, it is expected that parents who read a manual describing how to toilet train their child will be able to use the information to achieve this outcome or that readers of a self-help manual designed to decrease alcohol consumption will be able to use the information to decrease their drinking. That is, it is assumed that people can be their own agents of change with minimal or no counselor contact. A key step in behavior change is identifying and altering factors related to desired outcomes. Self-control or self-management involves a process in which we are the main agent in guiding and altering our behavior to achieved self-selected goals.

Bibliotherapy materials differ in views presented about how valued outcomes can be attained. Thus, self-help material not only implies a self-efficacy message but also describes a particular viewpoint as to how goals can be achieved. Different models of self-management include B. F. Skinner's operant model in which it is assumed that self-change behaviors consist of a repertoire of behaviors that are influenced by environmental contingencies (i.e., by the same behavioral principles that influence any behavior). If we ourselves use such methods to attain goals we have set for ourselves, we are engaged in self-management. One kind of self-management involves the rearrangement of antecedents related to behaviors of interest. This is known as stimulus control. For example, cues that encourage unwanted behavior can be removed or reduced, and those that encourage desired behaviors can be increased. We could for example use physical aids (written reminders) to encourage desired behaviors. A second involves rearrangement of consequences; positive consequences are provided for behaviors we would like to encourage, and negative consequences are removed. Negative consequences may be provided for unwanted behaviors, and positive consequences that usually follow such behaviors may be withheld. Reading about presumed sources of influence on behaviors of interest may help readers to alter behavior in valued directions by rearranging related cues and consequences (e.g, reminding

ourselves to focus on positive thoughts in stressful situations to keep anxiety in check).

Some authors emphasize the role of self-monitoring of behavior and our awareness of choice points (e.g., what to do next), which they argue also involves self-evaluation of behavior. Research suggests that self-observation may alter behavior. When we observe our behavior, we attend to it more carefully and may identify and change cues and consequences that influence its frequency. Other writers emphasize the role of attributions (assumed causes for behavior) noting that research suggests that we can enhance maintenance of positive changes by emphasizing the control we have over our behavior (e.g., attributing self-change to our own efforts in contrast to viewing our behavior as under the control of environmental consequences over which we have little influence). Self-management skills that may be involved in self-change include the following:

- Self-assessment skills in using written material to clearly define desired outcomes and to plan how to achieve them
- Self-monitoring skills to gather helpful assessment information and to evaluate progress
- Skills in arranging cues and incentives so hoped-for reactions will increase and unwanted reactions will decrease
- Skills in choosing next steps when positive gains are made
- Troubleshooting skills to overcome obstacles when change methods do not work
- Skills in generalizing and maintaining positive changes

IV. APPLICATIONS AND EXCLUSIONS

Certain kinds of individuals are more likely than others to profit from self-help formats. Attributions may influence the extent to which different people make effective use of bibliotherapy methods. Research suggests that those who score higher on internal locus of control (they believe that they have a great deal of control over what happens to them) are more successful in altering their behavior compared to people who are more externally controlled (they attribute what happens to them largely to external events). People differ in their repertoire of self-change skills and in their history of using them to attain valued outcomes. For example, some readers may not know how to set

clear goals. Some may not know how to rearrange cues and consequences related to outcomes of interest. Contraindications to use of bibliotherapy include limited reading ability and small probability that the client will follow instructions, perhaps because of personal or environmental obstacles. Countervailing personal characteristics include high anxiety that may interfere with successful use of material. Written material may not address key related factors, for example, excessive alcohol drinking may be maintained by peer support and written material may not address this. Literature on behavior change suggests that practice is related to acquiring new skills. Thus, arranging such practice will be needed, and this will require related self-management skills. Effective use of bibliographic methods requires generalization and maintenance of valued behaviors. This also requires self-management skills. Many clients do not have the self-management skills required to make effective use of written material to change their behavior. Counselor guidance and support may be necessary. Support also could be provided by group members or "buddies" who are involved in group programs. Research suggests that acquiring different kinds of skills requires different kinds of learning programs. Consider learning to play golf. Will reading books about how to play golf produce skilled golfers? Probably not, as many disappointed readers have found. Learning such a skill involves a complex sequence of behaviors that may only be acquired through on-the-spot coaching and practice.

V. EMPIRICAL QUESTIONS AND STUDIES

Compared to the abundance of self-help books and manuals available, the evaluation of these materials is skimpy in terms of whether they do more good than harm. For example, do they really help people achieve what they promise? Self-help books differ in the clarity with which hoped-for outcomes are described. Promising self-fulfillment is vague compared to helping readers lose weight, get better grades, or make friends. Self-help books differ in the evidentiary base of their views about how self-change can be achieved ranging from material that appeals to will power in motivating change (notoriously ineffective), to those that rely on empirical findings regarding what has been found to contribute to self-change. Research on self-management and self-instruction suggests that some methods and formats are more likely than others to facilitate self-help efforts. Key

to self-management is effectively dealing with the weak effects of delayed consequences (e.g., studying more today to avoid a bad grade on a test in 4 weeks). To what extent do self-help books build on knowledge about self-management? To what extent does a book help readers to take advantage of skills they already have? As with many other areas of psychotherapy, claims are often inflated. Gerald Rosen raised concerns regarding use of self-help materials and suggested guidelines for screening do-it-yourself-treatment books:

1. What claims are made in the book? What does it promise readers?

2. Is accurate information provided concerning the extent to which claims of effectiveness have been critically tested? Have the techniques described in the book been critically appraised in relation to claims of effectiveness and have the results been positive?

3. Can readers check whether they develop appropriate expectations as to what they can (and cannot) gain from reading the material?

4. Does the book describe methods readers can use for self-assessment to determine whether this book will be of benefit to them, and if so, in what way? Have these procedures been critically tested? A key question is the following: "Can the reader make an accurate assessment of what may be helpful in attaining desired outcomes?"

5. Has the book been evaluated in terms of clinical efficacy? If so, under what conditions, with what population, with what results? Some self-help books describe procedures that have empirical support but these procedures may not have been evaluated in a bibliotherapy format.

6. How does the effectiveness of one source of bibliotherapy compare to that of other manuals or formats? Have comparisons been made between the effects of reading a book with the effects of other self-help books on similar topics or use of other formats such as audiovisual material, and, if so, what are the results? (I am not aware of any study that compares client free choice of reading material with counselor-selected material in terms of effectiveness. This would be an interesting study.)

7. Is there any evidence that positive changes last? If so, over what period?

8. Has the possibility of negative effects been explored (e.g., a decrease in hoped-for outcomes and/or a worsening of disliked outcomes)?

9. Does contact with a therapist enhance effects?

10. Is bibliotherapy more effective for certain kinds of problems/people than with others?

As with any claim, we should carefully examine the extent to which it has been critically tested. For example, is there any evidence that reading a book about how to make and keep friends or how to improve your grades yields hoped-for outcomes? Many manuals have not been examined under conditions of intended use. In addition, subjects used in studies may differ from target populations, thus altering potential effectiveness. Follow-up studies are also vital—how long do positive effects last if they occur? In 1997 Cuijpers reviewed six small, short-term randomized controlled trials of bibliotherapy involving 273 participants recruited by ads who had mild depression. He reported a mean effect size of bibliotherapy of .82; 79% of participants in the control group had a poorer outcome compared to the average participant in the bibliotherapy group.

A meta-analysis of 70 bibliotherapy studies by Rick Marrs indicated a positive effect for bibliotherapy. This meta-analysis involved a total of 4,677 participants. Bibliotherapy was defined as “The use of written materials or computer programs, or the listening/viewing of audio/videotapes for the purpose of gaining understanding or solving problems relevant to a person’s developmental or therapeutic needs.” Only those studies were included that had a comparison group drawn from the same population as participants receiving bibliotherapy. The 79 studies included 2,315 subjects who participated in bibliotherapy, 455 who received a therapist-directed therapy (without bibliotherapy), and 1,907 who were in control groups. The studies averaged about 57 subjects each and retained 88% of participants through the posttreatment measurement. The average age of people involved in these studies was the mid-30s, and participants tended to be well educated. Problems addressed included anxiety (e.g., test anxiety), assertiveness, indecision about career, depression, impulse control (e.g., alcohol use, smoking), self-esteem–self-concept concerns, sexual dysfunction, study problems, and weight loss. The individuals in the bibliotherapy groups met with a therapist for an average of about 36 min per week, length of bibliotherapy averaged about 212 pages, and time spent in treatment averaged 6 weeks. Most studies (84%) used random assignment to a comparison group, and 80% used a book for the written material. Forty-eight percent of the studies used samples from a college population, and 39% used participants solicited from general adult populations. Thus, most of these studies did not involve clinical populations. The mean estimated effect size of the 70 samples analyzed was +0.565 indicating moderate effectiveness. The authors reported no signif-

icant differences between the effects of bibliotherapy and therapist-administered treatments and no significant erosion of effect size at follow-up. Bibliotherapy methods appeared to be more effective for certain kinds of problems such as assertion training, anxiety, and sexual dysfunction than for concerns such as weight loss, impulse control, and studying problems. The amount of therapist contact during bibliotherapy did not seem to be associated with effectiveness. However there was an indication that increased counselor contact resulted in better effects for some problem types such as weight loss and anxiety reduction.

Other follow-up studies of the effects of bibliotherapy have also yielded positive effects. For example Nancy Smith and her colleagues examined the effects of cognitive bibliotherapy for depression and found that treatment gains had been maintained at 3-year follow-up. Positive effects were also found by Jim White in his 3-year follow-up of the effectiveness of STRESSPAC. STRESSPAC is designed as a self-help package for people with anxiety. It is a 79-page booklet that includes a four-page introduction, handout, and a two-sided relaxation tape—one for rapid relaxation and the other for deep relaxation. The booklet is divided into information and treatment sections. The former section contains information on the nature of anxiety, describes different kinds of anxiety disorders, gives case histories, as well as information related to the causes and maintenance of anxiety. The intervention section is divided into four sections including controlling your body (progressive relaxation), controlling your thoughts (cognitive therapy based on the work of Beck and Meichenbaum), controlling your actions (emphasizing the importance of exposure to anxiety-producing cues and other behavioral advice) and, last, controlling your future (a relapse prevention information section).

VI. CASE ILLUSTRATIONS

Robert Gould and his colleagues compared the use of bibliotherapy involving minimal counselor contact in the treatment of panic with guided imaginal coping and a wait-list group. Changes assessed included frequency and severity of panic attacks, perception of ability to deal with panic attacks, and level of depression and avoidance. Participants in the bibliotherapy group ($n = 12$) were requested to read *Coping with Panic: A Drug-Free Approach to Dealing with Anxiety Attacks* over a 4-week period at their own pace. This book includes information on educating readers about the causes and

nature of panic disorder; describes a variety of cognitive and behavioral strategies including relaxation, cognitive restructuring, breathing retraining, and exposure; and advises readers how to use these strategies. It describes cognitive strategies such as exploring faulty logic, reconsidering attributions, exploring alternatives, decatastrophizing, and hypothesis testing. Participants were informed that reading the book was designed to help them deal better with their panic attacks and that they would be contacted at weeks 2 and 4 by the researcher to assess their progress in reading the book. Calls lasted about 10 min; a written protocol was followed, and callers were coached not to answer questions about any particular reader's program. Rather, participants were questioned to see if they were reading the book and to check their progress. The authors reported that, overall, participants in the bibliotherapy group were more improved than were participants in the wait-list group and were not significantly different from those in the individual therapy group. Participants in the bibliotherapy group and the individual therapy group had greater self-efficacy ratings and improvements in confidence in coping at posttest than participants in the wait-list group and did not differ from each other. Seventy-three percent of the participants in the bibliotherapy group showed clinical improvement compared to 67% of those in individual therapy and 36% in the wait-list group. Clinical improvement was defined as at least a 50% decrease in all symptoms of panic attacks. However, the authors reported that anxiety sensitivity was still high on posttest and there were no statistically significant differences between participants in the wait-list group and participants in the other two groups in the frequency and average severity of panic attacks. The authors noted that participants in this study were well educated and highly motivated. Thus, similar effects may not be found with poorly motivated clients.

George Allen compared group and self-administered relaxation training and study counseling. Twelve participants used a programmed text designed to enhance relaxation and effective study skills. The text described the same content as that discussed during the group meetings. In addition, readers of the text were asked to complete a check list of methods used during the week. One other contact was held with each individual in the self-help group. In this session participants were asked to discuss future applications of the material. In another self-administered condition, the same rationale was offered, however participants received a programmed study counseling text. Participants in both

self-administered groups received instructions in carrying out a functional analyses of their study behavior and were given forms to carry this out on a daily basis. Results suggested that both self-administered programs were as effective as counselor-provided help. Both programs were equally effective in reducing anxiety and improving grades, and both were significantly better than no treatment.

VII. SUMMARY

Bibliotherapy has been used to pursue a wide range of goals including educating clients, decreasing anxiety and depression, enhancing social contacts, and developing study skills. There are different kinds of bibliotherapy. One utilizes self-help materials designed to guide the client through assessment and/or intervention in relation to hoped-for outcomes such as losing weight or developing more effective study behaviors. Another kind requests clients to read fictional materials or poetry to attain certain outcomes. Yet another encourages readers to read spiritual literature. Many different formats are used and Internet-based material is likely to increase in use. An advantage of bibliotherapy is allowing people to achieve desired changes on their own, although some writers point out that use of self-help manuals still ties consumers to therapists because therapy "experts" are often the authors. Potential positive effects of bibliotherapy include acquiring skills that can be applied to other areas. For example, if a parent learns to use positive reinforcement with one child, she may use this with her other children as well. In addition, positive effects found at follow-up (e.g., White's finding of the maintenance of effects over a 3-year period), suggest that clients who cannot obtain access to services right away can benefit from bibliotherapy material that can be provided immediately, and this may provide as much help as seeing a counselor.

Dangers of ineffective self-help materials suggested by Gerald Rosen include an increase in hopelessness and helplessness when desired outcomes do not occur, neglect of other methods that might be successful—such as consulting a clinician—and a worsening of problems. One potential negative effect of bibliography is encouraging the belief on the part of clients that change is impossible because bibliotherapy did not work, when, in fact, change would occur within another format, perhaps including more contact with a counselor. Programs that are successful when presented

by a counselor may not be effective when self-administered. Review of self-exposure treatment for anxiety indicates that brief initial contact with a counselor is an important motivator for some individuals. Another possible negative side effect is excessive discomfort in the process of change due to lack of expert guidance. Although prescriptive advice offers guidelines (which may be more or less clear) about what to do, it may not provide the motivation to act on this advice. For example, knowledge about helpful rules does not provide the motivation to act on these rules. Not carrying out instructions is a common problem in self-change programs.

Self-help books may foster incorrect views about self-change and how it can be accomplished. They may obscure sources of influence over valued outcomes which decreases the likelihood of attaining desired goals. Self-help books may encourage unhelpful views of “the self” (e.g., as the seat of all change). They may encourage a dysfunctional focus on the self and on one’s problems or encourage the unrealistic view that life should be without problems. Encouraging a focus on the self may increase depression in people who already focus too much on themselves. Self-help focuses on the individual who is attempting to alter personal behavior, thoughts, or feelings to attain specific goals. Individual change, however, is but one level of intervention. Many other levels may be required to attain valued outcomes such as losing weight or decreasing anxiety or depression. The focus on self-help may obscure the role of political, social, and economic factors that influence many of our behaviors that we try to alter through self-change and thus exaggerate the potential we have to alter our behavior and related environmental influences on our own. Consider stress for example. Many stress-related factors are environmental such as a decrease in civility, high noise levels, and hours spent on crowded, smoggy freeways. The fundamental attribution error (overlooking environmental causes of problems and focusing on dispositional causes) is common and is encouraged by a focus on the self.

A key concern for future research is the rigorous testing of claims regarding the effectiveness of bibliotherapy in relation to particular outcomes. Given the possible rationing of counselor availability and indications that bibliotherapy can be effective and/or contribute to positive effects at low cost, it is certainly worthwhile to pursue research in this area. The effectiveness of bibliotherapy methods should be enhanced

by taking full advantage of empirical literature describing components of effective self-change efforts and making sure other information provided is accurate.

GLOSSARY

agent A human subject capable of making and acting on a moral choice. Synonymous with “moral agent.”

autonomy A question central to the work of Immanuel Kant. An independent and self-legislative stance taken in making moral judgments in the domain of justice. Emile Durkheim stated that autonomy requires the willingness to do one’s moral duty because reason commands it, and not from any external constraint. The demands and ideals of morality are willingly complied with as necessary for participating in a desirable and fulfilling collective life. Teaching children rational autonomy by explaining the reasons behind social rules and obligations is more effective than educating through indoctrination or preaching. He considered it to be the third goal of moral education after discipline and attachment to the group. Heteronomy is the antonym of autonomy.

bioethics A formidable expansion of medical ethics dating to the 1960s when the introduction of new medical technologies such as hemodialysis, kidney transplantation, reproductive control techniques, life support equipment, and the definition of brain death, introduced new and difficult ethical choices for medical personnel, patients, institutions, managed care organizations, and at the level of social

policy. The evolving role of bioethics has been to examine critically the moral ramifications of contemporary medical and scientific procedures, the criteria and responsibilities for decision-making responsibilities, and their implications on societal expectations and social policy. Since these contemporary medical and scientific procedures are widely publicized in the mass media, and may become generally available, the ethical discussions have involved a cross-section of the general public as well as physicians, scientists, journalists, philosophers, theologians, and sociologists.

collective norm Defines what is expected from group members qua group members in their attitudes and in their actions. For example, community group members care about each other and do not steal from each other. For a collective norm, the group members constitute its affiliative constituency. A universal affiliative constituency would include all of mankind. The typical collective norms of a community uphold the intrinsic value of community, and include caring, trust integration, participation, publicity, attachment to community, and collective responsibility.

ethics (Greek *ethos*—character) Often used interchangeably with morality, for example, professional ethics and personal morality. Ethics is generally accepted as being broader than morality, and includes some areas outside morality. Aristotle wrote that Ethics was a branch of politics because it was the duty of the statesman to create the best possible opportunity for the citizen (of a Greek *polis*) to live a good life. Ancient ethical theories all contained the understanding of obligation or moral duty, and this fundamental notion was reaffirmed in modern times by Kant (1724–1804), who held that virtue was secondary. He wrote, “By mere analysis of the concepts of morality we can quite well show that the principle of autonomy is the sole principle of ethics. For analysis

finds that the principle of morality must be a categorical imperative, and that this in turn commands nothing more or less than precisely this autonomy.”

moral reflection Re-visioning the environment or world as responded to by an ideal social system. When humans change their perception of the world or of moral quandaries through moral reflection, the process promotes favorable changing of their behavior. Assessment of moral reflection provides guidelines to classifying the level of moral sophistication of individuals and societies.

morality (*Latin mores—character, custom, and habit*) Morality concerns a narrower range of issues than ethics, focused on what we should do, and how we should live. A fundamental characteristic of morality is respect for oneself and others. Becker and Becker identify four specific characteristics that differentiate morality from the broader ethics term: First, morality makes a distinction of kind between moral and nonmoral reasoning. Second, morality makes a strict demand of responsibility, viz.; “ought” implies “can.” Third, duty or obligation represents a major moral precept. Fourth, morality assumes an essential concept of the noninstrumental good of others.

rationalization The process of thinking by which something immoral becomes transformed into something plausible.

social conventions Arbitrary norms that coordinate the activities of individuals in a social system, thereby serving the organizational goals of the system.

virtue The Latin term *virtus* and the corresponding Greek *arête* referred to all kinds of excellence. In contrast under ethical theory the moral virtues are generally narrowed to include courage, justice, wisdom, and self-discipline. More recently Michele Borba, in discussing how to build moral intelligence in children, added to this list the basic virtues of empathy, conscience, respect, kindness, and tolerance, to make a total of seven. More than 200 other virtues have been described in the literature.

*The life is short,
The art long
The right time but an instant,
The trial (of therapy) precarious,
The crisis grievous.*

*It is necessary for the physician to provide not only the
Needed treatment, but to provide the patient himself,
And those beside him, and for his outside affairs.*

Hippocrates
Aphorisms I

I. BACKGROUND

Psychotherapists need bioethics on a number of levels in the pursuit of their healing professions. Like our

North American society the psychotherapy disciplines are experiencing accelerated change unparalleled in human history. The last quarter century recorded vast changes in almost every area of life (communication, lifestyle, technology, social organization, physical and mental health, and religion) that have altered the perception of collective societal norms.

Behavioral health professionals and institutions have absorbed many seismic shocks as the tectonic plates of their paradigms have shifted. Shudders have been felt when the state mental hospitals were virtually emptied. This occurred as a result of national ethics debates about the rights of mental patients to autonomy and self-determination regarding hospitalization. The societal perception of mentally ill patients has radically changed. At the same time this movement overlapped the introduction of the first-generation tranquilizer drugs that largely replaced sedatives, hypnotics, and electroshock therapy. A new generation of psychoactive drugs was fully expected to one day permanently cure mental diseases. As a consequence of new drugs renunciation of paternalism toward the mentally ill occurred followed by the flight of the discharged state hospital patients to the streets, where they continue to form the core of the homeless. Few at that time grasped the notion that by rejecting paternalism this new social policy had actually caused harm (maleficence) while trying to effect social good (beneficence).

After this megashift in public policy the Darwinian economic rise and fall of private behavioral health facilities and private practices appeared, closely connected with the rise of bureaucratic restriction of behavioral health services and medications by managed care organizations (MCOs) that followed the Bentham-Mill utilitarian or consequential ethic. Psychotherapists had to rethink their accustomed psychotherapy practices under the harsh new scrutiny of MCOs' cost-conscious business rules. Meanwhile, second- and third-generation psychopharmacology agents appealed to the MCO utilitarian ethic as more economical than extended talking therapy.

As a result psychotherapists found themselves in an uncomfortable area between the conflicting imperatives of the patient and the MCO. Regardless of the therapist's theories and personal convictions about the care that was indicated for each patient, his or her treatment plans for patients could only be reimbursed if they were approved by the MCO. The developing theories of bioethics changed the perspective on the priorities of classical medical ethics and professional codes of conduct, giving the scientific and quantitative rational approach ascendancy over the prior humanistic and art-of-medicine approach. Subsequently the roles of the

psychotherapist have been forced to evolve to keep up with these new situations.

Changes in the practice of medicine and bioethics have also thrust the psychotherapist into newly reframed clinical ethics situations. During the 1960s many previously resolved issues were brought up for new public debate, including confidentiality, informed consent, truth telling, patient access to medical records, patient refusal of treatment, and end of life considerations. At the same time public debate engaged new technologies such as mechanical support of respiration, brain death, new reproductive technology, and organ transplantation. Psychotherapists regularly become involved in these bioethical issues in their practices. The dilemma in the field of psychotherapy involves the difficulty of defining and taking action on moral and bioethical issues that involve deciding between seemingly equally worthy conflicting values in mental health. But lest we feel overwhelmed, we might remember that the imposing twentieth-century ethicist W. D. Ross in 1939 cautioned against underestimating the natural value of our own moral character when he said, "The moral convictions of thoughtful persons are the data of ethics just as the sense-perceptions are the data of natural science. Moreover acts are either right or wrong, whereas motivation and character are either good or bad."

Former United States President Lyndon B. Johnson captured the contemporary ethical challenge in a nutshell. According to White House advisor Joseph Califano, one of Lyndon Johnson's favorite sayings was, "It is not doing what is right that is hard for a President, it is knowing what is right."

II. SCOPE OF THE ARTICLE

This article will briefly address the development and ramifications of bioethics in the health sciences, with particular emphasis on the profession of psychotherapy. Brevity requires the perspective be restricted to that of the Western industrialized societies. A case example will illustrate some commonly encountered mental health bioethical problems. The glossary complements the text with definitions of terms and concepts that could not be fully developed in this brief article.

III. CONCEPTS OF ETHICS AND MORALITY

Ethics may be broadly defined as the principles of moral behavior by individuals and by society. What are

one's duty to others and the duties of others to oneself? Many philosophers consider ethics to be a broader philosophical term than morality, to include political philosophy such as national and international policy making. Nevertheless some ambiguity exists in the current use of these terms.

Professional bioethical principles emphasize truth telling, client self-determination, and informed consent (autonomy), doing good for the patient (beneficence), avoiding harm (maleficence), and acting with justice (fairness). It is, however, deceptive to believe that every complex clinical ethical concern should be reduced to fit a narrow principled classification without sacrificing significant clinical issues of each case.

In 1996 a major conceptual breakthrough in the role of morality in bioethics was contributed by James Rest, who, after reviewing hundreds of contemporary professional publications on morality, concluded that all future discussions of morality should center around four intrinsic measurable components: moral sensitivity, moral motivation, moral judgment, and moral character. By separately weighing these four components it becomes possible to identify distinctive patterns of morality in and during the course of individual human development. Moral philosophy research allows these components to be accurately described at a certain point or even objectively scored, over a person's lifetime. Moreover, by using this method of assessment previously problematic historical personalities could be profiled in a more precise common language.

For example, one could assess the level of each of the four moral components of, let us say, Adolph Hitler, Lieutenant Calley of My Lai, or Mother Teresa. We might conclude that Mother Teresa possessed all four components at high levels, while Adolph Hitler and Lt. Calley possessed adequate potential capacity for moral judgment but were deficient in the necessary moral sensitivity, moral motivation, and moral character, to behave morally. In addition these four moral components could be used to reclassify the moral themes in Homer's epics and Aristotle's *Nicomachian Ethics* that have so profoundly affected Western civilization.

At a more contemporary pragmatic level, using James Rest's components can aid us in bioethical areas by making meaning of the diversity of moral visions, accounts of moral obligations, rights, and values that confront us in our increasingly pluralistic society. Different ethnicities, but also religion, class, socioeconomic status, education, gender assumptions, and language, affect the context and perspective of all four moral components defined by Rest.

In 1996 Marvin Berkowitz amended classical Aristotelian ethics by giving a new definition of “the complete moral person.” His proposal is complementary to Rest’s four-component model. Berkowitz’s vision of “moral anatomy” included six elements or “objects”:

1. Moral behavior
2. Moral character
3. Moral values
4. Moral reason
5. Moral emotion
6. Moral identity

In addition Berkowitz clarified the roles of self-discipline and empathy as metamoral characteristics that serve to support the moral life models that operate in the field of moral psychology. He wondered how we might best educate the moral person in our society. He asked the related question of how contemporary parents and teachers might best model for their children, and suggested they use well-known components of (1) the just community, (2) character education, (3) dilemma discussions, and (4) love of the good.

Despite the established principles of bioethics and the helpful recent moral clarifications of Rest and Berkowitz, there is no general universal theory of secular bioethics agreed to by all, although more consensus exists within religious and cultural subpopulations (“moral communities”) that share values and moral assumptions. This diversity has been highlighted by the increasing internationalization of North American communities by the flood of new immigrants who share different ethnic and religious concepts of morality. As H. Tristram Englehardt states in *The Foundations of Bioethics, Second Edition*, “Bioethics is a plural noun ... there is a swarm of alternative ethics ready to give rise to a babble of conflicting bioethics.”

Nevertheless in the health sciences professions the four moral components of Rest, combined with bioethical principles, precedence, and careful case analysis, help facilitate our recognition, motivation, judgment, discussion, and action on moral and ethical issues we may personally encounter on a daily basis with patients, families, other professionals, and medical care policies, however different the moral backgrounds, assumptions, and communities may be.

Medical ethics relates to the classical fixed philosophical themes of the responsibilities of doctor and patient as generally perceived up until the 1960s, when a new cycle of technological advances such as dialysis, organ transplantation, and mechanical respirators gave

medical professionals unprecedented control over extending life. Advances in reproductive technology such as contraception, *in vitro* fertilization, stem cell research, and surrogate motherhood created frightening new moral dilemmas, and brought to attention the value-laden nature of medical decision making.

Advances in medical diagnostic technology simultaneously made laboratory data more reliable and quantitative, and refocused medical diagnosis away from the bedside and toward the seductive computer video-display terminal. After all, was not high technology a way of providing the greatest good (beneficence) to the greatest number of patients at the lowest possible cost (utilitarianism)?

Health scientists found that new philosophical and ethical concepts were needed to deal with advances that put the tools and decisions affecting life and death into the hands of both patients and professionals in radically different ways. In 1970 the emerging new medical ethical philosophy that dealt with the dramatic technical advances acquired the name bioethics, borrowing a term that originally referred to the philosophy of social responsibility to preserve the biosphere. Bioethics concerns itself with much broader philosophical and public policy questions than traditional medical ethics, such as “What are the limits of science,” or “What does it mean to be a human being.” Bioethics stresses not a set of rules, like the Hippocratic Oath, but a better understanding of new and changing issues.

A. Uniform Ethical Standards

Despite the lack of a universal secular ethical theory, as the need for uniform ethical standards for government-funded medical research emerged, health department officials contracted with private groups such as the Hastings Center to develop a national consensus for bioethical principles and a National Bioethics Advisory Commission. These advisory groups helped set standards for the National Institutes of Health grant review process as well as for local institutional review boards in medical centers. The post–World War II Nuremberg trials documents provided important precedents for these bioethical deliberations.

B. The Dawn of Professional Ethics

Philosophers from Homeric times (about 700–800 BC) and from subsequent Socratic and Hebrew periods (after 500 BC) to the present have wondered how to define what is good and what is bad, striving to identify some

first principle and define universal rules that describe morality and virtue.

Homer's epic *The Odyssey* and *The Iliad* comprise the first widely adopted treatises on ethics. They contained an encyclopedic account of ethics, morals, politics, virtues, and vices of ancient Greek society encountered in daily life, medicine, commerce, politics, religion, and war. The epics provide numerous positive and negative examples of every important area of individual and group human behavior. These epics as well as subsequent classics such as *Aeneid*, *Beowulf*, and *Canterbury Tales*, became the standard tutoring literature for Western ethical and moral teaching for many centuries afterward and continue to enrich our culture even up to the present day. The Judeo-Christian and Islamic Scriptures and commentaries record the long enterprise of faith communities' attempts to understand and codify the moral life, the meaning of illness and insanity, and their relationship with God.

During the classical period (fifth century BC) while early Athenian philosophers were inquiring and teaching by dialectic, the early ethical commitments of the healing professions were formulated in the writings of Hippocrates, a revered physician who practiced and taught medicine on the Greek island of Cos. We have the solemn Oath of Hippocrates to attest to that. In fact, the etymology of the term "profession" derives from such oaths, which were required of physicians, priests, soldiers, temple virgins, and political leaders. Hippocrates asserted that the medical professional must be a model of unimpeachable ethical behavior. Physicians should honor and sustain their teachers, and should model honesty, morality, and integrity in dealings with patients, their families, and other health practitioners. The physician should avoid intentional harm, and act to benefit patients. The value accorded to life was exemplified by bans on euthanasia and abortion. The three basic principles of Hippocrates could be summarized as competence, caring, and commitment.

Hippocrates extracted the oath, sworn by Apollo, from each of his medical students that they would never abuse their trust by criminal practice, sexual immorality, or disclosure of medical secrets. The act of taking an oath was a solemn commitment.

Unaccountably the Hippocratic Oath, while clarifying the expected relationship between physician, teacher, and patient, fails to provide for the moral reasoning behind any of the elements of the Oath. Very likely the moral rationale was taken to be obvious, or else the documents were lost. Curiously, the commitment to teachers is listed before the commitment to pa-

tients. The Hippocratic Oath shows an unconscious paternalistic prejudice by failing to mention today's favored priorities of patient autonomy and justice. Nevertheless, the Hippocratic moral and technical prescription for physicians was unprecedented in Greek medicine, and it heralded a new course for the practice of medicine.

Subsequent medical professional codes have included at least six key concrete elements or rules of the Hippocratic Oath, including

1. Respect for the dignity of persons and life itself
2. Avoiding willful harm (maleficence)
3. Doing good (beneficence) to clients
4. Maintaining integrity in relationships (honesty)
5. Responsible caring (empathy)
6. Responsibility to society (good citizen, husband, parent)

Two additional elements appeared in modern times, including

7. Respect for patient self-determination (autonomy)
8. Respect for justice (fairness)

The modern Western terms "medical ethics" and "professional ethics," as well as "attending physician," were coined by the eighteenth-century Thomas Percival, an English physician trained in philosophy. Percival founded one of the first departments of public health, advocated the abolition of slavery, and near the end of his life wrote the first such book in English, *Medical Ethics: A Code of Ethics and Institutes Adopted to the Professions of Physic and Surgery*, based on his experiences heading a committee assigned to write rules of conduct for an infirmary where a medical scandal had occurred.

Each human society generates a different ethical structure. The Chinese have quite a different ethical vision, based to a great extent on Confucian thought. Similarly Buddhist, Hindu, African American, Native American, and other communities have distinctive philosophical and ethical traditions.

C. Meaning of Profession

Although the classical understanding of profession was associated with schooling and training that lead to taking a binding oath dedicating one's life and honor to a socially important vocation, in modern language the term "learned profession" preserves more accurately the classical concept of medicine, psychiatry, nursing,

law, and other vocations that assume rigorous selection of candidates, extensive formal education and training, difficult qualifying examinations, generous rewards, and a high degree of self-control through codes of ethics. Furthermore learned professionals are expected to work tirelessly for the good of society.

D. Ethical Standards after Completion of Professional Training

The new professional psychotherapist becomes aware that ethical concepts are embodied in the laws pertaining to many mental health professional and client matters. Bioethics often resides in an enigmatic extralegal gray area.

Ethical questions shadow almost every activity in psychotherapy. The psychotherapy disciplines including individuals practicing psychiatry, psychology, social work, nursing, and pastoral care subscribe to a body of ethical traditions making the benefit of the patient the top priority. As a member of one of the psychotherapy disciplines, each member must also recognize responsibility to society, to other health professionals, and to family and self. Each modern profession's membership is expected to adhere to a set of principles, called a "Code of Ethics."

As an example the following principles, adopted by the American Psychotherapy Association, are not laws but standards of conduct that define the essentials of honorable professional behavior of the therapist who has completed the journey of professional training. The American Psychotherapy Association's "The Psychotherapist's Oath":

As a psychotherapist:

I must first do no harm.

I will promote healing and well-being in my clients and place the client's and public's interest above my own at all times.

I will respect the dignity of persons with whom I am working and I will remain objective in all relationships with clients and act with integrity when working with other professionals.

I will provide only those services for which I have had the appropriate training and experience and will keep my technical competency at the highest level in order to uphold professional standards of practice.

I will not violate the physical boundaries of the client and will always provide a safe and trusting haven for healing.

I will defend the profession against unjust criticism and defend colleagues against unjust actions.

I will seek to improve and expand my knowledge through continuing education and training.

I will refrain from any conduct that would reflect adversely upon the best interest of the American Psychotherapy Association and its ethical standards of practice.

This oath is a good starting point for the study of contemporary codes since it is the briefest of all the current psychotherapy codes. In comparison, the 1992 Ethical Principles of the American Psychological Association is more extensive, running to 32 pages.

For an even more comprehensive resource, the reader is directed to the American Medical Association's 1998 publication, *The Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry*. This reference includes an appendix on "Guidelines for Ethical Practice in Organized Settings" and "Questions and Answers about Procedures for Handling Complaints of Unethical Conduct." This document includes a statement of the skeletal AMA ethical code that is then fleshed out with explicit discussions of each point in the code as it relates to contemporary issues in psychotherapy. The appendices include ethical standards and problems in health care organizations, as well as a detailed guide to the making and answering of allegations of unethical professional behavior. The full text of these and other codes for psychiatrists, psychologists, social workers, family counselors, school counselors, and social workers may be found through Internet links at the Canadian Counseling Association web site (<http://www.ccacc.ca/coe.htm>).

Although a code of ethics cannot guarantee ethical behavior, resolve all ethical issues or disputes, or fully develop the richness and complexity involved in working to make responsible choices within a moral community, it does set forth normative values, ethical principles, and ethical standards to which professionals aspire and by which their actions can be judged. The Hasting Center Reports, found in most medical libraries, are an excellent reading source for ongoing debates in bioethics.

IV. CASE ANALYSIS

The following case abstract and bioethical analysis illustrates considerations in working with an actual clinical bioethical scenario.

Crystal (a pseudonym) is a 14-year-old white female only child who suffers from depression and oppositional defiant disorder. She is from a financially stable

middle-class family. She was admitted to an acute inpatient adolescent psychiatric unit for the second time in one month after making her fourth suicide attempt in 2 years. Crystal's mother is self-described as strict and controlling, and admits that consequences for Crystal's rule infractions at home may be excessive. Crystal's stepfather sides with her mother. There is gloom in the household about unusual multiple recent suicides by aunts and uncles. After 10 days, the maximum allowable inpatient time under her health care plan, Crystal voluntarily signs a discharge safety plan, and the unit staff team determines that she is ready to transition to an intensive step-down day hospital program, which she will attend from home. Unfortunately, the parents do not wish to have Crystal back home yet, and they angrily object to her discharge.

Shortly after Crystal arrives home she gets into an altercation with her parents. They call 911, the police arrive, and she is arrested and taken in handcuffs to jail. The mother then calls the attending psychiatrist, Dr. Barnes (a pseudonym), and asks whether Crystal can be readmitted as an inpatient. Crystal, her parents, and Dr. Barnes are suddenly faced with a number of uncomfortable bioethical issues.

A. Choosing a Case Analysis Method

Case analysis is a practical or "applied clinical ethics" method of identifying, analyzing, and resolving (if possible) the ethical values and issues in a clinical bioethics case. Bioethical problems arise when health care professionals, patients, and health care providers do not agree on values or actions, or when they confront dilemmas about the bioethically conflicting clinical choices available. Mental health care may present extremely difficult choices, as illustrated in this case history of an all-too-common scenario with adolescent clients. Each individual agent involved in the ethical encounter may be calling on the same or on different ethical principles, or on multiple conflicting principles.

The two case analysis approaches most often used in the United States are the principled ethics approach, also called the top-down or deductive; and the clinical ethics approach, also called the inductive, practical, or bottom-up approach.

B. Principled Ethics

The principled ethics analysis begins with an ethical principle such as autonomy or beneficence and then applies it to the case. This principleism is theoretical and can be rather abstract. For example, Tom Beauchamp and James Childress, in their *Bioethics* in 2001 empha-

size the essential middle level ethical principles of (1) autonomy, the patient's independence in deciding what is best; (2) nonmaleficence, avoiding harm to the patient; (3) beneficence, doing good for the patient; (4) justice, fairness to the patient; and (5) professional-patient relationship.

Engelhardt in 1996 points out some limitations of the principled approach: "It is not possible to justify a canonical content-full morality, right-conduct, or bioethics, in general secular terms. . . . The appeal to middle-level principles may succeed in bridging the gulf between those who share a moral vision, but are separated by their theoretical reconstruction of that vision. But it will not bridge the substantive gulf between those separated by different moral visions or different moral senses."

C. Clinical Ethics

In contrast, the clinical ethics approach to applied ethics is a bottom-up or inductive approach. It provides a structured method to help psychotherapists identify, analyze, and resolve clinical issues in psychotherapy. This alternative approach facilitates thinking about the complexities of the data in actual cases in a clinical setting that therapists face, rather than looking up answers in a resource book and trying to match patients to standard models. A patient care situation is considered comprehensively in detail first, and then the ethical principles that best relate to the case are identified and discussed. Albert Jonsen, Mark Siegler, and William Winslade in 1998 use this approach in their *Clinical Ethics*, as do Mark Kuczewski and Rosa Pinkus in 1999 in their *An Ethics Casebook for Hospitals*. Rather than beginning with ethical principles, these authors sort the facts and values of each case into an orderly pattern and then call on principles in order to facilitate the resolution of each bioethical problem. Their basic pattern includes four clinical topics and six or more conceptual subtopics that define the major elements from which the case ethics can be identified: (1) medical indications, (2) patient preferences, (3) quality of life, and (4) contextual features. They consider that these four topics provide adequate information to guide the clinician through the problem and that no case can be adequately discussed unless these topics guide the analysis. Jonsen and colleagues comment that this method helps clinicians understand where the moral concerns meet the clinical circumstances of the case.

The Beauchamp and Jonsen approaches are not incompatible, since each is an organizing device to ensure that the basic topics necessary for analysis are

fully considered in the process of pursuing a bioethically acceptable course of action. In fact, in the latest edition of their textbook, Beauchamp and Childress have come so far from principleism toward clinical ethics that one reviewer described it as “the beginning of the end of principleism.”

While the previously espoused principled ethics approach of Beauchamp and Childress is traditionally used for funded research protocols and medical casework, the clinical ethics approach of Jonsen and colleagues may be more intuitive for mental health casework and professional training.

The reader should be aware of caveats that apply to theoretical approaches such as those discussed above. The theories are not able to provide full moral guidance unless one supplies them in advance with a particular moral content. In other words, although we may accurately portray the clinical case history, preferences, outcome, and context, and identify middle level principles, as we attempt to do in the following case, we may find ourselves divided about the case analysis conclusions because of conflicting moral visions of the participants in the discussion.

If we hypothetically assigned different moral vision and ethnicity labels to the participants, this inconclusivity might be even more inevitable. When that occurs, resolving concrete moral bioethics controversies must rely on peaceable negotiation and agreement among parties in order to reach a resolution.

On this issue Engelhardt in 1996 commented that

Each theoretical approach recapitulates the challenge of post-modernity: a moral theoretical account must either beg the question with regard to moral content (i.e., incorporate particular moral content without justification) or give no substantive guidance. Each attempt to justify a particular moral vision presupposes exactly what it seeks to establish so that moral theoretical arguments are at best expository, not justificatory. Even if one attempts a defense of secular ethics or bioethics on the basis of arguments that are not reducible to intuitionist, consequentialist, hypothetical-choice, or hypothetical-contractor arguments, or analyses of the nature of rational choices or game theoretic rationality or natural law arguments or middle-level principles analyses, the arguments will fail as well. All concrete moral choices presuppose particular moral guidance.

D. Clinical Ethics Analysis of Case

1. Medical Indications

a. Medical and Psychiatric History. The developmental history given by Crystal's mother revealed that

from about age 1 Crystal would behave normally and then have apparently unprovoked several-week-long periods of depression, oppositional behavior, irritability, and difficulty with relationships. These episodes occurred about every 2 months. Whether other family problems might have been occurring at that time was not yet fully explored.

When not in the abnormal moods, Crystal seemed to be a bright and happy child. She enjoyed playing the piano, singing, and dancing, and made friends easily. She was a straight-A 10th-grade student, described by her parents as artistic, outgoing, and active in her church youth group. During the prior 2 years she had twice secretly taken large doses of analgesic tablets from the family bathroom medicine cabinet and ingested them without telling anyone, and without apparent physical harm. These incidents occurred at a time when several relatives and a friend of the family were creating a climate of grief in her family by unexpectedly committing suicide, so that a posttraumatic stress phenomenon or grief and confusion might have been factors.

Crystal occasionally experimented with alcohol or marijuana. One month before the present admission Crystal got high on marijuana with a boyfriend, and according to her, he succeeded in sexual intercourse over her protestations (her first sexual encounter). That night she went home and ingested a large number of analgesic pills from the medicine cabinet and superficially cut her wrists. Then she told her mother what had happened, and her parents took her to an emergency room where she required a number of sutures to close the wounds. Her mother reported the alleged date rape to the police, and an investigation is ongoing.

Crystal was referred from the emergency room for admission to the same mental health unit as for the current hospitalization. Her admission evaluation led to the diagnosis of two Axis One disorders, depression and oppositional defiant disorder, that were confirmed by history, observation, and psychological testing. She was started on the antidepressant Paxil, and participated in multiple individual and group therapy sessions that were part of the inpatient program. She seemed to the staff to be intelligent and mature. Her assigned writing assignments about her family and personal behavioral issues seemed thoughtful and appropriate. She gave correct answers about the measures she needed to take to be safe and to reduce disputes and disrespectful conduct at home. She was discharged after her encouraging progress and after signing a safety contract. Her parents made arrangements for continued psychiatric treatment as well as outpatient rape counseling.

Because of the worrisome sexual incident her mother set strict new limits on her activities after she returned from the hospital, including restricting her dating or driving in a car alone with males, and severely restricting her socialization with her friends. The restriction on peer socialization was particularly disheartening to Crystal, since one of her most valued privileges in life was “hanging out with my friends and just laughing and playing music and being myself.”

On the other hand, her mother perceived Crystal to be at risk because of “poor social skills,” especially in setting safe personal boundaries. Her mother stated that Crystal was “not safe at home.” These strictures and assumptions led to increasingly angry confrontations and more oppositional behavior on Crystal’s part, more tension at home, and eventually to Crystal defying her parents and making threats to kill her mother. Her coping skills so much in evidence in the hospital had diminished as her despair increased. On the evening of the most recent admission she became angry when her stepfather would not permit her to invite her friends over to visit. After an angry confrontation Crystal went into the kitchen where she deliberately cut her wrists with a paring knife, and thereafter was brought by her parents to an emergency room, where she was transferred again to the adolescent psychiatric unit.

As on her prior admission Crystal was a model patient from the moment she stepped inside the unit. She took responsibility for her actions, but explained that she was hurting herself superficially so that “my parents will hurt,” and not to kill herself. She knew that by cutting herself she would regain, from her viewpoint, the more tolerable and tolerant hospital environment.

Dr. Barnes, the attending child psychiatrist continued Crystal’s Paxil medication for depression, and added Depakote for mood stabilization. He met individually with Crystal daily, and held one family conference. Crystal also participated daily in unit activities and group therapy. Once admitted Crystal was able to make a contract for safety and was a model patient. During the one family session there was much conflict and mutual blaming between Crystal and her parents.

Dr. Barnes expressed pleasure with the progress Crystal was making in treatment, and arranged a plan for her follow-up treatment in day hospital after discharge. He received a call from the MCO that she had used the maximum 10 days allowed under her insurance plan. Against the objections of her parents, who felt that she was not ready to return home, Dr. Barnes discharged Crystal. Her parents drove her home.

At home, her mother, who was still incensed about her “premature” discharge, icily informed Crystal of

the strict new house rules including confinement to the house and no telephone or television privileges. Her mother hid all the telephones in the house, and disconnected the televisions.

When Crystal found there was no way to call her friends, shouts rang out. Fear and anger escalated. The parents phoned Dr. Barnes and blamed him for the altercation because he discharged Crystal against their objection. The mother threatened Dr. Barnes with a lawsuit.

While this phone conversation was going on Crystal became furious, grabbed a kitchen knife, and brandished it at her mother, who was talking to Dr. Barnes about Crystal on the phone. Crystal then put down the knife and began choking her mother. At Dr. Barnes’ recommendation the stepfather called the police; they arrived in a patrol car and handcuffed Crystal, drove her to the police station, booked her, and placed her behind bars for the night.

b. The Goals of Treatment. In this potentially suicidal and homicidal scenario the first goal is physical safety for the patient and her parents (nonmaleficence, avoiding harm to Crystal or her parents), initially by placing Crystal in jail. Additional important goals of treatment are for beneficence, helping Crystal and her parents by referral to a structured treatment program to improve Crystal’s anger management, and upgrade her coping, negotiating, and prosocial interactions with family members. The program should incorporate active family therapy work. Before returning home she needs to make a contract for safety and other mutual behavior with her parents (nonmaleficence, prevention of harm). She and her parents will need to arrange for an intensive treatment program to gain insight into and find a way to change the dysfunctional family culture (beneficence), seeing to the good of the family unit. The three family members need to restore mutual respect and find a degree of protection and personal boundaries for Crystal that do not unfairly restrict her freedom of self-determination, or autonomy, as she works to earn their trust. The parents need to recognize Crystal’s good behavior with earned privileges, an exercise of parental justice.

c. Probabilities of Success. The probabilities of success with a course of treatment for Crystal depend on how well the goals can be realized. Because each case of this type is unique, and the endpoint for “cure” so vague, statistical data are not available to estimate the prognosis. At this point in the crisis, Crystal and her family have not yet had a comprehensive biopsychosocial evaluation by a multidisciplinary team including a social worker,

pediatrician, psychologist, chaplain, education specialist, psychiatrist, and occupational therapist.

Critical unknown areas in our information about Crystal may affect the possibilities of success, including psychosocial development history, family relations, history of neglect or abuse, peer support system, school history, preferred recreation, sexual orientation, sexual experience and practices, experience with drugs, and career aspirations. Without a thorough evaluation it will not be possible to develop an optimal treatment plan. The treatment team owes an ethical responsibility to evaluate comprehensively and accurately.

The best prognosis in cases like Crystal's is realized with clients who have adequate health insurance, are capable of making a therapeutic alliance with the psychotherapist and the mental health staff, are willing to participate in family therapy, are faithful in keeping mental health appointments, and are compliant with prescribed medications. The parental participation and sometimes individual or group parental psychotherapy may be necessary to work toward a more optimal home situation.

Treatment failure occurs when irreparable damage to the treatment program occurs, for example, by the client attacking treatment staff, family members, or peers; running away; or being incarcerated, which would undoubtedly increase the chance of maleficence or harm to her personal safety and possibility of recovery. Conditions like Crystal's are often chronic and can be self-perpetuating when the young person's potential is jeopardized through alienation from family, friends, and community. Treatment failure also occurs when financial arrangements break down or when custodians remove the minor child from treatment against medical advice, resulting in maleficence. In case of therapeutic failure clinical circumstances might indicate termination of parental rights. The new guardian could then arrange placement in a relative's home, a foster home, or a residential treatment center. Treatment failure in some cases would lead to court-ordered incarceration because of parole violation or a new offense.

In pediatric cases like Crystal's the psychotherapist's responsibilities are the same as with an adult, to save life, relieve symptoms, and restore health. However, since a minor child is under the supervision of parents or guardians, they, not the patient or psychotherapist, have the moral and legal responsibility and autonomy of acting in the child's best interests, termed paternal beneficence. Their decisions must take into account the family values and the needs of other members of the family, the family budget, and other paternalistic considerations. These may override some of the minor

patient's preferences. Where the parent's or guardians' conduct or choices are apparently not in the best interest of the child, the courts, acting with paternalism, *in loco parentis*, may alter the extent of parental or guardian authority in order to provide remedial justice on the minor child's behalf. For the past few decades, the wishes and opinions of adolescents have been increasingly sought and taken into account for treatment decisions, since it is difficult to carry out a successful treatment plan without some cooperation and participation by the adolescent. A disgruntled adolescent might also bring a lawsuit after reaching majority in cases of disagreement about treatments and alleged harmful outcomes while a minor.

2. Patient Preferences

a. Crystal. Crystal is an intelligent and sensitive adolescent, a talented musician, and an outgoing, fun-loving social person. She says she would prefer to live at home, to keep her anger under control, and learn how to avoid escalation, thus ensuring nonmaleficence. She wants to continue to do well in high school and go on to college and a good career, eventually achieving autonomy. She would like to be able to recognize her dark moods and be better able to manage them. She would like to be able to negotiate with her parents, especially her mother, so that she could have a "win-win" home life and have plenty of socialization with her friends, which she sees as justice.

She realizes that she made a mistake in judgment with the boy who assaulted her, and she wants to keep wiser boundaries with boys and drugs in the future, ensuring nonmaleficence. Without question, the boy is accountable for his sexual misbehavior. The family has made a police report of the incident with no outcome as yet, practicing responsible paternalism, and seeking justice for their daughter.

Crystal is fully aware that if she fails to fully cooperate with a mental health program, receiving beneficence, she may end up a suicide, a murderer, or an inmate, thus experiencing unwanted maleficence and criminal justice. She appreciated what she learned about herself and others while hospitalized, and feels she could form a positive alliance and transference with Dr. Barnes if he is to treat her in the future, and help her realize autonomy. Crystal also knows that after her assault on her mother, her parents could press charges against her and have her put away for a considerable period of time, an unwanted criminal justice outcome.

b. Her Parents. Crystal's mother on behalf of both parents expresses the parents' preferences. The father

remains silent. They want Crystal to be respectful, to learn how to curb her anger and to obey the rules necessary for her safety and for their peace of mind, providing justice to each family member. They admit in retrospect that they may have erred by instituting rules the severity of which was excessive, and by doing so they vindictively conspired to make Crystal's misbehavior at home a self-fulfilling prophecy, resulting in maleficence, so that she had to be rehospitalized.

c. Dr. Barnes. Dr. Barnes preference is to play the Hippocratic deontological, or duty-based role. He wants to behave as the tactful, truth-telling, and competent child psychiatrist who skillfully helps his client and her parents gain insight and clarity about the psychodynamic and family issues, while respecting the dignity, worth, and ethnic and cultural values of each individual in the family. He wants to guide them into committing to an intensive and effective long-term treatment plan for Crystal that will make the most of her positive potentials, build her responsible autonomy, and make treatment failure as unlikely as possible, thus achieving clinical beneficence and nonmaleficence. Acting as an agent of change, he wants to help the family understand and take ownership in the big picture of what the benefits of a good outcome and the downside of a bad treatment outcome would mean for Crystal and for them, resulting in socially responsible self-determination, a well-informed family autonomy. He wants Crystal to share actively in the decision making about her therapy program and be accountable by taking her medications faithfully and for all the other intelligent cooperation of which he believes her capable.

d. Police. The police want to keep Crystal safe toward herself through paternalism and beneficence, and keep her from harming her mother or others (non-maleficence), until it is safe to reduce the level of restriction when she demonstrates responsible autonomy.

e. Managed Care Organization. The MCO prefers to keep Crystal safe and optimize her psychiatric treatment (paternalism, beneficence) but wishes to obtain the best care for her at a cost-effective rate, preferably in outpatient or day hospital in a facility with which they have a discounted contract. They will remind the psychotherapist of the limitations of treatment under the parents' health plan under motives of paternalism and contract justice, but their in-house medical gatekeeper and appeal committee do have a process under which legitimate exceptions may be awarded if more expensive care is justified by submitted evidence (distributive justice).

The MCO has to be financially prudent and accountable in order to stay in business, remain within budget, and make profits for the shareholders, exercising both autonomy and beneficence.

3. *Quality of Life*

a. Crystal and Her Parents. The quality of life for Crystal and her parents is poor at present, and will be until some resolution can be worked out to bring the family function and feelings under control. There may be biases that would prejudice the psychotherapist's evaluation of the patient's quality of life. This could relate to information not yet brought to light that may be necessary to fully understand Crystal's present and past behavior, and that of her parents. For example, what was the situation leading to her mother's divorce from Crystal's biological father, and how is that affecting all parties now? Have events or relationships at school or with friends added to her present difficulties? Might any of these factors jeopardize her recovery "from out of the blue?" Where is she to live, where will she go to school, and what will she do with her life? Both Crystal and her parents currently do not feel safe or peaceful.

If treatment succeeds, Crystal may still experience cyclic periods of depression and interpersonal conflict, unless a cause can be discovered and remedied. It is possible that adjustment of her medications could ease those problems, but there is no guarantee that she will not have to endure this instability the rest of her life, thus avoiding maleficence. There is also a high likelihood that she will continue to have conflicts with her mother in the future over control issues such as paternalism and autonomy.

Crystal's parents want to improve their quality of life by having a tolerable family interaction, and by seeing Crystal keep her personal boundaries with them, with her friends, and especially with boys. They know she is intelligent and talented, and their quality of life and peace of mind will be enhanced by her success in school and in society, realizing autonomy and beneficence. They would like her to eventually gain her independence and use it wisely so that they would no longer have to feel responsible for her daily welfare and future, once they have resolved issues of paternalism and autonomy. Overall they want to act responsibly in the best interest of their child to achieve beneficence.

b. Dr. Barnes. Dr. Barnes would like the family to start working more effectively to bring peace (beneficence) and so that he would not have to deal with these recurring crises on the telephone when he is at home with his family (nonmaleficence, autonomy, justice).

4. Contextual Features

a. Family Issues. Family issues may affect Crystal's treatment decisions, such as the parents' anger, resentment, assumptions, and fear about Crystal, and the obligatory paternalism. Their family finances are sufficient currently; however if her stepfather lost his job, his insurance might be lost at some point, and Crystal could lack funding for her treatment program and prescription drugs, which would be a serious maleficence for her. The present psychotherapist and adolescent psychiatric program might be unable to treat Crystal if her health insurance were to change or her stepfather were transferred out of state, or if she were to have a court-ordered incarceration.

There are no apparent religious or cultural factors with the family or treatment personnel that currently affect care, and in fact, Crystal's religious participation is a positive factor if it can be maintained and reinforced, providing beneficence. There is no compelling reason to breach confidentiality in Crystal's case, or refrain from truth telling, thus promoting beneficence and autonomy.

There are no current legal charges since Crystal voluntarily cooperates with treatment, and has apparently not yet been charged with violating any laws, aiding nonmaleficence for Crystal. This could change if her parents press charges for the assault incident, which would not be possible to rebut; however, they appear to want to put this incident behind them. No clinical research or teaching is involved at this point (autonomy).

There is no provider or institutional conflict of interest at this point in the case. Dr. Barnes is pleased with the cooperation he has received from the MCO on behalf of his patient, Crystal, resulting in beneficence and justice for her.

Because of limitations of space the role and perspectives of the social worker, chaplain, teachers, and unit mental health staff are not given separately in the brief case account; however, their professional participation has been essential in the management of these bioethical issues.

While winding up our thoughts about context in clinical ethics we might profit from reflecting on the larger philosophical societal questions. How would the contextual nature and ethical issues of this case be different if the child psychiatrist were a Palestinian or Afro-American Muslim or an Orthodox Jew? What if the client and her parents had been newly arrived Hindu or Ethiopian Coptic immigrants? What is the goal of mental health treatment in our society? What are the ends of technology and pharmacology, and where will they take us in

the next decade? What is the future of bioethics? How much mental and behavioral pathology could we prevent by improving healthy attachment, security, and character building within the family, school, and peer social environment? (See Borba's work in 2001 and Lickona's research in 1983 on this important issue.) What are our special duties to adolescent sexual assault victims? (see American Academy of Pediatrics, Committee on Adolescence, 2001, and Care of the adolescent sexual assault victim, <http://www.aap.org/advocacy/releases/juneassault.htm>).

E. Case Analysis Summary

In the foregoing clinical case analysis procedure, although too condensed to include all the professionals involved, most of the known clinical details have been identified and discussed, and bioethical issues and principles have been identified. Areas of incomplete clinical information have been noted. In this complex polyethical problem-solving process the Solomonic challenge is to understand the interests, moral assumptions, and intensity of each party's issues, estimate the competency of each party, and keep focused on the optimal outcome for the client. The clinical ethics process attempts to resolve moral dilemmas without the use of force by seeking agreement among parties or peaceable negotiation.

The data can now be used for a variety of clinical needs. In any case the analysis is saved as a record in case of future need, discussed within the institutional professional staff's regular staff meetings, placed on the schedule for discussion in a periodic institutional ethics committee meeting, or submitted to the institutional risk committee or malpractice insurance carrier. An addendum should be added to the analysis to record the further use made of the analysis.

The case analysis may also be used as the agenda for an interdisciplinary meeting of all responsible parties. For example, if the client struggles with bioethical issues in the care given or the choices for future care, the clinical case analysis gives a framework for consideration and discussion, especially to help the client or other responsible parties to understand the ethical choices as well as the treatment choices, and who has the authority to make the choices of autonomy, beneficence, nonmaleficence, and justice. In the case of this adolescent the watchword of prudence is always to ask, "Who speaks for the best interests of the child?"

Three additional professional integrity issues not discussed in the text or case analysis should be mentioned. The first concerns ethics regarding colleagues such as co-workers, supervisors, and supervisees. In these relationships therapists should always be expected to keep the best interest of the client in mind, avoid boundary infringements, avoid personal conflicts of interest, and meticulously respect confidentiality. Such considerations are especially relevant to team relationships. This means keeping team roles clear, being mindful that a healthy milieu is the best treatment vehicle, being aware of transference, not acting out in colleague relationships in a way detrimental to clients, not exploiting supervisees, not “dumping” cases, keeping educational objectives in mind, keeping track of what may come up about being responsible for the training of students, and keeping track of the potentially unhealthy side of mentoring.

The second issue concerns the ethical use of the “special knowledge” of psychotherapy and the rhetorical power of expert language. The theoretical frameworks and special vocabulary of psychotherapy can be used to elucidate issues, and to teach important ideas and skills that are helpful to clients. Unfortunately they can also be used to enforce a power differential for the power/control/expertise/status needs of the therapist, which can be damaging and disabling for clients. The latter is a problematic, unethical use of our professional skills and status.

The third issue concerns the ethics of using the special intimacy of psychotherapy for personal gratification. It is safe to say that what makes a therapeutic relationship therapeutic is that it exists for the benefit of the clients, and for their growth and achievement of confident autonomy. The therapeutic relationship is not for meeting the personal needs of the therapist. The therapist uses aspects of herself or himself in service of the professional work, and that needs to be the priority. This is an area in which damage and retraumatization of clients can easily occur, and as professionals, psychotherapists need to set clear standards and hold one another accountable.

V. CONCLUSION

Bioethics and the clinical ethics case analysis approach presented here may help the psychotherapist to formulate and achieve the goal of every professional. That goal is to know what is right and to do

what is right for the patient, even in complex and ethically conflicted cases. In order to know and do the right thing as often as possible, the professional not only needs to pursue competence in ethical philosophy and clinical bioethics, but the professional needs to be as complete a moral person as possible. The professional's personal moral anatomy needs to be intact so that ethical issues are seen with sensitivity and handled with beneficent motivation. This moral sensitivity and motivation focus keen moral judgment and reflection on the problem. In the final step the necessary moral action can be carried to its completion through the agency of virtuous character effecting agreement among members of controversies or peaceable negotiations as the way to resolve concrete moral controversies.

GLOSSARY

alpha wave activity EEG activity generally associated with an alert but relaxed state, usually defined as 8 to 12 Hz.

anal sphincters The anal canal is surrounded by a voluntary or external (EAS) and an involuntary or internal (IAS) anal sphincter.

autogenic phrases A series of phrases developed by Shultz and Luthe to induce a relaxed state. The phrases are directed toward three domains: relaxing the major muscles in the body, warmth and heaviness in the limbs, and quieting the mind.

autogenic training The application of a list of phrases to induce a self-generated state of relaxation. Typically lasts 10 to 20 minutes and used by the individual once or twice daily.

beta wave activity EEG activity associated with an alert state, often defined within the range of 16 to 20 Hz.

biofeedback A technique in which a biological process is measured and information about that process is provided to the person being measured. The information must be contiguous with the biological event.

biofeedback facilitated relaxation training (BFRT) A biofeedback technique where any of several physiological events are being fed back to the individual to help the person to

learn deep levels of relaxation. The physiological events are usually one or more of the following: EMG, SCA, finger temperature, heart rate, or respiration rate.

bladder training A strategy used for urge incontinence whereby clients increase the intervoiding interval to normalize voiding frequency and increase functional bladder capacity.

diastolic blood pressure (DBP) Minimum blood pressure during relaxation of heart or during cardiac cycle.

dynamic EMG feedback Multichannel EMG feedback during different body postures and simulated tasks.

EEG biofeedback A type of biofeedback that measures the brain waves. Both the frequency and amplitude of the waves are of interest. There is also some interest in measuring the phase relationship between different sites. Most applications used for biofeedback are based on a quantitative analysis of the brain waves called QEEG. The most frequent used technique is the fast Fourier analysis.

electrodermal A general term for the electrical activity or potential of the skin. Includes skin conductance, skin resistance, and skin potential.

electroencephalography (EEG) The measurement of the electrical activity of the brain.

electromyography (EMG) The use of instruments to measure the electrical activity of skeletal muscles.

EMG biofeedback A type of biofeedback that measures the electrical activity of the muscles. The strength or amplitude of the signal is directly proportional to the degree of contraction of the muscles being monitored.

finger photoplethysmograph Instrument that measures the amount of blood flow passing through a finger.

finger temperature biofeedback This type of biofeedback measures the temperature of the fingers. Although finger temperature varies with many factors including air temperature, it

has been shown that at typical room temperature finger temperature covaries with general arousal. The fingers are warmer when a person is relaxed and cooler when stressed. Finger temperature is a relatively slow changing event with typical changes being less than 2 degrees per minute.

frontal EMG A general and common term referring to EMG of the forehead and adjacent areas. Commonly used in biofeedback facilitated relaxation training (BFRT).

galvanic skin response (GSR) A form of electrodermal activity. Older term but still accepted.

GSR/EDA biofeedback A type of biofeedback that provides information about the activity of the sweat glands. Several different terms are used in the literature to describe this type of feedback. The most frequent are galvanic skin response (GSR) and electrodermal activity (EDA).

heart rate Number of heart contractions per minute.

heart rate biofeedback A type of biofeedback that measures the interval between heart beats and converts that time to a number representing the number of beats per minute if that time interval was maintained for a minute.

hertz (Hz) Unit of frequency equal to cycles per second (cps).

paretic muscles Slight or incomplete paralysis of a muscle.

power spectrum Advanced method of analyzing electrical signals, especially the complex waveforms of the EEG. Provides frequency and amplitude components.

progressive muscle relaxation (PMR) A common type of muscle and general relaxation developed by Edmund Jacobson. Starts with tensing and releasing specific muscle groups and progresses to discriminating between tension in selected areas and relaxation in others, and eventually to releasing muscle tension without tensing.

respiration biofeedback A type of biofeedback that measures the number of breaths taken per minute. Various instruments and sensors are used to determine the interval between each inhalation and/or exhalation to determine breaths per minute.

respiration rate Number of breaths per minute. Normal range is between 8 and 15. Slower rates (6 to 8) are associated with relaxation.

relaxation-induced anxiety (RIA) A state of apprehension, discomfort, or unease experienced by some who are trying to achieve a state of general relaxation.

sensorimotor rhythm (SMR) An EEG rhythm recorded from the central scalp, usually defined as 12 to 15 Hz.

systolic blood pressure (SBP) Maximum arterial blood pressure during cardiac cycle.

theta wave activity EEG activity generally associated with a drowsy, nonattentive state, usually defined as 4 to 8 Hz.

volar surface Palm side of fingers.

while providing the client with feedback that is sensitive to small changes in physiology. The feedback signal needs to be informative to the client. It is also important to provide instructions to the client about proper interpretation of the feedback signal. The clinician should emphasize the role that learning to change the physiology plays in the client's condition. There also needs to be generalization of the learning to the client's home, work, and social environments. In some instances, the feedback may even be entertaining. The entertaining type of feedback is often used when providing feedback, especially QEEG biofeedback, to children. In these instances, the feedback is not only informative but provides an incentive to the client to change physiology in order to "play" such games as putting puzzles together.

The utilization of biofeedback techniques is somewhat unique in psychology and psychotherapy as the techniques have applications that are used by several other health care specialties. The techniques are also used to treat conditions beyond those traditionally considered the domain of psychology. These conditions have been primarily the domain of medicine and rehabilitation. Some examples of these conditions are tension and migraine headaches, hypertension, urinary and fecal incontinence, muscle paralysis, and Raynaud's disorder.

A brief history of the development of biofeedback is warranted in order to appreciate the diversity of applications it presently enjoys. The early work in biofeedback stems from a controversy in learning theory. This difference is between instrumental, or operant, and classical conditioning, with classical conditioning occurring in the autonomic nervous system and instrumental conditioning in the skeletal muscle system. A student of Neal Miller's, Leo Di Cara, was in 1967 one of the first to publish research on the laboratory demonstration using an operant paradigm to alter heart rate. Miller and Di Cara used an elaborate procedure of injecting curare, to block skeletal muscular involvement of heart rate changes, and then rewarded the rat with electrical stimulation in the pleasure center of the brain when the heart rate reached a predetermined threshold, for either raising or lowering the heart rate. With this procedure, they were able to demonstrate shaping of the heart rate based on the change that was being reinforced. They also measured other autonomic responses, such as intestinal motility, to demonstrate that the changes were specific to the system being shaped, not general autonomic changes.

The other significant research effort that initiated the early systematic study of physiological self-regulation

I. DESCRIPTION OF TREATMENT

The clinical application of biofeedback requires the accurate measurement of various physiological processes

(biofeedback) was the conditioning of the brain waves known as alpha and theta. These brain waves have been associated with low levels of arousal and it was thought that if individuals could be trained to increase the amount of these brain waves they would increase the feelings of relaxation.

This early research prompted the development of the professional group known as the Biofeedback Research Society (BRS). This organization's goal was to promote research in basic processes of physiological self-regulation and its possible applications. As the clinical applications of biofeedback became available, the organization changed its name to the Biofeedback Society of America (BSA). Then later, as general assessment of physiological processes became useful in various areas such as sports, the organization again changed its name and is now known as, the Association of Applied Psychophysiology and Biofeedback (AAPB).

In 1980, AAPB funded the development of the certification organization the Biofeedback Certification Institute of America (BCIA). BCIA initiated the establishment of the minimal requirements for certification in biofeedback. These requirements included a degree in a health care field, minimal didactic training in biofeedback, supervised self-regulation training, supervised clinical experience, and the passing of their written and practical examination. In addition to the general certification, in 1997, the organization started certification in the specialty of EEG biofeedback. The requirements for the specialty certification in EEG biofeedback differ from those of the general certification.

The fact that biofeedback fits into the general orientation of behavioral therapy and the field now known as behavioral medicine has allowed therapists who offer biofeedback training to take an increasing role in the treatment of what has traditionally been conceptualized as medical conditions. It is now common to find medical clinics and hospitals with a biofeedback clinic as part of their operation.

Another area of interest in the development of biofeedback is the concept of stress and the discovery that stress plays a major role in medical disorders as well as psychological disorders. This knowledge has initiated the search for techniques that manage stress. One of the major techniques currently used to manage stress is relaxation therapy. Relaxation techniques are usually based on muscle relaxation, autogenic training, or breathing techniques. For many applications, the relaxation strategy alone is sufficient, but some individu-

als have difficulty with the technique and therefore biofeedback plays a role in making relaxation a concrete, observable process. In this application, biofeedback is used to facilitate the relaxation response. The biofeedback training allows clients to observe objectively their physiological changes as they try to relax. Their physiological changes provide immediate information informing them when their strategies are inducing a relaxation response or an arousal response. Biofeedback is also often helpful because many people mislabel their physiological states. For instance, they may think they are relaxed when they are not or when they become relaxed, it feels strange and uncomfortable, so they tense up again until it feels normal and comfortable. As an example, the muscles in the neck might be held in sustained contraction while the individual thinks that the muscles are relaxed. This sustained contraction will often lead to a tension headache. For these situations the biofeedback provides concrete, observable information that can help therapists educate clients about their misinterpretation.

The other major development that moved biofeedback forward was advances in biomedical engineering, with the major contributor to the miniaturization of the equipment being the National Aeronautics and Space Administration (NASA). The physicians working for NASA wanted to measure astronauts' physiology in space. In order to do so, they needed reliable and stable pieces of equipment that required minimal electrical energy to operate; therefore, they developed low power requirement equipment that is durable, reliable, small, and light in weight.

NASA has also benefited from biofeedback as one of the successful applications of biofeedback has been the prevention of "space motion sickness." Space motion sickness is similar to motion sickness here on earth. As the vestibular system becomes adjusted to the sensation changes from near zero gravity, most of the astronauts have feelings of nausea, light-headedness, and often vomiting. Medications are available to reduce the symptoms of motion sickness but there are side effects such as drowsiness and slowed reaction times. These side effects cannot be allowed since astronauts can take 2 to 3 days, or longer, to adjust. In the early 1970s Patricia Cowings, as reported by Cowings, Billingham, and Toscano in 1979, started working on a series of studies to determine if she could raise the motion sickness threshold. She used a chair, which could be rotated at controlled rates with varying degrees of tilt. With this chair, she could take anyone, spin him or her, tilt the chair back, and demonstrate the symptoms of motion

sickness. Although the speed and degree of tilt necessary to induce motion sickness will vary, everyone will become symptomatic. She carefully assessed motion sickness thresholds and then began using biofeedback combined with autogenics phrases to train subjects to raise their threshold for motion sickness. Her research demonstrated successful raising of the threshold and she was allowed to train some astronauts. The results of her training with astronauts were successful and the individuals she trained were able to control their symptoms without medication.

Biofeedback is unique among types of psychotherapy in that it requires the use of instrumentation and knowledge of anatomy and physiology; therefore, it is necessary to briefly present the basic aspects of the types of instruments used and the physiological processes measured by these instruments. This article is organized by a presentation of the instrumentation often utilized along with the basic physiology, followed by a presentation of the diagnostic categories treated by biofeedback. The major instruments to be discussed will be the electromyography (EMG), finger temperature, sweat gland activity (GSR/EDA), electroencephalograph (EEG), and pelvic floor disorder sensors.

A. Electromyography

The EMG is the electrical energy generated by the muscles when they contract. The EMG utilized in most biofeedback applications is not the same as the traditional medical EMG used to determine damage to the nerves of the skeletal muscles. The medical EMG typically uses indwelling electrodes and measures latency and amplitude of muscle activity following nerve stimulation, whereas the EMG used in biofeedback applications is usually measured by using electrodes placed on the surface of the skin over the muscles of interest. When specific muscle activity is of interest, concern must be given to placement of the electrodes because research by Lawrence and De Luca in 1983 has shown that the amplitude of the surface EMG is highly correlated with the level of contraction of the muscles when the electrodes are appropriately placed. The EMG is measured with three electrodes by a differential amplifier, which is designed to reduce unwanted electrical signals. With this type of amplifier, one electrode is a reference and the other two are active electrodes. The strength or amplitude is measured in microvolts and is averaged over some time period to provide a running average of the amount of muscle tension detected. This running average is then provided to the individual

being monitored as information about the amount of tension of a muscle system from moment to moment. (See Peek's 1995 research for further details). In many, but certainly not all biofeedback applications, the focus of the therapy is not specific muscles but muscle activity in a specified area such as the face.

When EMG biofeedback is used for general relaxation therapy, most therapists use the frontal placement. In this placement, the electrodes are placed parallel to the eyes, above the eyebrows, with the reference electrode in the center and an active electrode over each eye. The electrodes detect the activity of the muscles from all of the face when in this placement, according to Basmajian in 1976. When specific facial muscle activity is of interest, the use of small electrodes with proper placement will allow specific muscle activity to be measured. However, in the frontal placement, the interest is in general facial muscle activity because in order to facilitate general body relaxation, most people relax all of the muscles in their face. The rationale for this placement is based, in part, on the hypothesis that we tend to express our emotions in our facial musculature. Darwin provides us with some of this rationale in the 1965 version of his book *The Expressions of the Emotions in Man and Animals*.

Other applications of EMG biofeedback are to reduce specific muscle activity in the treatment of tension headaches, back pain associated with skeletal muscle hyperactivity, and other conditions of inappropriate muscle activity such as writer's cramps. EMG biofeedback is also used to recruit muscle activity, to aid in the rehabilitation of muscle paresis resulting from injuries such as strokes.

Because EMG biofeedback is frequently used to facilitate general relaxation, this procedure is presented as an application. The client is selected for this procedure based on a clinical interview. When the clinical interview indicates that the client would benefit from general relaxation, the rationale for frontal EMG biofeedback is provided to the client and permission to place the electrodes is obtained. The skin is properly prepared, the electrodes are attached, and the nature of the feedback is explained. It is proper procedure to then conduct what is referred to as a "behavioral test." The client is asked to tense a facial muscle such as the frontalis, by raising the eyebrows, or by gently biting down on their teeth. If the system is working properly, it will respond. For instance, when you say, "lift your eyebrows" and the client does so, the signal should increase in level, indicating that the person is properly attached and the system is working.

During the first session and if necessary in later sessions, it is good practice to conduct what this author calls facial muscle discrimination training (FMDT). This is a behavioral test in which the client is asked to tighten and relax the major muscles in the face. This is an effective training strategy as the client can see the EMG increase as the muscles are tensed and then decrease when relaxed. The clinician should then sequentially instruct the client in the following activities: frown and then relax, squint the eyes then relax, bite down just hard enough to feel tension in the jaw and relax. With each of these maneuvers, the client will see the EMG feedback signal increase and then decrease as he or she tenses and then relaxes the specific muscles. Having the client press the tongue against the teeth can also show the muscles of the tongue. The client is then asked to take one hand and make a fist. There should not be any increase in the EMG levels in the face and if an increase is observed, then displaced effort or dyspnoia is occurring. This means muscles that are not involved in performing the task are being contracted. If an increase in activity is noted, it is a good opportunity to educate the client about the displaced effort. The clinician can explain to the client that the electrodes on the forehead do not detect muscle activity in the arm, and therefore activity should not be noted when clenching the fist. Then, instruct the client to concentrate and relax the facial muscles while at the same time clenching the hand. If any activity is detected, have the client repeat this procedure. FMDT allows the therapist to teach the client about muscle activity and helps the client recognize that he or she may be using muscles that do not need to be used. This exercise also allows the client to feel a sense of control, that he or she can “do” biofeedback and change physiology. It is also good to point out to the client that the instrumentation detects muscle activity from all the muscles in the face but is unable to discriminate which muscle or group of muscles is causing the increase. Therefore, it is the client’s role to become aware of the muscles he or she tends to tense and to learn how to relax all the facial muscles when trying to achieve a state of general relaxation.

B. Finger Temperature

Finger temperature is measured by using an electrical device called a thermister. The thermister is an electrical component, selected because it changes its resistance to an electrical current proportionally over the range of temperatures of interest. Therefore, the temperature-monitoring equipment is designed to

generate a small electrical potential that is passed through the cables, leading to and from the thermister. The device measures the change in current flow as the thermister changes its resistance due to temperature changes. The amount of current is calibrated in degrees and most systems label the degrees in Fahrenheit. It is to be noted that unlike skin conductance systems, which pass a small electrical current through the skin between the electrodes, this system only passes electrical current through the thermister. The thermister is then placed on the surface of the area with the temperature of interest.

Because the thermister measures the temperature present at its surface, care must be exercised in its proper placement on the area of interest. For most biofeedback relaxation training applications, the thermister is placed on the surface of the hand, specifically the fingers. Although there is no research indicating a particular finger or place on the hand as a superior location for the thermister, most clinicians have a preference. The location of choice for this author is the volar tip of the little finger. The rationale that it is the smallest finger and therefore can gain and lose temperature faster than other fingers or areas of the hand. Because skin temperature is determined by blood flow and heat lost to the environment, the smaller the area, the quicker changes in blood flow will be reflected in temperature changes. The thermister has its own mass, so it too must be cooled and heated. Thermisters are available in various grades and sizes. The most desirable thermister is one small in size, so it can readily lose and gain temperature as the skin cools and heats. Most biofeedback equipment manufacturers will offer a choice in the quality of the thermister. Although there is no research available on the value of the quality of the thermister, there is research indicating that the more accurate the measurement and feedback, the better the learning of finger temperature regulation. Therefore, it seems prudent to use the best thermister available.

A consideration regarding the placement of the thermister is that it needs to make contact with the skin, without the holding device cutting off the blood circulation. The method of choice is to use paper tape. Tape the thermister to the skin by pressing down on the tape around the thermister. If using the finger tip, gently wrap the tape around the finger to keep the thermister in contact with the skin, without forming a tourniquet on the finger. The wire leading to the thermister needs to be taped along the finger, keeping the wire the same temperature as the skin. Otherwise, what is referred to as the stem effect will allow temperature changes of the

thermister to be determined by changes in the wire leading to the thermister. Once the thermister is in place, care must be used to make certain that the hand is not moved to a position where the thermister comes in contact with furniture, such as the arm of the chair or a desktop, as the temperature will then be altered by the temperature of the object that comes in contact with the thermister.

Finger temperature is thought to reflect general stress levels or relaxation levels. The stress response of the cardiovascular system is to reduce blood flow to our organs, so blood will be available to our striated muscles. Because the skin is an organ, when we are stressed, finger temperature will decrease and when we relax, finger temperature will increase. Finger temperature can vary in individuals in a normal room environment, usually around 70°F, from the high 60s to the middle 90s. Finger temperature is not the same as core body temperature. Very seldom will finger temperature be above 96° or 97°F because as the blood leaves the core of the body and goes out to the skin, it will cool from the core body temperature. The physics of heat is such that when blood is flowing into the skin, it takes time for that heat to permeate through the skin tissue and warm it and if you have reduced blood flow in the skin, then it takes time for the skin to lose the heat to the environment. There is usually a delay, 5 to 15 seconds, between blood flow changes, as measured by a finger photoplethysmograph, and the temperature changes detected by the thermister. Thus, finger temperature is a relatively slow-changing phenomenon.

Because finger temperature is a slow-changing event, its interpretation is best used as an indicator of general relaxation level, not as a measure of instantaneous physiological events. Finger temperature monitoring has been used as a treatment modality in several autonomic nervous system related disorders, such as Raynaud's, hypertension, and migraine headaches, because warming the hands through relaxation strategies has a powerful effect on the cardiovascular system.

C. Sweat Gland Activity

There are two types of sweat glands located in the human skin, the apocrine and eccrine glands. The apocrine sweat glands primarily respond to thermal regulation and the eccrine sweat glands tend to respond to emotionality or arousal level. Therefore, the eccrine glands are of interest in most psychophysiology and biofeedback applications. Eccrine glands have the greatest density in the palm of the hands, the volar sur-

face of the fingers, the bottoms of the feet and toes, under the arms, the groin area, and between the lip and the nose. The skin on the palms of the hands contains as many as 2000 eccrine sweat glands per square centimeter. This physiological response has one of the longest and largest research histories in psychophysiology. It is of interest because it is a measure of the activity of the sympathetic nervous system uncontaminated by the parasympathetic nervous system. With only a few exceptions, dual intervention of the sympathetic and parasympathetic nervous systems provides control over body organs, such as the heart, stomach, and salivary glands. One system increases activity while the other decreases activity, and thus the level of functioning is the difference in balance between the two systems. Through stimulation and lesion studies, the areas of central activation of sweat gland activity have been shown to be the brain stem, limbic system (involved in emotional regulation), basal ganglia, and Brodmann area 6 of the temporal lobe, according to Boucsein in 1992. The involvement of these neural anatomical sites provides users of electrodermal activity (EDA) with confidence of the basis of cortical and emotional influence on the eccrine sweat glands.

The eccrine sweat glands have a tubular that travels upward from the gland, through the tissue to the surface of the skin. This tubular has smooth muscle surrounding it and the sweat glands are activated when the smooth muscle opens this tube. Most biofeedback systems measure sweat gland activity by passing a very small electrical signal through electrodes placed on the skin. The opening and closing of the sweat gland causes changes in the resistance of the skin to the electrical current passing through the tissue. The strength of this electrical source is far below that which would cause tissue damage or be felt by the participant. Opening the sweat gland tubulars, which are filled with sweat (primarily a saline solution and good conductor of electrical current) causes a reduction in the resistance to the electrical current, so an increase in the amount of current will be observed. The amount of current flowing is normally measured in micromhos. The number of micromhos increases as emotionally or arousal increases. This technique is called skin conductance activity (SCA). Therefore, the measurement of SCA is actually the measurement of the opening and closing of the sweat glands.

The sympathetic nervous system controls the number of sweat glands opened. During low arousal levels a few sweat glands are open, whereas many sweat glands are opened at high arousal levels. It is speculated that this is an adaptive response as it allows better gripping

and reduces tearing of the skin under moderate to high arousal conditions. The relationship between the skin conductance level and the number of sweat glands activated is linear. For a more detailed presentation on the technique of sweat gland activity see Montgomery's 1998 work or Boucsein's 1992 research.

There are two methods used to measure sweat glands; both were discovered in the late 1800s. One method involves measuring the electrical potential generated by the smooth muscles that surround the tubulars when they depolarize, thereby opening the tubulars. This technique is called skin potential activity (SPA). Most biofeedback systems do not use this technique, so it will not be discussed further. The other method used to measure sweat gland activity is to pass an electrical current through the skin. This is called skin conductance activity. SCA used to be called the galvanic skin response or GSR. The term GSR is still found in current literature, but most use the term skin conductance activity. Skin conductance activity has two terms associated with it, skin conductance level (SCL) and skin conductance response (SCR). SCL is the average ongoing level or tonic level of sweat gland activity that decreases as you relax. If an arousing stimulus is perceived, it will cause a shift in arousal and a skin conductance response. The SCR is a momentary increase in conductance usually lasting a few seconds to a minute.

The sweat glands can change their activity based on a multitude of factors, but there are some interpretable ranges. The range of SCL readings for most biofeedback systems is from 0 to 100 micromhos, with the typical level being observed between 1 and 20. Although there is no conclusive data indicating an optimal level, the usual range for most "normals" is between 1 and 10 micromhos when the individual is relaxed and resting, or involved in a nonstressful conversation. Although the above ranges are helpful for interpretation, there are many factors that determine the SCA. Therefore, the clinician needs to know the individual being recorded and what is "normal" for that person. It is important to be aware that at the extremes of sweat gland activity, the SCA may be attenuated. If the skin is very dry, SCRs may be difficult to monitor and if the skin is very moist, SCRs may be reduced. In the clinical setting if dry electrodes are being used, and if the skin is very dry or callused then it is usually helpful to add a small amount of electrode gel to the electrodes. It is important to remember that the greatest clinical value of SCA during clinical biofeedback is not in comparing individuals, but in observing an individual's changes during sessions.

In summary, the manner in which the sweat gland activity can be conceptualized is that a gradual decline in skin conductance level will be observed as the person relaxes, until an asymptote is reached. The rate of decline varies from person to person and from time to time, but is generally related to how quickly the person is recovering from an arousing event. The decline in level is interrupted by curvilinear increases in conductance, which usually last a few seconds and are called skin conductance responses. These increases in conductance are associated with evoking stimuli, whether external or internal. External stimuli are stimuli that have arousing properties or are novel to the individual, whereas internal stimuli are thoughts that have arousing aspects associated with them. Although the amplitude of the SCRs is not typically measured in biofeedback applications, psychophysicologists measure them and there is an abundance of literature on the interpretation of them. A large body of literature clearly demonstrates that the response amplitude is proportional to the intensity of the stimulus that evokes the response, and this is important in biofeedback applications. For example, if a small electric shock is presented, a small response will follow. If a moderate electric shock is presented, a moderate response will be observed, and so forth. This relationship is very clear across various stimuli and under most conditions. This is important in biofeedback applications because if a SCR is observed, it can be inferred that something happened to change the individual's arousal level. If this change is not related to an external stimulus, such as talking, then the change in arousal level was likely the result of the individual's thoughts. When several SCRs are observed, it can be inferred that the individual is having trouble with intrusive internal dialogue. The idea that skin conductance responds to thoughts or internal dialogue, and not just to the presentation of external stimuli, allows the therapist and the client to observe the impact that internal dialogue has on physiological processes. However, it is necessary to emphasize that the skin conductance level cannot be overly interpreted because many factors influence the observed level. For example, food and medications that are sympathetic agents or central nervous system agents can change skin conductance levels.

D. Electroencephalogram

EEG biofeedback is the fastest growing area in biofeedback today. Part of this interest is due to the fact that changes in instrumentation hardware and software have provided the means to quickly perform mathematical

analysis of brain waves so that feedback about the EEG characteristics can be provided within fractions of a second after they are detected. However, recording the EEG is of great technical difficulty because the electrodes must be placed in the correct location while maintaining acceptable levels of impedance. Impedance is the electrical resistance between the electrodes and the skin and must be kept to a minimum in order to reduce unwanted electrical activity. The electrode placements are based on what is called the 10–20 international system, as described by Jasper in 1958. The 10–20 international system identifies positions on the scalp, which are directly over structures of the cortex. The details of electrode placement are beyond the scope of this article, but must be learned before attempting this biofeedback.

Neurologists interpret the EEG to determine abnormal brain function, as certain wave patterns are associated with brain disorders such as seizures. The EEG is also used to determine sleep stages. In most biofeedback applications, the use of the EEG is based not on the interpretation of the raw or unaltered EEG, but on the quantitative analysis of the EEG, called the QEEG. Mathematical analysis of the frequencies of brain waves determines the amount of each frequency occurring within a period of time or epoch. The mathematical analysis used in most applications is the technique based on the theorem developed by Joseph Fourier in 1822, called the fast Fourier transform (FFT). This is a mathematical routine or algorithm that takes each wave, determines its length in time as well as its amplitude, and then determines the average amount of energy in all the frequencies of interest. Computer systems today are capable of providing feedback about the QEEG characteristics within about 3/10 of a second after it is monitored. The results of this analysis can then be displayed on a computer monitor, allowing the individual to become aware of the nature of his or her brain waves. This occurs fast enough for the brain to alter its activity, according to its ability and the instructions provided the person.

The brain waves have information of interest in their amplitudes and frequencies. The frequencies were categorized into different bandwidths in the 1920s by Berger, and reported in 1929. He recorded the EEG activity from his children and labeled the EEG frequencies that he observed. These labels are still being used today although many are starting to abandon them, as they may be too restrictive. Four bandwidths (theta, alpha, sensory motor rhythm [SMR], and beta) are used extensively in clinical applications. Thus, they will be briefly described. Researchers are inconsistent in the frequency definitions of these bandwidths, so the reader must determine how

each author defines them in an article. However, they are usually defined as follows: Theta is 4 to 8 Hz, alpha is 8 to 12 Hz, SMR is 12 to 15 Hz, and beta is 16 to 30 Hz. Beta has been used to define a wide range of frequencies, so it is extremely important for the reader to determine the definition of this bandwidth in an article. The reason these bandwidths have been identified is that they are loosely associated with psychological states: Theta with drowsiness, alpha with nonfocused attention, SMR with muscle activity inhibition, and beta with focused attention. Although these associated states have some heuristic value for adults, they are not consistent across individuals or age ranges. The other important characteristic of the QEEG is its amplitude, measured in microvolts or picawatts. This is a measure of the amount of energy within each frequency or bandwidth. Presently, there are a few databanks available for normative and abnormal values of the QEEG.

The methods presently used in most clinical QEEG biofeedback applications are based on determining which frequency or bandwidth is of interest and then providing the individual with information about its activity either via a shift in frequency or amplitude. There are other techniques used to provide information about the EEG, such as hemisphere asymmetries and average evoked potentials, but their use, at this time, is not as widespread as amplitude or frequency-based applications. The clinical protocol for QEEG feedback for the treatment of attention deficit disorder/attention deficit – hyperactivity disorder (ADD/ADHD) will be presented later in the section Case Illustrations.

E. Pelvic Floor Disorders

The primary biofeedback applications in pelvic floor disorders are the treatment of urinary and fecal incontinence through the use of EMG biofeedback and specially designed sensors. This section will briefly cover biofeedback for urinary and then fecal incontinence.

Urinary incontinence is the inability to maintain control over urinary functions. The goal of biofeedback treatment is to alter both smooth and striated muscle activities related to bladder control. The following methods are employed: reinforcement of bladder inhibition, pelvic muscle recruitment, and stabilization of intra-abdominal and bladder pressures during the recruitment of pelvic floor muscles. In order to accomplish these goals, bladder pressure is manipulated and measured while simultaneously measuring pelvic floor muscle activity with EMG sensors. The EMG sensors are specially designed vaginal and anal probes.

Fecal incontinence biofeedback is similar, yet different from urinary incontinence biofeedback. Fecal incontinence is the inability to maintain control over bowel movements. During normal anal functioning, when a bolus of feces moves into the rectum, two sphincters are involved in keeping the feces internal. The internal sphincter, which is smooth muscle and controlled by the autonomic nervous system, relaxes. The external sphincter, which is striated muscle and controlled by the somatic nervous system, constricts. The constriction of the second sphincter is a conditioned response and prevents the feces from being eliminated. The internal sphincter along with the puborectalis muscle normally maintain the stored feces by staying contracted. During elimination, both sphincters and the puborectalis muscle are relaxed and the contraction of the smooth muscles around the large colon and rectum provides the force to move the stool through the anal canal. Muscle weakness, injury to muscles in this area, or loss of temporal conditioning can cause fecal incontinence.

A medical examination is necessary to determine if biofeedback treatment is appropriate. If the results of the examination indicate that biofeedback is appropriate, then a probe that uses balloons is used in the biofeedback treatment.

The commercially available probe has three balloons attached to it. The pressure in the balloons is displayed on a monitor or polygraph record so the individual can observe changes in the pressure, as the manipulation of the walls of the rectum is accomplished by inflating the most internal balloon with air, causing a pressure wave that simulates feces moving into the rectum. The two other balloons are positioned on the probe to measure the contraction and relaxation of the internal and external sphincters. When proper sequencing of the internal and external sphincters occurs, the internal sphincter will relax, causing a decrease of pressure in the middle balloon, and the external sphincter will contract, causing an increase in pressure in the external sphincter balloon. When an inappropriate sequence is observed on the display, this is pointed out to the individual and instructions on what the display should look like is explained so the individual can then try to exert deliberate control of the sphincters. This feedback combined with instructions has proven effective in changing the patterns of sphincter contraction, allowing the individual to regain control over elimination. This technique usually requires only a few sessions for the individual to recondition a natural sequence so that no further symptoms are manifested.

II. THEORETICAL BASIS

Although some have conceptualized biofeedback as a technique without a theoretical basis, it is plausible to conceptualize the biofeedback process within a learning model of classical and operant conditioning. As mentioned earlier, one early development of biofeedback was based on a controversy between classical and operant conditioning. A parsimonious way of explaining clinical biofeedback is to postulate that both classical and operant processes are evoked in most clinical applications.

The operant portion of clinical biofeedback is that the information provided by the system is a consequence of the behavior. With proper instructions, individuals will perceive the feedback signal that changes with the physiology as reinforcement and will perform to bring the reinforcing stimulus into their environment. This is especially clear when a signal is contingent on the individual obtaining a predetermined level of the physiology. An example is when temperature feedback is being provided and a tone is turned on when the finger temperature reaches a defined temperature. The operant model is also obvious in QEEG feedback applications with children, where it is common for the biofeedback system to accumulate points when specific criteria are met. These points may be converted into reinforcements such as money or the opportunity to participate in a desired event.

The classical model is being utilized when clients are asked to imagine previous events that have a relaxing emotional memory associated with them. In this case, the relaxing imagery is the unconditioned stimulus (UCS) and the present situation is the conditioned stimulus (CS). This may seem like backward conditioning, but it is not in that the present situation is ongoing and the imagery is then placed temporally into the ongoing event, which places it, in time, after the ongoing event.

III. APPLICATIONS AND EXCLUSIONS

In order to present the disorders treated with biofeedback techniques, Table I was developed. Any listing of disorders must be taken as only a guideline as it is always biased by the interpretation and experiences of the author. The presentation should not be taken as all-inclusive or exclusive of any particular application. Although some applications appear well established by controlled outcome studies of clinical effectiveness and

cost-effectiveness, others are based on repeated single-case studies or multiple studies with relatively small sample sizes. Additionally, some applications are based on the clinical literature and the clinical experience of the author. For ease of interpretation, in Table I the listing of disorders treated with biofeedback is divided into three categories. The categories are A = well established; B = multiple research support, but not enough to firmly substantiate the application; and C = promising but not established at this time.

This section will present the biofeedback techniques used to treat the disorders listed in the category of well-established treatments. For information on the disorders in the other categories, except seizure disorders, see Schwartz's 1995 work.

A. Attention Deficit Disorders (All Types)

There are multiple studies that have shown QEEG biofeedback to be a successful treatment for attentional problems. These studies are based on the rationale that individuals with attentional problems generally have more slow waves in their EEG than individuals who do not have attentional problems. Therefore, the protocol requires the reduction of slow waves, either theta or alpha, while increasing faster waves, such as SMR or beta. The protocol for EEG biofeedback treatment of ADD/ADHD will be presented in the section Case Illustrations.

B. Anxiety Disorders

The biofeedback techniques primarily used in the treatment of anxiety disorders are frontal EMG, finger temperature, SCA, and heart rate feedback. These modalities are used to train a deep state of relaxation. The clinician can then use the deep state of relaxation as an incompatible response to the anxiety state. Although specific biofeedback such as heart rate might be used for a cardiac phobic, the most widely used technique is to train on the most active modality, based on the individual's ability and the clinician's experience.

C. Asthma

The asthmatic attack is caused by the constriction of the upper bronchial tubes, which restrict the passage of air in and out of the lungs. These tubes are dilated by the sympathetic nervous system and constricted by the parasympathetic nervous system. The link between

TABLE I
Selected Disorders Treated with Biofeedback Techniques

A	B	C
ADD/ADHD	Dyschezia (anismus)	Dysmenorhea
Anxiety disorders	Esophageal spasm	Hyperfunctional dysphonia
Asthma	Forearm and hand pain from repeated motion syndrome	Mild to moderate depression
Chronic back pain	Hyperhidrosis	Phantom limb pain
Diabetes mellitus	Insomnia	Tinnitus (associated symptoms)
Essential hypertension	Nocturnal enuresis	
Fecal and urinary incontinence	Specific seizure disorders	
Fibromyalgia	TMJ or MFP	
Irritable bowel Syndrome	Writer's cramp	
Motion sickness		
Muscle rehabilitation		
Raynaud's disorder		
Tension and migraine headaches		

Note. A: well-established; B: multiple research support, but not enough to firmly substantiate the application; C: promising but not established at this time.

biofeedback and this disorder is through facial muscle relaxation and correct diaphragmatic breathing. Facial muscle relaxation has been shown to reduce resistance of airflow in both asthmatic children and healthy adults. The rationale is through a demonstrated link between facial muscle relaxation and the trigeminal-vagal nerve. Following facial muscle relaxation training, reduced resistance to airflow has been observed for several hours. It is believed that this effect can be generalized and sustained over days.

D. Chronic Back Pain

The use of biofeedback facilitated relaxation training (BFRT) and specific muscle retraining have been shown to be successful in treating chronic back pain. When BFRT is used, it is often combined with specific

muscle feedback. The specific muscle feedback therapy is based on the finding that some chronic back pain is caused by hyperactivity in specific muscles of the back and neck. This pain may be the result of a unique learning history, in which hyperactivity was inadvertently reinforced, or after an injury in which protective muscle activity becomes maladaptive and the hyperactivity results in pain.

E. Diabetes Mellitus

Diabetes mellitus is caused by the dysregulation of insulin produced by a malfunctioning of the pancreas. Because insulin regulates the amount of glucose available to cells, this disorder has serious consequences for life expectancy. The traditional management of diabetes is lifestyle changes through education, diet, and physical exercise along with hypoglycemic medication. The role biofeedback plays in the management of diabetes is through stress reduction techniques with biofeedback-facilitated relaxation training. The BFRT techniques reported in the literature have been frontal EMG training and finger temperature training, usually combined with some form of general relaxation training such as PMR or autogenic phrases. This application helps to stabilize and reduce insulin demands.

F. Essential Hypertension

There is substantial research on the treatment of essential hypertension with biofeedback. Studies show that frontal EMG, finger temperature, SCA, and direct blood pressure feedback have all been used successfully. Most of the research supports combining the biofeedback with some relaxation strategy such as progressive muscle relaxation, or autogenic training. Although direct blood pressure feedback might seem superior because it is straightforward, the research does not support it as a treatment of choice, as the other techniques generally reduce blood pressure more than direct blood pressure feedback.

G. Fecal and Urinary Incontinence

Biofeedback treatment of this disorder is presented in the section Case Illustrations.

H. Fibromyalgia

Fibromyalgia is characterized by generalized muscle pain, fatigue, headaches, and insomnia. Although

there is debate about the nature and diagnosis of this condition, it will be assumed it is a unique disorder and that after its diagnosis there are treatments that have been helpful. The biofeedback techniques used to reduce the symptoms of this disorder have been frontal EMG biofeedback and in some instances, specific muscle biofeedback training.

I. Irritable Bowel Syndrome (IBS)

IBS is manifested in about 8 to 19% of the population and is associated with symptoms of abdominal pain, constipation and/or diarrhea, and gas. About 85% of those with IBS have an increase in symptoms when experiencing stress. Therefore, the treatment of choice is relaxation therapy and research has shown that relaxation therapy combined with finger temperature biofeedback is the most effective. Although more direct forms of feedback have been tried, such as colonic motility sounds, rectal feedback using rectal balloons, and feedback of the electrical activity of the lower gut, these techniques have not proven effective and at this time are not used in general practice. The biofeedback is usually combined with client education about the relationship between stress and symptoms.

J. Motion Sickness

Motion sickness was discussed earlier, but will be briefly presented here as well. Cowings and her colleagues, starting in the 1970s, conducted the early work in this area. They used physiological feedback of SCA, finger temperature, and heart rate along with autogenic training to train individuals to increase their threshold for motion sickness. She published many controlled outcome studies and was finally given permission to train some astronauts. The individuals she trained were capable of preventing space motion sickness during their space flights without medication. She successfully extended this work to high-performance jet pilots.

K. Muscle Rehabilitation

EMG biofeedback is used to monitor specific muscle activity in order to facilitate recruitment of muscle activity in hypoactive muscles and to reduce muscle activity in hyperactive muscles. The primary role of EMG biofeedback in paretic muscles is to allow the individual to know that some recruitment of muscle activity is being generated even though it may not be

enough to cause movement. EMG biofeedback therapy allows the individual to know he or she is correctly activating the muscle but not enough to cause movement, as then the slightest increase in effort is detected by the instrumentation. Any minor successes can be used to build further recruitment until enough activity is generated to cause observable changes, which can then be built into functional movements. For hyperactive muscles, the technique uses specific muscle feedback to reduce inappropriate and sustained muscle contractions.

L. Raynaud's Disorder

There are several outcome studies that demonstrate that the biofeedback treatment of choice for this disorder is finger temperature combined with autogenic training. Along with biofeedback, lifestyle changes are also recommended. These changes include avoidance of sympathetic nervous system stimulants, such as caffeine and nicotine; stress management techniques; and the avoidance of low-temperature experiences, such as holding ice drinks and picking up frozen objects.

M. Tension and Migraine Headaches

There is a wealth of outcome research demonstrating that these two disorders can be effectively treated with biofeedback techniques. For tension headaches, BFRT, with placements of the EMG sensors in the frontal location, combined with general relaxation techniques, such as PMR has been shown to be effective. Utilization of specific muscle feedback of the muscles of the face, neck, and cervical area has also proven effective. This author recommends the combination of frontal EMG feedback, PMR, and specific muscle feedback of the face, neck, and cervical area. The muscles selected for the feedback are determined by a dynamic EMG assessment.

For biofeedback treatment of migraines the treatment of choice is finger temperature feedback combined with a relaxation technique, such as autogenic training. For those clients unresponsive to the finger temperature feedback, usually frontal EMG feedback will be effective. Based on the outcome research, biofeedback should be the treatment of choice for children who suffer from migraines.

N. Exclusions

When considering clinical biofeedback for an individual, the following basic requirements must be met: The individual must be able to tolerate the application of the sensors; the individual must be able to under-

stand the instructions regarding the relationship between his or her physiology and the feedback signal; the individual must be motivated to change physiology, using the feedback signal to facilitate this process; and finally, the individual must be motivated to practice what he or she has learned in the clinic in his or her everyday world.

There are also cautions and contraindications for the use of clinical biofeedback. First, a determination must be made that a more appropriate intervention, such as an immediate medical treatment rather than biofeedback therapy, is not warranted. An example of this is that an individual may be suffering from the recent onset of headaches caused by an aneurysm. In this situation, providing biofeedback as the only treatment would not be sensible, as a surgical intervention may be needed. Although there is little literature on contraindications for psychological states, logic indicates that in certain psychological conditions, biofeedback should not be considered the treatment of choice. These conditions include psychological states such as severe depression, uncontrolled schizophrenia, delirium, and depersonalization. Caution or special considerations should be employed when the client has the following conditions: impaired attention, dementia, mental retardation, or if the client is taking medications, as the medications may need to be adjusted as therapy progresses.

Therapists should also be aware that some individuals might experience what is being referred to as relaxation induced anxiety (RIA). Although little systematic information is available on the incidence of this in clinical practice, it is of concern as some individuals feel a strong sense of apprehension when a deep state of relaxation is induced. These individuals often report disturbing cognitions, feelings of loss of control, depersonalization, and strange body sensations. For these individuals, it is necessary to gradually train them in moderate levels of relaxation until they can tolerate and enjoy the benefits from deep states of relaxation. For further information on cautions and contraindications see *Standards and Guidelines for Biofeedback Applications* published by AAPB in 1992, and Schwartz's 1995 work.

IV. CASE ILLUSTRATIONS

Because of the diverse areas of applications of clinical biofeedback, instead of case examples, two general clinical protocols will be presented. The two clinical protocols selected for presentation will be the protocol for biofeedback facilitated relaxation training (BFRT) and for QEEG feedback for ADD/ADHD. These protocols reflect the two

major strategies of clinical biofeedback applications: biofeedback for relaxation purposes and a specific biofeedback training technique based on specific physiological levels that are related to the diagnostic category.

A. Example of a BFRT Protocol

When using BFRT, it is first necessary to determine if the client would benefit from such therapy. General relaxation may be helpful in a variety of conditions and it may also be useful as an incompatible response during such procedures as systematic desensitization. BFRT normally takes between 8 and 20 sessions, depending on the acquisition skills and the distress level of the client before and during therapy. After determination of the need for BFRT, the therapist must explain the rationale for biofeedback therapy, outline the basic aspects of the physiological processes that will be trained, and discuss the potential benefits and risks of the training. This author recommends conducting the first BFRT session with frontal EMG feedback, while monitoring other modalities such as finger temperature, SCA, and/or heart rate. The therapist may also find it beneficial to monitor additional physiological events that are connected to the specific conditions being treated. During the first biofeedback session, facial muscle discrimination training should be demonstrated and the client should be provided time to use his or her relaxation techniques to reduce frontal EMG levels. The therapist should monitor the other modalities during the session to observe the changes that occur as the client tries to reduce frontal EMG levels. An example of the value of monitoring other modalities is that by observing SCA, it can be determined if the client is engaging in arousing internal dialogue by noting if several SCRs are observed. If so, the therapist can interrupt the session and suggest a change in strategy by the client. During the interruption, the therapist should ask the client what strategy he or she is using and then encourage him or her to select a different strategy, such as diaphragmatic breathing or changes in imagery. The most responsive modality is usually selected as the target of therapy after frontal EMG levels are acceptable.

B. Example of a QEEG Feedback Protocol for Treatment of ADD/ADHD

One of the applications of QEEG biofeedback is with children who are diagnosed with ADD/ADHD. These children have been shown to have more slow waves, such as theta and alpha, and fewer fast waves, such as SMR and beta, in their EEGs than non-ADD/ADHD

children of comparable age, according to Monastra and colleagues in 1999. The biofeedback technique provides QEEG therapy for ADD/ADHD children and trains for a decrease in theta or alpha and an increase in beta or SMR, while simultaneously keeping facial EMG levels at an acceptable level. The specific protocol requires a QEEG assessment to determine which specific bandwidth and microvolt levels will be trained. Several studies have been published that clearly demonstrate that the EEG patterns change according to the direction of training and that clinical improvements are observed with successful training. The number of sessions necessary is usually 40 to 60, depending on how quickly the EEG changes and the amount of behavioral improvements observed. It takes the brain longer to learn to control its own processes than body organ systems; therefore, the number of sessions needed for this protocol is greater than that typically required in most biofeedback applications. An additional reason for the greater number of sessions needed in QEEG biofeedback may be that we do not know how to best train the brain to change its functioning.

V. SUMMARY

In order to be effective in the clinical application of biofeedback, there must be a measurable physiological process that can be monitored with existing technology and feedback about the process must be provided with enough resolution and speed to allow the individual to obtain volitional change of the physiological event. Then, this change in physiology must alter the physiological processes causing the targeted disorder. In some instances the relationship between the monitored physiological event and the disorder is obvious, such as finger temperature for Raynaud's disorder; for others, such as BFRT for asthma and IBS, the relationship is less obvious. In some instances, training a physiological event indirectly related to the physiology of interest has proven superior to treating the event itself. An example of this is frontal EMG for the treatment of essential hypertension. Therefore, the clinician must be aware of the physiology underlying the disorder and of the literature that relates to the different biofeedback treatments used to treat that disorder. This information must then be combined with the individual's characteristics such as his or her unique physiological levels and the ability to benefit from the various types of biofeedback techniques available. The clinician must also be skilled in helping the client generalize the control acquired in the clinic to the individual's life situations.

Constant advances in computer technology and developments in bioengineering, which provide new sensor technology and signal processing, make the future of clinical biofeedback look very promising.

GLOSSARY

breathing retraining A self-control strategy used to regulate breathing behavior.

gas transference Delivery of oxygen to support metabolism and removal of carbon dioxide as a byproduct and maintenance of systemic acid-base balance.

I. DESCRIPTION OF TREATMENT

Breathing retraining refers to methods used to modify breathing behavior. Because breathing is essentially a self-regulatory process that marks the beginning of life with its initiation and the end of life with its termination, it is clear that one does not have to learn how to breathe. Thus, the word retraining is not entirely appropriate and may cause confusion because it implies that training has occurred prior to “retraining.” Although the term breathing training is coming into more popular usage, the bulk of the literature on the topic refers to “breathing retraining.”

Preliminary to a discussion of breathing and its modification the reader should also keep in mind that while the words breathing and respiration are often used syn-

onymously, “breathing” refers primarily to the mechanical process of moving air in and out of the lungs whereas “respiration” would include the exchange of blood gases at the cellular level. Thus, by holding one’s breath, breathing (the mechanical means of moving air in and out of the lungs) is temporarily inhibited voluntarily but respiration (the exchange of blood gases in cells) continues involuntarily.

Although the techniques of breathing retraining are essentially an art that depends on the therapist, patient, and other factors, there are in general two approaches. In one approach the therapist addresses the disordered breathing directly by explaining to patients some rudiments of basic respiratory physiology so that they can understand the relationship between their disordered breathing and the symptoms they present. The therapist then proceeds to teach patients how to control breathing (and thus reduce excessive ventilation) by means of relaxation of the abdominal muscles, contraction of the diaphragm, and relaxation of the intercostal muscles. The goal here is to teach the patient how to suppress thoracic breathing and thus restore slow rhythmic diaphragmatic breathing, that is, how to breathe in a manner that eliminates complaints or reduces their intensity.

In the other approach the therapist addresses the disordered breathing indirectly by deemphasizing breathing performance and instead emphasizing relaxation and encouraging self-awareness of interoceptive cues from all muscles involved in breathing. Whichever approach followed, the purpose of breathing retraining is to help the

client learn how to gain voluntary control of breathing in the short run and to establish habitual patterns of salutary breathing in the long run. In psychotherapy the specific goal of the adjunctive procedure of breathing retraining is to help the patient learn to reduce ventilation so that it is consonant with metabolic demand for oxygen, thus facilitating relaxation and clear receptive thinking while reducing anxieties.

II. THEORETICAL BASES

The principles of learning that underlie the methods of modifying breathing are essentially those that underlie behavior therapy. The specific breathing behaviors that are the targets of programs of breathing retraining include (a) frequency, (b) volume, and (c) patterns. Breathing frequency (respiration rate) refers to the number of breaths per minute or the number of respiratory cycles completed in 1 min, where a respiratory cycle consists of one inhalation followed by one exhalation. Breathing volume is measured in terms of either volume of air breathed in one respiratory cycle (tidal volume) or the sum total of air breathed per minute (minute volume); volume is expressed by expansion of the thoracic cavity caused primarily by contractions of the diaphragm, intercostal, and clavicle muscles. Pattern refers to combinations of respiratory frequency and contractions of particular muscles or groups of muscles, for example, fast contractions of intercostals and clavicles with little or no discernible contraction of diaphragm versus slow contraction of diaphragm with little or no discernible contraction of intercostals and clavicles.

Although breathing is the only vital function under direct and immediate voluntary as well as involuntary control, the limits of voluntary control, the limits to which breathing can be modified, are fairly narrow. The breaking point of breath holding marks one extreme; loss of consciousness by means of overbreathing marks the other. Involuntary control of breathing, especially during sleep, is maintained by a self-regulatory system governed primarily by neural pathways with origins in the medulla and pons. This self-regulatory system has been studied extensively.

While the physiological-vegetative role of respiration in gas transference, namely, the delivery of oxygen (O_2) to support metabolism and removal of carbon dioxide (CO_2) as a byproduct and maintenance of systemic acid-base balance (pH), is fairly well understood, the psychological effects of breathing on emotion and cognition has received relatively little scientific attention until about the middle of the 20th century. Al-

though programs of breathing retraining have been applied only recently in the treatment of psychological-psychiatric complaints and breathing-related somatic complaints, it should be noted that breathing retraining has been used through the years to modify breathing and thus facilitate speech, singing, playing wind instruments, swimming, running, as well as relaxing and reducing emotional reactivity in general. Breath control is at the heart of yogic exercises.

The relationship between disordered breathing and psychological-psychiatric disorders is not broadly understood. Part of the reason for this probably harks back to the separation of body and mind or corpse and spirit: life begins with inspiration (the body incorporating the spirit) and ends with expiration (the body giving up the spirit). Although few scientists would openly support the Cartesian notion of body-mind dualism, some would argue that there is a clear distinction between psychology and physiology beyond that of a convenient dialectic convention within biology. A simple example from respiratory psychophysiology that demonstrates how breathing provides a bridge between psychology and physiology is volitional overbreathing. Self-initiation of rapid and strong contractions of the diaphragm and intercostal muscles while resting (i.e., low metabolic demand for oxygen) will lead quickly to hyperventilatory hypocapnia (diminished arterial CO_2 and consequent rise in pH) and produce an almost immediate increase in heart rate, decrease in parasympathetic activation (i.e., sympathetic dominance), decrease in respiratory sinus arrhythmia, increase in electrodermal conductivity, and decrease in blood flow to the brain combined with a rise in pH and consequent decrease in dissociation of oxygen from hemoglobin to brain cell tissue. The immediate consequence of these reactions are acute cerebral hypoxia and a host of psychological, somatic, visceral, and neuropathic complaints. If some psychiatric disorders are a manifestation of faulty cognition that results from an inadequate supply of oxygen to the brain (cerebral hypoxia) then disordered breathing (viz., hyperventilation) can be a significant factor that contributes to the production or exacerbation of psychological-psychiatric and/or behavioral disorders.

Another part of the reason for the narrowly understood relationship between disordered breathing and psychiatric disorders may lie in problems of measurement. Although hyperventilation is correlated with both respiration frequency and tidal/minute volume, variables that are relatively easy to measure reliably, respiration frequency and/or volume can only be used as rough estimates of hyperventilation. The problem lies in fluctuations in metabolic demand for

oxygen. Changes in skeletal muscle tension or autonomic nervous system arousal (e.g., changes in mentation/emotion) will alter metabolic demand that in turn will effect changes in breathing. There are direct and indirect means for measuring hyperventilation (a reduction in partial pressure of arterial CO₂ and consequent rise in pH), independent of metabolic demand for O₂.

The direct means of determining hyperventilation is to assay samples of arterial blood for CO₂, an invasive and hazardous technique. The indirect means for estimating arterial CO₂ is the capnometer, an infra-red gas analyzer that samples expired air for its content of CO₂. This technique, which is neither invasive nor hazardous, uses a small tube attached just inside a nostril through which a vacuum pump relays air to the gas analyzer. The capnometer can provide both a continuous analogue readout of the percentage of CO₂ or a digital display of momentary readings of percentage CO₂ in expired air. The percentage of CO₂ at the end of a respiratory cycle (end-tidal CO₂) is richest in CO₂ because it contains a proportion of CO₂ that best represents the level of CO₂ at the point of diffusion of CO₂ from the arterioles to the lungs.

Although the determination of the proportion of CO₂ in the end-tidal peak of expired air by means of a gas analyzer (capnometer or capnograph) provides an accurate and reliable noninvasive estimate of partial pressure of arterial CO₂, this method seems to have escaped the attention of many psychotherapists. The reason for this may lie, in part, in tradition: psychotherapists study the mind, and physiologists study the body. Perhaps the time has arrived for a rapprochement; perhaps respiratory psychophysiology provides a bridge.

Recently, however, reports from patients suffering panic attacks and reports of laboratory findings, especially the occurrence of adventitious panic attacks during physiological assessments, have shown (1) the occurrence of hyperventilation in panic attacks, (2) the relatively low resting level of CO₂ in the arterial blood of patients who suffer panic disorder, and (3) the high incidence of complaints of severe dyspnea reported to occur in panic attacks. As a consequence of this connection between aberrant breathing and panic, programs for the treatment of panic disorder include breathing retraining in an attempt to reduce ventilation. Programs of treatment that do not directly address breathing either prescribe a drug, unwittingly or by intention, that reduces ventilation (e.g., benzodiazepines) or a method (e.g., relaxation) that indirectly reduces ventilation thus preventing hyperventilation and concomitant panic or terminating an attack soon

after its onset. Recognition of the role of breathing in panic places panic disorder in the realm of clinical respiratory psychophysiology.

The study of panic attacks in the laboratory has been confounded by four major factors: (1) inadequate criteria for the selection of subjects, (2) absence of a reliable panic challenge, (3) inadequate measures of psychophysiological functions, and (4) inadequate criteria for the determination of the occurrence or nonoccurrence of a panic attack. The criteria for the selection of subjects for experiments have typically been those of the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association. Although these criteria may be adequate for clinical diagnosis, they are not sufficiently specific for the purposes of scientific experimentation because they allow for the inclusion of several distinctively different categories or types of panic attacks. Challenges used in attempts to elicit panic attacks cover a wide range (e.g., lactic acid, caffeine, yohimbine, CO₂, false heart-rate feedback, forced voluntary hyperventilation, false information on effects of breathing compressed air). All studies on the effects of challenges report some success in eliciting panic attacks, but none have demonstrated high reliability. Inadequate measurement of psychophysiological factors (especially end-tidal CO₂) prevents an adequate evaluation of the effects of challenges and the detection of changes that occur concurrently with panic attacks. Criteria for the determination of the occurrence of panic attacks typically rely on self reports by the patients or judgments by experimenters; objective physiological criteria are usually not used. To date, the most valuable information on psychophysiological processes in panic attacks in the laboratory have been adventitious panic attacks that occurred in the absence of any intended challenge.

Because breathing retraining in the treatment of panic disorder and other psychophysiological complaints aims "to prevent" hyperventilation by training patients to reduce their ventilation, it is essential for both the patient and the reader to have a clear understanding of the meaning of "hyperventilation." Hyperventilation is often confused with tachypnea (fast breathing—rapid cycles of inspiration and expiration) or with hyperpnea (voluminous ventilation—large volumes of air inhaled and exhaled per breathing cycle). While tachypnea and hyperpnea are types of breathing that can produce hyperventilation, they are not hyperventilation. Hyperventilation can only be understood in terms of the magnitude of ventilation with respect to the metabolic need for oxygen. Thus, while climbing stairs or running one might be engaged in tachypneic and/or hyperpneic breathing but not be hyperventilating if breathing does

not exceed the amount of oxygen required by the muscles for the task. Alternatively, a sedentary person watching an emotionally arousing television drama or sports event (or the evening news) might be hyperventilating (breathing an amount of air that exceeds metabolic demand for a recumbent musculature) even though there are no apparent signs of either tachypnea or hyperpnea.

Given that hyperventilation is any breathing beyond metabolic demand for oxygen, the issue of the deleterious effects of hyperventilation is not simply a matter of its occurrence or nonoccurrence. Everyone hyperventilates throughout the routines of everyday life. Deleterious effects of hyperventilation depend on the degree of overbreathing in conjunction with a number of other variables: intensity, duration, speed of onset, frequency of occurrence (acute or chronic), the internal and external conditions under which it occurs (e.g., intense emotion in an unfamiliar or threatening environment), and the extent to which one experiences a sense of control over the hypocapnic effects produced (e.g., dyspnea/breathlessness, tachycardia). Hyperventilation is complicated because the consequences of its occurrence depend on such a complex interaction of so many physiological and psychological factors.

III. SUMMARY

Although breathing retraining (the modification of breathing behavior) has been briefly discussed in the context of panic and related anxiety disorders, mention should be made that breathing retraining is applied in

the treatment of a broad range of complaints. The salutary effects of breathing retraining can be found in the treatment of noncardiac chest pain, as an adjunctive procedure in stress management programs and cardiac rehabilitation programs, and in the reduction of intensity of symptoms of chronic lung disease (asthma, bronchitis, and emphysema).

GLOSSARY

brief therapy Psychotherapy, typically of short duration, where efficiency in achieving change is an explicit aim. Sometimes referred to as time-effective or short-term therapy.

common factors Treatment ingredients shared by the different models of therapy that can account for the similar outcomes achieved by those models.

contextual models Approaches to therapy that seek change by shifting the situational contexts that are associated with the enactment of problem patterns. Examples include strategic-systems and solution-focused therapies.

learning models Approaches to therapy that seek change by teaching coping skills and rehearsing these in situations that have been problematic. Examples include cognitive-behavioral and cognitive-restructuring therapies.

relationship models Approaches to therapy that seek change by introducing powerful emotional experiences within the helping relationship that challenge maladaptive interpersonal patterns. Examples include interpersonal and brief psychodynamic therapies.

time-limited therapy Brief therapy in which duration is capped at the outset of treatment.

I. OVERVIEW OF BRIEF THERAPY

Brief therapy, sometimes also referred to as short-term therapy, is a generic label for any form of therapy in which time is an explicit element in treatment planning. There is no uniform dividing line between brief and nonbrief therapies. Rather, the range of interventions described as brief range from single session therapies in the strategic and solution-focused literature to episodes of 20 or more sessions in the short-term psychodynamic tradition. It is not at all unusual, for example, to find models of cognitive restructuring therapy that last for 12–15 sessions. This might be viewed as very brief treatment for a client with a personality disorder, but not one with an adjustment problem. Clearly brevity is relative to the accustomed duration of treatment and the objectives undertaken by the therapist.

Defining brief therapy becomes even more difficult when considering the range of extant models. Some brief therapies, for example, are “time limited,” allocating a fixed number of sessions for clients. Such limits often are dictated by administrative policies, such as benefit limits among insurance plans or service restrictions within clinics or counseling centers that have limited professional resources. Other approaches seek to be “time effective,” maximizing efficiency in change processes, but not laboring under a fixed duration of care. “Intermittent” models are especially difficult to categorize, as in the case of monthly therapy sessions that continue for a full year. Such interventions may be

long term, yet still “brief” in their consumption of therapeutic resources.

Finally, there is Simon Budman and Alan Gurman’s important distinction between therapies that are brief by design and those that are brief by default. A hallmark of all brief treatments is their planned nature. Many clients drop out of therapy for a variety of reasons, including a lack of resources, low motivation, disenchantment with the therapist, or satisfaction with a small number of visits. Indeed, approximately one-half of all terminations appear to be unilateral, initiated by the client. Although such cases turn out to be of short duration, they are not brief in the planned sense. True brief therapy makes an active effort from the outset to streamline change processes. Defined in this manner, brief therapy is not a separate school of treatment, but an approach that is applicable to any school.

There are several elements common to brief therapies that distinguish them from treatments that do not explicitly address the component of time. These include the following:

- *Focus:* Brief therapies typically target specific patterns rather than attempt broader personality changes. Such a focus is explicitly addressed in treatment planning and generally is part of a mutual understanding between therapist and client.

- *Activity level of the therapist:* Brief therapists characteristically adopt active methods to maintain the focus of treatment and promote self-understanding and change. The role of the brief therapist is more akin to a catalyst than to the blank screen described by Freud.

- *Activity level of the client:* The efficient utilization of time requires that clients be absorbed in change efforts between sessions, as well as during them. Brief therapies, therefore, generally make use of explicit tasks, homework exercises, and between-session efforts to apply skills and insights obtained during meetings.

- *Client selection:* The great majority of brief therapists recognize that brief therapies are not appropriate for chronic and severe mental illnesses, although techniques borrowed from brief approaches may be of value. Accordingly, therapy typically begins with an assessment to determine the appropriateness of brief treatment for a particular client.

- *Enhanced experiencing:* People appear to be more receptive to change when they are in altered and enhanced states of experiencing. Many methods utilized by brief therapists, including hypnosis, relaxation techniques, introspection, confrontation, exposure, and role playing, enable individuals to experience themselves and their problems in new ways.

- *Emphasis upon readiness for change:* Following the work of James Prochaska and Carlo DiClemente, brief therapists typically target changes for which clients are ready. When clients are not aware of changes that need to be made or committed to making these, brief therapy goals will typically focus on advancing readiness for change rather than working through long-term resistance.

- *Emphasis on impact of intervention:* Brief therapists typically regard the emotional power of interventions, rather than their absolute duration, as critical to change. Accordingly, they tend to emphasize the promotion of corrective emotional experiences rather than exhaustive insight into past conflicts.

By actively maintaining focused efforts at change and maximizing the involvement of both parties within and between sessions, brief therapists attempt to make optimal use of time in treatment. There are, however, a range of persons and problems for which brevity is not feasible and, indeed, can even exacerbate problems. Among the dimensions that are important in determining whether or not treatment can be brief are:

1. *Duration:* Although there is no one-to-one correspondence between the duration of a presenting problem and treatment length, it is fair to assume that chronic, long-standing patterns have been overlearned and may require more intensive and extensive work on discrepancy and consolidation than recent, situational adjustment problems. Chronic problems pose a particularly significant risk of relapse, significantly extending the time that must be spent in consolidation work. Indeed, therapists specializing in substance abuse work and the treatment of the severely and persistently mentally ill view relapse as an integral part of change, not as a treatment failure. To the extent that clients must pass through iterations of change, relapse, and renewed change, treatment cannot be highly abbreviated.

2. *Interpersonal history:* A precondition of brevity is the formation of a quick, positive, and durable therapeutic alliance. This is most likely to be possible among clients who have not experienced significant interpersonal traumas. When clients have grown up within abusive, neglectful, or highly inconsistent homes, the capacity for trust and bonding may be impaired. Such individuals may need many months of meeting before they can feel sufficiently comfortable to open up about their true concerns. This greatly extends the time needed to effect change. In such cases, the formation of a positive alliance may itself comprise the bulk of the therapy, allowing clients to modulate their needs for closeness

and distance and establish consistent and caring relationships with others.

3. *Severity*: When presenting problems are so severe and complex that they greatly impair emotional, vocational, and interpersonal functioning, it may be difficult to maintain the singular focus that is the hallmark of brief treatments. Indeed, highly depressed, psychotic, and anxious clients—as well as those in the throes of drug or alcohol dependence—may require medical attention before being able to focus on targeted therapy. It is not unusual in such circumstances for therapists to conceptualize what would otherwise be a lengthy course of treatment as a modular series of brief therapies, each addressing a particular facet of the client's concerns.

4. *Understanding*: As suggested earlier, clients are most appropriate for brief work when they are aware of a problem in their life and committed to doing something about it. Many clients, however, are at a lower level of change readiness. Some realize that their lives are not going well but possess little or no insight into their patterns. Others may be aware of their shortcomings, but ambivalent about changing them, as in the case of someone who remains in a familiar but unsatisfying romantic relationship. In the absence of insight and commitment, therapy is apt to become elongated, helping clients explore problems and their costs prior to taking remedial action.

5. *Capacity to tolerate discomfort*: Much of the brevity of therapy is accomplished by provoking client patterns within sessions and creating active opportunities for new learning. Such corrective experiences may be highly threatening to a client with poor coping ability and/or one who is in a state of crisis. Habib Davanloo's notion of a "trial therapy," in which highly emotional techniques are attempted on a limited scale during an initial session, is quite useful in assessing the degree to which a vulnerable person can benefit from accelerated efforts at change. Indeed, the entire notion of brevity may be overly anxiety provoking—and hence inappropriate—for clients who are struggling with long-standing issues of attachment and rejection.

II. THEORETICAL UNDERPINNINGS OF BRIEF THERAPY

There are many specific schools of brief therapy and numerous variations within each school. It has been suggested that all these approaches may serve a common function: helping therapists and clients achieve a common understanding of patterns and the means by which patterns can be altered. Each approach, from this per-

spective, may be seen as a distinctive translation system that transforms a bewildering array of presenting problems into a meaningful set of patterns. To the extent that this is so, it may be less important to ask which approach to brief therapy is more effective than its alternatives than to find approaches that can serve as useful translation frameworks for particular therapeutic dyads.

In the broadest sense, there are three overarching models of brief therapy: contextual, learning, and relationship. These make different assumptions regarding the scope and genesis of problem patterns, the role of the therapist in addressing these patterns, and the techniques to be utilized in effecting change. As we see, these assumptions play a crucial role in determining the ultimate brevity of treatment.

A. Contextual Therapies

The contextual therapies owe their genesis to the pioneering work of Milton Erickson and the subsequent elaboration of his therapy in strategic-systems and solution-focused therapies. These are among the briefest of the brief therapies, sometimes addressing change in a single session.

Common to the contextual brief therapies is the notion that problems are constructed and not intrinsic to the individual. Once people construe a set of life outcomes as problems, they typically attempt solutions to these problems, sometimes making the initial difficulties worse in the process. The result is a circular difficulty in which problems and solutions become self-reinforcing and amplifying. A common and simple example of this is the insomniac client who tries as hard as he can to fall asleep, only to find that repeated trying keeps him awake.

Contextual brief therapy proceeds from the recognition that relatively small shifts in the context of the client's problem can be sufficient to interrupt these self-reinforcing cycles and set the client along a new trajectory. The emphasis is thus not on analyzing problems or their historical roots, but in finding contextual parameters that no longer sustain the unwanted behavior patterns. The insomniac client who is instructed to laboriously clean his floors whenever he cannot sleep is thus prevented from enacting his prior efforts at solution. The prescribed task becomes so monotonous that anything—including sleep—becomes an easier course of action.

In the solution-focused variant of contextual brief therapy, efforts are made early in the treatment process to discover exceptions to the problem patterns associated with presenting complaints. Problems rarely occur all the

time, and even troubled individuals possess significant coping resources. This allows the solution-focused therapist to help clients identify patterns of solution—that is, regularities in their ability to *not* experience problematic responses. Once people are able to identify what they are already naturally doing when they avoid falling into old patterns, they are encouraged to rehearse these “solutions” both within and between sessions.

An essential assumption behind the strategic and solution-focused approaches is that clients already possess the resources needed to shift their patterns. Indeed, contexts that can disrupt problem patterns and foster new, more desirable actions are generally available to clients. Because clients are so locked into their constructions of problems and solutions, however, they are unable to escape from their difficulties. From this perspective, spending significant time delving into client recitations of problems is counterproductive, as it reinforces the notion that these problems possess an existence apart from the client’s system of construals. The goal of therapy is less to solve a problem than to help clients see that there wasn’t really a problem at all; that the presenting complaints were artifacts of their particular context.

Accordingly, the contextual brief therapies are among the briefest of the short-term therapies. They do not actively discuss the relationship between client and therapist, and they move quickly from the initial presentation of problems to an action-oriented exploration of solutions. Indeed, an explicit goal of the solution-focused modalities is to construct solutions that can be self-amplifying, creating large developmental impacts from relatively modest interventions.

In terms of technique, several elements distinguish the contextual brief therapies. These include the following:

1. *An avoidance of resistance:* Resistances to interventions are viewed as signs that a particular construction offered by the therapist is not user friendly for a client. Accordingly, the therapist is apt to shift to a different construction rather than delve into the resistance. An underpinning of the literature in strategic therapy is the role of interpersonal influence in change processes. Efforts are made to maximize this influence by maintaining a positive, nonthreatening relationship between therapist and client. Indeed, strategic therapists sometimes adopt a “one-down” stance, disavowing their status as experts, as a way of minimizing distance between themselves and those seeking their assistance.

2. *The creative use of language:* Many of the interventions used by contextual brief therapists help clients reframe patterns in ways that create cognitive flexibility

and open new behavioral alternatives. Such strategies include the use of metaphors and stories that can stick in clients’ minds and help them see their problems in a different light. Many times, clients will provide their own language to describe incidents in which problems were not sustained. This language may be adopted by the therapist to anchor future discussions of solution patterns.

3. *The use of prescribed tasks:* The goal of many of the contextual brief therapies is to provide clients with a first-hand experience in which the constructed problem does not occur. Prescribed tasks are an effort to create such experiences in a vivid manner that can serve as the basis for new construals. For example, a therapist may prescribe a paradoxical task in which couples are instructed to hold their arguments at a given hour in the evening while standing in a ludicrous and unaccustomed setting, such as a walk-in clothes closet. The absurdity of standing in the closet—and the cooperation needed to make the argument occur at the appointed time and place—make it impossible for the couple to summon their normal rancor. With the anger defused, the couple can engage in a different mode of communication, more likely to constructively address their concerns.

4. *Shifts in states of consciousness:* Milton Erickson’s realization that much of therapy involves a process of interpersonal influence led him to work with trance induction as a strategy for accelerating change. Many of the prescribed tasks offered by strategic therapists have a novelty or shock value that maximizes their emotional impact. The goal is to facilitate the deep processing of new information, bypassing the normal critical awareness that helps to sustain problem constructions.

B. Learning Therapies

The learning models begin with a different set of assumptions, defining problem patterns as learned, maladaptive responses to situations. The goal of therapy from this perspective is to unlearn these self-defeating responses and replace them with more constructive alternatives. This places the client in the role of student and the therapist in the role of teacher. Instead of affecting client constructions with novel framings and experiences, the therapist engages in active instruction. These nascent skills can then be rehearsed in situations that have led to problems in the past, eventually becoming part of an established repertoire.

In the approaches derived from operant and classical conditioning—often designated as cognitive-behavioral therapies—treatment begins with an extensive behavioral analysis of the situational determinants of problem

patterns. Such an analysis can be undertaken through direct observation in school, hospital, or other structured settings or might be conducted through homework exercises involving self-monitoring. The key idea is that problem patterns are elicited by a limited set of internal and environmental cues. Once these triggers are identified, they can be targeted as opportunities for introducing, rehearsing, and reinforcing skills. The goal is to introduce an element of self-observation into behavior patterns that have been automatic, creating flexibility in response. In behavioral modification, for example, when trigger situations are encountered, efforts are made to withhold any reinforcement of problematic behaviors and systematically reward approximations to new, desired actions—including those that have been modeled for the client. The creation of incentives, such as those found in a token economy, can be especially effective in sustaining awareness of skill-based responses in problem situations. This is often undertaken in structured environments, such as school classrooms, where professionals possess a high degree of control over environmental and interpersonal variables and can observe clients on an extended basis.

The idea of enacting new patterns in contexts that have generally fostered problematic behaviors is a hallmark of brief therapies that derive inspiration from classical conditioning. These exposure-based methods, well exemplified in the work of Edna Foa and David Barlow, actively provoke problem patterns, such as anxiety episodes, while the client engages in cognitive and behavioral coping efforts. Through repetition, clients learn to control responses previously viewed as out of control, gaining a sense of mastery. Such exposure can be gradual, as in systematic desensitization, or it can be undertaken all at once, as in flooding methods. Many times, the exposure is first tackled through the use of vivid imagery (imaginal exposure), in which clients invoke anxiety by imagining themselves in stressful situations. Later, the work can proceed to *in vivo* exposure, as clients tackle actual situations within and between sessions.

The exposure-based therapies generally follow a sequence of steps that are common to the learning modalities. These steps include the following:

1. *Monitoring*: Clients are encouraged to become aware of situational precursors of problematic responses and internal cues that precede these responses. Many times these cues are fairly subtle, as in the case of bulimic clients who may become overly sensitive to interoceptive stimuli of bloating or fullness during menstrual cycles or

following meals. The use of journals or self-rating forms can be especially helpful in these efforts, requiring clients to exercise self-awareness between sessions.

2. *Skill introduction and modeling*: Before a skill, such as a relaxation technique, is actually taught to a client, it is first introduced and explained in detail. Its rationale is described, and client questions are addressed to facilitate compliance. The skill is also modeled by the therapist for the client, with a step-by-step explanation of how it is performed. The goal is to help a client understand and feel comfortable with a skill before attempting it directly.

3. *Skill rehearsal*: Learning models emphasize the role of rehearsal in generating new and lasting behavior patterns. Rehearsal is first undertaken within the session, with copious feedback offered by the therapist. Only when the skill is mastered within the session is it assigned as between-session homework. Often such homework encourages repetition of the skill in nonthreatening situations to maximize the probability of early success.

4. *Pairing of skill enactment with problem cues*: Once a person has mastered a coping skill, therapy attempts to actively invoke cues that provoke problem patterns. These challenges are utilized as opportunities to rehearse and apply the coping skills, with the idea of extinguishing anxiety and preventing unwanted behavioral responses. By invoking stresses on a graduated basis, therapists can help to ensure client successes, building the sense of mastery. The intensity of repetition with which the pairing is undertaken is adjusted to the client's tolerance level, with special care taken to avoid traumatizing vulnerable individuals.

5. *Generalization*: Once a person can successfully invoke coping in a former problematic situation, the situation may be rehearsed many times—in and out of session—to promote the internalization of the skill and its application to new situations. Daily homework makes maximum use of time between sessions, allowing clients to benefit from regular experiences of self control.

The classical conditioning paradigm has been extended to the treatment of trauma by Francine Shapiro in her work on eye movement desensitization and reprocessing (EMDR). In this approach, clients are asked to relive emotionally upsetting episodes in their lives while rehearsing repetitive patterns of eye movement or other bodily action. Shapiro postulates that change is accelerated when clients can actively reprocess painful emotional experiences that have not been properly assimilated. EMDR appears to benefit individuals by eliciting their emotional memories in a relatively

nonemotional context. Most of the EMDR tasks are routine and even somewhat boring. By pairing traumatic memories and fears with the performance of emotionally neutral tasks, EMDR may extinguish anxiety in much the same way as exposure-based behavioral therapies, allowing clients to experience stressors in a less aroused state and build a sense of mastery.

Cognitive restructuring approaches, popularized by the work of Aaron and Judith Beck, apply principles of learning to the modification of problematic thought patterns. The key idea behind this work is that patterns of construal underlie emotional responses. If these schemas are altered, individuals can respond to situations in new, healthy ways.

Many of the schemas that individuals draw on to make sense of the world embed information processing distortions. For example, people may engage in a process of selective abstraction, focusing on the most negative aspects of a life event and generalizing these to themselves. These distortions have become overlearned to the point where they now are automatic. In essence, the client mistakes his or her faulty processing of the world for reality. The automatic thoughts thus affect both feeling and behavior, creating problem patterns as distorted as their underlying schemas.

Brief therapy with a cognitive-restructuring model tends to be somewhat longer term than the exposure-based therapies largely because of the time devoted to identifying and understanding these information processing distortions. Exposure-based work often targets a very narrow behavioral pattern for change—phobic responses being a common example—while cognitive-restructuring methods are frequently employed to deal with broader problems of depression and personality disorders. Because the underlying distortions of thinking manifest themselves in multiple arenas for clients—emotional, interpersonal, vocational, etc.—the generalization process often takes more time. As a result, cognitive restructuring therapy can be expected to last 10–20 sessions, instead of the 5–10 sessions often associated with other cognitive-behavioral work.

The first step in cognitive-restructuring work involves psychoeducation. Clients are introduced to the cognitive model, drawing on examples from everyday life and specifics from the client's past. A particular point of emphasis is the linkage between thoughts, feelings, and behaviors and the ways in which our construals of events mediate responses. Individuals are much more likely to undertake the in-session and homework demands of therapy if the rationale of the treatment makes sense.

As with the aforementioned exposure-based modalities, self-monitoring is also a key initial phase of short-term cognitive work. Clients are encouraged to think about their thinking, often by keeping a written record of emotional events in their lives and the thoughts surrounding these events. A review of these journals within the initial therapy sessions helps clients identify distortions and appreciate the emotional and behavioral consequences. Once participants become adept at identifying their distortions in the sessions, they are encouraged to use their journals to become aware of their problematic thoughts between meetings, as they are occurring. With consistent practice and feedback, clients can build their self-observation skills and increasingly catch themselves in the act of engaging in problematic interpretations of events.

The core of cognitive-restructuring work occurs when clients learn to dispute their automatic thoughts with more rational, constructive ways of construing their lives. Once again this is first modeled within sessions by the therapist, using examples elicited from clients wherever possible. It may be possible, for instance, for individuals to reflect on how other people might interpret similar situations, or they might be aware of situations in which they would make very different interpretations. It is often helpful to encourage people to identify how they would respond to a best friend or significant other who was facing a similar situation. Interestingly, given such a scenario, many clients will spontaneously generate constructive construals that completely bypass their automatic, self-relevant schemas.

When these alternative interpretations are generated, they are rehearsed in a Socratic fashion within sessions, first with the therapist challenging the client and then with clients challenging themselves. The objective is to interrupt the automatic thoughts by initiating an internal dialogue in which one distances from one's schemas and evaluates them for accuracy. It is not unusual for therapists to suggest small experiments to be conducted between sessions in which clients test their automatic thoughts as if they were hypotheses in a scientific study. Such experiments can provide a powerful firsthand confirmation that the negative schemas are not accurate depictions of the world.

The extension of written journals to embrace efforts at disputing troublesome automatic thought patterns is another common technique employed in cognitive-restructuring therapies. The process of writing down negative thoughts and generating more constructive alternatives helps clients rehearse their thinking skills in

real time under controlled conditions. At first, such written work may require considerable time and effort. With practice, however, the skills themselves become automatic, and clients find themselves naturally questioning their old thought patterns as they are occurring. This generalization is aided by targeting challenging events between sessions and rehearsing ways of using the journal to respond to the challenges.

C. Relationship Therapies

Whereas the learning-based brief therapies rely heavily on skills-teaching and homework-based rehearsal, the relationship brief therapies emphasize interpersonal experience as a change vehicle. Central to these approaches is the idea that individuals internalize their interpersonal experiences, cementing their identity in the process. When these experiences have been conflicted, the person internalizes a fragmented, negative, and/or inconsistent sense of self. This disrupts mood and action and potentially impairs future relationships. Unlike the contextual therapist, the relationship therapist emphasizes the internal experience of clients and its social origins. Unlike the learning therapist, the relationship therapist stresses the curative impact of the helping relationship, rather than didactic instruction.

The brief relationship therapies differ from their longer-term siblings—client-centered and psychoanalytic treatment—in their focus on specific relationship patterns and relative emphasis upon the present. The Interpersonal Therapy for Depression (IPT) introduced by Gerald Klerman and colleagues links the depressive syndrome to several core issues, including delayed grief reactions, interpersonal role disputes, role transitions, and interpersonal deficits. Clients are helped to appreciate the interpersonal sources of their feelings, making their depression more understandable and less threatening. Sessions then focus on addressing the interpersonal challenges, interrupting the client's negative focus on self and promoting constructive action.

The psychodynamic brief therapies make particular use of in-session events between therapist and client to facilitate change. Like their longer-term counterparts, the brief dynamic therapies emphasize that problem patterns in the client's life will be replayed within the therapeutic relationship. This transference offers an opportunity for clients to see their patterns as they are occurring, to appreciate the costs of these patterns, and to initiate efforts to engage the therapist in a more constructive mode. Once clients are able to become better observers of their patterns within the sessions and initi-

ate efforts at change, their successes can serve as templates for shifting those patterns in other, extratherapeutic relationships.

The underlying model of problem creation and maintenance is also shared between the brief and longer-term analytic approaches. Early childhood conflicts are defended against through a variety of mechanisms. If these conflicts are repressed or otherwise left unresolved, they tend to resurface whenever the individual faces similar challenges in later life. At such times, people are apt to regress to their prior, less mature modes of coping. Whereas these defensive modes may have worked in the past, they are no longer adaptive for the current, adult context and yield new, painful consequences. For instance, a child who was abused may have warded off her anxiety by learning to dissociate. This no longer proves adaptive, however, in coping with conflict in mature working and loving relationships.

The brief and longer-term dynamic therapies differ in three crucial respects:

1. *Therapist activity*: In longer-term analysis, interpretation is a gradual process that is only undertaken after considerable work has been done to resolve resistances (defensive patterns that interfere with the therapy). The interpretive stance of the brief dynamic therapist is much more active, emphasizing present-day manifestations of patterns rather than their historical roots. Such practitioners as Lester Luborsky, Hans Strupp, and Hanna Levenson narrow their focus to specific cyclical interpersonal patterns that lead to maladaptive outcomes. Instead of waiting for clients to recognize these patterns on their own, brief dynamic therapists are much more likely to actively interpret their presence and associated consequences.

2. *Use of confrontation*: Longer-term analytic therapies emphasize interpretation as a primary intervention mode in dealing with resistances. Such brief dynamic therapists as Peter Sifneos and Habib Davanloo replace this interpretive work with a more direct confrontation of defenses, vigorously pointing out their maladaptive nature. This tends to heighten clients' anxiety level, placing them in greater touch with the thoughts, feelings, and impulses being defended. The brief analytic therapist largely abandons the analytic blank screen and instead acts as a catalyst for change by strategically heightening anxiety and bringing conflicts to life within sessions.

3. *Corrective emotional experiences*: The goal of traditional analysis is to foster insight into unconscious interpersonal conflicts and their consequences and support novel, adaptive efforts to deal with these. The

brief dynamic therapist, building on the framework first offered by Franz Alexander and Thomas French, attempts to speed this process by offering immediate relationship experiences that challenge the client's repetitive patterns. Davanloo's work, for instance, derives much of its power by goading repressed patients into expressions of anger against the therapist. By responding to this anger constructively, the therapist actively disconfirms the client's expectations of rejection and abandonment, making it easier to deal with conflict openly. This strategic use of the therapeutic relationship in brief dynamic therapy draws significant inspiration from interpersonal therapies, including the work of Sullivan. Providing powerful emotional experiences that challenge client patterns is more important than offering verbal insight into these patterns.

Although briefer than traditional psychoanalysis, many short-term dynamic therapies are longer term than other brief modalities. Indeed, it is not unusual for a brief dynamic therapy to extend for 20 sessions or longer, falling well outside the utilization guidelines and benefit limits of many managed healthcare plans. Once again, this is typically a function of the breadth of change being sought. The brief dynamic therapies generally target long-standing conflicts that have interfered significantly with emotional functioning. Because of the time required for these conflicts to play themselves out in the transference, for the therapist to earn the trust of an interpersonally troubled individual, and for adaptive efforts to take root, it is difficult to imagine brief dynamic work of only a few sessions. In summary, it appears that the term brief therapy actually masks a variety of interventions of differing scope and duration, with highly directive and focused modes at the shortest end of the continuum and more exploratory and broad treatments at the opposite end.

III. RESEARCH FINDINGS

A great deal of what we know about the effectiveness of therapy and the processes that contribute to favorable outcomes is derived from investigations of treatments that are brief. For this reason, researchers have noted that the outcome literature in therapy actually is a literature on brief therapy outcome.

Reviewers of the literature on brief therapy outcome have generally concluded that short-term treatments are effective in helping people who are suffering from situational and less severe disorders, such as anxiety

and grief. There is also ample evidence that brief therapy is helpful in the treatment of trauma and stress-related disorders. More chronic disorders, such as major depressive and psychotic conditions, appear to be more refractory to brief intervention.

A number of methodological factors appear to mediate brief therapy outcomes, generating several important conclusions:

- *Outcomes are a function of the time of assessment:* As the large National Institute of Mental Health (NIMH) study of depression found, outcomes tend to be more favorable at the end of treatment than at longer-term follow-up periods. The phenomenon of relapse is especially acute for disorders with long-term, chronic courses, such as major depressive disorder, compared with more situational anxiety problems.

- *Outcomes are a function of the criterion being measured:* Change in therapy appears to not occur all at once, but in phases. Symptom relief—reduced depression, anxiety, anger—tends to precede functional improvements in work, home, and interpersonal spheres. A brief therapy is most likely to look successful if symptom relief is the criterion. More interesting, clients appear to draw on different criteria in assessing change than their therapists, stressing symptom relief measures. They thus rate brief therapy outcomes more highly than their therapists, who place greater emphasis on measures of functioning.

- *Outcomes are a function of the client population:* Research by Kenneth Howard and colleagues found that, overall, change occurs relatively quickly—within the first few sessions—for the majority of neurotic clients. Adding sessions beyond the first 10 brings sharply diminished returns. Clients with personality disorders and severe psychopathology, however, continue to benefit from sessions beyond brief parameters and display only modest change within the first 10 visits.

- *The achievement of a rapid alliance is crucial to brief therapy outcome:* Howard's work also suggests that successful clients tend to experience a rise in well-being early in treatment, as they bond with their therapists and perceive the possibility of change. The failure to reach a working alliance early in therapy is a poor prognostic indicator of brief therapeutic outcome.

An important finding of the aforementioned NIMH study is that different forms of therapy conducted within brief parameters, including cognitive and interpersonal, did not produce unique changes among clients. That is, therapies with different explanatory models and intervention techniques may produce very

similar types of outcome, as well as similar magnitudes of change. This supports the notion that common factors may be the most important effective ingredients in short-term work. Indeed, therapy may be brief to the extent that it can harness these common ingredients and apply them intentionally and systematically to targeted problem patterns.

Studies of change processes in brief therapies tend to support this common factors hypothesis. It appears that brief therapy is not so much different from time-unlimited treatment as an intensification of longer-term modalities. The brief therapist emphasizes the effective ingredients in all therapies and attempts to maximize these in a planned, deliberate manner so as to catalyze desired changes. This can be described as a several-step process, an overarching, integrative model of brief therapy that can account for the shared elements among the contextual, learning, and relationship approaches:

1. *Engagement*: The earliest phase of therapy features a vigorous encounter between therapist and client in which the dimensions of the presenting problems are explored. Very often, this features a ventilation of the emotional upset that has brought the individual for help. By listening attentively, inquiring actively, and responding sensitively, the therapist facilitates a building of rapport and trust.

2. *Pattern search*: Bernard Beitman has emphasized the importance of pattern searching in the earliest phases of treatment. Presenting problems such as depression, anxiety, and relationship conflicts frequently arise under specific conditions. By asking for many examples of presenting problems, it is possible for therapist and client to identify the similarities among these instances and the conditions that serve as contexts for the generation of distress.

3. *Translation*: Clients typically enter therapy only after they have unsuccessfully attempted other means for solving their problems. As a result, by the time they sit for their first session, they are typically somewhat frustrated and discouraged. Not infrequently, the ways in which they have defined their problems—and hence the possible solutions to these—have led them to a dead end. When a brief therapist translates presenting problems into the new terms of a pattern—helping clients see this pattern for themselves—the result is often a sense of relief and hope. If the brief therapist has been effective in building trust and rapport and successfully identified outstanding patterns, the translation can serve as a mutual focus for therapy, engaging the client's readiness for change.

4. *Discrepancy*: A key process feature across the brief therapies is the attempt to elicit problem patterns within therapy sessions. This helps to heighten emotional experiencing and more deeply process efforts at change. It also speeds the change process by allowing clients to work directly on targeted patterns. Because the brief therapist takes an active role in eliciting problem patterns, brief therapies can be anxiety provoking for clients. Indeed, the heightened anxiety may serve as a spur for change. Many of the techniques specific to the brief therapies—exposure methods in behavioral desensitization, journal keeping in cognitive restructuring approaches, confrontation in the short-term dynamic methods, directed tasks in strategic work—allow clients to experience their problem patterns in a controlled and safe context. This allows for the possibility of responding to these patterns in a discrepant and adaptive manner, generating true corrective emotional experiences.

5. *Consolidation*: Once new, constructive patterns have appeared, the task of the brief therapist is to aid in their internalization. Although initial change can bring meaningful symptom relief, clients remain at significant risk of relapse if they have not truly made a new pattern part of their cognitive, behavioral, and emotional repertoire. Accordingly, the latter phases of brief therapy feature significant efforts at rehearsal and generalization, encouraging clients to extend their in-session changes to out-of-session contexts. Frequent feedback from therapists and rehearsal of anticipated future challenges facilitate generalization, as the focus comes full circle, from the identification of problem patterns to the facilitation of adaptive responses. Not infrequently, therapy moves to an intermittent basis of meeting as clients develop the capacity to sustain this consolidation on their own.

IV. SUMMARY

The term brief therapy subsumes a variety of treatment approaches derived from different models of change and spanning a range of treatment durations. Brief therapies share a number of procedural elements, including criteria for inclusion and exclusion, the maintenance of a sharp treatment focus, a high degree of therapist activity and client involvement, and concerted efforts to elicit and rework client patterns within and between sessions. Brief therapies range from very short-term strategic and solution-focused modalities to cognitive-behavioral and cognitive-restructuring models and more extended short-term dynamic approaches. All appear to be effective in helping people deal with situational problems and less severe anxiety and stress

concerns but may be limited in sustaining change among clients with chronic and severe disorders.

less attention to “care,” the process of helping ill people live with cancer as well and as long as possible. That latter perspective is the focus of this article.

GLOSSARY

- active coping** Finding some aspect of a stressor that one can do something about and formulating a plan of action to respond to it.
- affective expression** The direct ventilation of emotion.
- hypnosis** A state of relaxed, attentive, focused concentration with a reduction in peripheral awareness.
- personalization** Bringing discussion of problems into the “here and now” by discussing problems as reflected by issues among group members rather than involving others outside the group.
- social constraints** Aspects of a social network that discourage open expression of feelings and thoughts.

As treatment for cancer has become more effective, it is better thought of as a chronic rather than a terminal illness. However, given the progressive nature of the disease, and the fact that approximately half of all people diagnosed with cancer will eventually die of it, a readjustment in the medical approach to cancer is needed. Currently, we focus almost exclusively on cure, despite the fact that cure is often impossible. We pay far

I. DESCRIPTION OF TREATMENT

A. Content

1. Social Support

Psychotherapy, especially in groups, can provide a new social network with the common bond of facing similar problems. Just at a time when the illness make a person feel removed from the flow of life, when many others withdraw out of awkwardness or fear, psychotherapeutic support provides a new and important social connection. Indeed, the very thing that damages other social relationships is the ticket of admission to such groups, providing a surprising intensity of caring among members from the very beginning. Furthermore, members find that the process of giving help to others enhances their own sense of mastery of the role of cancer patient and their self-esteem, giving meaning to an otherwise meaningless tragedy.

2. Emotional Expression

The expression of emotion is important in reducing social isolation and improving coping. Yet it is often an aspect of cancer patient adjustment that is overlooked or suppressed. Emotional suppression and avoidance are associated with poorer coping. At the same time,

there is much that can be done in both group and individual psychotherapies to facilitate the expression of emotion appropriate to the disease. Doing so seems to reduce the repressive coping strategy that reduces expression of positive as well as negative emotion. Emotional suppression also reduces intimacy in families, limiting opportunities for direct expression of affection and concern. Indeed, there is evidence that those who are able to ventilate strong feelings directly cope better with cancer.

The use of the psychotherapeutic setting to deal with painful affect also provides an organizing context for handling its intrusion. When unbidden thoughts involving fears of dying and death intrude, they can be better managed by patients who know that there is a time and a place during which such feelings will be expressed, acknowledged, and dealt with. Furthermore, disease-related dysphoria is more intense when amplified by isolation, leaving the patient to feel that he or she is deservedly alone with the sense of anxiety, loss, and fear that he or she experiences. Being in a group where many others express similar distress normalizes their reactions, making them less alien and overwhelming.

3. Detoxifying Dying: Processing Existential Concerns

Death anxiety in particular is intensified by isolation, in part because we often conceptualize death in terms of separation from loved ones. Feeling alone, especially at a time of strong emotion, makes one feel already a little bit dead, setting off a cycle of further anxiety. This can be powerfully addressed by psychotherapeutic techniques that directly address such concerns.

Exploring and processing existential concerns is a primary focus of supportive-expressive therapy. Irvin Yalom has described the ultimate existential concerns as death, freedom, isolation, and meaninglessness. Rather than avoiding painful or anxiety-provoking topics in attempts to “stay positive,” this form of group therapy addresses these concerns head-on with the intent of helping group members better use the time they have left. This component of the therapy involves looking the threat of death right in the eye rather than avoiding it. The goal is to help those facing the threat of death see it from a new point of view. When worked through, life-threatening problems can come to seem real but not overwhelming. Following a diagnosis of cancer, a variety of coping strategies come into play, including positive reappraisal and cognitive avoidance. However, denial and avoidance have their costs, including an increase in anxiety and isolation. Facing

even life-threatening issues directly can help patients shift from emotion-focused to problem-focused coping. The process of dying is often more threatening than death itself. Direct discussion of death anxiety can help to divide the fear of death into a series of problems: loss of control over treatment decisions, fear of separation from loved ones, anxiety about pain. Discussion of these concerns can lead to means of addressing if not completely resolving each of these issues. Thus even facing death can result in positive life changes. One woman with metastatic breast cancer described her experience in this way:

What I found is that talking about death is like looking down into the Grand Canyon (I don't like heights). You know that if you fell down, it would be a disaster, but you feel better about yourself because you're able to look. I can't say I feel serene, but I can look at it now.

Even the process of grieving can be reassuring at the same time that it is threatening. The experience of grieving others who have died of the same condition constitutes a deeply personal experience of the depth of loss that will be experienced by others after one's own death.

4. Reorganizing Life Priorities and Living in the Present

The acceptance of the possibility of illness shortening life carries with it an opportunity for reevaluating life priorities. When cure is not possible, a realistic evaluation of the future can help those with life-threatening illness make the best use of remaining time. One of the costs of unrealistic optimism is the loss of time for accomplishing life projects, communicating openly with family and friends, and setting affairs in order. Facing the threat of death can aid in making the most of life. This can help patients take control of those aspects of their lives they can influence, while grieving and relinquishing those they cannot. Having a domain of control can be quite reassuring. Previous studies by Roxanne Silver, Phillip Zimbardo, and colleagues of the sequelae of past traumatic events indicate that long-term psychological distress is associated with a temporal orientation that is focused on the past rather than on the present or future. For cancer patients who are experiencing the traumatic stressor of anticipating their imminent death and its impact on their loved ones, adjustment may be mediated by changes from past- or future-focused orientation to a present-focused orientation that is more congruent with the reality of

their foreshortened future. In addition, progress in life goal reappraisal, reorganization of priorities, and perception of benefits of cancer may also mediate improvement in symptoms and enhance quality of life.

5. Enhancing Family Support

Psychotherapeutic interventions can also be quite helpful in improving communication, identifying needs, increasing role flexibility, and adjusting to new medical, social, vocational, and financial realities. There is evidence that an atmosphere of open and shared problem-solving in families results in reduced anxiety and depression among cancer patients. Thus facilitating the development of such open addressing of common problems is a useful therapeutic goal. The group format is especially helpful for such a task, in that problems expressing needs and wishes can be examined among group members as a model for clarifying communication in the family.

In addition to enhancing communication, group participants are encouraged to develop role flexibility, a capacity to exchange roles or develop new ones as the pressures of the illness demand. One woman, for example, who became unable to carry out her usual household chores, wrote an “owner’s manual” to the care of the house so that her husband could better help her and carry on after her death. Others wrote letters to friends asking them to cook an extra bit of dinner one evening a month to share with them to relieve them of the pressure of cooking.

6. Improving Communication with Physicians

Support groups can be quite useful in facilitating better communication with physicians and other health care professionals. Groups provide mutual encouragement to get questions answered, to participate actively in treatment decisions, and to consider alternatives carefully. Research by Lesley Fallowfield has shown that cancer patients are more satisfied with the results of intervention, such as lumpectomy versus modified radical mastectomy, to the extent that they have been involved in making the decision about which type of treatment to have. Such groups must be careful not to interfere with medical treatment and decisions, but rather to encourage clarification and the development of a cooperative relationship between doctor and patient. The three crucial elements are communication, control, and caring: improving communication, enhancing patients’ sense of control over treatment decisions, and finding caring physicians and other health care professionals who are interested in the patient as a person.

7. Symptom Control

Many treatment approaches involve teaching cognitive techniques to manage anxiety. These include learning to identify emotions as they develop, analyze sources of emotional response, and move from emotion-focused to problem-focused coping. These approaches help the patient take a more active stance toward the illness. Rather than feeling overwhelmed by an insoluble problem, they learn to divide problems into smaller and more manageable ones. If I don’t have much time left, how do I want to spend it? What effect will further chemotherapy have on my quality of life?

Many group and individual psychotherapy programs teach specific coping skills designed to help patients reduce cancer-related symptoms such as anxiety, anticipatory nausea and vomiting, and pain. Techniques used include specific self-regulation skills such as self-hypnosis, meditation, biofeedback, and progressive muscle relaxation. Hypnosis is widely used for pain and anxiety control in cancer to attenuate the experience of pain and suffering, and to allow painful emotional material to be examined. Group sessions involving instruction in self-hypnosis provide an effective means of reducing pain and anxiety, and consolidating the major themes of discussion in the group.

B. Treatment Process (see Table I)

1. Personalization

Leaders are taught to bring group discussions “into the room” by keeping the focus on interactions occurring among group members, rather than directing discussion toward people and events outside the group. Although some discussion of family, friends, and outside events is inevitable, the processing of issues raised on the “outside” is best done on the “inside.” Thus when one patient discusses how she feels that she is a burden to her husband, the discussion is better directed toward the question, “Do you feel like a burden to the group?” or “Do other group members feel you are a burden?”

2. Affective Expression

Leaders should “follow the affect” in the room rather than the content. If a silent group member shows signs of emotion, the leader should respectfully direct attention toward her: “You seem upset now—what are you feeling?” Expression of emotion produces vulnerability, and it is important to make sure that those who express feelings are heard and acknowledged.

TABLE I
Group Process Goals for Leaders

Personalization
Facilitating an examination of personal and specific cancer-related issues.
Affective expression
Facilitating the expression of here-and-now feelings
Supportive group interaction
Facilitating supportive interactions among group members
Sharing group time and access to group attention
Avoiding scapegoating
Maintaining boundaries
Active coping
Facilitating the use of active coping strategies

3. Supportive Group Interactions

The leader is responsible for starting and ending the group on time, and seeing that there are few interruptions of the group time. Each member should be made to feel that her problems are as important as anyone else's. It is necessary to inquire about missing members, and to make sure that very silent members have a chance to talk. Also, avoiding scapegoating—the group's "fixing" one patient as a displacement of dealing with their own problems—is critical. Leaders must remember that their "patient" is the group, not just a series of individuals.

4. Active Coping

As problems are discussed, it is helpful for the leader to direct the group toward means of responding to them, rather than merely accumulating a series of unresolved difficulties, or avoiding discussing them. Finding a means of addressing problems reduces the helplessness engendered by them.

II. THEORETICAL BASES

No one is well prepared by life to deal with a life-threatening diagnosis and the rigors of treatment, and yet medical treatment has focused almost exclusively on the necessary problems of undergoing diagnostic tests, surgery, radiotherapy, chemotherapy, hormonal treatments, and other biomedical interventions. Far less attention has been paid to educating patients about their illness and its effects on their lives, processing emotions inextricably intertwined with the disease, and enhancing social support, which is often damaged by the presence of the disease.

There is strong evidence that social contact has not only positive emotional effects, but that it reduces overall mortality risk as well as that from cancer. In a major review James House showed that social isolation is as strongly related to age-adjusted mortality as serum cholesterol levels or smoking. Indeed, being married predicts better medical outcome with cancer, while social stress such as divorce, loss of a job, or bereavement is associated in some studies with a greater likelihood of a relapse of cancer. Thus, constructing new social networks for cancer patients via support groups and other means is doubly important: It comes at a time in life when natural social support may erode, and when more is needed.

A. Social Constraints

The social-cognitive processing model of adjustment to trauma developed by Stephen Lepore contends that it is not merely the act of thinking about trauma-related information that facilitates processing, but it is disclosure and active contemplation of meanings, feelings, and thoughts with supportive others that is pivotal. A social environment that inhibits such disclosure may cause patients to avoid thinking and talking about the stressful experience and interfere with cognitive processing, resulting in prolonged distress and a failure to come to terms with the cognitive and emotional information in question. These social constraints cause cancer patients to feel unsupported, misunderstood, or otherwise alienated from their social network and have been associated with greater cancer-related intrusive ideation and avoidance. A similar construct, aversive emotional support put forward by Lisa Butler, has been found to amplify the impact of past stressful life events on current traumatic stress symptoms in cancer patients. Treatment-related changes in patients' perception or elicitation of social constraints should therefore result in greater processing of the cancer experience.

Living with the traumatic stressor of cancer creates an unending series of existential challenges. The threat to life is continuous, and reminders are constant, through symptoms such as pain, treatments and their side effects, loss of social roles, and the response of others to the condition. Thus the successful treatment of symptoms and the enhancement of quality of life for cancer patients requires interventions that focus on emotional and cognitive processing of the cancer experience and addresses the themes and issues that are specific to living with cancer. Successful treatment of cancer-related symptoms and improvements in quality

of life are mediated by engagement of cancer-related fears and other aversive emotions, increases in patient emotional self-efficacy for coping with the challenges of living with the illness, the degree of processing of existential cancer-related concerns and stressful cancer-related events, reduced social constraints that inhibit processing, the degree to which patients can reorganize their life priorities and live more fully in the present, and utilization of techniques such as self-hypnosis for pain and anxiety control.

Many of the psychotherapies that have shown promise in improving emotional adjustment and influencing survival time involve encouraging open expression of emotion and assertiveness in assuming control over the course of treatment, life decisions, and relationships.

III. OUTCOME

Psychotherapeutic treatments for cancer patients, both group and individual, have been shown to have a variety of positive effects, ranging from reduction in anxiety and depression to several recent studies suggesting increases in survival time.

A. Beneficial Effects of Group Interventions on Psychiatric Symptoms and Mood

Group interventions are of proven benefit in improving quality of life for cancer patients. For example, research on university- and hospital-based group interventions by Catherine Classen, David Spiegel, Fawzy Fawzy, and others has shown that they reduce traumatic stress symptoms and other psychological distress, improve coping skills, enhance disease knowledge, improve quality of life, and reduce pain.

B. Effects of Social Support Interventions on Health Status

Recently, a provocative literature has emerged indicating that group psychotherapy may affect the quantity as well as the quality of life. Our research group found that the metastatic breast cancer patients in our original randomized trial who had undergone supportive/expressive group therapy lived, on average, 18 months longer than did the randomly assigned control sample. By 48 months after the study had begun, all of the control patients had died, but a third of the treatment sample were still alive. There is now a larger and

divided literature on this survival effect. Four other studies have shown an effect of psychotherapy on cancer survival time of cancer patients: two involving lymphoma, one with melanoma, and one with gastrointestinal cancers. All of the psychosocial interventions were effective in reducing distress. Some involved supportive-expressive interventions, while others emphasized more cognitive-behavioral approaches and training in active coping. However, five others studies show no effect of psychotherapy on survival time. All but one involve breast cancer patients; the other lung and gastrointestinal cancers. Only two of these five studies were able to demonstrate psychological effectiveness in reducing distress. One study conducted by Pamela Goodwin was a major multicenter trial using the supportive-expressive model. This program was quite effective in reducing distress, but there was no treatment effect on survival time. Clearly further evidence is needed to resolve the provocative question of whether or not group psychotherapy affects cancer survival time. The mechanisms underlying such an effect may involve influence on daily activities such as diet, exercise, and sleep, or on adherence to medical treatment, or may involve changes in endocrine and immune function as well. Thus there is growing evidence that psychotherapy for the medically ill is a powerful and important treatment, with marked psychological and possible physical effects. The medicine of the future would do well to take these psychosocial effects into account. When we rediscover the role of care as well as cure in medicine, we will help patients and their families better cope with disease, and may also better mobilize the mind and body's resources to fight illness.

IV. SUMMARY

Group therapy for cancer patients involves attention to enhancing social support; encouraging emotional expression and processing; confronting existential concerns; improving relationships with family, friends, and physicians; and enhancing coping skills. These include taking a more active stance toward disease-related problems, and learning techniques such as self-hypnosis for pain control. Group leaders emphasize the here-and-now, personalizing discussion by making the group interaction itself the focus of discussion. Thus group relationships, feelings, and coping experience intensify learning and solidarity. Such group therapy approaches have been shown to reduce distress, enhance

coping, and ameliorate symptoms. There is some evidence that they may even enhance the quantity as well as the quality of life.

GLOSSARY

conditioned reinforcer A previously neutral stimulus that acquires its reinforcing properties through its pairing with an unconditioned reinforcer or another conditioned reinforcer.

discriminative stimulus Stimulus in the presence of which a response is reliably reinforced.

fading The systematic removal of prompts or other supplementary discriminative stimuli so as to facilitate independent responding.

prompt A supplemental discriminative stimulus that is presented to facilitate the emission of a correct response, but is gradually removed so as to encourage independent responding.

reinforcement A contingent relationship between a behavior and a behavioral consequence, in which that consequence causes the behavior to increase in frequency.

stimulus generalization The spread of the effects of reinforcement to stimuli not correlated with reinforcement, but that are similar along some dimension to a stimulus or stimuli that are correlated with reinforcement.

task analysis Breaking a complex task or skill down into its correct sequence of components.

I. DESCRIPTION OF TREATMENT

Chaining is an instructional procedure used to teach complex skills or tasks that are made up of several individual discrete components, which must occur in a specific sequence in order for the skill to be correctly performed. Such a sequence of responses is defined as a chain. Many daily living skills can be conceptualized as chains of responses. Preparing a bath, for example, is a task that requires the emission of several responses in a specific sequence in order to be performed correctly. In order to identify the individual responses comprising a chain, a task analysis must be conducted, in which the skill or task is broken down into a detailed listing of its component subtasks or subskills. For preparing a bath, a task analysis may include securing the plug in the drain, turning on the faucet, testing the water temperature, adjusting the water temperature, and stepping into the tub. When performed correctly, there is no break from the completion of one response of the chain to the next, and the final reinforcer of a warm bath becomes available only after the completion of the entire chain. Cooking a meal, getting dressed, and setting a place-setting are similar examples of chains.

In order to establish new behaviors via chaining, several variables will enhance the likelihood that a procedure is successful. First, it is imperative that an accurate task analysis be completed before instruction begins. Each response in the chain must not only be identified, but the correct order in which each response

occurs must also be specified. Observing the demonstration of a skill by a person who has mastered that skill will help ensure the accuracy of a task analysis. Second, only complex skills that include responses that are already in the individual's repertoire should be taught; this will be much easier than attempting to establish a complex skill that includes responses that are difficult for the individual to perform. Third, over the course of instruction, it may be necessary to prompt the individual to respond correctly. Prompts can be modeled, verbal, gestural, or physical, and will facilitate acquisition by ensuring that the individual is successful. Prompts will be particularly beneficial in helping the individual transition between each response of the chain. However, because the ultimate goal of chaining is for the individual to perform the task independently, it is important that the degree of assistance with which an individual is provided is gradually faded or reduced over the course of teaching. Fourth, reinforcing or providing verbal feedback for the correct emission of each response in the chain will also facilitate acquisition. But because outside of the context of instruction reinforcement is not made available until the entire chain has been completed, it will be necessary to gradually fade or reduce feedback that is provided during the chain.

II. THEORETICAL BASES

Chains that an individual has mastered are performed fluently; each individual response is performed with ease and the individual demonstrates a smooth transition from one response to the next. Because reinforcement does not occur until the end of the chain, it may be difficult to understand how responding during the chain, particularly one that is made up of many individual responses, can be maintained. Delayed reinforcement is seldom as effective as reinforcement that is delivered immediately following a response. We can understand how delayed reinforcement maintains responding during the chain if we acknowledge that with the emission of each response of the chain, new stimuli are introduced into the environment that may come to have both discriminative and conditioned reinforcing properties. For example, turning on the faucet introduces a new stimulus into the environment, the sight of running water. This stimulus may now occasion the next response of the chain, the response of testing the temperature of the water. This response also introduces a new stimulus into the environment, the feeling of

water of a certain temperature on the finger. This stimulus may now occasion the next response of the chain, the response of adjusting the temperature of the water, and so forth. Thus, response-produced stimuli may be established as discriminative for the next responses in the sequence of responses making up a chain. In addition, because those stimuli are temporally paired with the delayed reinforcer that becomes available at the end of the chain, they may be established as conditioned reinforcers, which maintain the responses that produce them. For example, the sight of running water may come to reinforce the response of turning on the water, and the feel of water on the finger may come to reinforce the response of touching the running water to test its temperature. It seems, then, that chains need not only be regarded as complex tasks made up of a series of individual responses, but as sequences of response-produced discriminative stimuli and conditioned reinforcers. Very lengthy chains can thus be easily executed and maintained by the stimuli that are produced as the chain is completed, despite the fact that the final reinforcer is delayed.

III. PROCEDURES FOR ESTABLISHING CHAINS

Chains that are frequently performed or for which individuals have had a great deal of practice are often performed with ease. Although persons with developmental disabilities may prove capable of demonstrating the individual components of a skill or task, they may experience considerable difficulty executing the entire sequence of responses consistently and accurately. Special instructional methods must be employed in order to ensure an individual's acquisition of a response chain, as well as his or her completion of a chain in the absence of adult instruction or intervention. There are three methods that are typically used to establish new behaviors via chaining. These include forward chaining, backward chaining, and total task presentation (also sometimes referred to as whole, concurrent, and simultaneous task presentation).

A. Forward Chaining

The first procedure for establishing new behaviors by chaining is forward chaining. In this procedure, the first response of the sequence is taught to an individual. When he or she has mastered that first response, the first and second responses of the chain are linked together,

and are then taught until the link has been mastered. Next, the first three responses of the chain are linked together, and are then taught until that link has been mastered, and so forth, until the individual eventually masters the entire chain. Thus, forward chaining is used to teach chains by constructing longer and longer links and adding one response at a time, starting at the beginning of the chain and working forward. The individual's success determines when each next response is added to the most recently taught link. An advantage of forward chaining is that it is conducted according to the natural order in which the individual responses comprising skills or tasks occur in everyday situations.

B. Backward Chaining

A second procedure for establishing behavior by chaining is backward chaining. As the name suggests, in this case the chain is constructed by teaching response links in the opposite order from which the skill will eventually be performed. In other words, the last response to be emitted before the chain is completed is taught first, then the second-to-the-last response and the last response are linked together and taught next. The third-from-the-last response is then linked to the second-to-the-last and the last responses, and that link is taught next, and so on, until the first response of the chain has been linked. Thus, like forward chaining, new behaviors are established by constructing longer and longer links and adding one response at a time, contingent on the individual's success. In this case, however, instruction starts at the end and proceeds backward through the chain. Backward chaining may seem to be counterintuitive, for in no situation would we wish for an individual to actually perform a skill backward. However, backward chaining is a very effective procedure for establishing new behaviors in the repertoires of persons with developmental disabilities. By beginning at the end of the chain, the stimuli that are produced by each response of the chain are more proximal with reinforcement than is the case for the stimuli that are produced by responses at the beginning of the chain. For a neutral stimulus to be established as a conditioned reinforcer, it must be highly correlated, or closely paired temporally, with another conditioned reinforcer or an unconditioned reinforcer. When a new behavior is taught via backward chaining, the discriminative stimuli that are produced by responses near the end of the chain are thus established as highly effective conditioned reinforcers, which maintain the responses emitted earlier in the chain as instruction proceeds

backward. Likewise, as training continues, the discriminative stimuli produced by each preceding response in the chain is then temporally paired with already established conditioned reinforcers, thus establishing new conditioned reinforcers that maintain the beginning responses of the chain. Hence, backward chaining may be desirable when one wishes to establish lengthy response chains, and for individuals who have trouble tolerating delay-to-reinforcement intervals.

C. Total Task Presentation

The third procedure for establishing a new behavior by chaining is total task (also known as concurrent, simultaneous, or whole task) presentation. This procedure requires that the individual attempt to correctly emit all of the responses from the beginning to the end of the chain on one training trial, and the trial is not considered complete until the individual has worked through the entire chain. In other words, unlike forward and backward chaining in which single response units are gradually linked together until the entire chain is mastered, total task presentation requires that the individual attempt the entire chain from its onset. As was the case with forward chaining, an advantage of using total task presentation is that the skill is taught in the natural sequence in which it occurs outside of the context of instruction. For very lengthy chains, however, it may prove challenging for an individual with a developmental disability to work through the entire chain on one trial.

IV. EMPIRICAL STUDIES

A. Forward Chaining

In 1987, John LaCampagne and Ennio Cipani used forward chaining to teach four adults with developmental disabilities the complex task of paying bills. Specifically, check-writing was defined as the occurrence of a sequence of six discrete responses: (1) Payee recorded on check, (2) date entered on check, (3) amount of payment entered in numerical form, (4) amount of payment entered in written form, (5) check signed, and (6) account number from bill entered on check. The first response of this chain was taught until the individual demonstrated the response correctly and independently five to eight times consecutively, after which the second response was added. The first two responses were then taught until the individual demonstrated this

link correctly and independently on five to eight consecutive trials, and so forth. Verbal instructions, modeling, and rehearsal were used to prompt correct responses as the links of the chain were mastered, and verbal feedback was provided for correct and incorrect completion of each response link. Prompts were gradually faded until the particular links of the chain could be successfully performed independently, and feedback was gradually faded until it was eventually only presented following the correct execution of the entire chain. This procedure was effective in establishing check-writing skills for all four participants; moreover, these skills were maintained over a 2-month period during which instruction was not provided. The established chain of responses was also shown to generalize to bills that were unfamiliar to the individuals or had not been used during the original training.

B. Backward Chaining

In 1996, Louis Hagopian, Debra Farrell, and Adriana Amari used backward chaining as a treatment for liquid refusal that was demonstrated by a developmentally disabled child with severe gastrointestinal problems. The authors hoped to teach the individual to independently drink water from a cup, using a preferred activity as a reinforcer. The task analysis consisted of the following: (1) Bringing a cup of water to the mouth, (2) accepting water into the mouth, and (3) swallowing the water. On each trial that the child responding correctly, he was reinforced with the opportunity to cut paper with scissors for 90 seconds. Each teaching session consisted of five trials, and the child was required to perform with 100% accuracy on two consecutive sessions before a new response was added to the link. First, reinforcement was delivered contingent on the child's swallowing, in the absence of water in the mouth, after being prompted. When the child demonstrated this response to criterion, reinforcement was provided contingent on swallowing after a syringe of water was depressed into his mouth. When this response link was demonstrated to criterion, reinforcement was then delivered contingent on accepting and swallowing water placed into his mouth from the syringe. When this response link was demonstrated to criterion, the amount of water that the child was required to accept and swallow from the syringe was gradually increased. Next, reinforcement was provided contingent on the child's bringing a cup of water to his mouth, accepting it, and swallowing the water. This chaining procedure was thus successful in establishing water consumption, and the child's drinking of water

was shown to generalize to settings different from that in which the original training had been conducted.

C. Total Task Presentation

In 1988, John McDonnell and Susan McFarland used total task presentation to establish laundromat skills in the repertoires of four high school students with severe developmental disabilities. The task analysis for the operation of the washing machine consisted of the following six steps: (1) locating an empty washing machine, (2) adding soap, (3) loading the clothes, (4) setting the wash cycle, (5) inserting the four quarters into the coin slide, and (6) activating the machine. The students were required to complete all of the responses in the chain in order on a given trial, and were provided with verbal feedback for the correct, independent emission of each of the six individual responses. Students received three training trials on the entire chain during a given session. A response was considered correct if the student completed the response accurately and independently. A response was considered incorrect if the student did not initiate the response within 5 seconds from the time the last response was completed, performed the response incorrectly, or was physically or verbally prompted to complete the response. Probe trials were inserted into the sessions of training trials, in which the students' ability to complete the entire task without assistance or feedback from teachers was assessed. The procedure was successful in establishing laundromat skills for all four participants.

D. Effectiveness of Each Procedure

It may not always be easy to discern under what conditions each of the three chaining procedures may be the most effective. The nature of the task at hand, the individual, and the amount of instruction time available are all variables that must be taken into consideration when deciding which procedure to use. As mentioned previously, an advantage of forward chaining and total task presentation is that the instruction occurs in the natural sequence in which the skill will be performed in everyday situations. However, some individuals may have difficulties tolerating the delay interval before which the reinforcer at the end of the chain is made available. This may be particularly problematic when establishing very lengthy chains, and when using total task presentation. When establishing a new behavior that consists of a number of individual responses via total task presentation, it may be wise to divide the chain into smaller segments, and teach one smaller segment at a time.

The challenges posed by the length of the delay-to-reinforcement interval in forward chaining and total task presentation make backward chaining seem like a desirable option to use in teaching persons with developmental disabilities. As was stated previously, the response-produced stimuli may serve as more effective conditioned reinforcers with this approach. In 1981, Thomas Zane, Richard Walls, and John Thvedt compared the amount of instruction time that was required to teach adults with developmental disabilities to assemble nine-part assemblies, using both backward chaining and total task presentation. Interestingly, total task presentation resulted in substantially less instruction time than did backward chaining. Similarly, in 1984 Fred Spooner demonstrated a higher acquisition rate for vocational tasks established via total task presentation than for backward chaining for persons with developmental disabilities. However, in 1989, John McDonnell and Brent Laughlin discovered no differences in the acquisition and maintenance of skills established by total task presentation or backward chaining. Moreover, in 1981 Richard Walls, Thomas Zane, and William Ellis showed that forward and backward chaining resulted in substantially fewer errors than did total task presentation when teaching vocational assembly tasks to persons with developmental disabilities. Thus, there is no unequivocal answer as to which is the best chaining procedure to use; the decision must depend on the specifics of the situation at hand. An appropriate resolution would be to base one's decision on data, and attempt all three procedures and select that which suggests the most success.

V. SUMMARY

Chaining is a procedure used to establish complex skills that are made up of several responses, which must

be performed in a particular sequence for the skill to be executed correctly. Reinforcement does not become available until the end of the chain. The responses constituting a chain may be maintained by response-produced stimuli, which function as conditioned reinforcers. Such stimuli may also have discriminative properties. Forward chaining, backward chaining, and total task presentation are all procedures for establishing new behaviors by chaining. There are different advantages associated with each of the three types of chaining, and research has provided different answers. Which procedure to use depends on the particular situation. Chaining will be most effective if a thorough and accurate task analysis of the skill is completed, if the chain includes responses already in the individual's repertoire, and if prompts and reinforcers are provided for individual responses within the chain, but are gradually faded.

difficulty with mental tasks, feelings of worthlessness or guilt, or possible thoughts or plans of suicide.

psychosocial functioning Ability to perform in psychological, social, and occupational realms.

psychotic Psychosis is characterized by significant disruptions in thought patterns due to intrusions by hallucinations, delusions, or gross disorganization of speech or behavior.

transference Childhood prototypes for interacting with significant others are unconsciously applied to figures in one's adult life; that is, old wishes, expectations, and conflicts may unwittingly shape current relationships.

GLOSSARY

conflict (intrapsychic) When requirements or elements are opposed to each other within a person's mind, such as a wish being judged internally as wrong or unacceptable, or two contradictory emotions.

countertransference Defined most broadly, the therapist's internal reactions—thoughts and feelings—both conscious and unconscious, to the individual patient.

defense mechanisms Mental operations unconsciously directed toward internal states of mind that a person desires to keep out of awareness because of threatened distress. For example, if someone is very angry with another but unintentionally behaves in an overly friendly or solicitous manner because experiencing the anger would be too threatening, it might be said that the defense mechanism of reaction formation is being used.

drives Internal pressure arising from innate patterns of experience such as aggression or sexual attraction.

major depression A sustained period of at least 2 weeks during which a person has a substantial lowering of mood or loss of interest or pleasure in normal activities, accompanied by changes in appetite or weight, sleep disturbances,

I. INTRODUCTION TO THE CONCEPT OF CHARACTER

The construct of character is a complex one, with a long and illustrious history. Robert Liebert has aptly articulated the conundrum we face when considering the meaning and significance of character:

It has become customary that any paper on character begin by emphasizing the confused conceptual status of the term—a term that comes down to us from ancient Greece. Its etymological roots, significantly, refer to that which is carved or engraved. Character has been a subject of concern for Aristotle, the Stoics, and every theologian, dramatist, gossip, Boy Scout leader, and psychoanalyst ever since. Our exploration of character is further complicated by the fact that the term has technical meaning in our discipline and also has varied connotations that are established in common parlance.

We must, then, at the outset define what we mean when we talk about character—a person's typical ways of perceiving and thinking, forms of emotional experience, and behavioral and activity patterns—what we generally think of as personality. Although specific proclivities may wax and wane, most individuals are recognized by others as having a style of approaching the world, even if that might be predictably unpredictable. For instance, we might use more commonplace terms such as easygoing, odd, or high-strung to describe various types of people. However, because we are considering character within the context of treatment, our discussion is focused more on trait clusters, enduring conflicts, and pervasive coping deficits that cause significant impairment and distress. The general term we use is character pathology, but specific "personality disorders" are mentioned, as well. Finally, it is important to note that the phenomena described exist on a continuum, with most of the pathological traits representing exaggerated versions of traits seen in normal personality.

Nearly four decades ago, David Shapiro proposed a collection of "neurotic styles" to capture a range of character pathology: obsessive-compulsive, paranoid, hysterical, and impulsive. The obsessive-compulsive character is associated with more stable interpersonal relationships than some other styles, but typical defenses are centered on the repression of instinctual sexual and aggressive drives, with patterns of highly regulated gratification and ongoing denial of interpersonal and intrapsychic conflicts. Self-willed and obstinate, with a constant eye toward rules and regulations, and a never-ending list of "shoulds," people with obsessive-compulsive attributes guard against any meaningful consideration of their impulses toward others. Maintaining control over internal experience and the external world is a top priority, so rigidity is often a hallmark of this character type. Except in its most severe manifestations, obsessive-compulsive character pathology is less impairing than some of the others and more readily ameliorated by treatment.

First written about at length by Sigmund Freud, the hysterical style conjures up images of dramatic scenes staged by people who are impressionable and highly distractible. When asked to describe themselves, others, or daily situations, people with this style will produce global and diffuse portraits. Because of associated inhibition in cognitive functioning and memory due to internal conflict, individuals with the so-called hysterical character may appear to be deficient in intellectual knowledge and shallow in emo-

tional experience. It has been traditionally more associated with women.

Considered to be more severely pathological than the others discussed, the paranoid style is associated with pervasive suspiciousness. Others' motivations are constantly called into question, with diligent surveillance for evidence to confirm these assumptions, making the individual guarded and tense. Although this type of personality must be distinguished from schizophrenia and other primarily psychotic disorders, the paranoid dynamic may, at times, become severe enough to cause lapses in the ability to grasp reality. The potential for difficulty in treating people with such traits should be readily apparent.

The impulsive label relates to a group of styles sharing the common characteristics of lack of control and impairment in deliberateness, leading the individual to act on a whim, being unable to delay gratification or tolerate frustration. There is a disjunction between taking action and any understanding of the motivation behind it. Shapiro attributed impulsive character pathology to a diverse range of problems and behaviors ranging from those of psychopaths, to alcoholics and drug addicts, to people with narcissistic issues.

Narcissistic character traits have received considerable attention in the clinical literature. Andrew Druck has described individuals for whom there is a fundamental deficit in the ability to regulate self-esteem without resorting to omnipotent strategies of overcompensation or overreliance on admiration by others. Some people who are narcissistically vulnerable have difficulty in maintaining a cohesive sense of self because of ubiquitous shame, resulting from a notion that they fundamentally fall short of some internal ideal. They look for constant reinforcement from others to bolster their fragile self-images. On the other side of the narcissistic "coin" are people who are intensely grandiose, seeking to maintain self-esteem through omnipotent fantasies and defeating others. They defend against needing others by maintaining fusions of ideal self, ideal other, and actual self-images. Thus, there is an illusion maintained whereby this type of narcissistic person has a sense that, because he or she is perfect, love and admiration will be received from other "ideal people," and so there is no need to associate with inferiors. This character type has been called the malignant narcissist by Otto Kernberg and is one of the most daunting treatment challenges because the patient's psyche is both disorganized and potentially disorganizing to the analyst.

Kernberg has also written extensively on the borderline character, which is characterized by instability in the areas of mood, interpersonal relationships, self-image,

and impulse control. John Gunderson and Mary Zanarini have done extensive work with such patients and have identified central characteristics of what has come to be specifically called "borderline personality disorder": quasi-psychotic thought, self-mutilation, suicide gestures and attempts, abandonment and engulfment fears, a sense of entitlement, and unstable identity. Patients with more severe forms of this disorder may be frequently hospitalized because of life-threatening behaviors. Kernberg's concept of borderline personality organization emphasizes a fragile and shifting sense of self, use of primitive defense mechanisms, and temporary lapses in awareness of reality. This is a broader formulation than that of borderline personality disorder and subsumes other personality traits such as narcissistic, antisocial, and schizoid.

The antisocial personality is associated with ongoing violation of society's norms, manifested in such behaviors as theft, intimidation, and violence to people and animals, or making a living in an illegal fashion such as by fraud, selling drugs, or stealing, for example. Clearly, this style would be found extensively within the prison system. Michael Stone has suggested that there are gradations of the antisocial style, with the milder forms being more amenable to treatment. However, within the broader label of antisocial is a subset of individuals who are considered to be psychopathic. These people, sadistic and manipulative, are pathological liars, show no empathy or compassion, no remorse for hurting others, and take no responsibility for their actions. The most extreme form is manifest by individuals who torture or murder their victims. This represents the extreme end of the spectrum of antisocial behavior and would be the most difficult to treat.

One system for more specifically describing different character pathology is the *Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition* (DSM-IV). Specific diagnostic criteria have been established for ten personality disorders, characterized within three broader clusters. The Cluster A disorders are associated with odd or eccentric presentations and include schizoid, paranoid, and schizotypal disorders. Cluster B disorders are of an erratic or dramatic nature and include borderline, antisocial, narcissistic, and histrionic disorders. The Cluster C group, characterized as anxious or fearful, includes obsessive-compulsive, avoidant, and dependent personality disorders. This is a categorical approach to the classification of character pathology, and it has been widely noted that many people meet criteria for

several of these personality disorders, either within the same cluster or across clusters.

II. GENERAL ISSUES IN THE TREATMENT OF CHARACTER PATHOLOGY

Regardless of the system used to describe the phenomenology of character pathology or personality disorder, it is clear that these are long-standing, problematic and rigidly held patterns of organization. As such, patients with character pathology are likely to present for treatment with impaired coping strategies, troubled or nonexistent relationships, and related difficulties, such as anxiety, substance abuse, and depression. Thus, transcending diagnosis and treatment approach, the fundamental goal is to assist patients with character pathology to develop more flexible thought and behavior patterns to replace their maladaptive ways.

To accomplish this broad goal, the clinician must be able to engage the patient in a constructive therapeutic endeavor. Although establishing an alliance is important in all types of treatments for patients with all types of presenting problems, it is of fundamental importance in working with individuals with character issues. Forming an alliance is often extremely difficult, particularly in work with patients with severely narcissistic, borderline, or paranoid proclivities, as troubled interpersonal attitudes and behaviors will also infuse the patient's engagement with the therapist. Narcissistic patients may not be able to allow the therapist to be a separate, thinking person for quite a long time, whereas someone with borderline issues may exhibit wildly fluctuating emotions, attitudes, and behaviors, thwarting the potential helpfulness of the treater.

Countertransference on the part of the therapist must be monitored closely, as interactions with difficult patients may often be provocative, inducing reactions that must be carefully managed. Treatment approach and technique must also be flexible, so that interventions can be made appropriate to the individual patient's style. One-size-fits-all treatment is inappropriate and ill advised. Otherwise, the alliance may be jeopardized, the patient will not benefit or may leave treatment altogether. Furthermore, it can be expected that noticeable improvements in symptoms and functioning will likely require a significantly longer period of treatment when compared to patients with no character pathology.

III. PSYCHODYNAMIC PSYCHOTHERAPY AND PSYCHOANALYSIS

A. Description

The practice of psychodynamic psychotherapy and psychoanalysis is based on a collection of perspectives that have evolved since Freud's original work began over a century ago, and the basic concepts and techniques are explicated elsewhere in this volume. However, it is important in setting a context for the discussion of the treatment of character pathology to reiterate that the psychodynamic/psychoanalytic approach, most generally speaking, utilizes the relationship between patient and therapist as a primary vehicle for change and focuses on enduring patterns of thoughts, emotions, and behaviors that may or may not be in conscious awareness. Psychodynamic psychotherapy is informed by psychoanalytic theory, and psychoanalysis is considered to be a more intensive form of treatment compared to psychotherapy, because it most often entails four or more sessions per week.

The therapist's stance toward the patient and the kinds of interventions chosen should be based on the particular types of character issues most salient for the individual patient, and the approach may vary according to the patient's needs in any given session or during different phases of the treatment. Glen Gabbard has stressed the importance of understanding that there is usually a mixture of expressive and supportive elements in every analysis or psychodynamic psychotherapy. That is, the expressive, insight-oriented mode of assisting patients in uncovering unconscious conflicts, thoughts, or affects through interpretation or confrontation may be appropriate at times, while a more supportive approach of bolstering the patient's defenses and coping abilities is preferable in other circumstances.

For instance, the severely narcissistically impaired patient may not be able to tolerate the analyst's interpretations of his or her unconscious motivations for quite a long time, so that supportive, empathic communications may be more effective interventions in building an alliance by helping the patient feel heard and understood. Similarly, it may be difficult to focus on more insight-oriented interventions with a patient with borderline impairments until that patient is assisted in achieving a safe, more stable working relationship in treatment. Conversely, a patient who is characterized by obsessional difficulties may benefit earlier in treatment by interpretations of the repressed conflicts that may underlie the symptoms.

B. Theoretical Bases

Therapeutic work is also guided by the clinician's utilization of various theoretical models about the nature of the etiology of character pathology. Although psychoanalytic theories abound about the nature of psychopathology and its treatment, we focus on several main schools of thought that relate directly to character: object-relations theory, self psychology, and ego psychology.

1. Object Relations

The object-relations (the term "object" refers to person) perspective views the individual's earliest relationships with primary caregiving figures as focal points for understanding the salient features of how he or she relates to others as an adult. Explaining this phenomenon from the perspective of internalized object relations, Fred Pine described the psychology of the individual as "coming about through the laying down as memories and fantasies of early interactions (or imagined interactions) between the person and significant caretakers, so that behavioral expectancies, longings for particular gratifications, knowings of behaviors that will produce expectable responses are recorded and can be repeated." Clearly, central to this way of thinking is that all people construct mental representations of self in relation to others that become influential entities in both the conscious and unconscious mind.

Character pathology, within this framework, may result from disruptions at various points of development causing the child to internalize relationships as "bad," leading to maladaptive psychic constructions. The more primitive the level at which the early representations remain, the more distorted later representations are likely to be. Object-relations theory posits a model of treatment, then, that is based on modifying pathological images of self and others.

2. Self Psychology

Originally formulated by Heinz Kohut, and elaborated on by others, the self psychology paradigm focuses on the role of external relationships in the shaping and maintenance of self-concept and self-esteem. Kohut developed this approach while treating severely narcissistically disturbed patients who appeared to require certain kinds of responses from others in order to be able to function. Although everyone has the need throughout life for a certain amount of affirmation from others, people with narcissistic problems require excessive ongoing validation and confirmation to maintain any equilibrium. Kohut suggested that there may not have been appropriate "mirroring" of self by

caretakers who could not empathize with the child's experience when exhibitionistic behavior was a phase-appropriate part of development, consequently impeding the child's formation of a stable identity. As a result, an adult person with narcissistic difficulty cannot internally regulate his or her sense of self and so may feel required to be perfect, or to perform for others to gain adequate attention, constructing a grandiose self. Others do not exist as separate individuals, but merely as objects for gratifying needs.

This dynamic for need gratification might be manifest in treatment in the form of a "mirroring transference," whereby the patient is compelled to act in various ways to try to gain the therapist's admiration and approval. At the same time, Kohut also described an "idealizing transference" in which the therapist is seen as the powerful and perfect figure who can protect and heal, and the patient's status is boosted merely by association. The self psychology approach has been influential in informing therapists about the nature of narcissistic issues, and the important role of empathy in helping patients with character pathology to develop more cohesive and stable self-identities.

3. Ego Psychology

Freud, in *The Ego and the Id*, proposed the structural model of the mind with its three components: the id, ego, and superego. In his earlier work, he described a conscious aspect of the mind, responsive both to external stimuli as well as to intrapsychic events relating both to the natural impulses and wishes residing with the id, and to the directives and prohibitions issued by the superego, the residence of societal and parental values. This mediator between internal and external was designated as the ego, and from here ego psychology arose. The concept has been studied and greatly elaborated on as psychoanalytic thinkers realized the complexity of the ego's functions.

As the discussion continued, two branches of ego psychology and structural theory eventually arose. The first, which emerged in the 1930s and was most closely associated with Anna Freud, was oriented toward the defensive functions associated with the ego—those unconscious operations that occur in response to instinctual drives and fantasies that must be tempered to accommodate social demands in the real world. Pathology arises from conflicts among structures, id versus superego, ego versus superego, id versus ego. Therefore, the role of the analyst is to address the patient's unconscious conflicts by making these dynamics conscious.

However, as psychoanalytic discourse continued to evolve during the 1940s, there were others such as

Heinz Hartmann who shifted the emphasis to the ego as an entity primarily concerned with adaptation. That is, the importance of understanding patients' ways of dealing with reality became the emphasis, which helped to expand psychoanalytic theory's explanation of normal as well as pathological psychology. While Anna Freud's approach focuses on conflict (although she recognizes adaptive functions as well), Hartmann underscored the ego's functioning in nonconflictual spheres as well.

Within the ego psychology model, a system of unconscious defenses was elaborated. When there is conflict among structures, id versus superego, for example, painful anxiety may arise that the person may not want to experience. Therefore, various kinds of compromise formations occur as the result of defenses such as repression, projection, reaction formation, and splitting. Defenses are pertinent for understanding character pathology, as different styles are associated with different emphasis on the types of defenses typically employed.

To illustrate, as described earlier, a person with an obsessional style may be prohibited in some ways by his or her superego from expressing anger and aggression, leading to the repression of these emotions to keep them from conscious awareness. The price of repression, however, from a character standpoint, may be ongoing unemotionality, rigidity, and anxiety. The person who is predominantly paranoid uses projection as a defense, that is, he or she ascribes his or her own aggressive impulses to someone else. One of the key features of borderline personality is the use of the splitting defense, whereby ambiguity that cannot be tolerated because of the emotional turmoil it creates leads the person to see the world in black-and-white terms, vacillating between all good or all bad. This picture can be very disruptive to treatment, as there is often a pattern of alternative idealization and denigration of the therapist.

C. Case Example

Consider a vignette from the treatment of a 26-year-old female patient, whom we will call T. T. is a graduate student, recognized as quite promising in her field. She came to session wanting to talk through a recent incident occurring at a conference where she presented a paper. She was the only member of the panel who had not yet obtained a Ph.D., and the others, and many in the audience, were already professors. T. described how she had taken a stand in her paper that sounded reasonable but was apparently considered iconoclastic. Thus, although she took a risk in asserting herself in this way in this forum, she did so knowing she usually had no problem discussing her intellectual ideas. T.

was upset, partially because she was attacked by the discussant and various audience members for her position, but mostly because she found herself capitulating and not making much of an attempt to defend her argument, cheerfully accepting their comments. (T. often finds herself avoiding conflict.) Furthermore, as is typical for her, she had subsequently become depressed because her talk was not uniformly praised and lauded by all present. She wanted assistance in understanding her behavior and ensuing reaction.

There are various ways to conceptualize T.'s dynamics, but we suggest one possibility using the three approaches of object relations, and self and ego psychology. First, from the perspective of ego psychology, we might view T.'s capitulation and putting on a positive face, frequent behavior that could be considered characterological, as stemming from the id-generated aggressive and competitive strivings that were met, not only with external opposition, but also with superego prohibitions against challenging her elders. Her solution was a passive surrender to the authority figures as a defense against her unconscious wishes. The defense mechanism used in this case would be considered a reaction formation, meaning she responded in the opposite manner to the way she really felt. She wished to attack back, but instead, was cordial and friendly. This would be a more traditional conflict–defense way of understanding her behavior, and the therapist would most likely interpret this dynamic by drawing the patient's attention to how she staved off undesirable impulses.

The fact that she became depressed because she was not responded to as a superstar reflects ongoing narcissistic issues. From a self psychology standpoint, it is apparent that T. needs a great deal of validation and admiration from others or her self-esteem collapses into depression. The object-relations piece might be that she has an internal model of herself needing to be perfect or she will be rejected as bad by others. The interventions that would follow from formulating this aspect of the case in this manner might be to empathize with how difficult it must have been for her to get the reaction she did, and to try to help her reflect on her tendency to condemn herself for not being perfect, ending up becoming depressed.

IV. COGNITIVE-BEHAVIORAL THERAPIES

The cognitive-behavioral tradition, generally speaking, focuses predominantly on consciously available

thoughts and observable behaviors. Compared with psychoanalysis and psychodynamic psychotherapy, cognitive-behavioral treatments tend to be shorter in duration, more specifically goal oriented and skills focused, with more directive interventions by the therapist. There are several treatment variations from within this paradigm that have been developed specifically for character pathology.

A. Cognitive Therapy for Personality Disorders

1. Description

Aaron Beck and his colleagues originally developed a cognitive approach for treating depression and subsequently extended its application to problems associated with personality disorders. Fundamental to this approach is assuming a stance of “collaborative empiricism,” that is, the therapist and patient together collect information about the patient's typical and troubled ways of thinking, feeling, and behaving, particularly in the context of problematic situations. An explicit profile of the patient's problems is proposed, goals for the treatment are agreed on, and treatment is focused on modifying maladaptive thoughts and behavior patterns. Because of the nature of character pathology, particularly those with more severe problems such as borderline personality, certain modifications were made to the cognitive approach. First, it is assumed that treatment will take longer, that the collaborative approach between patient and therapist must occur within clearly established boundaries, and that more pervasive and entrenched patterns of thinking and activity will be the focus of therapeutic work. In addition, the therapy relationship in and of itself may be the focus of attention at times because character pathology often serves to make an ongoing collaboration difficult to sustain.

2. Theoretical Bases

Cognitive therapy rests on the assumption that people are information-processing beings who develop characteristic ways of thinking about and interacting with the environment. Psychopathology arises when maladaptive responses are developed stemming from perceptions and beliefs that became distorted because of innate sensitivity, early social learning, and, in certain cases, traumatic events. People are thought to respond to the environment based on their established “schemas,” which include intrinsic assumptions about how the world works and how one should respond. Behaviors become programmed based on the individual's

particular collection of schemas. In most cases, patterns have become automatic and so are outside of the person's immediate awareness.

When cognitive therapy is applied to character pathology, it is assumed that broader core beliefs, rather than merely selected processing errors, are at the root. Character pathology is seen as resulting from dysfunctional "pervasive, self-perpetuating cognitive-interpersonal cycles" in which experiences often end up confirming long-standing maladaptive schemas. Beck believes that personality traits evolved originally as a set of stereotyped, but adaptive, strategies for responding to the environment. Personality disorders arise when traits are no longer appropriate to environmental circumstances.

B. Schema-Focused Cognitive Therapy

1. Description

As an extension of Beck's cognitive therapy for personality disorders, Jeffrey Young and his colleagues formulated the concept of an "early maladaptive schema," defined as "a long-standing and pervasive theme that originates in childhood; defines the individual's behaviors, thoughts, feelings, and relationships with other people; and leads to maladaptive consequences." Applied specifically to characterological issues, the goal of schema-focused therapy is to help patients to identify cognitive distortions and challenge underlying beliefs that routinely result in impaired psychosocial functioning. For example, one might hold to a maladaptive schema centered on the fear of being abandoned, which results in excessive jealousy and clinging in relationships. The therapeutic approach would be to assist the patient in uncovering his or her assumption that significant others will inevitably leave and the connection of that assumption to particular behavioral and emotional responses. Over time, the patient is encouraged to develop other ways of relating to replace the counterproductive modes, accompanied by shifts in thinking and affective reactions.

2. Theoretical Bases

Maladaptive schemas arise as deeply entrenched patterns of response that developed as the child tried to organize personal experience of himself or herself and others in a world that may have been filled with abuse, instability, or neglect. Although they may have served as logical solutions in childhood, they remain in play in adulthood as ineffective means for meeting basic security and intimacy needs, and, thus, are asso-

ciated with negative emotions and impaired functioning. David Bricker, Jeffery Young, and Catherine Flanagan have proposed three domains, or groupings, of schemas: instability and disconnection, impaired autonomy, and undesirability.

C. Dialectical Behavior Therapy

1. Description

Dialectical Behavior Therapy (DBT), developed by Marsha Linehan, is a method developed specifically for the treatment of borderline personality disorder, particularly for those patients with chronic problems with suicide gestures and attempts. Combining techniques from cognitive, behavioral, and supportive approaches, the goals of the therapy are to reduce life-threatening behaviors, behaviors that interfere with the treatment process itself, and behaviors that significantly impair quality of life. DBT is based on a manual, and patients participate in both weekly individual and group therapies for 1 year. During this time, individual therapists are accessible by telephone between sessions, and the groups focus on skills training targeting interpersonal, distress tolerance, and emotional regulation issues.

2. Theoretical Bases

Within the DBT paradigm, the nature of borderline disturbance is thought to revolve around impaired regulation of emotions, stemming from biological sensitivity interacting with an early environment lacking in emotional validation. Linehan has defined the term dialectics as "the reconciliation of opposites in a continual process of synthesis." This applies most broadly to the notion that treatment must provide an environment of acceptance of the ways patients currently are while also trying to help them change. That is, because of the presumed roots of borderline issues, the patient's current experiences are validated by the therapist, while at the same time, problem-solving efforts are aimed at modifying maladaptive thinking patterns and information processing, and teaching new ways of coping. The therapy relationship is considered central as the laboratory for change, but also because, at times, it is the only thing that is keeping seriously suicidal patients alive.

D. Case Example

The following is an application of various aspects of the cognitive-behavioral models presented to a particular case. K. is a 30-year-old unemployed woman who sought treatment because of difficulties holding down a

job, problems getting along with people in general, frequent outbursts of temper, and intermittent suicide gestures. Initial evaluation confirmed that K., along with symptoms of major depression, suffered from borderline personality pathology. Although highly intelligent, with an advanced degree, K. described how she would always get into struggles with her supervisors because they were envious of her ability and highly critical of her. Both in professional and personal relationships, she would become enraged over perceived minor slights, either blowing up at the other person, or injuring herself with a knife or a razor blade.

If K. found her way to DBT, she would be assigned an individual therapist and join a group. The individual therapist would help her learn how to manage emotional trauma through establishing a hierarchy of issues. Problem-solving techniques would first target those issues at the top of the hierarchy, such as her self-harm behaviors and emotional reactions that may jeopardize the treatment. K. would be assisted in reconstructing in detail the series of events that led to a self-harm incident, so that alternative solutions may be explored. From week to week, her hierarchy would be revisited to determine what issue was of highest priority for intervention. Once safety issues were adequately addressed, the treatment would be able to focus more directly on the nature of K.'s troubled interactions with others. The therapist would be diligent in attempting to avoid reinforcing any of K.'s maladaptive patterns. At the same time, in group treatment, K. would receive skills training, such as improving social tactfulness, which helps to enhance and reinforce the work in individual treatment.

In cognitive therapy, K. would collaborate with her therapist in developing a list of goals, with changing self-harm behaviors as top priority. In general, the focus would be on identifying maladaptive thoughts and behaviors so that alternative approaches could be developed. Given K.'s interpersonal sensitivity, the therapist would also be attentive to her engagement or resistance to cooperating in the therapeutic endeavor. If Young's specific schema-focused view were applied, K. would be assisted in identifying specific internal scripts that were not serving her well. For example, K. most likely has some form of an "abuse/mistrust" schema whereby she expects that others will hurt her or react negatively to her in some way. Using the therapy relationship as a model of safety and trust, K. could begin to examine and challenge her assumptions that others always approach her with ill intent.

V. EMPIRICAL STUDIES

In 1999, J. Christopher Perry published an analysis of 15 studies of the effectiveness of psychotherapy for patients with personality disorders. The studies reviewed were the most rigorous of their kind in that the investigators used systematic methods to diagnose the disorders, along with validated outcome measures. 4 of the studies focused on borderline personality disorder: there was one on borderline and schizotypal disorders, one each on avoidant and antisocial personality disorders; and 8 examining mixed types of personality disorders. 6 studies evaluated psychodynamic psychotherapy: three evaluated cognitive-behavioral psychotherapy, and three compared the psychodynamic and cognitive-behavioral treatments. Treatment duration varied, with a median of 28 to 40 sessions. The frequency of sessions ranged from daily in an inpatient study to once or twice weekly for outpatient therapy.

Despite wide variation in patient type, treatment type, and duration and frequency of sessions, an overall pattern emerged indicating significant improvement in psychopathology for patients with personality disorders receiving psychotherapy. In studies reporting the proportion of patients no longer meeting criteria for a personality disorder at follow-up, 52% had "recovered" after a mean of 78 sessions over a mean of 67 weeks. This corresponded to a recovery rate of 26% per year of treatment, seven times greater than the rate observed when the course of these disorders is followed when no treatment is received.

There have also been a number of other research endeavors, such as the Menninger Psychotherapy Research Project, that have employed a variety of methodologies targeting different aspects of psychotherapy treatments of character pathology. Separate review articles highlighting many of these other studies have been written by Mary Target and Glen Gabbard. In addition, a very recent study by Anthony Bateman and Peter Fonagy demonstrated significant reductions in symptoms, including self-mutilation and suicide attempts, and notable improvements in functioning for patients with borderline personality disorder who received intensive psychodynamic psychotherapy over 18 months in a partial hospitalization program. Benefits increased or were sustained at a follow-up evaluation 18 months after discharge. Thus, although some would hold that those with more severe character pathology may not be treatable, empirical work has shown that psychotherapy can be quite effective.

VI. SUMMARY

Character pathology is associated with a long-standing and rigid set of personality traits that cause impairments in a person's ability to adaptively function in interpersonal and occupational realms. Because there are many types of character pathology, or personality disorders, any psychotherapy addressing such problems must take into consideration the salient features of the particular patient's personality so that an effective therapeutic partnership can be formed and appropriate interventions can be applied. There is a range of therapies available from psychodynamic/psychoanalytic treatment that utilizes insight-oriented and supportive elements and the therapeutic relationship as vehicles for change, to cognitive-behavioral strategies that focus on consciously available thoughts and observable behaviors. Regardless of the type of psychotherapy chosen, it should be expected that enduring changes in personality pathology will require an extended period of treatment.

GLOSSARY

conflict Refers either to psychic conflict, which is a struggle between incompatible or opposing forces within the mind or external conflict. Psychic conflict may be between incompatible wishes (e.g., the child's wish to please a parent and his wish to be in control) or between different psychic structures or aspects of the mind (e.g., a wish to make a mess might be opposed by the individual's conscience that upholds values of cleanliness and order). Sometimes psychic conflict may become externalized in the individual's effort to avoid anxiety or other uncomfortable feelings. In this situation a conflict that originates within the individual is experienced as originating from outside forces (e.g., the adolescent who is ambivalent about his sexual wishes may experience himself as unconflicted by imagining that his parent is opposed to his developing sexuality). External conflict describes essential conflicts that arise between the individual and aspects of the outer world, when there are incapacities in either the individual or the environment to meet the other's needs and expectations.

countertransference A complementary term to transference and refers to the therapist's experiencing thoughts and feelings toward the patient that are derived from an earlier period and earlier relationships in the therapist's life. Countertransference is usually mobilized in response to a particular transference of the patient and reflects the therapist's unconscious reaction to aspects of the patient. It may be manifested in the therapist's identification with the patient, by intense emotional reactions both positive and negative to the patient or particular material. When countertransference is unrecognized it can create significant blind spots for the therapist compromising, his or her ability to work clinically by impairing objectivity and empathy. In contrast, when the therapist is able to recognize and analyze his or her own countertransference, he or she may gain significant clues to the patient's thoughts and feelings.

representation Usually refers to a psychic representation, which is an image or configuration of images within the mind. This may be an image that roughly corresponds to a figure or experiences that an individual has had in real life. Representations are very often based on a composite of memories, affects, impulses, and wishes associated with important figures and interactions with those figures that have been experienced in an individual's life. Representations also refer to the images of oneself that are also based on a range of experiences, especially those involving the earliest and most significant relationships.

transference Refers to the displacement of feelings, thoughts, and behavior about significant childhood figures (usually the parents) onto another person. Transferences are thought to be ubiquitous, occurring in and coloring any individual's important current relationships. When the term is used in the context of psychotherapy transference refers to the displacement of thoughts, feelings, and behavior originating

in relation to the individual's parents (or other emotionally significant figures) at an earlier point in time (usually childhood) onto the therapist. Transference is unconscious and involuntary, the sources being unrecognized, and may be experienced by the individual as rational or may feel inappropriate and be a source of internal distress. There is disagreement within child psychoanalysis whether young children are capable of transference since the young child is actively involved with his or her parents in reality. A young child may behave toward his therapist in much the same way he behaves with his parents but this may be less an issue of transference and more the result of habitual ways of interacting with others. For example, a 3-year-old who is imperious and demanding with his parents may be equally so with his therapist, but this is less likely to be transference and much more likely to be the way this child treats any important adult. Latency-age children in the course of psychotherapy may exhibit behavior or feelings that more closely fit the definition of transference in that the behavior can be understood as referring back to an earlier time and relationship with the parent. Adolescents readily exhibit transference and indeed this may form a significant resistance to psychotherapy as the adolescent experiences the therapist as the all-powerful, controlling parent from very early childhood. When transference is understood it can provide clinically useful material that can be used to help the patient better understand himself.

unconscious Used both as a noun to describe hidden aspects of the mind and as an adjective to describe mental content that is not available to conscious awareness. Freud originally believed that the unconscious was a dynamic system within the mind that contained contents and activities representative of the drives that had never been conscious. Characteristics of the unconscious are that there is no negation, contradiction, or ambivalence and that unconscious thought follows idiosyncratic associative paths rather than logical connections. Although the unconscious is not available to direct inspection, derivatives can be seen in dreams, in slips of the tongue, and disconnected thoughts. Current psychoanalytic theory argues that aspects of psychic structure involving adaptation to reality, defenses, and moral judgement are unconscious. Mental content may also become unconscious through the operation of defenses against the experience of intrapsychic conflict.

Psychoanalytic theories of human functioning begin with a focus on the interplay between the child's fantasy world, the organization of mental life and functions, and the experience of the real world. How these domains are elaborated and interact over the course of development is central to psychoanalytic inquiry. Psychoanalysts and psychoanalytically oriented psychotherapists are especially interested in the most

personal of emotions and thoughts and the ways in which individuals reveal or conceal their longings, wishes, fears, pleasures, and dreams to and from themselves and others. Psychoanalytic clinicians are interested in the way children behave and in the interaction between children's inner experiences and their actions in daily life. Of particular concern for analysts and analytic therapists are the ways in which the child comes to understand and represent his or her own inner life and the minds and behavior of others. As such, psychoanalytic theory is primarily concerned with the dynamics of mental processes and individual experience that are influenced by biological, social, and environmental contributions. With psychoanalytic theories as a conceptual frame of reference, psychodynamic psychotherapy attempts to observe the rich details of children's individual experiences as a way into understanding the origins and functions of symptomatic behavior that brings them into treatment.

Psychodynamic interventions are based on the notion that symptoms and problematic behavior that have not yielded to time or changes in the external world derive from a complex matrix of constitutional, developmental, and environmental factors that find representation in children's fantasies and theories about themselves, their expectations of the world, and their adaptation to it. In this context, symptoms are seen as a result of children's best efforts both to resolve and to express in disguised form solutions to conflicts among their wishes, the demands of external reality, and developmental capacities. What distinguishes a psychodynamically oriented intervention from other types of clinical intervention is the therapist's conviction that children's behavioral difficulties have as their source the complex interplay between the wishes and fears inherent to children's inner world; the status of biologically driven, maturational capacities; the pressures of progressive development; and the demands of external reality. Psychodynamic interventions may be employed in varying forms, including psychoanalysis, intensive psychotherapy with several sessions per week over a long period of time, weekly psychotherapy, brief psychotherapy, structured sessions, and parent-child guidance. The guiding principle of psychodynamic intervention is that throughout development, there is a complex interaction between internal and external demands and children's unfolding capacities to meet these demands. The goal of psychodynamic psychotherapy is to help children find alternative solutions to conflicts that have given rise to symptoms that interfere with current functioning and progressive development.

Essential to psychodynamic interventions is the recognition that defenses against danger—whether experienced as emanating from the inner or external world—are felt by the child to be necessary, regardless of how disruptive these defensive maneuvers may be. On that basis, the central task of intervention is to learn in what way symptoms serve to protect children from and help them adapt to unconscious conflict aroused by the demands of development and of everyday life. The therapist's capacity to understand meaning in the child's presentation in play, activity, and discussion occurs in the context of a relationship that provides a safe forum for the communication of feelings, impulses, and ideas that children have about their life, self, and others. As the relationship between a child and therapist deepens, the child becomes better able to tolerate and be curious about his or her inner life and the multiple ways internal conflicts may compromise development and daily functioning.

The clinician's choice of dynamic psychotherapy may be made when considering a range of presenting clinical situations. In addition to being the treatment of choice for children suffering internal conflict, a dynamic perspective also informs treatment considerations for a diverse range of clinical presentations in which internal conflict appears to be absent, such as conduct disorders. In conjunction with pharmacological, educational, and behavioral management interventions, psychodynamic psychotherapy may be the treatment of choice in working with a child who is coping with chronic illness or a matrix of constitutional, cognitive, and developmental deficits or with a child who has experienced acute or cumulative trauma. In each of these clinical situations, the dynamic psychotherapist's primary tasks are to learn the language of the child and to develop a relationship that provides a forum in which the child can explore his or her experience of self and others while trying on new solutions to difficulties that have blocked the path to optimal development.

I. DEVELOPMENTAL FRAMES OF REFERENCE

Conceptualizations about unconscious conflicts are central to any psychodynamic approach to intervention. Here, "unconscious" refers to the dynamic interaction of thoughts, feelings, memories, bodily experiences, and thought processes that operate outside of an individual's conscious awareness. These unconscious configurations of experience exert influence on patterns of

behavior, interactions with others, perceptions of the world, and feelings about the self. Many behavioral symptoms of childhood reflect children's defensive efforts to ward off dangers that they experience as originating in the intensity of their urges and wishes; in the severity of internal, superego judgment of those wishes and feelings; or in the limitations and demands imposed by the environment.

A. Case Example

Five-year-old Jerry was referred by his kindergarten teacher because of his aggressive attacks on the other boys in his class. Jerry's attacks appeared to be unprovoked: He might be playing in an apparently cooperative way with another boy and suddenly become quite angry, accusing the other boy of having tried to grab something from Jerry or of having somehow insulted him. Following these outbursts, Jerry appeared unremorseful, adopting a swaggering, somewhat threatening stance. At times Jerry could be heard bragging loudly to the other boys about his athletic accomplishments as well as his many possessions; some of these tales seemed to reflect reality, albeit with a bit of exaggeration, but others were quite clearly false. Jerry got along very well with his female teacher toward whom he was quite affectionate and whom he sought out frequently for special attention. On the playground Jerry often raced around wildly, drawing attention to himself, declaring dramatically that he was Batman or the fire chief or some other heroic figure. After a careful evaluation, Jerry was referred for once a week psychodynamic psychotherapy. Gradually, in talking and playing with Jerry, his therapist began to understand that Jerry's braggadocio and swagger masked an intense underlying anxiety that he was not big enough or adequate enough in comparison with his classmates. Jerry had anticipated starting kindergarten with some trepidation, worried that he did not know enough academically. His dreams of being a big successful grade school boy were accompanied by fears that he would instead be humiliated by not knowing enough. His attacks against the other boys were Jerry's attempt to restore his precarious self-esteem by appearing aggressively manly at those moments when he felt most threatened by another child's accomplishments, whether real or imagined. Jerry was still quite dependent on his teacher's affection and interest to sustain feelings of self-worth. When he was in situations with his classmates that were more competitive and in which he could not count on his teacher's ready attention, Jerry's self-esteem was

more fragile and more easily threatened by perceived slights. At those moments, Jerry felt in danger of being overwhelmed by feelings of humiliation brought on by his own age-appropriate but quite intense wishes for success that he felt were eluding him. His hitting out and swaggering involved an underlying compensatory fantasy that he was not a little boy who did not know enough but that he was a big, powerful man who would win the admiration of others, especially his teacher, through force.

Children's struggles with basic conflicts between their desires and the limitations imposed by reality and internal moral prohibitions motivate their exploration of alternative forms of expression that both satisfy strong urges and meet acceptable internal and external standards. This compromise solution is shaped by the specific age-typical wishes in conjunction with the child's capacities as set by endowment as well as by opportunities available in the environment. Children's unfolding intellectual and physical resources; opportunities afforded in the social realms of home, school, and the community; and ability to tolerate delay and accept substitute gratification all contribute to their ability to create compromise between competing demands of their inner worlds and external reality. As such, symptoms may also reflect children's efforts to negotiate developmental conflicts as they seek mastery, independence, and pride in midst of increasing demands and dangers.

At each phase of development there tend to be nodal conflicts that inevitably give rise to crises and symptoms of childhood that evoke concern in the adults who are most involved with children. Although the disruption of sleeping and eating behavior and separation anxiety typical in toddlerhood are troublesome to caregivers, they do not necessarily indicate deviation from normal trends in development. These developmentally expectable symptoms are especially salient during the time of children's emerging recognition that they are individuals, separate and different from their parents, whom the children wish to please. Similarly, the nighttime fears, transient phobias, and defiance of 4- to 6-year-old children do not automatically represent psychopathology but, rather, reflect their active attempts to negotiate conflicts between normal feelings of love, hate, jealousy, and competition. Older preschoolers or early grade school children have ambivalent feelings about establishing a greater sense of autonomy. These mixed feelings may be expressed in testing rules, tattling on others, social difficulties, rapid shifts in mood, or heightened concerns about bodily changes; they do not automatically signal the need for clinical intervention.

Additionally, above and beyond the symptomatology of normal development, children's behavior or mood may change in direct response to clear external precipitants, such as moving to a new house, changing schools, parental discord and divorce, acute illness, or exposure to exceptional, traumatic incidents, or it may reflect the stress of coping with cognitively based learning difficulties. Children undergoing such external stressors may require supports or interventions that are informed by an appreciation of the dynamic interaction of multiple contributions, but they do not necessarily warrant extensive individual psychotherapy. When conflicts and attendant symptoms are primarily reactive in nature, work with parents and teachers to alter a child's environment or to increase adult appreciation for the nature of developmental struggles may be sufficient. Such intervention, when based on psychodynamic principles, can help a child mobilize adequate resources to achieve a more adaptive set of responses and so resolve the immediate crisis. Alternatively, at times, a careful evaluation reveals a history of a child's failure to successfully negotiate previous developmental tasks.

When presenting difficulties have not yielded to environmental manipulation, the severity and persistence of symptoms may reflect a relatively intransigent adaptation to internalized conflict that the child experiences as protective but that actually exacts a high price for both the child and those around him or her. In this situation, the adult's logic, suggestions, and admonitions are at exasperating odds to the child's counterproductive, albeit best attempts to resolve the internal conflicts that seem to elude conscious recognition and rational response. In such a case, the psychotherapeutic task with the child is to provide a new, different setting in which the therapist and patient can develop a language for exploring what has heretofore been unknown to both. A therapist should decide to engage a child of any age in dynamic psychotherapy based on a careful evaluation of the patient's presenting difficulties, developmental history, and family and environmental circumstances. Dynamic psychotherapy is called for when the child's difficulties reflect a failure to negotiate conflicts that are at once an essential part of every phase of development and at the same time have become elaborated, and fixed, requiring an expenditure of psychic energy that impedes rather than promotes developmental progression. As such, children may adopt and rigidly adhere to defenses that help them to ward off the danger while constricting the development of new defensive strategies that might provide more flexible adaptation to both internal and external demands.

The adolescent's tasks are negotiating parental emancipation and the sexual and aggressive drives. It has also

been noted that adolescents in some ways recapitulate tasks faced in the first few years of life. During that early age, children must learn to control their volitional outflow. The preschooler, for example, becomes aware that his or her sexual attributes are not sufficient “in that way” to attract the parent of the other gender and that his or her fortitude is not sufficient to fend off the jealousy of the same gender parent. With puberty the adolescent now feels sexually ready and available. A true oedipal victory becomes actually possible. At this time the universal incest taboo comes into play and the adolescent must learn to control the associated emotional outflow. Although adolescents possess the strengths of greater experience and the cognitive ability to think abstractly, their task of becoming an adult is hampered by both the upsurge of their drives and the developmental need to individuate from parents. This latter change partly removes the primary sources of stability and support counted on during childhood. Oedipal feelings suppressed with the advent of the superego often reemerge. The adolescent feels the need to increase the emotional distance from both parents. Not only are parents avoided as people, but also their parental prohibitions internalized within the superego may be distanced. Although unacceptable aggressive or sexual behavior often brings an adolescent into treatment, inner conflicts between progressive and regressive urges are the chief foci of psychodynamic psychotherapy.

II. AIMS OF DYNAMIC PSYCHOTHERAPY

As trial action in thought, fantasy is a testing ground that serves as a refuge from the disappointment of wishes that cannot be fulfilled by reality. When the child is not yet able to give up certain wishes and has been unable to find acceptable alternatives for satisfying the underlying urges, fantasy may serve as both a retreat and as a means of titrating their intensity as new solutions are sought. Thus, fantasy can serve as a respite and as a staging ground on which new responses to internal and external demands and new solutions to conflicts can be practiced. Fantasy solutions themselves may prove to be enormous sources of anxiety and guilt. While serving as a retreat from conflicts aroused by disappointment and/or by frightening reality, fantasy solutions for conflict can also become a distorting lens through which the child now perceives his or her world. These phenomena may best be demonstrated in the case of a child whose experience of real danger invokes fantasy solutions that also contribute to the patient's difficulties.

A. Case Example

Annie was 6 years old when she was involved in a traffic accident while riding on her school bus. She was unhurt, but a classmate suffered serious head injuries after he was slammed against a bus window. Annie entered two times a week psychotherapy when, 6 weeks following the accident, she continued to be symptomatic. She had difficulty sleeping and eating, had multiple new fears, and needed to remain close to her mother at all times. Annie's previous school functioning was good, as was her adaptation in an intact family that included mother, father, and a 10-month-old brother. Her developmental history was unremarkable.

In her individual sessions, Annie repeatedly returned to the scene of the accident, reviewing an increasing array of details in both play with toy figures and in her drawings. Each narrative was ended with Annie looking and stating that she felt scared or “bad.” Over time, the therapist probed these feelings further—either within the action of the play or the narrative that accompanied the pictures. Annie would elaborate that she felt scared she might have been injured in the accident and very bad because her friend had been hurt. In one session, she drew a picture of herself and her friend on the bus. Although the two children had in fact been sitting in different sections of the bus, in her drawing, they both sat on the same seat. She pointed out that even though they were together only one of them was hurt. She then grew quiet and looked forlorn. With the suggestion that there was a connection between her feelings and the story that lay behind the picture, Annie revealed a secret whose telling spanned many sessions and was accompanied by a dramatic reduction and final resolution of her presenting symptoms.

The first part of the secret was that for several days before the accident, Annie had been reprimanded by the driver for bad behavior on the bus. She thought that perhaps she should have been the one injured, as a punishment. Later, she told the therapist that her “bad” behavior had really been about her teasing and poking at the very classmate who was hurt in the accident. The third part of the secret was about her baby brother. With great anxiety, Annie reported that she teased the baby on numerous occasions and that, in fact, she often wished the brother was no longer around. With this, the pieces of her worry and guilt became clearer. She was able to articulate her fear that somehow her bad wishes about pesty brothers had come true in the injuries sustained by her schoolmate in the accident. Annie was terrified that her wishes would be discovered and severely punished. The therapist was able to

point out that Annie was punishing herself as if the reality of the scary events had somehow been under her magical control.

Annie's hostile wishes toward a rival baby brother and their displacement onto a schoolmate was not at all unusual. However, for Annie, the realization of these wishes—if only in the displacement—constituted the central source of her overwhelming anxiety and traumatization. In addition, her sense of magical control reflected age-expectable phenomena but was relied upon for the purposes of restitution and recovery. That is, a belief in magical control would revise the original experience of traumatization or “absence of control” in the accident, even if the belief in magic might also lead to a tremendous sense of responsibility for and guilt about the real and imagined events. Annie's presenting symptoms resolved as play and discussion with the therapist revealed the connection between the traffic accident and her age-expectable wishes and conflicts. When no longer unconscious, the distorting and anxiety-laden solutions to Annie's conflicts became clear to her. Symptoms were no longer necessary as Annie's fear and guilt were replaced by her tolerance of her own feelings. She could recognize that being frightened in the face of an external danger was not a permanent state of infantile helplessness, that hostile feelings about family members did not obliterate loving ones, and that whatever the benefits, a belief in magic does not make wishes come true.

As suggested in the case of Annie, the use of fantasy as refuge from conflict and anxiety may not always be successful or may evoke its own set of problems for the child. While unable to give up the original aims, fantasy configurations may themselves become a source of internalized conflict. Clinging to the solutions found in these fantasies may block more reality-based compromises between wishes and consequences that might be developed. In the face of challenges the child faces in the present, he or she may return to earlier configurations of wishes, unable to utilize new developmental competencies to mediate as well as express current feelings. Retaining their original force, these developmentally regressive fantasies are also experienced as unacceptable; the conflicts that ensue may only find expression in disguised form in symptoms and age-inappropriate behavior. For all of these reasons, Freud's guiding principle of “making the unconscious conscious” remains central to the psychotherapeutic task of alleviating symptomatic presentation and helping children return to the path of optimal development. Psychodynamic treatment attempts to provide a setting in which the child and thera-

pist can observe the different manifestation of their feelings and fantasies and their representation in symptoms and behavior. With the therapist's help, the child achieves a greater appreciation of the conflict between wishes and the demands of external reality and internal moral judgments. Through play, discussion, and interactions in the consulting room, children have the opportunity to try out new solutions in an effort to find a compromise that permits some realization of their wishes while simultaneously adapting to the limitations imposed by reality and by internalized moral values.

Regardless of the unconscious, conflictual sources, academic difficulties; constant fights with peers, siblings, and parents; soiling; enuresis; disturbed sleep and eating; social isolation; drug and alcohol abuse; avoidant behavior and phobias; and depressive withdrawal may cause a great deal of discomfort to patients themselves and to their families. However, from a psychodynamic perspective, these symptoms represent the individual's best attempts to simultaneously defend against conflictual wishes and to give expression to them in a disguised form. While attempting to avoid or modulate threats to well-being, symptoms are highly condensed modes of communication that parents, teachers, or patients themselves have been unable to translate fully and understand. In making the unconscious conscious, dynamic psychotherapy aims to provide a setting in which the patient can safely explore previously “unknowable” aspects of their inner world that give rise to conflict, defense, and maladaptive ways in which they negotiate daily life.

Threats to self-esteem arise from internalized conflicts involving the guilt and shame associated with internal moral judgment as well as with failures of achievement in the external world. For example, by the late preschool years, children recognize that their destructive wishes toward parents or siblings are incompatible with their intense loving feelings and need for these same people. The little boy who wants to destroy all of his competition from the field, particularly his father or older brother, also loves his father, wants to be like him, and needs to feel that his father loves and approves of him. The child may experience so much pain about this struggle between his loving and hating feelings for the father, or other loved figure, that they are pushed out of consciousness, only emerging now in highly disguised or displaced forms. Such conflicts between intense feelings, wishes, and aims occur naturally in development. However, they may be complicated by multiple and interweaving contributions from children's lives, such as (1) a history of risk, or realization

of attack, either emotional or physical, by parents or other caregivers in response to the child's expression of developmentally appropriate needs; and (2) the failure of age-expectable capacities to regulate impulses and needs that lead to feeling flooded and overwhelmed. Children may also fear being overwhelmed by impulses and needs when (1) their capacities for self-regulation are compromised by constitutional hypersensitivities, inadequate visual-motor apparatus, chronic illness, disordered language and cognitive development, skeletal or neuromusculature abnormalities; (2) the mental capacities that are in place are not able to reduce the level of environmental overstimulation—for example, interpersonal violence in the home and in the neighborhood; the absence of external order as represented by consistent parental rules and expectations; exciting exposure to parental nudity or sexual activity; or (3) a history of repeated failure of satisfaction of children's basic needs—such as poor bodily and physical care—with the associated somatic distress, discontinuous and unreliable presence of the caregiver, or inconsistent and unpredictable communication of affection. However powerful the specific stressors or risks might be in the child's life, his or her capacity to mediate their impact is determined by a combination of endowment, available defenses, and countervailing external supports. Optimally, an increasingly broad and sophisticated array of mediating activities, and the background of experience that needs will be met in a timely fashion, allow children to achieve satisfaction, pleasure, and mastery.

Seeking safety and securing pleasure are the most central of human endeavors that guide children's attempts to guard against danger and helplessness. When the dangers and threats are based in current experiences, interventions first must focus on remedying or alleviating the most immediate and persisting risks to the child's development (e.g., mandated referrals to protective services when a child is neglected, abused, or sexually exploited; intensive work with parents, educators, and social services in altering the child's milieu). Similarly, when neuropsychological and other impairments of the physical and cognitive apparatus can respond to pharmacological interventions or remedial assistance, these approaches need to be considered as central to the overall treatment plan. Often, the history of environmental failures or inherent problems of affect regulation or cognitive processing will have had an impact that changes in the environment, educational and pharmacological interventions alone will not ameliorate maladaptive attempts at conflict resolution. At the point that children need to enter psychotherapy,

their attempts to defend against internal pain and discomfort are at too high a price. Their symptoms, effects, and behaviors reflect both the child's best efforts, and failure to negotiate the challenges, demands, and conflicts that are essential components of progressive development.

Unlike adults, children and adolescents rarely are the ones who request or make decisions about entering into psychotherapy. Children are often told that they are going to see a special kind of doctor who helps get rid of worries and difficulties in order that the child is able to feel happier and more successful in life. It is essential that therapists remember that seeing a therapist does not magically or immediately relieve children of their suffering or decrease the need for the defenses and symptoms that have brought them to the consulting room. In fact, many children feel particularly guarded in the treatment situation, believing that their inner thoughts and feelings will leak out or be readily discernible to the therapist who is invested with intrusive and dangerous "mind-reading" powers. Engaging in an evaluation or entering into psychotherapy is especially difficult for most adolescents. Referral usually stems from the desire of a parent or other authority figure whom the adolescent does not fully trust, and may be in outright conflict with. The aim of the therapy to make the unconscious conscious does not vary from the aim with younger children or with adults, but patient-clinician trust is often more difficult to establish with adolescents than at any other developmental phase.

If the patient is to give up current, maladaptive attempts at resolving conflicts, a new setting, a new relationship, and a new language will be required. It is in this new situation that the patient and therapist have an opportunity to explore—through themes and consistent patterns of play, discussion, modes of expression, and ways of engaging—the dynamic interaction between what is internal and what is experienced in daily life. The psychotherapeutic intervention provides a stage on which, over time, the language of the unconscious fantasies, conflicts, defenses, and symptoms can become observable, translatable, and gradually understood. To this end, the psychotherapist engages in the process as an observer, a participant, and an anchor in reality, helping children clarify what they are thinking and feeling as well as noticing repetitive themes and patterns, making connections between themes and feelings for children. Interpretations assist children in understanding and mastering thoughts, feelings, and behaviors of which they previously had been unaware and that have given rise to the current difficulties. The

therapist uses verbalization, clarification, and interpretation in the context of a relationship that includes elements of transference, displacement, and therapeutic alliance.

III. THERAPEUTIC TASKS

For psychodynamic psychotherapists, children's play in the context of the clinical setting provides an important window into the inner life. The play themes, materials chosen, and the child's affects and verbalizations are viewed by the clinician as revealing complex aspects of the child's internal life of which he or she may be unaware and unable to verbalize directly. In the course of treatment and in the context of a developing therapeutic relationship, the clinician makes observations about the unfolding narratives that emerge in the play activities and what they reveal about children's conflicts, defenses, and consequent behaviors and modes of relating. The clinician does not comment on everything that is observed. The therapist chooses the material to be interpreted based on his clinical judgment about what is uppermost or closest to consciousness in the child's mind at that particular point in time. The clinician's goal in interpreting this material is to increase the child's conscious awareness of and insight into the relationship between unconscious conflicts, defenses, and manifest behavior and symptoms. For other clinicians the child's capacity to play and talk freely in the presence of another and to develop multiple narratives that give expression to underlying conflicts, interests, and concerns is therapeutic in and of itself. Particularly with regard to young children, this latter conceptualization emphasizes the action of play as serving the function of mastery through repetition and elaboration of central themes in their lives, trying on new solutions to problems as well as practicing and expanding the modes of representing them. In this model, the goal of interpretive work is not to create or enhance children's insight *per se* but rather to decrease the anxiety and defensive operations that disrupt or interfere with the expansion and unfolding of the play and/or discussion itself.

IV. TRANSFERENCE

Transference is the term used to describe or characterize the patient's attitude toward the therapist. The term derives from psychoanalytic treatment with adults

and refers to the ways in which a patient's perceptions of and relationships with significant figures from childhood are expressed in current perceptions, thoughts, fantasies, feelings, attitudes, and behavior in current relationships. In the clinical situation, transference refers specifically to the ways in which these experiences from the past are organized around and expressed within the relationship with the therapist. A major difference in considering this phenomenon in work with children lies in the fact that, unlike adults, children continue to live with and rely on parents. Much of what children bring to the treatment situation reflects not only a transference of aspects of relationships from the past but significant aspects of current experiences, fantasies, perceptions, feelings, and attitudes from current relationships, particularly those with parents and other family members.

The attitudes that children direct toward the therapist are one of the central markers of the transference relationship. These attitudes are also an essential ingredient in considering the child's ability or inability to play or engage in discussion with the therapist. This is especially the case at the beginning of a treatment, when children's expectations of what will occur in the sessions are not determined by specific past experiences with the therapist, but rather by expectations that derive from habitual modes of relating, current relationships, and past experiences with others.

In an attempt to clarify the phenomena of transference, particularly as it is observed in the treatment of children, Anna Freud and her colleagues developed a topology of transference of (1) habitual modes of relating (2) current relationships, (3) past experiences, and (4) transference neurosis. The first type refers to fixed ways of relating to others that, while deriving from earlier relationships, have now been applied to the world at large or to whole categories of people with whom children have contact. The second category refers to the transfer or displacement of current preoccupations with real situations in children's lives or with aspects of current developmental challenges. The emphasis here is on the distinction between a revival of past experiences versus the displacement of current ones that can be observed in children's relationships with the analyst. The third category involves children's attitudes, fantasies, and memories from the past that were previously repressed and that are now manifested in the current relationship with the therapist as it develops during regular contact over a sustained period of time. In the last category, there is a "very special intensification of the transference involving an externalization of a major pathogenic internal conflict

onto the therapist, so the conflict is felt by the patient to be between himself and the therapist, according to Sandler and colleagues in 1980 (p. 92). In child psychotherapy, it is much less common to see as much evidence of the transference neurosis as occurs in the analysis and psychotherapy of adults. When this form of the transference does emerge, the child's attention, interests, and preoccupations shift toward his or her interactions and relationship with the therapist.

Narrowly defined, the child's attitudes to the therapist are based solely on the internal configurations of experience, urges, feelings, and fantasies that are, in the main, a reflection of life outside of the consulting room. This notion assumes that the therapist's presentation and modes of relating to children have no or only minimal bearing on the ways in which the children present themselves in this particular setting. The opposite view suggests that the therapist's demeanor is always determining the child's attitude to the clinical encounter. Therefore, the child's attitude to the therapist cannot be used as a prominent source of data or window into the inner world. These two views reflect the extremes in considering the extent to which children's manifest attitudes toward the therapist are a pure reflection of their inner life or of their day-to-day experiences outside of the consulting room. That is, children's attitudes in isolation from other aspects of the fuller presentation of themes and emotional presentation may, in fact, tell the therapist very little about the children's central interests, fantasies, concerns, and modes of regulating and communicating them. In addition, even when considering children's attitudes in the broader context, initial impressions may not be borne out as the fuller picture of the children emerges over the course of the psychotherapy treatment. Rapid shifts in children's presentation may occur, from friendly, positive engagement to attitudes of hostility, disappointment, and fear. It is important to remember that children's attitudes to the therapist develop in the context of a unique setting and special relationship. As such, the clinical data emerge from observations of two people in the consulting room who set the stage for understanding the patient's experiences of themselves in relations to the many others who have and have had significance in both inner and daily life.

Transference issues with adolescents in psychodynamic psychotherapy are often very intense and threaten the formation or continuation of a therapeutic alliance. The aims of adolescence and psychodynamic psychotherapy are, at times, essentially hostile to one another. In structural terms, the ego's defenses are already tenuous because of the pubertal upsurge of drives.

Probing by a clinician of resistance and transference may seem to the patient too threatening to endure. This is particularly the case during early adolescence from approximately age 12 to 14 or 15. The transference reaction is often negative and that of a parent with whom the patient is having conflicts. The therapist can also represent an other-than-parent-adult transference that is positive in the way of a cult leader. This presents the difficulty of the patient's expectation of "cure" coming almost magically from the guru rather than from the patient's therapeutic work. Adulation of the therapist can also raise hostility on the part of the parents who must support and pay for the treatment.

A. Case Example

Mark was a 14-year-old who entered twice-weekly psychodynamic psychotherapy because of a drop in his grades in school and arguments with his father, which had transcended from only verbal interchanges to physical pushing and shaking. Both males were worried about this escalation. The referral was made by the boy's pediatrician. Mark did not want his parents involved with his therapist, and they as a couple began seeing another clinician. Mark was immediately impressed with the therapist, based on what his pediatrician had told him and because of various certificates and plaques on the office walls. Mark's father was an extremely successful attorney, not only locally but also nationally. In the almost instant transference, the therapist became the "good" father who was even more powerful than the biologic "bad" father. It was very difficult for the boy to acknowledge any good in his father or bad in the therapist until the transference took on an erotic component. As the homosexual urges became apparent to him, the patient struggled with whether to stay in treatment or flee. Remnants of the nonerotic positive transference allowed him to continue therapy. Now fearful of submitting to the clinician's control, Mark began working in therapy. He challenged the therapist's power, declaring it was not so much due to the therapist's excellence, but because he was part of an excellent university. Mark became more interested in flirting with girls in school and in improving his grades. He also came to appreciate his father's accomplishments, and the love the father must have for him in order to support and pay for the psychotherapy. The tussling between father and son undoubtedly also had a drive-defense sexual component for the boy, but after working through erotic feelings for the therapist, the son-father love also lost its overt sexuality.

Countertransference is an entity that all therapists must keep in mind. Countertransference is the unconscious influence that a therapist's past needs and conflicts have on his or her understanding, actions, or reactions within the treatment situation. James Anthony was the first writer to assert that because of the regressive pull inherent in working with children and the fact that child therapy is more primary process activity than secondary process talk, that countertransference is more commonly experienced in therapy with children than with adults. Burlingham in 1935 noted that in work with younger children, therapists may drift into a wishful role of being a superior parent. With the sexual and hostile proclivities of adolescents, therapists have a particular challenge not to be seductive or counteraggressive. The therapist's narcissistic concerns may also cloud his or her listening carefully, regardless of the patient's age.

V. THE THERAPIST-CHILD INTERACTION

A central focus of the clinician's observations is the way in which children relate to him or her, from the first introduction in the waiting area to the myriad shifts in attitude presented in the consulting room throughout the course of psychotherapy. From a psychodynamic perspective, ways of relating to the therapist reveal a great deal about children's attitudes to the most important people in their daily lives and suggest observable surface markers for a range of internal configurations involving their fantasies about those people. Children's attitudes toward the therapist suggest their feelings about being with an adult other than the parent. At most, the attitude children present in this particular setting may reflect a generalized set of expectations and modes of relating that have referents outside the consulting room, in the children's daily lives—from the present or the past. At the very least, the attitude presented may reflect aspects of children's expectations of the current situation in the consulting room itself.

Children's comfort in the room and their experience of their interaction with the therapist will be a key determinant of the play, discussion, and activities that occur in a given hour. Representations of self and others as reflected in play and discussion reveal the organization of the variety of composite images of self and others that children have constructed on the basis of experiences, urges, and feelings. These representations of the self and others, although never fully conscious, are reflected in children's ever-changing conscious fan-

tasies, attitudes, and behavior. In other words, the children's attitudes, suggested by the way they relate to others, reveal an internal frame of reference that draws on (1) their experience of interacting with similar figures and their awareness of an expectable set of social conventions; (2) the status of specific urges and the relative balance between the pleasure gained from their expression versus fear of potentially negative consequences in the form of shame, guilt, anxiety, or actual danger that might result from a clash with either internal or external expectations; and (3) the developmental status of a sense of self, that is, an appreciation for personal abilities that are now experienced as autonomous in relation to the parents.

Unlike other approaches to clinical interviews with children, psychodynamic technique eschews structured questions that aim at eliciting "mental status" on the basis of verbal responses and verbal information regarding attitudes and interests. It is assumed that children are most likely to reveal their interests, attitudes, and capacities in a situation that can become familiar and comfortable. This sense of familiarity and comfort can best be established by children themselves as they become acclimated to the therapeutic setting. The therapist is in the best position to observe what children bring to the sessions if the therapist's questions, suggested activities, direction of play narratives, and the like are kept to a bare minimum. When the session is not directly shaped by themes that the therapist introduces, children will bring to therapy their own versions of personal experiences that are configured and represented in play, activities, and discussion. This does not mean that the therapist must remain inactive, silent, or vacant in his or her presentation, but rather that he or she should convey a friendly interest and respect for children by attending to what children themselves introduce in the session.

VI. THE INTERVIEW SETTING

At the beginning of any treatment, the therapist's knowledge of children's phase-specific concerns contributes to his or her ability to set the stage for a therapeutic atmosphere in which therapist and child can learn about and work on the dynamic intersection between inner life and the external world of the child.

In the clinical situation, the child psychotherapist has the task of introducing the consulting room and the psychotherapy as a safe situation in which the therapist and child together have an opportunity to explore and

work through the difficulties that have been brought into the treatment. Children's sense of safety is influenced by the ways in which the therapist conveys appreciation for the dangers children confront throughout the process. The child's comfort level during the session will also vary according to what is uppermost in the patient's mind at any given time.

Preschool children experience the sense of safety in the familiarity and pleasure of the imaginative play with a friendly adult who can follow their lead while maintaining effective limits on potentially dangerous or overly exciting behavior. Safety also will be experienced in the comfort or confidence the parents convey in their attitude toward the therapist and by their availability before, after, and at times during the session. Children will begin to develop a sense of safety as they discover that the therapist will do no harm—whether in response to provocative behavior or to any thoughts, fantasies, or feelings that may emerge.

These same issues may be equally prominent for school-age children. However, there is now an additional burden for these children. They are invited to reveal aspects of their inner life at a time in development when the need to renounce the open expression of infantile longings is paramount. School-age children's increased interest in privacy and secrets, games with rules, cause-and-effect thinking, engagement with peers and activities outside the home, curiosity and learning, and bodily self-care are products of newly emerging mental structures made possible by advances in both cognitive and physical capacities. These interests reflect children's ability and need to move away from their earlier dependence on parents as well as from a fantasy life in which the parents figured prominently as direct objects of sexual and aggressive impulse. In many ways these new developmental acquisitions add additional challenges to the usual ones of establishing a psychotherapeutic relationship. For school-age children, anxiety is aroused from the intimacy of the relationship with the therapist to reawaken old, now-unacceptable dependent longings as well as stimulate the emergence of wishes and fantasies experienced as dangerously regressive.

For adolescents, the dangers of yielding to a resurgence of longings and interactions that resonate with earlier phases of development are now intensified by biological maturation. Asking for or being sent for psychotherapy may confirm the adolescent's worst fear that his fluctuations in mood, preoccupations with sexual and aggressive fantasies and feelings, and anxiety about negotiating aspects of daily life are indications that he is crazy, infantile, and incompetent.

In therapeutic work with each of these age groups, the child's sense of safety will, in large part, derive from the therapist's appreciation of the specific dangers that are evoked for this particular child by the introduction of the psychotherapeutic situation as well as from an understanding of the developmental importance of the defenses that are called into play.

VII. DEVELOPING THE THERAPEUTIC PROCESS

The first meeting with children usually is preceded by meetings with the parents in which the presenting difficulties and developmental and family history are discussed. These meetings with the parents are conducted either by the child therapist or by a colleague. This background information will provide a context for direct observations made by the therapist over the course of two or three evaluative sessions. In the context of these meetings, it is suggested to parents of young children that the child be told in simple terms that they will be meeting with someone who helps children who are having worries. The parents can introduce their child to the idea of meeting with the therapist by saying that they know that the child has been having troubles and that they would like to help so the child will feel happier and free of the worries that are making life so difficult. Additionally, parents may briefly describe the nature of the contact with the therapist by telling the child that they will have a chance to play and talk, get to know the therapist over time, and slowly figure out worries with the help of the therapist. Although the details of what parents tell their child may vary, parents of children younger than 5 years of age are counseled to keep the explanation brief. Parents should be helped to understand the importance of following the child's lead regarding how elaborate the explanation about the consultation should be. For example, in response to the child's questions, parents may distinguish the difference between the kind of doctor who does examinations and gives shots and the doctor who helps children through play activities and/or words.

Children under 6 may feel most comfortable if a parent accompanies them and the therapist into the consulting room for the initial meeting. Young children frequently make verbal and nonverbal requests—by holding onto a parent's hand, climbing onto the parent's lap, or leaning up against the parent's body—that the familiar adult remain in the consulting room for some

time. The therapist's initial communications are meant to demonstrate that the setting and the therapist are free of external demands or threats that might prove overwhelming. These opening communications should be kept simple but should include a verbal introduction of herself and her intentions (i.e., "We are going to a room where we can play and talk"); an awareness of the child's wishes about the timing of separating from the parent; and a friendly but low-key invitation to the child to explore the contents of the playroom and to use the toys and drawing materials. Just as the parents have introduced their child to the idea of seeing the therapist, the clinician also may tell the child that he or she is there to help them with their worries. Some psychotherapists prefer to say more, describing in greater detail the schedule as well as the nature of their work; others say very little, preferring initially to learn from the child his or her initial ideas about treatment.

The choice of play materials should invite the child's imaginative use of them as well as be appropriate to the child's level of developmental functioning. For younger children, the use of small animal and human figures, puppets, a doll house, toy cars, and paper and markers all serve as relatively neutral objects that they can use in developing play themes and narratives. In contrast, using toys that derive from television shows may evoke scripts that even when personally elaborated by children were originated in the imagination of someone else and therefore confuse and diminish their projective and communicative value in the therapeutic process. Similarly, too many toys or activities that increase the potential for regression and direct enactment of impulses—play with water, paints, swords, and guns with projectiles—may succeed in engaging children in the room but may be overstimulating for many children who come to experience the consulting room and the therapist as dangerous.

A. Case Example 1

A psychotherapist just beginning her work with a 5-year-old girl expressed surprise and some anxiety as she reported in supervision on the first 3 psychotherapy hours with the girl. The therapist reported that the girl, Yvonne, had been referred because of chronic battles with her mother, frequent nightmares, fights with kindergarten classmates, and obstinate refusal of her teacher's requests to join in-group activities. There were no immediate external precipitants to these difficulties, which had been apparent in varying degrees for the previous 18 months. Her history was unremarkable

except for her mother's acknowledgment that both she and her husband were perhaps overly strict, demanding compliance to their expectations that, from age 2, Yvonne should behave like a "little grown-up." Mother reported that prior to the current difficulties, both she and her husband as well as other adults frequently had commented on how well-behaved and mature their daughter seemed—"she was such a sweet, good little girl . . . maybe too good."

The therapist went into some detail in describing the first three sessions and her consternation about the dramatic fluctuations in Yvonne's presentation. In the first hour, the girl had separated easily from her mother, was friendly, and seemed comfortable accompanying the therapist into the consulting room. However, once in the room, Yvonne stood in one corner, finger in her mouth, eyeing the therapist and the contents of the room quietly. After several minutes the therapist invited her to explore in sequence, the dollhouse, human figures, and finally the crayons and paper. Yvonne stood her ground and quietly shook her head. The therapist posed several questions about favorite toys and activities, to which Yvonne gave brief responses. After 30 minutes in the room, Yvonne walked over to the dollhouse and explored it for the next several minutes. She ignored or did not respond to any of the therapist's attempts to engage her but remained seated in front of the dollhouse fingering the figures and furniture inside. Suddenly, 40 minutes into the session, Yvonne looked up at the therapist and announced, "I'm done," and walked out of the room with the therapist trailing behind her. She was not interested in the suggestion that perhaps it might feel more comfortable to have Mom in the room with them and instead informed both therapist and mother that it was time to go home.

The second session began in a similarly quiet fashion. However, the therapist had decided to become more active in this meeting and to bring more play materials that might be of more interest to the girl. She equipped the room with an easel, paints and brushes as well as several cans of Play-Doh, and several different size dolls. The therapist described her demeanor as more upbeat, for example, greeting Yvonne with a buoyant announcement that she had a number of surprises waiting for her in the room. Yvonne declined the offer to have her mother in the room. Again she stood for several moments surveying the room as the therapist began unpacking Play-Doh, mixing paints, and describing what fun they might have playing with these items. After several moments, Yvonne did engage in painting, at first slowly and carefully on the paper and then with

less care, which then culminated in a frenzy accompanied by wild giggles as she flung paint onto the paper, the walls, and the floor. Before the therapist had any time to comment, Yvonne went to the Play-Doh, which she rolled in balls and excitedly threw against the wall while darting about the room, glancing in a challenging way at the therapist. And so the session continued as the therapist spoke of the need to keep her patient safe, the rules for being able to continue to use the materials, and so on—all accompanied by the therapist's frozen smile and strained attempts to retain her composure. The session ended abruptly when Yvonne gleefully ran out of the room screeching her way down the hall until she reached her mother and again grew quiet as she looked out from behind her mother's dress, gazing at the therapist who had finally caught up with her.

The third hour presented yet another picture of Yvonne and a new set of challenges for the therapist as her young patient was now terrified of entering and then remaining in the consulting room. Yvonne insisted on having her mother in the room and sat quietly on her lap for the entire session. The therapist hypothesized that her eagerness to engage Yvonne in exciting activities was an attempt at seduction that had been too overwhelming for a child whose threshold for excitement and retaining self-control is especially low. The therapist and the sessions themselves had become the focus of fear as they represented the invitation to give full rein to impulses that Yvonne found both exciting and dangerous. In subsequent hours, the therapist verbalized how excited and frightened Yvonne had become and how important it was for her to feel safe again. In addition to inviting the mother into the room, the therapist eliminated the more stimulating paints and Play-Doh while assuming a more low-key and patient approach to Yvonne. After several sessions Yvonne was again comfortable being alone with her therapist and continuing, at her pace, the exploration of this new setting and the struggle over expression of impulses that brought her into treatment.

In contrast to the younger child, many school-age children are well aware of the troubles that have prompted their referral for treatment. With children of this age, the therapist will need to discuss more directly the children's and therapist's ideas about why children are coming for psychotherapy. When appropriate, the therapist may want to negotiate directly with older school-age children such issues as the scheduling of sessions and elicit their interest in helping with the therapist's choice of materials available in the room. The goal here is to create a bridge,

or neutral ground, in which children can begin to describe directly or in displacement their experience of themselves internally and in relation to others in day-to-day life. Although school-age children may choose the same materials as younger children, such as play figures, puppets, a doll house, and markers and paper, older children may prefer activities less clearly associated with their younger selves. A deck of cards, checkers or chess, and models to be constructed may all play a role in the psychotherapy of older school-age children. Children may employ such activities as "something to do" while they talk, or children may use them in the service of representing their difficulties around aggressive, competitive, and superego conflicts.

B. Case Example 2

John was a 10-year-old, highly constricted boy who shied away from engaging with peers or attending to his schoolwork when referred for evaluation and subsequent psychotherapy. Over the course of his 18-month treatment, the theme of competition became increasingly linked to danger as he developed play and written stories about armies fighting over a country and the affections of its ruler, the queen. The sessions often would end with each of the armies being decimated. As the therapist eventually commented on how dangerous the battles seemed for both sides. John replied outside of the play, "Well, that's what can happen when you want something too badly." During the work, John could reveal through play and discussion the extent to which his wish to be the best at everything preoccupied him. This longing was accompanied by intense rivalrous and destructive fantasies that were directed toward his father and siblings whom he felt were competitors for his mother's exclusive attention and, by extension, toward peers for the teacher's. Equally intense were John's sense that his wishes were morally unacceptable and in direct conflict with the positive attachments he felt to his rivals. For John, any competitive strivings engendered the same massive superego repudiation, guilt, and accompanying anxiety that greeted his unconscious fantasies and the conviction that his destructive wishes would come true. As John became more conscious of the link between his fantasies and his symptomatic avoidance of any show of competence and competition, his academic and peer involvement significantly improved. Exploring the origins of intensely rivalrous feelings through play and talk led to a greater tolerance for himself and an increased sense of safety in

the fact that, as he put it, "Wishes are only wishes, you know."

The use of elaborate board games, while reflecting age-appropriate interests, often narrow the focus of the therapeutic work to the task of mastering specific rules and strategies, thereby closing off other avenues of representation and communication that might be expressed and observed more easily in a less demanding game. The repetitive and circumscribed nature of elaborate games may, in fact, serve the defensive function of avoiding conscious awareness of fantasies and associated troubling feelings. In addition to the tasks of listening, observing, and exploring the contents of the imaginative play, games, or discussions, the therapist must be able to appreciate the importance of children's defensive operations in order to assist in developing a safe enough forum in which fantasies and feelings can be elaborated. In some treatments, such as John's, the original use of displacement (or the expression of conflictual themes and feelings via characters in play, narratives accompanying drawings, or discussion of the lives of "others") may lead to greater insight, conscious recognition, and verbalization of the links between inner life and patterns of behaviors. In many other treatments, however, the use of displacements themselves may provide just the opportunity children need to work through new solutions to conflicts that have given rise to the symptoms and troubles that have brought them into psychotherapy. Verbalizing formulations that reflect hard-won insight into the presenting problems may be more of a need for the therapist than for such children.

Similarly, the developmental tasks of adolescence demand a very different approach from preschool and school-age children, usually from the moment of referral. Although young and mid-adolescents may come for treatment primarily at the instigation of parents or school, usually they have a very clear idea of why others think they are in trouble. It is important in the beginning work for the therapist to recognize that adolescents' protests that it is parents or others who have the real problems does not determine or predict the extent to which they will be able to engage in the psychotherapeutic process. Instead, adolescents may have a very different agenda concerning psychotherapy from the adults who have encouraged, or required, them to seek help. Although the therapist may want to make some effort to negotiate with adolescents the differences between their agenda and that of the adults, if adolescents are to be engaged successfully in their own treatment, the therapist must acknowledge and, when possible, accept their agenda as the central psychotherapeutic task.

With adolescents whose feelings of mistrust, displays of negativism as a defense against fears of passivity, and a negative transference are common, it is important for the therapist to ally with those parts of the patient's ego that strive for harmony. An initial focus on the adolescent's strengths is often the best way to foster a therapeutic alliance. Adolescents, even more than adults, find it easier to fight external conflicts than internal ones. Helping the patient put the former in better perspective often builds confidence in the therapist that allows for later exploration of the latter. The therapist's ability to use language that stretches the patient's awareness, but does not talk down or sound autocratic to him, is crucial for the patient to hear what the therapist is conveying. Two other aspects of psychoanalytic psychotherapy with adolescents must be kept in mind. One is that adolescents frequently have a confused sense of time. It is not uncommon that only the near future is recognized. The past is what as soon-to-be-adults they want to put behind them, while adulthood beyond the 20s is too much like their parents' lives to comprehend. This concentration on "now" may leave a feeling of rapid movement and of being in a hurry to go they know not where that requires understanding by a therapist. Another aspect of adolescence that may intrude into the therapeutic interaction are the paradigms of love and mourning, which may intrude to take the patient's mind off the therapy. These are typical of the age and, rather than resistance, are usually short-lived and can be learned from.

Unlike preschool or school-age children, adolescent patients may be much more comfortable sitting and talking "like an adult" rather than playing. However, the psychodynamic developmentally informed therapist understands that the operative word here is "like," not "as." Young to mid-adolescents, although wishing to appear adultlike, often are not able to sustain for long the sort of introspective, self-reflective stance that characterizes many adults seeking treatment. Adolescents may feel most comfortable talking about their life with peers or about the failings of their parents. On the other hand, they may be very reticent to engage in or reveal the self-reflection and troubling affects that may accompany such "neutral" topics that are seemingly so distant from internal experiences. It is the therapist's task to introduce adolescents gradually to a more self-reflective stance and to help them to sustain such a stance during sessions. Because it is the central developmental task of the young to mid-adolescent to achieve greater psychological independence and separation from parents, adolescents experience any thoughts, fantasies, or feelings that they associate with earlier

developmental levels as a dangerous move backward toward earlier childhood feelings (i.e., regression); therefore, they go to great pains to avoid them. When adolescents experience the psychotherapeutic process as exerting a regressive pull toward psychological reengagement with the parent of childhood, they are most likely to flee psychotherapy in the service of reestablishing what they are convinced is a developmentally necessary separation and attainment of greater autonomy. For these reasons, it is the therapist's task to approach the inner conflicts of adolescents, which inevitably carry with them this regressive valence, with great tact and developmental understanding. Young to mid-adolescents may be most comfortable "chatting" during their hours about sports, apparently superficial peer relationships, or television shows and characters. During the early phase of treatment, the therapist may have to work almost exclusively through the displacements afforded by such seemingly bland topics, which, over time, may help both to establish a feeling of control and safety in sessions as well as to provide his or her version of the bridge to discussing more directly increasingly relevant personal material.

In attempting to make adolescents feel comfortable, the therapist may make the mistake of trying to present himself or herself as a "hip" pal by initiating conversation that adolescents experience as dangerously seductive or intrusive (e.g., presenting as knowledgeable and "up" on culturally current topics, such as the latest sports or cultural figures and popular music). Adolescents in treatment are most comfortable with a therapist who is clearly an adult, but one who is an especially careful and thoughtful listener. Young adolescents often will become more comfortable as they feel confident that the therapist will not intrude on their burgeoning sense of psychological autonomy by moving to intolerably "deep" levels too quickly or making interpretations that they experience as "wild" and tactless. For adolescents who have the greatest difficulty in tolerating any verbal engagement or face-to-face contact that increases the sense of being scrutinized, the offer of simple games (e.g., card games, checkers, chess) may provide a more neutral basis of interaction. Again, adolescents' experience of control and of the therapist as nonintrusive may allow them to feel safer revealing themselves in their own good time and guided by their own wish to feel relief from struggles that have brought them to treatment.

The choice of materials, scheduling, and frequency of meetings is crucial in setting the tone of the therapeutic relationship. These decisions should be informed by the therapist's understanding of the patient's

developmental level. For preschool children, a minimum of twice-a-week appointments usually is necessary to provide the continuity in which psychodynamic lens can be employed usefully. Although older children may be able to develop a sense of therapeutic continuity in a once-a-week treatment, here, too, more frequent weekly appointments help therapist and children to cultivate a sustained "therapeutic atmosphere" in which the material of sessions can be understood by both participants to reflect the children's inner world with its conflicts and defenses. This therapeutic atmosphere, which includes the even, observing attention of the therapist to children's underlying conflicts and defenses as they are revealed in their play, behavior, and talking, permits children and therapists to develop a shared therapeutic language.

More so than with younger patients, the possible use of psychopharmacological agents arises increasingly with age. If medication is prescribed by someone other than the psychotherapist, this can affect the patient-therapist relationship. Up until the past 10 to 20 years, there was also much debate as to whether medications negatively affected the therapeutic relationship even if the psychotherapist was also the prescriber. It is now clear that if the patient has a disorder for which medication is helpful, alleviation of symptoms make psychotherapy more effective. At the beginning of the 21st century, there is more concern that psychoactive medications are given without psychotherapy, than the reverse. For the psychodynamic psychotherapist, the important aspect of medications, often overlooked in other types of psychotherapy, is the monitoring of the patient's fantasies and/or symbolic meanings of, and expectations, appreciation, and/or disappointment with, the medication.

VIII. WORKING WITH PARENTS AS AN ADJUNCT TO TREATMENT

Collaborative work with parents can be a crucial component when working psychodynamically with children under the age of 13. Children, even of grade-school age, are not able to present a full picture of their daily lives and behavior. In particular, children may wish to avoid reporting external events for fear of the critical judgment of the therapist. Meetings with parents during which they can report on events in children's daily lives are important for filling out the therapist's understanding of the children. Here we offer a few guidelines and warnings.

Collaborative work with the parents is critical to the psychodynamic treatment of children age 6 and under.

Unless parents share information concerning a child's daily life and behavior with the therapist, his or her capacity to understand the referents of the child's play may be severely compromised. In addition, parents of young children in treatment frequently are quite anxious or confused about how to handle their children's behavior. Developmental child guidance attuned to the needs of the specific family and child can be extremely useful in ensuring the parents' continuing support of the treatment. When necessary, helping the parents understand why they should alter their approaches to the child and in helping them develop new strategies may be an important factor in supporting gains the child may be making within the treatment hours. Children younger than age 5 have not yet developed a firm cognitive understanding of privacy or secrets and expect that the significant adults in their life share a mutual concern for their well-being; for these reasons, children under 5 usually are quite comfortable with the idea of meetings between parents and therapist.

Children over age 5, however, have begun to develop a strong sense of privacy and secrets and may be much less comfortable with the notion that material from their sessions might be shared with parents. For this reason, the therapist of school-age children must not only assure the children of the confidentiality of material from sessions but must in fact be careful during parental child guidance sessions that the material children wish to have kept private is not revealed.

Parental meetings should be scheduled often and regularly enough that parents understand their importance in conveying significant information about their child's ongoing life. Frequency and regularity of contact between parent and therapist also helps parents recognize that they have a critical contribution to make to the success of their child's treatment; under such circumstances, parents are less likely to retain the magical notion that they can turn their child over to the therapist to be "fixed." In addition, parental meetings underpin the development of sufficient trust in the therapist for the parents to utilize any development child guidance that is offered. Finally, such meetings permit the therapist to gain adequate understanding of the parents' personalities to know whether it would be useful to the success of the child's treatment to refer one or both parents for their own treatment. If such a referral is indicated, the therapist who has developed a collaborative relationship with the parents will have an adequately informed working alliance so that he or she can decide how to best approach the question.

Although it is usually the parent of the adolescent who initiates the contact with the therapist and un-

doubtedly pays for any treatment undertaken, collaboration with parents of children of this age is more difficult. Because adolescents are moving toward greater psychological independence and autonomy from their parents, they may experience any collaboration with their parents as threatening; collaboration thereby runs the risk of compromising the usefulness of the treatment to the adolescents. In general, adolescents are also better reporters of their daily lives and behavioral difficulties than younger children. For these reasons, parental contacts should be infrequent in the treatment of adolescents and in most cases they should not occur without the adolescent being present. Often, however, parents of adolescents feel most confused and upset about how to handle their child's behavior; they may express the need for increased contact with the therapist as a way of allaying their own anxieties and of developing new ways of handling their child. During the initial contact with the parents, the therapist must make clear the developmental reasoning behind the necessary restriction of contact between parents and therapist. Often treatment of adolescents is enhanced or successful only when the parents are seen on a regular, or as needed, basis by a colleague. With information about the parents and their contributions to family interactions alongside of reports from the adolescent's therapist, the collaborating clinician will be in a good position to help parents develop and assess new ways of understanding and responding to their adolescent more effectively while helping to maintain the confidentiality of the adolescent's treatment itself.

IX. CHILD PSYCHOANALYSIS

The principles we have described for psychodynamic psychotherapy have been derived from child psychoanalysis. The differences between psychoanalysis and psychodynamic psychotherapy lie in the frequency of appointments, the analyst's more consistent focus on defense and transference issues, and the relative abstinence of the analyst's stance toward the child patient. Children in analysis are generally seen four or five times a week. This frequency allows the analyst to be more patient for material to emerge; he or she can be confident that important psychic material will appear over and over again in different forms. As a result, the analyst does not need to rush to understand or to make what may well be premature interventions based on limited material. The frequent sessions also make the child's characteristic modes of defense against conflict much more clear and the child's attention can be more

easily drawn to his or her defensive activities. In a similar way, it becomes easier for the analyst to sort out what aspects of the child's relationship with him or her are being driven transferentially and what aspects may constitute the "real relationship." Finally, the analyst's confidence that significant clinical material will emerge in a context that both analyst and child can understand allows the analyst to be somewhat less active, or relatively more abstinent, in the clinical setting, counting on the interpretation of conflict, defense, and transference to carry the primary therapeutic action.

The intensity and details of the treatment relationship and material that can emerge in a psychoanalysis require additional training for the clinician who engages in this specialized area of clinical practice. Graduate psychoanalysts have had a rigorous and extensive clinical training following completed graduate education as a psychiatrist (M.D.), psychologist (Ph.D.), or clinical social worker (M.S.W.). Psychoanalytic training consists of three parts. Candidates attend a multiyear sequence of courses on development, psychoanalytic theory, and technique. They undergo a personal analysis. They conduct a number of psychoanalyses under close clinical supervision. Usually child psychoanalysts have completed training in adult psychoanalysis as well as child and adolescent psychoanalysis. The latter training involves an additional sequence of courses and the supervision of the psychoanalysis of children and adolescents. There are a small number of training programs that train candidates in the practice of child and adolescent psychoanalysis without training in the practice of adult psychoanalysis. There is no federal or state accreditation for psychoanalysts, but the standards of training are maintained by two major professional organizations: The American Psychoanalytic Association and the International Psychoanalytic Association. Training programs are affiliated with either or both of these organizations, which establish, accredit, and maintain the affiliated training programs.

When, then, is psychoanalysis the recommended treatment for a child as opposed to once or twice weekly psychodynamic psychotherapy? Why would a child analyst make the decision to recommend analysis for a particular child and when would it be appropriate for a nonanalyst to make a referral of a child to an analyst?

A child would be an appropriate candidate for psychoanalysis if (1) he or she is strongly defended against acknowledging the severity of his or her problems; (2) if the relationship with the clinician is dominated by transference dynamics that have not yielded to a less intense form of intervention; and, (3) at times, when the severity and intractability of the child's symptoms have resulted in a developmental arrest that seriously

impedes the child's ability to move forward developmentally. This latter situation may, at times, include children with ego vulnerabilities.

Some children, particularly latency-age children, are quite resistant to being able to recognize the severity of their problems. Grade-school age children in once-a-week treatment may use board games to ward off the encroachment of reality outside the clinician's office, the reality in which they are most symptomatic. Attempts on the part of the clinician to confront the child with his or her symptomatic behavior outside the office are met with staunch denial and an insistence that "everything is fine." Such a child is well able to maintain the comforting fiction that whatever problems he or she may face are really someone else's problems. When externalization successfully deflects the patient's capacity for self-observation, psychoanalysis may yield a great deal more data and opportunity for joint scrutiny of the sources of internal conflict and discomfort and the counterproductive ways in which unwanted struggles are characteristically jettisoned.

A. Case Example 1

Ten-year-old Amy had a history of sabotaging her friendships by her passive-aggressively expressed critical stance toward others; she would roll her eyes mockingly, make a low-voiced angry comment, or fail to interpret correctly the social cues given by other children. Amy experienced herself as endlessly falling victim to the meanness of others, whether it was to her classmates' "cattiness" or to her parents' "unfairness." When her attention was forcefully drawn to these reported problems, she would respond at first with denial and then would sadly insist that she "couldn't help" being so angry "because my parents are divorced." Amy's relationship with her therapist was dominated by her need to present herself as a nice cheerful girl who enjoyed coming to therapy to play cards. A year of once-weekly psychodynamic psychotherapy had not allowed Amy to make any real progress; she remained as insistent as ever that the world had dealt her a bad hand of cards and that other people should change. A recommendation for psychoanalysis would be appropriate for Amy. The frequency of sessions would make it more difficult for Amy to sustain her "niceness" with her therapist; it would be expected that her symptomatic critical, hostile behavior would come more directly into the relationship with the analyst, even if her mode of communication continued to be to play cards. In addition, the frequency and intensity of the clinical hours would allow the analyst to scrutinize more carefully the defen-

sive aspects of Amy's pleasant facade with him. Amy's attention could then be drawn to the defensive aspects of her "niceness," her underlying fear that she was a stinky, nasty girl whom nobody could really like, as well as provide a better understanding about what drove her aggressive conflicts.

Similarly, the intransigence of symptomatic behavior may be an important indication that too little about the nature of the underlying internalized conflicts has been revealed, understood, or worked through. This may be especially the case when the child has, in fact, been well-engaged in a psychotherapy and the parents have been able to alter life circumstances of and responses to the child based on their full involvement in parent guidance work.

B. Case Example 2

Five-year-old Joey was referred for treatment because of his provocative, combative stance toward people in authority, not only his father, but his female kindergarten teacher and the playground monitor. Parental child guidance had helped the father and mother change their handling of Joey, recognizing that much of his provocative behavior was driven by an underlying anxiety. The parents had also intervened with his classroom teacher who responded by making the rules and structure of her classroom clearer and praising Joey for his academic success. In his once-weekly treatment, Joey continued to play out stories of knights stealing beautiful princesses, fighting the king for the castle, and stories of motorcycle daredevils who took life-threatening risks to great acclaim. Joey's relationship with his male therapist was at times provocative, but when his therapist attempted to draw Joey's attention to his behavior, Joey quickly "settled down," turning from his dramatic play to some sort of "busy work." His behavior outside the classroom continued to be very problematic, with Joey hitting other children, disrupting playground games, and seeming to invite a punitive response from those in charge. Joey's analyst hypothesized that if Joey were in analysis, his attention could be drawn to the ways in which his occasional provocative behavior within his sessions was driven by his underlying fantasy that his "kinglike" analyst was out to take away Joey's power, making him feel once again helpless and little as he had so often in the past with his exciting and powerful father.

Psychoanalysis may also be indicated when symptoms and age-inadequate functioning derive from vulnerabilities in ego functioning that intensify the intransigence of

internalized, neurotic conflicts. Difficulties involving poor impulse and affect regulation, deficits in capacities for synthesis and integration of stimuli, or paucity or primitive nature of defenses may only be observed, understood, and addressed fully in the context of an intensive, long-term analytic relationship.

C. Case Example 3

Six-year-old Betsy was referred for psychoanalysis because of her inability to adapt to many age-appropriate expectations. Her parents, though loving, had had little ability to set any appropriate limits for Betsy: She was not expected to go to bed at any particular time, she watched unlimited television, she ate only what she wanted and when she wanted. Weekly meetings with the parents helped the clinician understand the severity of the parents' own conflicts around aggression; the parents experienced any limit setting as dangerous and cruel. They recognized that their daughter was ill-prepared for life outside the family but felt quite helpless to do anything about it. Clinical evaluation revealed that Betsy was a bright child who was unusually comfortable at retreating into her own fantasy world of happy, magical fairies whenever reality made a demand on her. Betsy expressed a high level of anxiety about how dangerous the world outside the family was; she found it hard to concentrate in school because of her preoccupation with the idea that a fire might break out. She was equally concerned with the idea that the weather might suddenly and inexplicably turn seriously bad; in her mind there was a constant possibility of tornadoes or catastrophic storms. When she had such thoughts, Betsy quickly turned away from reality and withdrew into her magical fantasy world. The evaluating clinician viewed Betsy as a child with clear ego vulnerabilities, particularly in the realm of tolerating frustration, delaying gratification, vulnerability to ego regression under the press of her anxiety, and a reliance on a retreat from reality as a primary mode of defense. The clinician felt that once- or twice-weekly psychotherapy would prove inadequate to addressing the severity of these vulnerabilities because of the comfort Betsy experienced in withdrawing from the demands of reality. It was felt that only with the development of an emotionally significant relationship with the analyst would Betsy be able to tolerate the level of anxiety she experienced and become able to relinquish her reliance on such primitive modes of defense.

As suggested earlier, adolescence may be the most difficult period of development in which to engage a youngster in a close therapeutic relationship that involves

self-revelation. Although the diagnostic indications are similar to those described for younger children, there must be a particular urgency, either from the adolescent himself or herself or from his family or community that is necessary to sustain an analytic treatment in this phase of development. The analyst's recognition of the normative developmental demands that pull the adolescent away from an intensive therapeutic process require a level of flexibility with regard to frequency and continuity of treatment even when the adolescent has agreed in principle to its necessity.

D. Case Example 4

Having been involved in a series of delinquent acts, Dean was 15 years old when he was referred for treatment by the state run group home to which he had been remanded as a condition of probation. Dean had a long history of outpatient and residential treatment for a range of depressive, antisocial, and anxiety symptoms that had made it impossible for him to live at home from the age of 9. With an extensive traumatic history that included exposure to domestic violence between his parents, their subsequent divorce, witnessing his mother's suicide attempts, and leaving his mother to live with his father and stepmother, Dean frequently provoked fights with peers, teachers, and family members. His use of alcohol and drugs, like his involvement in burglaries and vandalism, were exciting refuges from feeling sad, abandoned, frightened, and helpless. While he entered psychotherapy as an adolescent under duress, Dean enjoyed regaling the therapist with excited stories about illegal and dangerous activities. He eagerly agreed to the suggestion that he might have a great deal on his mind and that once-a-week meetings were insufficient. Dean was eager to meet more regularly and agreed to the suggestion of four sessions per week.

In the context of the frequent contact, Dean was able to sustain the treatment even when furious with the analyst about his suggestions of a possible link between Dean's unhappiness and provocative behavior. Missed appointments occurred most predictably when Dean experienced his increasing longings for an idealized mother most keenly in the transference. At these times, Dean needed to reassert his independence at precisely the time when he felt most like a helpless infant. However, the analyst's continued availability combined with sanctioned expectations of probation forced and allowed Dean to sustain his treatment. In the context of reliable and intensive engagement with his analyst, Dean was able to tolerate his intense longings as he explored, and

increasingly understood their early origins. Behavioral, academic, and social symptomatology diminished significantly when he could appreciate that the ways in which he defended against feeling small, helpless, and enraged also invited the rejection that confirmed bad feelings about himself and the sanctions that restricted his freedom and autonomy. The regularity, frequency, and relative flexibility of contact allowed Dean to sustain a treatment experience that replaced the dangers of infantile regression with mastery that accompanied insight. The intensity of the therapeutic relationship provided an opportunity for Dean to locate the sources of his current difficulties in the disappointment, fear, and rage of the past. As a result, he was more able to relinquish hope of recovering what could not occur in the past, in favor of seeking relationships and accomplishments that could be gratifying in the present.

X. CONCLUSION

All psychodynamic interventions focus on the dynamic interplay between internal agencies of the mind, the inner life of fantasy, cognitive abilities and neurophysiologic regulatory capacities, and how the demands of external reality are experienced. Psychodynamic treatment may take a variety of forms: psychoanalysis, intensive long-term psychotherapy, weekly play therapy, brief treatment, semistructured sessions, and consultation with parents. The multiplicity of methods employed in psychodynamic interventions are linked by a set of shared principles:

1. The individual has an "inner world" that includes representations of central wishes and fears, associated feelings, characteristic modes for avoiding discomfort, displeasure, and tension (defenses) as well as for obtaining pleasure.
2. Aspects of the inner world are unconscious.
3. Conflict is inherent within the inner world between wishes, within and between psychic structures, and between the inner world and the demands of reality.
4. Conflict within the inner world may either stimulate or impair developmental progression.
5. The inner world unfolds developmentally, supported, enhanced, or compromised by constitutional givens and environmental responses.
6. Behavioral symptoms reflect the child's efforts at finding a compromise solution to conflict.
7. The nature of the child's inner world can be understood through observations of play, verbalizations,

behavior, and relationship to the therapist and significant others.

The data that inform clinical decisions are derived from observations of the child in the consulting room—modes of relating, thematic content, regulation of emotions, activity levels, and self-observation capacities—as well as what is reported about the child's life outside of the consulting room. The form of the psychodynamic intervention is determined by the child's developmental level, the nature of environmental stresses and supports, and the child's constitutional endowment. The fundamental techniques employed are influenced by the child's level of developmental organization but are likely to include imaginative play; discussion; observation of behavior and feelings; and exploration, verbalization, and clarification of wishes, fears, and feelings.

GLOSSARY

teaching films Use of films for demonstrating clinical pathology.

Modern psychotherapy and movies were invented at the same time. In 1895, Lumiere first publicly demonstrated the new motion picture system, and, in the same year, Freud and Breuer published *Studies in Hysteria*. The histories of the two inventions have been strikingly parallel. Both started humbly and in their long, early development were seen as dangerous or immoral. The pioneers in both endeavors were largely outsiders or members of minority groups. After a period of increasing respectability, intellectual acceptance, and popularity, both became powerful cultural forces but then began to wane under pressures from competing systems, TV and medications. Both inventions responded with modification and experimentation and are now fighting for survival in a changing world.

From the beginning, both psychiatry and the movies have borrowed themes and terms from each other. Dreams, madness, and old motivations have been the

subject of countless movies; dream screens, frame analysis, and flashbacks have infiltrated psychological discourse. But beyond this, the movies and psychiatry have always demonstrated a special affinity for each other, because to an uncommon extent they share an interest in human behavior in general and deviations from the norm in particular. Movie stories and psychiatric case histories have always drawn their content from the same reservoir of heightened emotions and unusual motivations.

As early as 1900, 5 years before the proliferation of nickelodeons, Clifford Beers testified to the psychological power of the new medium in his groundbreaking *A Mind That Found Itself* when he described his psychotic break in these terms:

I imagined that these visionlike effects, with few exceptions, were produced by a magic lantern controlled by some of my myriad persecutors. The lantern was rather a cinematographic contrivance. Moving pictures, often brilliantly colored, were thrown on the ceiling of my room and sometimes on the sheets of my bed. Human bodies dismembered and gory, were one of the most common of these.

As therapy and cinema developed, they have interacted in three major directions: the commercial film has depicted psychiatry and psychotherapy in various ways; teaching films have been developed to illustrate psychopathological states and treatments; and movies have been used in therapy to highlight themes of troubled patients.

I. HISTORY OF COMMERCIAL FILMS AND PSYCHOTHERAPY

Early movies, apart from a variety of trick and fantasy subjects, were mainly depictions of real-life events, and real or faked historical occurrences. A number of physicians, intrigued by the new invention, used it as a teaching tool to photograph an array of neurological and psychiatric pathological states. Only a year after the first public showing of a motion picture in 1897, Paul Schuster of Berlin filmed patients with a variety of neurological disorders. A year later the Romanian clinician, George Marinesco, filmed the gait in hemiplegia and paraplegia. About 1905, Emil Kraepelin in Munich began to make films of psychiatric cases. In 1908, Camillo Negro of Turin made a number of medical films of neuropathic disorders. The first attempt to use movies to depict neurological patients in the United States was made by Dr. Walter Chase of Boston. It was a film demonstrating characteristics of epileptic seizures. On a sunny day in 1905, he assembled on the lawn 125 naked patients, covered only with blankets, and waited. A fixed movie camera stood in readiness. As soon as a patient began to have a seizure, the blanket was removed, and the patient was placed in front of the camera. On that one day, 21 grand mal seizures were filmed.

By the middle of the first decade of the century, story films began to predominate. These were one reelers, about 10 min in length, leaving little room for character development or subtlety. The first treatment of psychiatric patients consisted mostly of comic chases in which asylum patients, dressed as Napoleon in some films, outwit their attendants in escaping from the hospital, lead them a merry chase through the countryside, tormenting them along the way, and then return to the asylum. *The Escaped Lunatic*, *The Maniac Chase*, and *Dr. Dippy's Sanitarium* are examples of these films. Other films of the period featured such titles as *The Kleptomaniac*, *What Drink Did*, and *A Drunkard's Reformation*. More serious and dramatic treatments of mental illness appeared in D. W. Griffith's 1909 *The Maniac Cook* and *The Reformation*.

The 1906 chase film *Dr. Dippy's Sanitarium* depicted the first psychiatrist, an asylum doctor, to appear in films, and the 1909 Griffith one reeler *The Criminal Hypnotist* featured the first outpatient psychiatrist. However, these movies are interesting for another reason. These two crude films present, at the very outset of movie depiction of psychiatrists, the three dominant models of mental health workers that would recur throughout film history. First, a brief synopsis of the films.

Dr. Dippy's Sanitarium opens with Dr. Dippy hiring a new attendant. The employee is introduced to four patients who are to be in his care, one of whom is a woman. The four inmates perform comic "lunatic" routines and then begin to harass him. Finally, the three male patients escape from the hospital, closely followed by the corpulent, frantic Dr. Dippy and excited attendants. As was characteristic of other maniac chase films, the escape ends up back at the hospital where the goofy doctor distracts and soothes the increasingly violent patients by giving each a pie (is this the first major tranquilizer in the movies?).

The Criminal Hypnotist tells the story of a party hypnotist who puts a young woman under his spell and instructs her to steal money from her father's desk drawer. He absconds with the money and leaves her in her home still in a trance. Her father sends for a "mind specialist," a term apparently more meaningful in that era than psychiatrist or alienist. The large, stocky, bearded specialist quickly responds. He immediately recognizes the problem and lightens her trance, preserving enough of it to enable the young woman to lead him, her father, and a policeman to the hypnotist's lair. As the policeman takes the villain away, the "mind specialist" fully clears the young woman's mind, and she falls happily into her father's embrace.

What appears in these films is the emergence of three distinct types of mental health specialists (when the hypnotist is included as a mental expert), essentially archetypes. Irving Schneider has named them Dr. Dippy, Dr. Wonderful, and Dr. Evil. All movie depictions of therapists can be seen as featuring one or another of these types. Dr. Dippy is the typical comical movie psychiatrist, the one who is crazier or more foolish than his patients. Some classic films in which he has appeared are *Mr. Deeds Goes to Town* (1936), *Bringing Up Baby* (1938), *Carefree* (1938), *What's New Pussycat?* (1965), and *High Anxiety* (1977).

Dr. Evil, as he appears in so many movies, has an urge to master or control, often for criminal purposes, but just as often for the sheer pleasure in power. He is willing to experiment without regard to human consequences, and those who come under his control are often driven to murder, suicide, or crime. When he treats patients, he is likely to use methods seen as coercive: ECT, lobotomy, drugs. Examples of his appearance are *The Cabinet of Dr. Caligari* (1919), *Nightmare Alley* (1947), *I, the Jury* (1982), *Dressed to Kill* (1980), and *Frances* (1982).

Dr. Wonderful is all that Dr. Evil is not. He is humane, earnest, modest, and deeply caring. He is always ready to come to the patient's rescue, whatever the time or circumstance. He is gifted at improvisation, especially when necessary to uncover traumatic events, and thereby achieves instant cures. His treatment is almost always the talking cure, seldom drugs or procedures seen as coercive. Some classic examples of these films are *Secrets of a Soul* (1926), *Now, Voyager* (1942), *Spellbound* (1945), *The Snake Pit* (1948), and *Ordinary People* (1980).

Throughout movie history the Dr. Dippys and Dr. Evils have outnumbered the Dr. Wonderfuls, which is either a commentary on movie plots or a reflection on how the profession is viewed by much of the public. Some typical movies of the decades since the 1930s that are examples of each of the three archetypes follow, representing a Dr. Dippy, a Dr. Evil, and a Dr. Wonderful. The 1930s had few psychiatric movies, but among them were *Mr. Deeds Goes To Town*, *The Testament of Dr. Mabuse*, and *Private Worlds*. In the 1940s, *Miracle on 34th Street*, *Nightmare Alley*, and *King's Row*. In the 1950s, *Harvey*, *I, the Jury*, and *The Three Faces of Eve*. The 1960s saw *Three On a Couch*, *A Fine Madness*, and *Pressure Point*. The 1970s featured *Deep Throat*, *One Flew Over the Cuckoo's Nest*, and *I Never Promised You a Rose Garden*. The 1980s had *Lovesick*, *Dressed To Kill*, and *Ordinary People*. The 1990s, *What About Bob?*, *Basic Instinct*, and *Good Will Hunting*. A complete filmography of psychiatric movies appears in the Krin Gabbard and Glen O. Gabbard book *Psychiatry and the Cinema*.

The very first film to depict psychotherapy was made in Germany in 1926. An executive of UFA, the principal German film company, suggested to Karl Abraham that he participate in making a film that would illustrate some of the mechanisms of psychoanalysis. Freud was not happy with the project but did not actively discourage it, so it proceeded with Abraham and Hans Sachs (who was increasingly involved because of Abraham's fatal illness) acting as consultants. The resulting film, directed by G. W. Pabst, was the famous *Secrets of a Soul* (*Die Geheimnisse Einer Seele*), subtitled *A Psychoanalytic Playlet*.

The story, taken from life according to the credits, tells of a chemist who develops a knife phobia, impotence, and homicidal impulses and is cured by psychoanalysis. Dream analysis plays a significant role in the treatment, with somewhat sophisticated visuals and interpretations.

The film is prefaced by the following statement:

There are desires and passions which are hidden beneath our conscious minds. These unconscious desires come to the surface especially in moments of mental conflicts and depressions. At such times, mysterious sickness can develop which are part of the field of psychoanalysis. The progressive teaching of the university professor Dr. Sigmund Freud showed doctors trained in psychoanalysis the way toward healing such sickness.

As it turned out, psychoanalysis has become the principal theory and method of movie psychiatry. Sometimes wacky and sometimes serious portrayals and explanations of psychotherapy have taken off from the psychoanalytic model. Consider how psychoanalyst Fred Astaire explains his profession to reluctant patient Ginger Rogers in *Carefree* (1938):

Miss Cooper, you understand the principle of psychoanalysis, don't you? ... You do know that you have two minds, the conscious and the subconscious? The conscious mind is the ego; that's a thing that says, "I am I and you are you" ... let me put it this way. [Hand to back of head] Back here is a jungle full of the most noble and horrible things. ... That's your subconscious mind. It works all the time, even when you sleep. It dreams. It never forgets anything. Your conscious mind lies here [Hand to front of head] It doesn't dream. It thinks. What we try for is perfect coordination between the two. Do you understand? ... To psychoanalyze you, I have to interpret your dreams. What sort of things do you dream?

A somewhat more sophisticated statement appears in the 1945 film *Spellbound*. By that time, psychoanalysis had become popular in the movie colony. The producer, David Selznick, had been in personal analysis with May Romm who became consultant to the film, and the screenwriter, Ben Hecht, had done his homework interviewing several analysts. Here is how European analyst, Michael Chekhov, explains his work to amnesiac patient, Gregory Peck:

I'll explain to you about dreams so you don't think it is hokey. The secret of who you are and what has made you run away from yourself – these secrets are buried in your brain, but you don't want to look at them. The human being very often doesn't want to know the truth about himself because he thinks it will make him sick; so he makes himself sicker trying to forget. You follow me? ... Here is where dreams come in. They tell you

what you are trying to hide, but they tell it to you all mixed up like pieces of a puzzle that don't fit. The problem of the analyst is to examine this puzzle and put the pieces together in the right place and find out what the devil you are trying to say to yourself.

In recent years, such explanations of psychodynamic principles have not been necessary. Both Hollywood and the movie public have grown more sophisticated about psychotherapy. The treatment course in movies, however, remains stereotyped and elementary. It follows a typical path. As doctor and patient get to know each other, sometimes with initial conflict, they begin to explore the patient's life. At a critical moment, perhaps as a result of some outside event, the Dr. Wonderful makes a crucial intervention, and the causative traumatic event is unveiled. The patient is cured; often patient and doctor fall into each others' arms, and they all live happily ever after. To achieve this outcome, drugs or invasive treatments are almost never used. Examples of this include *Home of the Brave* (1949), the first modern film about race; *Ordinary People* (1980), *Good Will Hunting* (1998), and *Analyze This* (1999).

In contrast to this felicitous but uncommon outcome, real therapy requires patience and attention and yields occasional, but not so dramatic, breakthroughs. Probably the most realistic therapy scene depicted in the movies occurs in Paul Mazursky's *Bob & Carol & Ted & Alice* (1969). It features Don Muhich, a real-life psychiatrist, as the therapist, and Dyan Cannon as the patient. As Muhich sits stonefaced in his chair, she sits on the couch talking animatedly about her marriage. At one point, she makes a significant slip of the tongue, which he points out to her. She is startled about what the slip may mean, but as she starts ruminating about it the hour comes to a close. The doctor's problem now becomes how to get the reluctant patient out of the office in time for his next patient, while at the same time not closing out her new insight. The scene is played for comedy, but most therapists will immediately recognize the genuineness of the scene, as they might in some other realistic portrayals in *Blume In Love* (1973), *An Unmarried Woman* (1978), and *Lovesick* (1983).

Many of the rules for Dr. Wonderful do not seem to apply to female therapists. The career path for female therapists is quite different from their male counterparts. As Glen Gabbard has pointed out, no film in Hollywood history has ever shown a satisfying personal life and a successful analytic career co-existing in the same woman. Female therapists are either single, unhappily married, divorced, childless, or otherwise unfulfilled. And in their work there is almost no example of the fe-

male therapists effectively and ethically treating the male patient. The most glaring boundary violations occur in the area of romance. In real life, the most frequent occurrence of patient-doctor sexual violations takes place between male therapists and female patients. In the movies, however, female therapists frequently and approvingly fall in love with a male patient. The female side trumps the therapist's side. Consider Ingrid Bergman in *Spellbound*, Barbra Streisand in *The Prince of Tides* (1991), Lena Olin in *Mr. Jones* (1993).

Another difference between movie therapy and real-life therapy is manifest in the mental conditions being treated. Rather than the more common cases of depression, anxiety, bipolar illness, schizophrenia, and just plain unhappiness that therapists treat most often, movies, although including these, that is schizophrenia with *David and Lisa* (1962) and *The Snake Pit* (1948), have concentrated on the more dramatic diagnoses. The list of disorders overly represented in the movies includes dissociative reaction, especially amnesia and multiple personality (*Spellbound*, *Three Faces of Eve* 1957); homicidal mania, especially when combined with dissociative identity disorder (*Psycho* 1960, *Dressed To Kill* 1980, and *Halloween* 1978); substance abuse (*The Lost Weekend* 1945, *Days of Wine and Roses* 1962); disorders of impulse control; hysterical paralysis (*Home of the Brave*); phobic disorders (*Vertigo* 1958 and *High Anxiety* 1977); paranoid disorders (many action and horror movies); and no mental illness, with or without greater wisdom. This last category has been the terrain in which Dr. Dippy reigns supreme. Many of the Woody Allen movies are examples of this category. A popular version is *What About Bob?* (1991) in which a patient pursues his pompous psychiatrist to his summer home, ingratiates himself with the doctor's family and colleagues, and proceeds to take over his practice.

Psychological conflict and heightened emotion have been the dramatic material for commercial movies since the industry started. From the beginning and all through the years, psychotherapists and psychotherapy have periodically appeared to add a professional identity to the plot. This juncture at which therapy and dramatic content meet has been the subject of the first part of this article.

II. TEACHING FILMS

As already noted, the use of films for demonstrating clinical pathology began early in motion picture history. This effort has continued, but because of problems with sound reproduction and other technical

issues, this endeavor has tended to concentrate on neurological problems, and studies in infant and child behavior rather than therapy. The most famous of these were Arnold Gesell's films at the Yale Clinic of Child Development, Kurt Lewin's Iowa State University studies of social behavior, Rene Spitz's films of emotional starvation in infants, and Margaret Fries's studies of the effects of different maternal attitudes on the child's development. Though not directly dealing with therapy, these films had an effect on therapeutic theory and practice.

World War II led to John Huston's famous *Let There Be Light* (1945), which depicted the sodium pentothal treatment of various combat-related neuroses. However, the use of actual patients limited the showing of the films, ostensibly to protect the identity of the patients. Parenthetically, a similar fate befell Frederick Wiseman's *Titicut Follies* (1967), filmed in a Massachusetts prison hospital for the criminally insane with actual inmates.

After the war, the National Film Board of Canada made one of a series of mental health films, *The Feeling of Rejection* (1947). This was intended as an aid to group therapy, but like many of the Board's films it received a response from all audiences. By 1949, there was a heightened demand for films on mental health. The National Institute of Mental Health of the U.S. Public Health Service participated in establishing the Mental Health Film Board. This group supervised the production of many mental health films, including *Angry Boy* and *Fears of Children*.

In the late 1940s and early 1950s, the Veterans Administration produced a series of mental health films, including a group titled Psychotherapeutic Interviewing Series. Carl Rogers conducted a group of therapy sessions on film for teaching purposes. Several pharmaceutical companies sponsored films for therapists. The National Institute of Mental Health in the 1960s filmed a complete psychoanalysis, lasting for years. This film required extra-long reels of film, special projectors and cameras, and a room with a one-way mirror. There were high hopes for the research gains from this project, but very little was accomplished. Hundreds of film cans are stored somewhere but never seen.

From 1960 through the 1990s, Edward A. Mason, a psychiatrist/filmmaker at Harvard University Medical School produced a well-made series of teaching films. The subjects include consultation techniques, interview methods, street corner research, and above all, children's issues. His Wediko Series featured residential treatment of a group of conflicted adolescent boys. Unlike many of previous mental health films, his films are not acted; they depict real people in real-life situations.

Filmmaking is an expensive undertaking. Filmmakers like Mason are always concerned with budget and fund-raising. With the advent of video, it suddenly became possible with a small investment in equipment to become a moviemaker. Film and processing costs were no longer a problem. Many therapists began making films at centers all over the country. Two pioneers in this endeavor were Milton Berger on Staten Island and Ian Alger in New York City. The video revolution deserves notice but cannot be dealt with here.

III. USE OF FILMS IN THERAPY

The use of commercial films as a stimulus to therapy has become popular, but it also has a history. In the late 1930s, the Commission of Human Relations of the Progressive Education Association used material from 30 feature films for group discussion. However, given the costs and practical requirements of renting that many films, the effort had little influence.

Similarly, when Steven Gressitt in the 1970s compiled a catalogue of films dealing with a variety of mental traits and diagnoses for teaching psychiatry students and laypersons about varieties of human behavior, getting that many films was a problem in cost and accessibility. Harvey Greenberg avoids that drawback. In his book, he advocates asking patients about their favorite movies. He has found this to be a useful device, almost a projective test for highlighting patients' dynamics.

With the advent of videocassettes, all the problems of accessibility have been resolved. A spate of books has been published that describe the use of video in therapy. Typically in these books, commercial movies are catalogued according to theme. This may involve a diagnosis, a dominant feeling, or a painful event. All are generally available in the local video store. According to what the therapist sees as the patient's problem, the appropriate video is assigned for home viewing. The resulting experience is then discussed in the therapy session that follows. The claim is that this process illuminates the issues and frees the pent-up emotion. One example of this approach is included in the Further Reading section.

IV. SUMMARY

Movies are one of the principal inventions of the 20th century. Whole populations have been educated

in the ways of dress, manners, vocations, romance, sex, criminal behavior, and history. Censors have forever fought to limit access to one or another of these influences. Throughout the history of movies, one theme has remained prominent, the vagaries of human behavior. This, too, has been the realm of psychotherapy. Inevitably, cinema and psychology have found common ground. Some aspects of this interaction have been presented in this article.

GLOSSARY

clarification Technique for gaining clearer understanding of the meaning of a patient's conscious (manifest) behavior and experience.

confrontation Technique of directing a patient's attention to inner experiences or perceptions of outer reality of which he or she is conscious or is about to be made conscious.

interpretation Verbalized understanding of meaning, conscious or unconscious, of patient behavior or experience.

introjection Form of internalization by which properties or functions of another person in a relationship are assimilated to the self-structure but remain partially integrated, instinctually motivated, and defensively organized. Introjective structure is reflected in self-representations.

reconstruction Recovery and formulation of past events to gain understanding of hidden meanings.

entiate meanings more accurately, and particularly to gain clearer and more accurate differentiation of self-organization and the relationship to the world he or she lives in. Earlier views saw clarification as consisting in restating the patient's feelings or thoughts in clearer or more precise terms. A fundamental distinction lay between clarification and interpretation: Interpretation involved conveying meaning or some form of explanation, however hypothetical, whether of meaning or causality. The general consensus was that clarification did not refer to unconscious (repressed or otherwise warded off) material but to conscious and/or preconscious processes, of which the patient was not sufficiently aware or which escape attention, but which can be recognized more-or-less readily when clearly presented to the patient. In contrast, interpretation may deal with conscious or unconscious content and processes and typically focuses on unconscious rather than conscious material.

Clarification is also distinguished from confrontation, which, along with clarification, provides another technical channel for dealing with conscious content in the patient's ongoing behavior. Although clarification has the function of making clear or of bringing about recognition, it does so in a more neutral and dispassionate fashion; confrontation adds the note of activity on the part of the therapist, emphasis, even forcefulness, and the overcoming of resistance. Clarification does not target resistance, but unclarity or lack of awareness. There may be defenses behind these

I. MEANING OF CLARIFICATION

The concept of clarification is centered on the basic idea of helping the patient to see more clearly, to differ-

obscurities, but clarification goes no further than calling attention to them when apparent. But even more subtle differences may come into play. There is a difference between accusing the patient of wasting time versus observing that the patient is still reacting as if his or her work with the therapist were doomed to be unproductive. The former is confrontative of resistance and renders a judgment, the latter provides merely a translation. The latter statement is more in the order of directing the patient's attention to a subsequent line of interpretation. The difference has to do with the presence of the therapist in the intervention. The patient's assent to the first intervention necessarily involves accepting both the fact and the role of the therapist, whereas assent to the latter requires only acceptance of the fact. In a sense, then, confrontation involves the therapist's forcing of the self on the patient, an intrusiveness involving real activity on the part of the therapist beyond transference considerations.

In these approaches, clarification is treated as a form of intervention aimed at clarifying something in the patient's mind. But before that can be done, clarification has to take place in the therapist's mind. Clarification, then, is involved in the inquiry directed to understanding for both patient and therapist. Its objective is seeking information. The focus of clarification can be something the patient tells us about his or her experience outside the consulting room, something related to activities or relations with other people. What we want to find out are the details, the specifics of action and interaction to whatever extent the patient can remember or reconstruct them. The basic tactic is to encourage the patient to tell us more about the event or events in question, to convey interest, to ask questions to elicit more information. The point of course is that the devil is in the details—the more we can know about the specifics the better purchase we can get on the meanings and motives embedded in the account, the more opportunity we have of hearing the subtle reverberations of repetitive themes and transference enactments. Among the more important details are whatever affects or feelings the patient can recount; the closer one gets to the concrete details of the situation, the more available are the relevant affects. In addition, the closer one gets to the specifics, the greater the likelihood that the material in the current event will reverberate with comparable events in the patient's network of associative material, and that parallel or comparable material from the patient's life history will become available, thus facilitating the process of free association.

II. RECOUNTING AND RECONSTRUCTING

Fundamental to the therapeutic role of clarification is the fact that as the patient develops his or her account of the events, whether that be some recollection of past, even childhood, events, or events occurring in recent or current experience, the patient subjects the material to a process of objectifying in constructing the narrative material, first in his or her own mind and then in telling it to another listener. In so doing, the patient reviews the material in his or her own mind, objectifying it in the process of reconstructing details. In this way, patient and therapist take the first steps along the path toward interpretation. Not only does the therapist gain a better understanding of what was involved in the event and why, but the patient does also—not by reason of any input from the therapist, but solely by reason of personal objectifying review and reconstruction.

As has been noted from the time of Freud, the patient's reconstruction, whether of a memory, fantasy, dream, and so on, is not necessarily a veridical recounting of actual events, but a rendering conducted through the lenses of retrospective construction (Freud's *Nachträglichkeit*), screen functions, selection, defensive distortion, and so on. These introjectively derived fantasy-related phenomena and their role in early object relations as well as current transference relations can be further clarified, helping to specify the patient's introjective configuration and progressively delineate it from reality. The interpretive process aims ultimately at maintaining a distinction between fantasy and reality: this issue, the clarification of the boundaries between the patient's fantasy life and its derivatives and reality is one that pervades the interpretive process from beginning to end. Even at the earliest stages of interpretive work with many patients, the therapist's effort is also directed toward beginning to establish the rudiments of a working alliance, which may require some clarification and at least phenomenological interpretation of the patient's experience in the therapeutic relationship as reflecting more therapeutic misalliance than therapeutic alliance.

Drawing the account closer to the concrete specifics does not eliminate these factors but does modify their impact to a degree. We are consequently forced to accept a degree of partiality or probability in any such account, that will usually yield to further elaboration or correction as the therapeutic inquiry continues, but never allows us the consolation of achieving an assuredly factual narrative, that is we may never get beyond narrative truth. If we do not arrive at the certitude of a factual account, however, neither do we necessarily have to settle for an

historical fiction. I would question the assumption that the truth generated in the course of therapeutic inquiry is either exclusively narrative or historical; the account of the past rather shares to some extent in aspects of both. The account of the past reconstructed from the patient's memories and associations is basically a subjective account that may or may not approximate to some degree the veridical historical events. However, the therapist is not directly interested in establishing such a veridical account but is concerned with finding the meaning of the reconstructed events in the patient's mind. If the account is not based in some degree on historical truth, that is based on data that bear the stamp of real happenings in the patient's memory and thus have a verifiable factuality, the reconstruction remains a fiction or illusion lacking credibility and impact for the patient. Thus, I would argue, not any reconstruction will do, but only that reconstruction that conveys a sense of factuality and resonance with the patient's experience and achieves a level of consensual acceptance for both therapist and patient.

From this point of view, then, clarification can be seen as integral to the interpretive process. Even more tellingly, clarification emerges as a process involving therapist and patient in a dialectic of inquiry, each enacting a contributory role in the process—the patient remembering, reconstructing, and recounting, the therapist listening and inquiring. This emphasis on the interactive quality of clarification process moves beyond early views of clarification in a one-person paradigm and locates the therapist's clarifying activity in a two-person process without changing the essentials of what the therapist does or what it means. In the classic view, the therapist clarifies by presenting a clarifying comment for the patient's consideration; but in the present view such an active intervention is only one dimension of clarification that reflects an underlying process of seeking for clearer information and understanding.

III. CLARIFICATION OF THE SELF

Clarification has another and even more important focus, namely what is involved in the patient's experience of self in whatever context of action and reaction or interaction encountered. We are concerned here with clarification with respect to the patient's self-introspection, that is the subjective experience of self as object. Clarification in this respect involves the same attention to specifics and detail as described earlier with regard to external events, but here the focus is on the patient's subjective self-experience, with special attention to affective states and feelings. The supposition

here is that the configuration of qualities the patient attributes to himself as a person plays a crucial and central role in the patterns of maladaptive, self-defeating, and pathogenic action and experience that lie at the root of the neurotic difficulties or character faults. This aspect of the subjective inner world can be described phenomenologically in terms of pathogenic self-images or self-representations, that is of the patient's self- and object representations and their relation to self- and object roles in the therapeutic interaction, or in more structurally oriented terms as introjective configurations.

The introjects are derived from internalizations of significant objects in the patient's developmental history, but in distinction from identifications, are based on instinctual motivations, largely aggressive and narcissistic, and reflect corresponding defensive organization and expression. The introjective configuration can be schematized along the lines of aggressive and/or narcissistic derivatives distributed in polarized components. The aggressive components are centered in the aggressor introject versus the victim introject; narcissistic components find expression in the superior versus inferior introjects. These introjective configurations are all present and active in all forms of psychopathology, but with varying patterns of expression and emphasis. One component may dominate the structure of the self as object, while the rest are repressed or left operating more subtly in the background. In masochistic patients the victim introject may hold sway and determine the patient's self-experience, but not without contributions from the other components. In shame-prone patients, the narcissistic inferior introject is prominent, while the others remain in the background. Moreover, where one component dominates, the polar opposite is always in one way or other operative and will in time and with continuing inquiry and clarification come into play. Where the aggressor introject predominates, there is always a corresponding sense of the self as victim; where the narcissistic inferior introject is on display, the superior introject (grandiose self) is not far behind.

The clarification of these pathogenic introjects, including the gradual delineation of the component elements, identification of the polarized aggressive and narcissistic dimensions, awareness of their reciprocal defensive involvement, and the manner in which they form an integral whole within the subject's experience of himself, as well as progressive differentiation between elements of fantasy and reality, all contribute to the gradual delineation and undermining of the embeddedness and investment in the introjects. This much of the process is rarely sufficient for effective therapeutic intervention but leads to a further step of exploring and establishing their derivation.

The introjects are internalized derivatives of relationships with important others, so that exploration of their derivation requires clarifying the specific ties to past and/or present individuals in the patient's experience. How to accomplish this is a matter of clinical judgment and technique. With some patients exploration of this area of their experience can be done fairly actively, but this is not often the case. More frequently, the exploration must be more indirect and subtle and requires a considerable degree of self-discipline and patience on the part of the therapist. Little by little, the picture of the patient's past relationships, particularly with parental figures, becomes clearer. The pitfalls are familiar enough, and it often takes a considerable amount of time and work before more reliable information about the patient's past experience becomes available. Early reminiscences or even the first or second rendition of the patient's past experience cannot be taken as having unquestionable validity. The picture that the patient paints in the first rough sketching of his or her past will be progressively filled in, resketched, refined, and recast as the therapy progresses. It is not simply a matter of recapturing a past reality. Rather, what is in question is the recapturing of the patient's experience, which may be overladed and permeated with elements of fantasy, wish, desire, and defense. The task is to retrace the patient's experience, to establish the links between the present organization and structure of the introjects and the patient's past experience of personal relationships. The critical persons in this context are, of course, the parents, though not exclusively. Other important figures may enter in, depending on the peculiarities of the patient's life experience. Siblings may play a vital role, or other relatives such as aunts or uncles, or even nonfamily figures.

Likewise, the clarification of important relationships can only be usefully undertaken in the context of a reasonably good therapeutic alliance; it may not be useful to try to clarify or confront the patient's convictions about important objects, because disruption of such object connections may be more damaging than helpful. Patients can be brought gradually to a point of recognizing and understanding the more realistic aspects of their relationships, but this comes as the fruit of therapeutic effort and can be achieved only in the context of a solid therapeutic alliance.

IV. CLARIFICATION AND THE TRANSFERENCE

Nonetheless, confrontation along with clarification may have an important role to play, especially early in

the course of the therapy. Interpretation is not possible or useful until the patient has developed some degree of at least a working alliance. As long as the therapist's interpretations are caught up in the vicissitudes of the patient's projective distortions and negative transference reactions, they will be heard as either threatening or destructive, or if reflecting a more idealized transference situation as unempathic reinforcements of the patient's transference views. Consequently, a relative focus on the patient's daily life experience and a process of gentle and gradual clarification can lead not only to the establishing of a better alliance but can also gradually clarify and delineate the pathological patterns of interaction that the patient generates both within the therapeutic interaction with the therapist and in important relationships outside the therapy. Success with many more severely disturbed patients is a function of the accuracy, empathy, and timeliness of the therapist's gentle and understanding clarifications and confrontations that lay the basis for later interpretations and to a degree contribute to unveiling transference. Especially, gentle confrontation and clarification of the patient's feelings about the therapist can open the way to clarification of therapeutic alliance issues and further analyze transference reactions.

Part of the process of clarification of the introjects depends on their display in the transference. The clarifying process tries to link aspects of both aggressive and victim introjects and superior and inferior narcissistic introjects, as discovered in the other aspects of the therapeutic work, with the patterns emerging in the transference, as deriving from a common root. Recognizing and acknowledging these patterns in the ongoing interaction with the therapist can often make a powerful impression on the patient and add conviction and vividness to the basic patterns.

In the interest of maintaining the therapeutic alliance, the therapist must pay careful attention to negative transference elements. A consistent element in many therapies is the patient's efforts to defeat the therapist, to make the therapy into a meaningless and ineffectual game as well as to destroy whatever there is in the experience that may be positive and constructive. Behind this lies the inner necessity on the part of the patient to maintain the introjective configuration that provides the core of the often-fragile and unstable self-organization. As I have already suggested, the projective elaboration underlies and induces a transference-countertransference interaction, the underlying motivation for which is preservation of the pathogenic introjective organization. Thus, a constant attention to focusing, clarifying, and eventually interpreting negative transference elements is of particular

importance in the interest of establishing and maintaining a therapeutic alliance.

Therapeutic clarification is particularly useful when the patient adopts the victimized position, reflecting the underlying victim introject. The need for some patients to preserve the sense of victimization (victim introject) forces them to provoke aggressive or devaluing responses from the therapist, often in the form of acting out around the dimensions of the therapeutic structure, forcing the therapist, for example, to take remedial limit-setting measures. It is essential for the therapist to set limits to maintain the parameters of the therapeutic situation, but the risk of being drawn into a transference-countertransference interaction cannot be ignored. A clear statement of the patient's victimized position, or of the potential victimizing effects of a projected course of acting out, can serve as a useful way of focusing on the underlying dynamics and the motivations related to them and of bringing into focus their effects on the therapeutic work and particularly the therapeutic alliance. Such clarifications, and where necessary, confrontations with the patient's potential self-destructiveness, and need to assume the victimized position carry with them a reassurance that the patient is not on this account abandoned or rejected, and undercut the pull in the countertransference reaction to playing into the patient's victimization, thus reinforcing it.

The risk of acting out of the transference can be dealt with by a combination of clarification, confrontation, and interpretation. The extent to which these interventions can be usefully employed in such situations depends on the degree to which the therapeutic alliance is effectively intact. Where the alliance is disrupted or significantly distorted, interpretive efforts are liable to yield little fruit. Nonetheless, active confrontation and clarification of the issues, particularly in alliance terms, and a clarification of the possibly harmful consequences for the patient and the role of the patient's intended acting out in undermining the work of the therapy is often sufficient to short-circuit the patient's impulse.

These experiences have considerable potential value in that they immediately involve both patient and therapist in the process. The therapist does not have to rely on a secondhand account with all its potential for distortion and obscurity but is himself engaged in the process with the patient, so that the elements that enter into the patient's need to act out can be more directly and effectively identified and dealt with. In a mild form, for example, the patient may act out around the issue of coming to the appointments on time. Usually, this reflects some distortion in the therapeutic alliance and may or may not reflect underlying transference dynamics. Yet the con-

tributing factors lie ready at hand for examination as a part of the ongoing therapeutic interaction and can be clarified, explored, and dealt with in those terms. The patient who comes late following the therapist's vacation is usually expressing some degree of resentment or anger at abandonment by the therapist. Clarification and interpretation of the feelings of abandonment can usually effectively modify the patient's behavior.

For some patients in whom the impulse to act out is inconsistent with their self-image and creates anxiety, the therapist's effort to clarify, and even at times interpret the basis of the impulse and the possible consequences are enough to forestall the behavior and enable the patient to reestablish reasonable control. Often, the clarification of the patient's feelings, particularly what the feelings may be about and against whom they would be directed, or a clarification and exploration of possible consequences of the actions envisioned by the patient, or even clarification and interpretation of the patient's impulse by comparing it to similar impulses in other contexts, whether in the patient's current life situation or in the past life experience, to whatever extent that is available, enables the patient to gain some perspective and objectivity about the projected course of action and allows him or her to bring resources to bear to forestall a self-destructive or potentially detrimental course of action. At times substitute actions can be discussed, which would be in the long run more adaptive and even effective for the patient. At times it is also useful for the therapist to anticipate patterns of acting-out behavior, especially when the previous experience of the ways in which the patient has dealt with similar stimulus situations would lead the therapist to expect that some parallel pattern of behavior might evolve. The classic example is the exploration of a patient's projected behavior during the therapist's vacation. The exploration of these possibilities and the comparison of the anticipated pattern of behavior with similar previous experiences can be both clarifying and extremely helpful.

One young man who was given to impulsive rage attacks became furious during an argument with his girlfriend and put his fist through a wall. The consequences were that not only did he have to pay for the damage to the wall, but he also broke his fist, which had to be put in a cast, which meant that he could not work and subsequently lost his job. In subsequent therapeutic work with this patient, it was extremely helpful to anticipate situations of conflict and tension in which his impulse to act out in some self-destructive way could be discussed, clarified, the feelings explored and connected with a variety of similar and previous contexts, and some sense of

adaptive options developed that might provide more mature and even constructive outlets for his anger.

Extending the exploration and clarification to include the derivation of the introjects has the additional benefit of clarifying that the patient's experience of self and the world around—and particularly relationships with other important figures—is dependent on experiences and patterns of responding deriving from the patient's own infantile past. The disparity between that past and the present experience reinforces insight into the fantasy quality of the experience generated from the introjects and clarifies the distinction between elements of that experience and the real world of the patient's present life. In the transference neurosis, of course, this understanding and realization are borne in on the patient with particular force, because it allows him or her to see most clearly and vividly how the patterns of infantile relating play themselves out in inappropriate and unrealistic ways.

V. THERAPEUTIC CONTEXTS

There is some differentiation in the role of clarification with respect to expressive versus supportive approaches to therapy, although the climate of opinion has shifted somewhat to seeing psychotherapy for the most part as combining supportive and expressive techniques. More expressive approaches seek to bring about structural change by way of clarifying and interpreting the patient's distortion of self and the object world primarily through analysis of transference. More supportive approaches, in general, recommend focusing on current events and recent sources of stress in the patient's life and tend to focus away from transference elements, particularly where they seem regressive; attention is directed to clarifying feelings and reinforcing a sense of reality. The therapist takes a more active stance in supporting and reinforcing the patient's adaptive capacities, supporting useful defenses, and generally acting as an auxiliary ego. Thus, supportive approaches tend to rely more extensively on techniques of clarification focused on current conscious manifest experience, whereas expressive approaches seek to go further and deeper to interpret psychogenetic, dynamic, and unconscious implications of the patient's behavior. If therapy shifts more in the direction of an expressive modality, interpretation comes to play a more prominent and central role. When the therapy is more supportive, interpretation is by no means ruled out but tends to assume a more modest role in favor of a more prominent use of

other more supportive techniques, including clarification, confrontation, giving support, encouragement, advice, and so on.

Clarification has a special role to play in family therapy. In dealing with the family, the therapist must be clear about the nature of the relationship to the patient and how that interdigitates with the relationship to the family and what his or her purpose and role is in each of those related contexts. Ultimately, the desire for all parties involved must be taken as seeking the well-being of the patient as connected with the better- and healthier functioning of the family system and ultimately to the benefit of all parties involved. This clarification and stance must be maintained in the face of continual pressures from all sides, on the part of both the individual patient and the family, to undermine this position, to draw the therapist into one or other transference position, and to elicit from him or her some form of countertransference response that will serve to undermine the therapeutic alliance, destroy the therapeutic position and make him or her ineffectual as a therapist, and thus preserve the underlying fantasies and narcissistic and aggressive distortions that are an integral part of the neurotic family system.

Often enough treatment of adolescents involves work with the family. The difficulties in maintaining a therapeutic alliance with a disturbed adolescent patient are monumental enough, but when the therapist moves into the realm of family therapy, in addition to the work with the patient, the situation inevitably becomes more complex and difficult. There is a kind of cost-benefit analysis involved—the cost in terms of the jeopardy to the alliance and the individual therapeutic effort versus the gains to be gotten from the work with the family. That analysis is not always negative. Where the therapeutic alliance with the adolescent is sufficiently stabilized, where the therapeutic interaction is such that the potential difficulties in the alliance that may arise from the involvement with the family system can be explored and clarified and understood, and where the therapist is able to maintain a sufficiently balanced position in the dual role as individual and family therapist, the process can often be gratifying and successful.

VI. SUMMARY

This article discusses the nature of clarification as an integral component of the interpretive process, and as distinct from both confrontation and interpretation. Clar-

ification concerns inquiry and seeking for understanding, thus providing the basic material essential for further interpretation. Clarification focuses not only on the patient behavior and experience with others in external interactions, present or past but includes consideration of the person's inner subjective experience of self as acting and experiencing, especially aspects of the affective experience. Clarification of both aspects of the experience provides the basis for clearer and more meaningful understanding both of self and of his or her behavior.

GLOSSARY

classical conditioning A form of associative learning in which a neutral stimulus is paired with an unconditioned stimulus. After a sufficient number of trials the neutral stimulus comes to elicit responses similar to those originally evoked by the unconditioned stimulus.

counter-conditioning A classical conditioning procedure in which a stimulus that formerly elicited one response (e.g., pleasure) is conditioned to elicit a different response (e.g., nausea). Sometimes used in the treatment of paraphilias and substance use disorders.

exposure A group of methods commonly used to treat phobias and other anxiety disorders. Exposure involves presenting the person with harmless but fear-evoking stimuli until the fear response is extinguished.

extinction Reduction of a learned response by presenting the conditioned stimulus in the absence of the unconditioned stimulus.

operant conditioning A form of associative learning in which a given behavior is shaped by its consequences. In the case of phobias, for example, avoidance and escape from feared stimuli increases in frequency because these behaviors are reinforced by short-term fear reduction.

Classical conditioning, as conceptualized in early work and in contemporary theories, provides a way of understanding the occurrence of a range of maladaptive emotional and behavioral responses. Although there are multiple ways in which these responses can be learned, classical conditioning appears to represent an important pathway. Classical conditioning theories provide a basis for understanding how such responses can be treated. Exposure therapies for treating fears are among the most useful interventions to arise from these theories. Exposure therapies also are effective for reducing fears arising from other forms of learning.

I. DESCRIPTION OF TREATMENT

A. Overview

Treatments based on classical conditioning fall into two broad categories: aversion therapies, which are designed to reduce appetitive responses, and exposure therapies, which are designed to reduce aversive or unpleasant responses. Aversion therapies have been vividly portrayed in novels and films such as *A Clockwork Orange*. The focus is on reducing maladaptive responses that the patient might find enjoyable, such as the elimination of excessive alcohol consumption or, in the case of Little Alex, the protagonist of *Clockwork Orange*, the elimination of his passion for “ultraviolence.” Classical conditioning methods for reducing alcohol consumption include emetic treatments, where the person ingests

a nausea-inducing drug and then is asked to sample his or her favorite alcoholic beverage. Over a series of trials, the person learns to associate drinking with immediate nausea. Thus, the former association between drinking and pleasure is replaced by an aversive association, thereby reducing alcohol consumption. Similar treatments have been devised for treating self-injurious behavior in children and paraphilias in adults.

Aversion therapies are not commonly used today. This is because of ethical concerns about inflicting harm on patients, and concerns about patient welfare. The efficacy of aversion therapies is also debatable. Some critics argue that these treatments are short-lived in their effects, and that they only suppress maladaptive responses without teaching the patient more adaptive alternatives. Aversion therapies are widely regarded as interventions of last resort, to be used only when more benign methods have failed. If used, aversion therapies should be administered by a trained professional, with the approval of the institution in which the professional is working. Informed consent should be obtained and regional laws should be considered, because aversion therapies have been outlawed in some jurisdictions.

A more popular application of classical conditioning is the exposure therapies. These treatments are used to help people overcome specific phobias and other anxiety disorders in which excessive fear plays a prominent role, such as agoraphobia, social phobia, posttraumatic stress disorder, and obsessive–compulsive disorder. Given that exposure therapies for treating phobias are the most widely used applications of classical conditioning, these treatments and their theoretical bases will be the focus of this chapter.

The treatment of fears is not a trivial undertaking. Severe phobias can produce extreme distress and can severely impair a person's functioning. Driving phobia, arising after a motor vehicle accident, for example, may prevent the person from earning a living and may lead to social isolation if the person lives in a remote area. Even common phobias such as spider phobias can be debilitating. One patient reported being too afraid to enter rooms of her house in which she had seen spiders, and experienced intense panic attacks whenever she unexpectedly came across a spider. She lived in an area in which spiders were commonly encountered, and therefore was chronically hypervigilant for spiders, and worried about encountering them. This was associated with persistent tension and irritability. Her fear, avoidance, and preoccupation significantly interfered with her marital relationship. Fortunately, even severe phobias such as this one can readily be treated by exposure therapies.

During exposure therapy, the person is presented with fear-evoking stimuli in a controlled, prolonged fashion, until the fear diminishes. Patients are encouraged to focus on the stimulus and to notice their anxiety, without engaging in distraction or other forms of avoidance. Treatment is collaborative, with the patient and therapist working together to decide how and when exposure will take place. Exposure duration depends on many factors, including the type of feared stimuli and the severity of the person's fears. Typically, an exposure session lasts 20 to 90 minutes, and sessions are repeated until the fear is substantially reduced. Sessions may be either therapist-assisted or completed by the patient as a homework assignment. Antianxiety drugs such as benzodiazepines should be used sparingly or not at all with exposure therapies, because these drugs can interfere with the effects of exposure. Sources of perceived safety, such as the therapist or significant others, are also faded out during exposure therapy, so that patients can overcome their fears in the absence of safety cues.

There are several ways that exposure can be conducted. The person may be exposed to real stimuli or may simply imagine the stimuli. Exposure may be to intensely fear-evoking stimuli, or may be gradual, working up a hierarchy of feared stimuli. Type of stimuli (real vs. imagined) and intensity of exposure (gradual vs. highly fear-evoking) are the variables distinguishing the four main types of exposure therapy: graded *in vivo* exposure, flooding, systematic desensitization, and implosion.

B. Graded *in Vivo* Exposure

This is the method most commonly used to reduce fear. It has two components. First, the patient is instructed how to rate the intensity of discomfort using a Subjective Units of Distress Scale (SUDS). This measure of fear and distress ranges from 0 to 100, where 0 = none, 50 = moderate, and 100 = extreme. Second, the therapist and patient devise a hierarchy of real-life fear-evoking stimuli, ranging from stimuli that evoke little or no fear or distress, to extremely frightening or upsetting stimuli. Table 1 shows an example of a hierarchy used in the treatment of agoraphobia.

Typically there are 8 to 10 stimuli in the hierarchy, separated by SUDS increments of approximately 10 points, so that the stimuli are not too discrepant in the levels of fear or distress they evoke. Patients begin by exposing themselves to items lowest on the hierarchy. Exposure to a given stimulus is repeated until the fear or distress abates. When fear of a given stimulus is

TABLE 1
Sample Exposure Hierarchy for Agoraphobia: Fear of Traveling Far from Home

Exercise: Walking to ... and then returning	SUDS ^a
1. End of street (2 blocks away from house), accompanied by spouse	10
2. End of street, unaccompanied	25
3. End of street and one block around the corner (so house is not visible), accompanied	35
4. End of street and one block around the corner, unaccompanied	50
5. To the nearby park (6 blocks from house), accompanied	60
6. To the nearby park, unaccompanied	75
7. To the grocery store (8 blocks from house), accompanied	80
8. To the grocery store, unaccompanied	90

^a Subjective Units of Distress Scale, ranging from 0 (no fear or distress) to 100 (extreme fear or distress).

reduced, the other stimuli on the hierarchy also tend to become less fear evoking. The patient gradually works up the hierarchy; once the fear of one stimuli is diminished, exposure to the next stimulus is attempted. This continues until all the stimuli on the hierarchy no longer evoke fear or distress.

Sometimes it is necessary to develop more than one hierarchy to reduce all the patient's fears. For a person with generalized social phobia, a patient might work through a public speaking hierarchy, a hierarchy of situations involving one-to-one conversations with people of the opposite sex, and a hierarchy involving asserting oneself to authority figures. The disadvantage of graded *in vivo* exposure is that it is slower than the more intensive flooding method. The advantage of graded exposure is that it teaches patients a skill for overcoming their phobias in a simple, step-by-step fashion. By progressively working up a hierarchy, patients can overcome their phobias gradually, without enduring extreme fear or distress. After a formal course of therapy ends, patients can continue to devise hierarchies on their own for overcoming any remaining fears.

C. Flooding

Flooding involves exposure to real-life fear stimuli that are at the top of the person's hierarchy. A person with a dog phobia might be exposed to a large boisterous dog until the person is no longer afraid. The advantage of flooding is that it is the most rapid method for reducing phobias; four 2-hour sessions are often all that is required. Sometimes phobias can be successfully reduced within a single 3- to 4-hour session.

There are several disadvantages to flooding. First, it requires the person to tolerate a great deal of distress.

Some people, particularly those with severe phobias, are unable to do this. Second, flooding can produce temporary but intense side effects such as irritability and nightmares. Third, flooding is often too difficult for patients to conduct alone, and so this treatment does not teach patients a skill they can readily use on their own. A further concern is that patients may be more likely to refuse or drop out of very intensive programs, compared to less demanding programs. When used, flooding is typically implemented with the support and encouragement of a therapist. It is most often used when there is some pressing need for the rapid elimination of the fear. If a person had a phobia of hospitals and medical staff, for example, flooding might be used if the person were to be admitted to the hospital for an urgent medical procedure.

D. Systematic Desensitization

Systematic desensitization consists of gradual, imaginal exposure to stimuli organized on a hierarchy constructed using SUDS ratings. The stimuli in Table 1, for example, could be used in systematic desensitization by having the patient imagine each stimulus. Typically, systematic desensitization is combined with some form of relaxation training. The patient is asked to sit back in a comfortable chair and practice a relaxation exercise. Once a state of deep relaxation is attained, the patient is asked to imagine the least upsetting stimulus on the hierarchy. Exposure duration might be only for a few minutes, alternating relaxation with imaginal exposure until the imagined stimulus no longer evokes fear or distress. The procedure is then repeated with the next stimulus on the hierarchy. The disadvantage of systematic desensitization is that it is slow, and that it is

often necessary to eventually implement some form of real-life exposure in order to fully reduce the fears. The advantage is that it is easily tolerated and is therefore a good place to start when treating patients with extremely severe fears.

E. Implosion

Implosion involves exposing the person to intensely fear-evoking imagined stimuli, which lie at the top of the fear hierarchy. Often exposure is embellished by having the patient imagine extremely terrifying forms of the stimuli. Implosion is often used in the treatment of posttraumatic stress disorder, where the goal is to reduce the fear and associated distress associated with traumatic memories. More often, however, the feared stimuli are simply imagined in great detail, with the person imagining all the sensory aspects of the stimulus (e.g., sights, sounds, smells), along with any bodily sensations, emotions, and thoughts that might occur when the stimulus is encountered. A person who developed posttraumatic stress disorder as a result of being in a motor vehicle accident, for example, would be asked to repeatedly imagine the traumatic experience, typically for 30 to 45 minutes per treatment session over several sessions. The narrative of the experience might be spoken into a tape recorder or written down, and the person would be encouraged to repeatedly go over the tape or transcript until the memory of the traumatic event no longer evokes distress.

The advantage of implosion is that by reducing the distress associated with traumatic memories, the other symptoms of posttraumatic stress disorder also tend to abate. In other words, implosion can lead to reductions in reexperiencing symptoms (e.g., nightmares, flashbacks), hyperarousal symptoms (e.g., irritability, increased startle response), and avoidance and numbing symptoms (e.g., avoidance of reminders of the traumatic event). A further advantage is that implosion enables the patient to overcome fears for which live exposure is impossible or impractical. Fear of thunderstorms, for example, can be reduced by having the patient repeatedly imagine such events.

The disadvantage of implosion is that it can be demanding on patients; they must be able to tolerate intense distress. A further problem is that implosion does not teach patients a skill that they can readily employ by themselves at home, simply because it is often too difficult because of the degree of emotion generated. Even if a patient is able to complete a course of implosion, it is often necessary to add some form of real-life exposure in

order to completely reduce the fear. A person with a thunderstorm phobia might need to actually experience a thunderstorm in order to fully overcome his or her fear.

II. THEORETICAL BASES

A. Two-Factor Theory

During the 1960s and 1970s the most influential conditioning model of fear was O. Hobart Mowrer's *two-factor theory*, which has its origins in the 1920s work of Ivan Pavlov and John B. Watson. Mowrer proposed that fears are acquired by classical conditioning and maintained by operant conditioning. *Classical conditioning* is the learning of associations between an unconditioned stimulus (UCS) and conditioned stimulus (CS). In the case of learned fears, UCSs are stimuli that evoke pain or fear in the absence of any prior learning. Fear or pain evoked by UCSs are called unconditioned responses (UCRs). Conditioning occurs when a CS is paired with a UCS over one or more trials. Gradually, the organism learns that the CS is premonitory of the UCS. Thus, the CS becomes fear-evoking. The acquired fear is the conditioned response (CR). Operant conditioning is learning in which a given behavior is shaped by its consequences. Avoidance and escape from feared stimuli increases in frequency because these behaviors are reinforced by short-term fear reduction. Thus, avoidance and escape behaviors fall under the influence of operant conditioning.

A rodent phobia, for example, might arise from a traumatic incident where the person is bitten on the hand by a rat while organizing boxes in a dark cellar. Stimulation of the pain receptors in the hand might represent the UCS, which evokes pain and fear (UCRs). Through the process of associative learning, pain and fear become paired to stimuli associated with the UCS (e.g., CSs such as rats, mice, places frequented by rodents). In turn, the CSs elicit fear (the CR). The strength of the CR is determined by a number of factors including the intensity of the UCS and factors influencing the strength of the association between the CS and UCS, such as the number of pairings between the two. Stimuli resembling fear-evoking CSs can become fear-evoking in their own right by processes of stimulus generalization and second-order conditioning. As a consequence, a wide range of rodent-related stimuli may elicit fear and associated behaviors, such as escape or avoidance.

The strength of the CR tends to decline over successive trials in which the CS is presented without the UCS.

Thus, fear would gradually decline if the rodent phobic had repeated harmless encounters with rats. Given a sufficient number of trials of CS without UCS, the CS eventually ceases to elicit the CR. When this occurs the CR is said to be *extinguished*. Extinction does not occur if the UCS is occasionally encountered. Driving phobia would be unlikely to extinguish if a person occasionally experiences “near misses” while driving. For many people with phobias, the process of extinction is blocked from occurring because the person learns that fear can be minimized (at least in the short term) by avoiding or escaping from the CS. In other words, avoidance or escape (operant behaviors) prevent classically conditioned fears from being unlearned.

Mowrer’s theory is supported by a good deal of evidence (see Marks, 1987; O’Donohue, 1998). In brief, evidence from a variety of sources supports the theory, including (1) studies of the experimental induction of fear in animals; (2) naturalistic observations of soldiers during military combat; (3) clinical observations from anxiety-disordered patients; (4) incidental findings from studies of aversion therapy. Studies of the experimental induction of fear in children provide mixed support for the theory, possibly because of methodological limitations and ethical constraints that preclude the induction of intense fears.

B. Are Conditioned Associations Indelible?

It was once believed that extinction was a process of weakening or even breaking the CS–UCS association. Findings emerged, however, to call this assumption into question. When the CR is extinguished by repeatedly presenting the CS in the absence of the UCS, it was found that the CR could be rapidly reestablished by only a few CS–UCS pairings. Reinstatement of the CR is often more rapid than the original conditioning of the CR. Moreover, extinguished CRs sometimes “spontaneously” reemerge, or reappear when the person undergoes some unrelated stressful experience. These findings suggest that the CS–UCS link is preserved to some extent even when the CR is extinguished. Indeed, some researchers have argued that fear memories (i.e., representations of a link between a CS and aversive UCS) are indelible.

If CS–UCS links are preserved (to some extent) even after the CR is extinguished, then how does extinction occur? There are several possibilities. CR extinction may be due to counter-conditioning, where the CS is conditioned to competing UCSs. To illustrate, in a con-

ditioned dog phobia, dogs (CSs) are associated with pain or physical injury (aversive UCSs). Over a course of exposure trials, consisting of exposure to friendly, harmless dogs, the conditioned fear (CR) extinguishes. This may occur because the extinction trials cause dogs to become associated with pleasurable UCSs (e.g., pleasurable tactile stimulation from patting dogs; or a state of enjoyment from playing with dogs). If the link between the CS and a pleasant UCS is stronger than the link between the CS and an aversive UCS, then the CR will tend to be pleasure rather than fear. Thus, extinction can be regarded as a process of building up competing responses that inhibit or interfere with the link between the CS and an aversive UCS. Other models of extinction also have been postulated. The interested reader should consult O’Donohue (1998).

The preservation of links between the CS and aversive UCS has important implications for exposure therapy. It suggests that successfully treated phobic individuals are at risk for relapse if, for example, some event caused the CS–aversive UCS link to become strengthened. A former dog phobic might discover that his or her phobia reemerges after an unpleasant encounter with a dog. Therapists need to prepare patients for the possibility of relapse. This can be done by discussing the issue with the patient, and formulating a plan for dealing with any reemergent fears. It is important that the patient understands that if the phobia returns, it can be readily eliminated by reapplying exposure techniques such as graded *in vivo* exposure.

C. Pathways to Fear

Despite its strengths, there are several problems with Mowrer’s two-factor theory: (1) It sometimes appears that fears are acquired in the absence of conditioning; (2) conditioning theory fails to account for the uneven distribution of fears; that is, some stimuli are more likely to become feared (e.g., harmless snakes and spiders) compared to others (e.g., guns, knives, electrical outlets); and (3) people sometimes fail to acquire fears in what should be fear-evoking situations (e.g., air raids). Rather than reject the two-factor theory, theorists have attempted to modify it to account for these findings.

To account for fear acquisition in the absence of conditioning, S. J. Rachman postulated three pathways to fear acquisition: (1) classical conditioning, (2) modeling (e.g., vicarious fear acquisition due to observational learning), and (3) verbal information (e.g., receiving fear-evoking information or misinformation from others) (see Rachman, 1990). Several retrospective studies

of fears have assessed the relative importance of these pathways. Results show that approximately half of clinical phobias are associated with classical conditioning, with a smaller proportion of phobias associated with modeling or verbal information. Research also suggests that classical conditioning plays a greater role in phobias than in milder fears. A minority of people with phobias appear unable to recall the origins of their fears. This may be because they have forgotten the precipitating events. Another possibility is that some people cannot recall the origins of their fears because some fears are innate.

Aversive conditioning experiences are not just reported by phobics; they also occur in nonfearful people. As noted earlier, the fact that some people may have a history of “conditioning events” without developing phobias is one of the criticisms of the two-factor theory. To account for this anomaly, it has been proposed that aversive conditioning experiences are less likely to produce phobias when the person has a history of fearless contact with the stimulus in question. For example, an aversive experience (e.g., falling from a horse) may not be phobogenic when the person has a history of mishap-free equestrian adventures. This fear-impeding effect is known as latent inhibition or fearless familiarity. Latent inhibition has been experimentally demonstrated in a variety of organisms, including children and (under certain circumstances) adults. Latent inhibition appears to occur because the CS fails to become fear-evoking because a history of fear-free CS presentations causes the CS to be a predictor of the *absence* of fear. The high incidence of condition events for nonfearful people may be due to the mechanisms responsible for latent inhibition.

D. Prepared Fears

In 1970, Martin E. P. Seligman observed that phobias have a number of characteristics that seem inconsistent with the two-factor theory. Phobias can be (1) rapidly acquired (e.g., single-trial learning), (2) resistant to extinction, (3) “nongenerative” (i.e., phobias persist even when the person “knows” the stimulus is harmless), and (4) differentially associable with stimuli of evolutionary significance. With regard to the latter, the two-factor theory assumed an equipotentiality of stimuli; all neutral stimuli can be converted into a conditioned stimulus. Yet, some stimuli (e.g., small animals) are more likely to be fear-evoking than others (e.g., guns, knives, electrical outlets). As Seligman observed, only rarely, if ever, do we have pajama phobias, grass phobias, electric-outlet pho-

bias, hammer phobias, even though these things are likely to be associated with trauma in our world.

Seligman proposed that people (and other organisms) are biologically prepared to acquire fears of particular stimuli. That is, evolution has predisposed organisms to learn easily those associations that facilitate species survival. As a result of a sufficiently long period of natural selection, organisms are prepared (“hard wired”) to fear some events, unprepared for others, and contraprepared for still others. Stimuli such as guns, knives, and electrical outlets have not been around long enough for such preparedness to occur. Seligman conceptualized preparedness as an ease of learning continuum; that is, the relative preparedness for learning about a stimulus is defined by the amount of input (number of learning trials, bits of information, etc.) required in order for an output (responses) to occur reliably.

Preparedness theory has stimulated a large body of research. The most impressive evidence comes from the studies of Rhesus monkeys. In some studies, “observer monkeys” watched videotapes of other monkeys behaving fearfully with a toy snake or crocodile. As a result, the observers acquired a fear of those stimuli. In comparison, observer monkeys who watched videotapes of monkeys showing the identical fear behaviors (via videotape splicing) to artificial flowers or toy rabbits generally did not acquire fears of the flowers or toy rabbits. Thus, there were significant differences in the conditionability of fear to fear-relevant stimuli compared to fear-irrelevant stimuli.

Evidence from human studies has not been so compelling. An extensive review of the research by Richard J. McNally found that some experiments supported Seligman’s preparedness hypothesis, while other studies did not. The evidence most consistent with the theory is enhanced resistance to extinction of electrodermal responses to “prepared” fear stimuli. Moreover, “prepared” phobias are generally no more difficult to treat than “unprepared” phobias. What we are left with is the fact that there is a nonrandom distribution of fears and phobias; that is, fears of some stimuli (snakes) are more common than others (e.g., hammers). Latent inhibition to stimuli such as hammers, electric outlets, and so forth may account for the rarity of fears of such stimuli (i.e., children typically receive parental instruction as to the safe use of such stimuli).

In summary, to attempt to overcome the more important limitations of the two-factor model, it has been proposed that (1) there are multiple pathways to fear, of which conditioning is one, (2) the failure to acquire fears may be due to latent inhibition (i.e., a history of

fearless familiarity with potential fear stimuli), and (3) the uneven distribution of fears arises because some fears are prepared in an evolutionary sense. Although these explanations have their merits, they also have some weaknesses, including weak or equivocal empirical support.

E. Neo-Conditioning

Contemporary approaches to classical and operant conditioning are known as neo-conditioning models (e.g., Davey, 1992; Rescorla, 1988). They propose that conditioning involves processes that draw on cognitive mechanisms such as expectations and memory representations of the CS and UCS. Here, UCS–CS links are acquired because CSs are predictors of the occurrence of the UCS. To illustrate, a person with a fear of driving might learn that poorly lit, wet roads (CSs) are predictive of life-threatening motor vehicle accident (UCS). The strength of the conditioned fear is a function of two factors: (1) the strength of the UCS–CS link (i.e., subjective probability that a given CS will lead to a given UCS), and (2) the perceived aversiveness of the UCS (e.g., perceived dangerousness of motor vehicle accidents).

The neo-conditioning approach also entails a revised view of operant conditioning of avoidance behavior. Here, avoidance is not directly determined by the experience of fear, but by the individual's expectation of whether a given behavior (e.g., driving in the rain) will lead to an aversive outcome (e.g., a fatal accident). Avoidance behavior is not reinforced by reduction of fear; it is reinforced by full or partial confirmation of one's expectations (e.g., by a "close call" while driving). According to the neo-conditioning perspective, UCS evaluation (and reevaluation) can influence the acquisition, extinction, and inflation of fears. When an association between a CS and UCS has been formed, the representation of the CS (stored in long-term memory) evokes a representation of the UCS. Information about the UCS contained in this representation is evaluated, and the result of this evaluation process determines the strength of the CR. If the UCS is evaluated as aversive or noxious, this will result in a fear CR.

Mild conditioned fears can escalate into phobias when the UCS is reevaluated. To illustrate, a person might acquire a mild fear of spiders after sustaining a painful but harmless spider bite. The fear may escalate into a phobia if the person later learns that spider bites are often lethal. Thus, the intensity of the UCS is inflated from a harmless painful bite to a painful and potentially life-threatening bite. As a consequence, the

nature of the CS changes (i.e., spiders now become predictive of life-endangering events) and the conditioned fear increases accordingly.

F. Emotional Processing

The neo-conditioning model proposes that the CS and UCS are cognitively represented, possibly in networks of interconnections among CSs, CRs, UCS, and UCR. The emotion processing model developed by Edna B. Foa and others (e.g., see Foa and Kozak, 1986) can be seen as an extension of the neo-conditioning model. According to the emotional processing model, fears are represented in networks known as fear structures stored in long-term memory. The networks contain cognitive representations of feared stimuli (e.g., oncoming trucks, driving at night), response information (e.g., palpitations, trembling, subjective fear, escape behaviors), and meaning information (e.g., the concept of danger). In the network the three types of information are linked (e.g., links between oncoming trucks, danger, and fear). Links can be innate (i.e., UCS–UCR links) or acquired by processes such as classical conditioning (CS–UCS links and CS–CR links). Fear structures are activated by incoming information that matches information stored in the network. Activation of the network evokes fear and motivates avoidance or escape behavior. According to Foa and colleagues, fears are reduced by modifying the fear structure through the incorporation of corrective information (e.g., safety information acquired during behavioral exposure exercises).

The neo-conditioning perspective and the emotional processing model are useful ways of conceptualizing fears, and can account for phenomena that are not explained by the two-factor theory (e.g., postconditioning fear inflation due to UCS inflation). A further advantage is that these models are compatible with other cognitive models of fears, such as those discussed in the following sections. The emotional processing model has the advantage of readily including multiple pathways for the acquisition of fears, such as classical conditioning, modeling, and verbal information. The possibility of innate fears is also consistent with the model, if one assumes that some networks or fragments of networks are innate. The model also includes a role for dysfunctional beliefs, which may amplify fears and other emotional reactions. Beliefs are represented in the network as links between meaning concepts and stimulus or response concepts (e.g., "tunnels are dangerous" is represented by a link between "tunnel" and "danger").

G. Dysfunctional Beliefs

Theories of fear have become increasingly complex in recent years. Classical conditioning and many other factors are thought to be involved. Consistent with the neo-conditioning and emotional processing models, some theorists have proposed that exaggerated beliefs about the probability and severity of danger may play an important role in motivating fear and avoidance. Such dysfunctional beliefs play a prominent role in contemporary theories of agoraphobia and social phobia, and may play a more important role in these disorders compared to specific phobia. People with social phobia tend to be preoccupied with their social presentation and have heightened public self-consciousness. They also tend to be self-critical, to excessively worry about being criticized or rejected by others, and to overestimate the likelihood of aversive social events. This suggests that such dysfunctional beliefs may be important in maintaining generalized social phobia. These beliefs appear to persist because of a variety of factors, such as avoidance of fear-evoking stimuli. Avoidance behavior limits the opportunity for collecting information that might disconfirm erroneous beliefs. Recent empirical studies support the role of distorted beliefs and appraisals in social phobia, and may be important targets for treatment. However, treatment outcome research provides mixed support for the view that adding cognitive restructuring to exposure improves treatment outcome. This may be because exposure is a potent vehicle of cognitive change.

H. Anxiety Sensitivity

In an effort to account for individual differences in the tendency to acquire conditioned fears, Steven Reiss and colleagues proposed that anxiety sensitivity is a fundamental fear that amplifies or exacerbates other fears, such as fears of animals, social situations, blood–illness–injury stimuli, and agoraphobic situations. Anxiety sensitivity is the fear of anxiety-related sensations (e.g., fears of palpitations, dizziness, and tremulousness), which arises from beliefs that these sensations have aversive somatic, psychological, or social consequences.

Anxiety sensitivity can be considered to be a fundamental fear because (1) anxiety is inherently noxious and therefore feared by most people, and (2) anxiety sensitivity provides reasons for fearing a variety of stimuli, whereas ordinary fears do not have this property. To illustrate, fear of flying can be exacerbated by, or entirely due to, the following: (1) Fear of the plane crashing (ill-

ness–injury sensitivity), (2) fear of anxiety evoked by bumpy flights (anxiety sensitivity), and (3) fear of embarrassing oneself by becoming airsick (fear of negative evaluation). Thus, a common fear (fear of flying) may be logically reduced to one or more fundamental fears such as anxiety sensitivity. Empirical support for this proposition has been provided by a number of studies.

Several studies have reported that the severity of anxiety sensitivity is correlated with the severity of various common fears, and that anxiety sensitivity predicts the person's risk for developing later fears and other anxiety symptoms. Anxiety sensitivity is reduced by exposing the person to feared arousal-related body sensations. This is called interoceptive exposure. For example, aerobic exercise can be used to extinguish the person's fear of palpitations. Voluntary hyperventilation exercises can be used to reduce fear of dizziness.

III. EXPOSURE THERAPIES: APPLICATIONS AND EXCLUSIONS

A. Medical Contraindications

Exposure techniques, such as graded *in vivo* exposure, are safe for the great majority of patients. The only medical contraindications are serious diseases that prevent the patient from entering the situations or make the experience of intense emotions hazardous to the person's physical health. Pregnancy or serious heart disease would contraindicate the use of flooding therapy. Medical conditions that seriously limit mobility—such as severe obstructive lung disease—can prevent the patient from completing some forms of *in vivo* exposure (e.g., walking long distances from home in the case of agoraphobia). In practice, however, it is rare to encounter a patient who is medically unsuited for at least some form of exposure.

B. General Guidelines for Conducting *in Vivo* Exposure

Given that graded *in vivo* exposure is the most commonly used exposure technique, it will be described in detail. There are several protocols for conducting *in vivo* exposure. Rather than describe them all, we will review the general guidelines. The guiding principle is for the person to remain in the situation until the fear has declined. Ideally, exposure also teaches the person that exposure to a feared stimulus has no harmful consequences. Thus, in addition to fear reduction, it is

important that patients remain in the feared situation until they can observe the true consequences of being exposed to the feared stimulus. Persons with a fear of heights would be encouraged to remain at, for example, the fourth floor balcony until they learn that they will not “lose control” and topple over the edge. The goals of exposure—fear reduction and expectancy change—are derived from modern conditioning theories, which emphasize the role of expectancies (see Section II).

Exposure therapies should only be implemented by a suitably trained therapist. The therapist should not only be skilled in exposure therapy, but should have a good understanding of psychopathology and psychiatric diagnosis, and should be skilled in the psychotherapeutic interventions commonly used in conjunction with exposure therapy (e.g., cognitive therapy, social skills training, relaxation training). Relaxation training is particularly useful for phobic individuals who are chronically anxious. If the patient experiences intense anger or guilt during exposure, as sometimes happens when treating patients with posttraumatic stress disorder, it is often necessary to combine exposure with cognitive therapy. The latter is used to address any dysfunctional beliefs associated with anger or guilt.

The patient should be a willing participant in the process of exposure therapy, with complete control over the nature and timing of any exposure exercises. Exposure may be traumatizing if forced on an unwilling patient. Exposure should be used only if the patient is able to tolerate some degree of distress, and is sufficiently motivated to overcome his or her fears. Patients should be told about the side effects of exposure treatment (e.g., transient increases in irritability), so they can make an informed choice about whether or not to proceed with treatment. Therapists also need to consider the patient’s other problems before initiating a course of exposure. If an agoraphobic patient was suicidally depressed, then one would need to consider whether the distress caused by exposure therapy would precipitate a suicide attempt. In such cases the depression would be the first target of treatment.

In vivo exposure exercises should be specific and well-defined, in terms of duration, situation, and what the patient must do (or not do). The exercises should be written down so they are not forgotten by either patient or therapist. The patient and therapist might generate an assignment such as the following: “Walk seven blocks from home to the supermarket. Don’t take your Ativan, cell phone, or Medi-Alert bracelet. As you walk along, pay attention to your anxiety and to your surroundings.”

In vivo exposure exercises can be practiced during therapy sessions and as homework assignments. The exercises should be ones that patients can realistically accomplish, given their current levels of functioning. Patients should not be asked to attempt exercises that they are too frightened to complete. The patient should actively participate in the exposure situation in order to be exposed fully to the various stimulus elements. Joanne N., who suffered from agoraphobia, was asked to park her car at the back of the shopping mall parking lot so she would have to walk some distance to the mall and would not have rapid access to the “safety” of her vehicle. Instead of racing through the mall, she was encouraged to stroll through, taking time to browse through the stores and ask questions of sales clerks. Contrast this therapeutic exposure to her brief exposures prior to treatment, in which she would park her car as close as possible to the mall entrance, then run in to purchase what she needed, and then race out.

In vivo exposure should be comprehensive, with different exercises covering different manifestations of the feared situations. A patient who fears and avoids shopping at supermarkets, for example, would be advised to perform this activity in many different shopping conditions, including different stores (e.g., small vs. large stores), at different locations (e.g., near vs. far from home), at different times (e.g., times in which the store was busy vs. quiet), and with different purchases (e.g., few vs. many items). This ensures that learning generalizes across settings and difficulty levels.

C. Frequency and Duration of *In Vivo* Exposure Sessions

Long, continuous periods of exposure tend to be more effective than short or interrupted periods. Although short exposure sessions (e.g., 10 to 15 minutes) can be effective, longer sessions (20 to 60 minutes) are often necessary. With regard to the frequency of exposure exercises, the research has produced conflicting results. Some studies have found that the higher the frequency of exposure sessions, the greater the rate of dropouts, the greater the short-term response for treatment completers, but the higher the rate of relapse later on. Some *in vivo* exposure is better than none, and so phobic patients should be counseled to practice their exposure exercises as frequently as they reasonably can, depending on the type of exercise and on the logistic constraints. Patients frightened of riding on buses might practice this activity 4 times per week. Patients frightened of riding as a passenger in a car might

be only able to practice this activity only 1 to 2 times each week, depending on the availability of someone to drive them.

D. Assisted Exposure

There are numerous ways that patients can be assisted in completing *in vivo* exposure exercises. Among the more commonly used are (1) therapist-assisted exposure, conducted either from the clinic or from the patient's home, and (2) exposure in which the patient is assisted by a friend, partner, or family member. Assistance consists of initially accompanying the patient, and by providing prompting and encouragement for attempting the exposure exercises. Assistance can be particularly useful during the initial attempts at exposure. Therapist-assisted exposure is also a good way for the therapist to learn about the patient's subtle avoidance behaviors. There are several ways that the therapist can directly help the patient complete *in vivo* exposure exercises:

1. The therapist can provide just enough assistance for the patient to perform the exercise, and then the assistance is faded out. If the task is to walk around a 10-block circuit from the patient's house, the therapist might accompany the patient all the way on the first trial. On the second trial the therapist might accompany the patient for 5 blocks, and on the third trial the patient might complete the circuit alone, with the therapist waiting outside the patient's home. On the fourth trial the patient might complete this task without the therapist's presence.

2. The therapist can demonstrate (model) how the exercises are performed. Here, the patient observes the therapist perform the exercise *in vivo*. For example, the patient and therapist might travel to the foot of a bridge, and then the patient would observe the therapist walk to the midpoint of a bridge without holding onto the railing, then pause and look over the edge. The therapist would then return to the foot of the bridge and the patient would perform the task. Alternatively, each step of the task could be modeled. For example, the therapist could walk to the midpoint, and then the patient would do so. The therapist would then look over the edge. The patient then follows suit.

3. The therapist can provide any support that may be required. The therapist might offer his or her arm for assistance when the patient is first approaching a bridge railing. A therapist in a hospital setting who is helping a patient overcome fear of elevators might reserve a service elevator for some of the exposure session. The therapist and patient would have exclusive

control of the elevator, and so it could be used for various exposure assignments (standing in a stationary elevator with the doors open, then with the doors closed, then traveling to the next floor, etc.). The interested reader should consult Williams (1990) for detailed descriptions of these methods.

A friend of the patient or significant other can be recruited as a "coach" to provide prompting, encouragement, and guidance. This person also can be used as a stimulus in the exposure hierarchy, as illustrated in Table 1. Later in treatment, all forms of assistance should be faded out, along with other safety signals and safety behaviors. Otherwise, patients may attribute their gains to the aid they received, rather than to their own efforts.

E. Troubleshooting

Adherence problems are the most common difficulties encountered when using *in vivo* exposure. Patients may refuse to perform the exercises. Other, more subtle, adherence problems consist of using distraction during the exercise, or limiting the intensity or duration of exposure. The best strategy for dealing with adherence problems is to avoid them before they occur. The following can help avoid these difficulties:

1. Ensure that patients understands why the exercises are important. Periodically check their understanding.

2. The interventions should not be too complicated. Understandably, patients might become confused if asked to do many things at once in a given situation.

3. Ensure that the patient understands that the selection of exercises is a collaborative venture, negotiated between patient and therapist. Tasks can be readily modified in such a way that the patient can perform them.

4. Perform the exercises yourself so the patient can see they are safe (i.e., modeling). As a rationale, the therapist might say to the patient, "I wouldn't ask you to do something I wouldn't do myself, so I'm to show you how this exercise is done."

5. Adherence can be maintained at an adequate level if the patient is sufficiently motivated to complete the various treatment exercises. To sustain motivation it can be useful to (1) reinforce (e.g., verbally praise) the patient for his or her efforts in completing each therapy assignment, and (2) have the patient self-reinforce for these efforts (e.g., praising oneself or using other incentives). Initially, reinforcement from the therapist should occur frequently. As therapy progresses, reinforcement

from the therapist can be faded out as the patient continues to use self-reinforcement.

If adherence continues to be poor then it is important to identify the source of the problem. Does the patient regard exposure exercises to be relevant to his or her problems? If not, then the patient may regard the task as pointless. Is the timing right for using exposure? More time may need to be spent on developing a trusting therapeutic relationship. Also, more time may be needed for cognitive restructuring to address beliefs about feared stimuli. For patients on PRN (as needed) medication, it is important to ensure that medication is not used as a way of avoiding the experience of fear.

F. Variations on Exposure

Exposure therapies have been applied to all kinds of disorders in which excessive fear plays an important role. Apart from the disorders discussed earlier, exposure therapies have been successfully used in treating obsessive-compulsive disorder. Here, the treatment consists of exposure and response prevention. A person with contamination obsessions and cleaning compulsions, for example, would be exposed to a “dirty” object such as a doorknob, and then asked to refrain from engaging in handwashing compulsions. In this way, the contamination-related distress gradually diminishes, and the obsessions about contamination and associated compulsions similarly abate. Exposure and response prevention are most often used in the form of graded *in vivo* exposure, although flooding is sometimes used.

Other anxiety disorders can be similarly treated with exposure methods. Acute stress disorder and posttraumatic stress disorder can be successfully treated with implosion or systematic desensitization. Here, the person is exposed to traumatic memories of the trauma, and also exposed to harmless but distressing real-life trauma-related stimuli. For example, the person might be asked to return to the site of a traumatizing motor vehicle accident. Panic disorder is treated by exposing the person to feared body sensations that lead to panic attacks (i.e., interoceptive exposure). Generalized anxiety disorder, for which excessive worry is a central feature, can be treated by exposing the person, in a prolonged fashion, to his or her worries. The person might spend 20 minutes each day writing out his or her main worries. The distress associated with the worries gradually abates, and the person correspondingly learns to dismiss the unrealistic concerns.

IV. EMPIRICAL STUDIES

A. Efficacy of Exposure

Decades of research have established that exposure therapies, particularly graded *in vivo* exposure and flooding, are the treatments of choice for specific phobias and play an important role in treating other anxiety disorders. These treatments produce clinically significant reductions in fear in about 60 to 80% of cases. Systematic desensitization is the least effective of the exposure therapies. Although it is not often used as a stand-alone treatment, this mild, undemanding intervention is a useful starting place in an exposure program for patients who are extremely phobic.

A growing number of studies have investigated whether the efficacy of real-life exposure (flooding or graded *in vivo* exposure) can be enhanced by combining it with other interventions such as relaxation training, cognitive restructuring, or social skills training. For the average phobic patient, exposure alone is no less effective than exposure combined with either cognitive restructuring or relaxation training. Few studies have investigated whether particular treatment packages are best suited to particular patterns of symptoms. Combined exposure and relaxation, compared to exposure alone, may be most effective for phobic patients who have intense chronic anxiety. Similarly, combined cognitive restructuring and exposure, compared to exposure alone, might be most effective for phobics who have a great deal of negative thoughts (e.g., many pessimistic or self-disparaging thoughts, or numerous catastrophic thoughts about the occurrence of threatening events). There is some evidence to support these conjectures, although further research is required.

In clinical practice it is common for patients to be receiving a combination of drug treatment and psychological therapy. This raises the question of whether combined exposure and antianxiety medication is more effective than exposure alone. The research on this topic has focused mainly on combining real-life exposure (flooding or graded *in vivo* exposure) with benzodiazepines such as Valium (diazepam) or Xanax (alprazolam). These are among the most widely prescribed antianxiety drugs. Research shows that adding benzodiazepines to exposure therapy either has no effect on treatment outcome, or may actually impair the efficacy of exposure.

It has been suggested that drugs interfere with exposure because of state-dependent learning. That is, the learning that takes place during treatment (e.g., learning

that agoraphobic situations are not dangerous) may be available in the patient's working memory only when the retrieval conditions match the conditions under which the learning originally took place. Learning acquired under the effects of an antianxiety drug may not be retrieved when patients are in a drug-free state. Research has provided mixed results for the state dependency hypothesis. Although state dependency might explain the exposure-impairing effects of antianxiety drugs in animal research, the same effects might not be as important in humans.

Recent research shows that a good predictor of relapse from combined exposure and drug treatment is the degree to which patients attribute their improvement to their antianxiety drugs rather than to their own efforts. Patients who attribute improvement to their drugs tend to be less confident about coping and have more severe withdrawal symptoms during the drug taper period. Withdrawal symptoms may further lead patients to attribute treatment gains to their drugs (instead of their own efforts) and also lead patients to expect to relapse once the medication is withdrawn. Attributing improvement to effective self-initiated action (i.e., self-directed exposure exercises), rather than to an external agent like a drug, may reduce the chances of relapse. This is because attributing improvement to self-initiated action encourages the person to persist with exposure exercises even while experiencing drug withdrawal effects. People who attribute their gains to the drug are less likely to enter feared situations when they notice the waning effects of the drug.

If patients are taking benzodiazepines when they commence exposure therapy, it is not uncommon for the exposure therapist, in consultation with the prescribing physician, to gradually taper the patient off their drugs, so that they may eventually complete an exposure program without relying on drugs.

B. Long-Term Follow-Up

Conditioning research suggests that fear memories (i.e., representations of the link between the CS and an aversive UCS) are relatively permanent, and that exposure may exert its beneficial effects by inhibiting links between a CS and an aversive UCS, possibly by creating competing links between the CS and a pleasant UCS. The animal research on the reinstatement of fears suggests that exposure therapies should be short-lived in their effects, with relapse common. Outcome studies on people with phobias have examined the durability of the benefits of exposure therapy, with follow-up assessments typically conducted 6 to 12 months post treat-

ment. Although relapse sometimes occurs, the majority of patients maintain their treatment gains. How are we to reconcile this with the putative "indelibility" of fear memories? It may be that such memories are indelible and that patients often do experience minor resurgence of fear, of insufficient severity to represent a relapse of the phobia. During exposure therapy patients are taught skills for overcoming their fears, such as the skill of constructing a fear hierarchy and systematically exposing themselves to fear-evoking stimuli. These skills may help patients deal with minor resurgences of fear, thereby reducing the fear before it can escalate into a full-blown phobia. Thus, even if fear memories are indelible, that does not mean that patients will inevitably relapse. Patients who do relapse can be successfully treated with a further course of exposure therapy.

C. Symptom Substitution

Psychodynamic theories posit that phobias are expressions of unconscious conflicts. In Sigmund Freud's famous case of Little Hans, for example, the child's horse phobia was conceptualized as arising from an Oedipal conflict (i.e., unacceptable impulses consisting of libidinous longing for the mother and aggression toward the father). Such theories imply that exposure therapies simply treat the symptom (i.e., the phobia), without treating the underlying conflict, and that if one symptom is eliminated, then another will emerge in its place as a further expression of the unresolved conflict.

Research on exposure therapies for phobias has revealed no convincing evidence of symptom substitution. Once fears or phobias are eliminated by exposure therapy, the treatment-related gains tend to be maintained. Although new symptoms may sometimes later emerge (e.g., depressive symptoms), a more common pattern is that there is a generalization of treatment effects; once a patient's phobia has been reduced by exposure, the patient's mood may improve and he or she may become happier in general. This effect is most often seen when debilitating phobias have been eliminated, thereby enabling the person to enjoy a higher quality of life. Interestingly, in the treatment of phobias, even Freud recommended *in vivo* exposure as an important component of therapy.

V. CASE ILLUSTRATION

Michelle K. was a 32-year-old single woman working as an administrative assistant in a large corporation. She had a long-standing history of generalized social phobia

and intermittent alcohol abuse. Michelle had been shy for as long as she could recall. During her adolescent years she was overweight and suffered from bad acne, which bought her ridicule and rejection from schoolmates. As a result of a series of particularly disturbing episodes of teasing during grades 10 through 12, she became increasingly anxious in social settings, including talking in groups and having one-to-one conversations, particularly with members of the opposite sex. Michelle also developed intense fear of eating in public after an episode in which she vomited during lunchtime in the school cafeteria. This appeared to have been the result of influenza combined with the effects of high anxiety.

Michelle suffered for many years until she saw a television program describing cognitive-behavior therapy for social phobia. When she presented for treatment, at age 32, her major problems were eating in public, giving oral presentations at work, and initiating and maintaining conversations with men. Whenever she had to eat in public, her hands trembled and she worried that others would think she was “weird.” While giving oral presentations, she would tremble, blush, and sweat profusely, and sometimes would have a panic attack. As a result of these problems, she recently turned down a promotion because it would have required her to give speeches and to attend business dinners. Although Michelle very much wanted to be in an intimate relationship, she rarely dated because of fear of being rejected. She believed it would be “terrible” to be rejected. Michelle attempted to cope with her anxiety by consuming “a few drinks” before social engagements. On occasion this resulted in her become extremely intoxicated and behaving inappropriately. These embarrassing episodes exacerbated her social fear and avoidance.

Michelle’s history suggested that aversive conditioning experiences (e.g., vomiting at school) gave rise to some of her social fears (e.g., fear of eating in public). Operant conditioning also appeared to play a role (i.e., reinforcement of avoidance and escape behaviors, and reinforcement of using alcohol to dampen her social anxiety). Conditioning alone seemed insufficient by itself to account for all of her problems. The fact that her shyness was long-standing suggested that some form of *diathesis* (vulnerability factor) predisposed her to acquire social fears. This might have been due to some combination of genetics and childhood learning experiences. With regard to the latter, Michelle recalled that her father had long emphasized the importance of being popular with others. Maladaptive beliefs, arising from these diatheses or from other sources, also seemed to play a role (e.g., the belief that it would be “terrible” to be rejected). Social skills deficits (e.g., deficits in conversation

skills) appeared to exacerbate her social anxiety. Thus, as is often the case in anxiety disorders, Michelle’s problems appeared to be multifactorial in origin. Accordingly, treatment was multifaceted, with different interventions addressing different aspects of her problems.

Michelle received 16 sessions of cognitive-behavior therapy, involving cognitive restructuring of maladaptive beliefs, social skills training, and graded *in vivo* exposure. She was also counseled to abstain from alcohol before and during social engagements. This was for several reasons. First, it was important that she avoided exacerbating her social fears by drunken behavior. Second, without the mind-clouding effects of alcohol, Michelle was better able to concentrate on practicing her social skills. Third, alcohol may have inhibited the effects of *in vivo* exposure in the same way that benzodiazepines interfere with exposure.

Given that this chapter is concerned primarily with classical conditioning and associated treatments, the remainder of this case illustration will focus primarily on the exposure exercises used in Michelle’s treatment. To reduce her fear of public speaking, Michelle completed a series of graded *in vivo* exercises, conducted during therapy sessions and as homework assignments. She began by delivering increasingly longer speeches to her therapist during the sessions. Her SUDS were initially 75/100. After two sessions of repeated practice her SUDS declined to 10/100. For homework she practiced giving these speeches to her dog, who turned out to be a generally attentive listener (although he tended to doze off during the boring parts). Then she practiced giving speeches to her sister and elderly neighbor. As her confidence grew, Michelle asked her supervisor for permission to present aspects of the weekly reports at staff meetings. Before and during each of her oral presentations, Michelle’s therapist encouraged her to “feel the fear” without distracting herself or using alcohol, and to treat each presentation as an opportunity for honing her presentation skills.

Michelle’s fear of eating in public was similarly treated with graded *in vivo* exposure. Initially, exposure exercises took place during treatment sessions held at lunchtime, during which Michelle and her therapist would eat at the hospital cafeteria. During the first exposure session, Michelle ate “nonmessy” foods (e.g., sandwiches), which evoked low levels of anxiety. She later progressed to eating “messy” foods, such as soups, salads, and spaghetti. Michelle was encouraged to allow herself to feel anxious and to allow her hands to tremble. During these exposure exercises her fear gradually declined and the trembling also abated. Michelle’s in-session exposure exercises were complemented by a series of homework assignments. The latter began with relatively easy tasks (e.g., eating by

herself in the food court of a large shopping mall). As she became comfortable with these tasks she moved on to more fear-evoking exercises, such as eating with co-workers in the office lunchroom.

Her fear of dating was treated with a combination of graded *in vivo* exposure and social skills training. Michelle was encouraged to attend social functions whenever the opportunity arose, and to make increasing efforts at being actively involved in conversations. Michelle began to take up offers from her friends to join them on social outings, and thereby had numerous opportunities to enter into conversations with people she met, both women and men.

By the end of treatment Michelle's social phobia had abated considerably. She was able to comfortably give oral presentations at work and to attend work-related dinners. She also had accepted a promotion. The added opportunities for *in vivo* exposure entailed in her new job led to further reductions in social anxiety, and to increases in self-confidence. Treatment concluded with a review of the gains made during therapy, a discussion of the goals that remained to be attained, and a discussion of how she would go about using the skills learned in therapy to attain these goals. For example, Michelle was still anxious about dating, and was also frightened of making extemporaneous speeches. For each fear, she was encouraged to construct a hierarchy of feared situations, and systematically exposed herself to them. Michelle was also counseled on the situations that might lead her social phobia to worsen (e.g., an episode of being criticized by a supervisor) and how to use exposure and cognitive restructuring for dealing with any exacerbation. Michelle was advised to recontact the clinic if she experienced any further problems.

VI. SUMMARY

Classical conditioning theories have become considerably more complex since the early formulations by O. H. Mowrer and others. Modern conditioning models emphasize the role of cognitive factors such as memory processes and expectancies in the etiology and maintenance of conditioned responses. As theories of fear have developed, other pathways to fear acquisition have been added, although classical conditioning continues to be seen as important. Classical conditioning theories have led to a number of important treatments, with the most widely used being the exposure therapies for reducing fear. According to contemporary views, extinction of the CR can be regarded as a process of exposure to corrective information. Exposure involves having the person repeatedly expose himself or her-

self to a feared stimulus until fear abates. Patients play an active role in choosing what they will be exposed to, and when the exposure will occur. Exposure therapies can successfully reduce conditioned fears and fears arising from other forms of learning.

Of the exposure therapies, graded *in vivo* exposure and flooding are among the most effective treatments of phobias, and play an important role in treating disorders in which fear plays a prominent role (e.g., social phobia, agoraphobia). For patients who are extremely phobic, the least demanding form of exposure (systematic desensitization) is typically the exposure intervention to be used first. Graded *in vivo* exposure is particularly important because it involves teaching patients skills for overcoming their fears. Patients can continue to apply these skills on their own, without the aid of a therapist. Exposure therapies can be combined with other psychological interventions, such as relaxation training and cognitive restructuring. For the average phobic patient, combination treatments tend to be no more effective than exposure alone. However, there are likely to be exceptions to this rule, and some patients may benefit most from a combination of psychotherapeutic procedures. Combining exposure with anti-anxiety drugs does not improve outcome, and may actually impair the effects of exposure. The benefits of exposure therapy tend to be long lasting, with no evidence of symptom substitution. Patients sometimes relapse, although their reemerged fears can usually be successfully treated with a further course of exposure therapy.

I. DESCRIPTION OF TREATMENT

Cognitive appraisal therapy (CAT) began as a form of cognitive-behavior therapy (CBT) and evolved into an integrated psychotherapy for personality-related disorders. CAT departs from conventional cognitive-behavior therapy in its view of affect and motivation:

- Affect is a result of prior cognitive processing in CBT; in CAT cognition can also be the result of emotional processing.
- Behavior is affect-driven in CAT, not cognition-driven. Nonconsciously motivated attempts to reexperience familiar feelings (personotypic affects) account for symptomatic behaviors and self-handicapping actions.

Whereas reduction of symptoms of anxiety and depression and improvements in social and familial functioning are the ultimate goals of treatment, they are not the primary focus in CAT. Instead, the emphasis falls on the discovery of a person's patterns of personality (affect, behavior, and cognition).

These patterns emerge in therapeutic dialogues, especially during initial contacts. The Millon Clinical Multiaxial Inventory is used to confirm preliminary diagnostic impressions of personality functioning, but another test (e.g., the MMPI) could also be used for this purpose.

To achieve self-understanding, the therapist assists in describing affective, cognitive, and behavioral patterns,

GLOSSARY

emotional setpoint A nonconscious prescription about how and what a person should feel. When affect deviates from the setpoint processes are automatically activated to restore the setpoint. Negative deviations prompt defensive maneuvers; positive deviations prompt security-seeking behaviors and justifying cognitions.

justifying cognition Perception and thought that elicit and rationalize personotypic affect, and restore the emotional setpoint.

personal rule of living Conscious and nonconscious cognitions that form a personal rule book for guiding decisions, behavior, and the processing of social information. They may function as mediators of emotional experiences or as nonconscious algorithms for value-based responses.

personotypic affect Certain emotional experiences that are frequently experienced by the individual, depending on his or her socialization environment; the person's emotional "default" setting.

security-seeking behavior Behavior, especially interpersonal, that elicits personotypic affect and restores the emotional setpoint.

their interrelations, and their functions in a person's life. Together client and therapist develop plans to work against these patterns using the client's new awareness.

CAT is not a set of specific procedures, but rather a portrayal of emotional and behavioral processes the client can readily comprehend and work to change. Because self-awareness and understanding can be achieved in various ways, the techniques employed vary with each individual. Special attention is given to three areas:

1. *Affect*: Methods of comforting oneself and soothing one's feelings are encouraged. These new methods usually replace ones that have been more maladaptive than adaptive (e.g., alcohol, drugs, avoidance).
2. *Behavior*: Clients are encouraged to do what they deem to be right at any given moment in time, and thereby give expression to their moral code and the raising of positive self-appraisals. They also identify self-handicapping actions (security-seeking behaviors).
3. *Cognition*: Clients work to identify and change cognitive distortions, especially those concerned with poor self-image and pessimism about the future, and justifying cognitions that support familiar affect. These in turn promote effective future actions.

Sessions are conducted in plain language. All forms of jargon (including our own), psychobabble, and counseling clichés are actively discouraged. Theoretical assumptions are divulged only when they might prove helpful (e.g., in understanding failure to maintain changes). Formal homework is not assigned. Bibliotherapy, thought records, daily logs, and the like, common in CBT, are seldom used. The emphasis is on establishing new patterns of interaction and self-care, not intensive self-examination of cognitive content or of one's past.

By speaking in an open, self-disclosing manner, therapists attempt to create a strong working alliance and a shame-free environment. Therapists disallow self-criticism and call attention to the minutest self-critical remark. It is expected that anger be expressed respectfully, and when necessary therapists model ways to express anger and other emotions. The endless expression of affect is discouraged because catharsis is counterproductive.

In an effort to reduce self-pity, therapists do not sympathize with clients but affirm the respectful and optimistic position that everyone has the capacity to cope with personal tragedies, and that humans are far more resilient than they may realize. Complaining is discouraged and clients are required to behave actively rather than passively and not to continue as helpless victims stuck in an unresolvable paradox.

All clients address two questions: "What do you want?" and "What are you willing to do to get what you want?" These questions identify therapeutic goals and get the client's commitment to them and to the assuming of responsibility while relinquishing the self-imposed status of victim or incompetent.

Self-appraisals, central to most forms of psychological therapy, receive special attention in CAT. Most clients set arbitrary standards of worth or goodness that they must attain, and view themselves negatively when they fail. These standards often involve achieving success or social popularity or other outcomes not fully under the control of the individual. Because human worth is a moral or ethical question, clients are urged to adopt a different standard: Positive self-appraisals should only be made when one acts ethically and morally. Actions are controlled by the person (a humanistic aspect of CAT) and therefore clients can control self-appraisals by doing what they think is right.

When clients do not act in accord with their personal values, it is suggested that most of us are tempted to do what feels good rather than what is right. A self-respecting life comes not from pursuing hedonistic pleasures, but from acting responsibly, morally, and ethically; only then can self-respect be achieved.

The CAT therapist understands setbacks, so-called resistance, and stalled therapeutic progress by using the concept of emotional setpoint and the person's nonconscious motives to reexperience personotypic affects.

There are no formal termination procedures in CAT, because therapy is viewed as a continuing resource to clients. (Administrative policies in some settings may prohibit this.) Rather, clients are asked to decide when to schedule their "next session," which, of course, may never occur.

II. THEORETICAL BASES

The phrase cognitive appraisal therapy was adopted to distinguish it from other forms of cognitive behavior therapy, especially rational-emotive therapy. The phrase also emphasizes the fact that evaluative cognitions (a synonym for appraisal) are centrally involved in emotional processes and are a target for therapeutic intervention.

People seem unaware of their most significant appraisals, which function as nonconscious algorithms—stored routines for the processing of social information. These algorithms, in the form of therapeutic hypotheses about covert mental functioning, can be inferred from what people say and do. Cognitive evaluations,

along with patterns of behaving and emoting, are used in CAT to describe personality.

Personality vulnerabilities are the central focus of CAT. Clinical conditions result from psychosocial stressors interacting with personality variables within a social context. These clinical conditions are personality-related disorders. CAT thus has a holistic orientation rather than a syndromal focus.

Emotion and behavior are viewed as the end result of cognitive processing in most forms of cognitive-behavior therapy. Beliefs or cognitions are said to mediate between stimulus and response, producing the “frightened animal” model of emotion: An animal reacts with flight and fear to a stimulus it interprets as dangerous.

In humans, the interpretive process uses cognitive inferences and appraisals to create an emotional response, and these cognitive processes are targets of therapeutic interventions. In CAT, inferences and appraisals are labeled personal rules of living—personal versions of correlational and cause-and-effect relationships, and of moral principles and social values. For example, if one has an inferential rule that all dogs will bite and an evaluative rule that pain is bad and should be avoided, the person will avoid dogs in order to avoid pain—exactly what phobic persons do.

This mediation model of episodic emotion accounts for a person’s reaction in specific situations, and can be helpful in relieving emotional distress in crises. However, most patients are not in psychotherapy for crisis intervention. The disordered emotions for which they seek treatment are habitual rather than reactive, chronic rather than episodic. They are emotional habits rather than emotional responses.

In order to sustain emotional habits thinking and acting must be brought into harmony with feelings. Each person, it is assumed in CAT, has one or more emotions that have been practiced so often they become, in computer terminology, his or her “default setting.”

CAT hypothesizes that people need to reexperience familiar feelings in order to have a sense of psychological security that originated in preadult patterns of attachment. People feel most comfortable and secure in familiar surroundings, with familiar people, and with their own possessions (familiar objects). Too much familiarity can be boring, but too much novelty can be threatening. CAT postulates an emotional setpoint—a familiar prescription about how a person should feel.

When a person’s subjective feelings fail to match his or her setpoint automatic processes are activated. Deviations below the setpoint are corrected by mood-lifting thoughts and actions (psychological defenses) that raise the emotional state. When one feels too good, au-

tomatic processes (security-seeking maneuvers) lower the individual’s affect to his or her accustomed, and therefore secure, state.

Two important but easily overlooked feelings that receive close attention in CAT are shame and self-pity. Shame is a feeling of personal deficiency, a form of self-criticism so extensive that one feels like an outcast from one’s community of friends and family. Self-pity is the feeling that one is weak and disadvantaged through no fault of one’s own. Prompting pity in others may result in motivating them to assist, but self-pity does not lead to self-help initiatives because the feelings confirm that the person is powerless. When shame and self-pity are personotypic affects, they move people to engage in behaviors that elicit criticism (shame) or tempt others to take advantage of them (self-pity). Although consciously abhorring these feelings, when people repeatedly act as if they seek them it provides evidence that the feelings are personotypic and their actions fit a pattern of security-seeking.

Both shame and self-pity are implicated in rage. The target of rage is often people who shamed or victimized the enraged person or who refuse to help. Because of the self-image of weakness, the person seldom expresses rage directly due to fear of retaliation.

Self-respect is necessary to combat shame and self-pity. It is difficult to feel ashamed when doing what is right, nor is it easy to feel sorry for oneself. Self-respect based on moral actions gives power to the person, and a powerful person cannot readily feel shame or self-pity, because the person feels adequate and worthwhile, not inferior and vulnerable.

III. EMPIRICAL STUDIES

CAT originated as individual psychotherapy, and its concepts have been applied to children, adolescents, adult groups, and couples. Because it is a theoretical perspective on personality and motivation, CAT can be adapted to other forms of psychotherapy. When therapy stalls, CAT concepts offer a fresh perspective on resistance to change; familiarity is a powerful force in people’s lives. Developed in a private practice setting, CAT has not yet stimulated empirical studies.

IV. SUMMARY

CAT treats the personality vulnerabilities that underlie anxiety and mood disorders. It assumes that people seek to restore their emotional setpoint by distorting

perception and cognition and by pulling responses from others that prompt personotypic affects. Failure to change or maintain change is due to the power of the emotional setpoint. Therapeutic procedures focus on the understanding of these patterns of personality and using such awareness to work against them. Special attention is given to achieving self-respect, based on personal responsibility for doing what is right, to combat shame, self-pity, and rage.

GLOSSARY

cognitive behavior group therapy (CBGT) Therapy that occurs within the context of a group and that incorporates a variety of cognitive strategies, modeling techniques, and other behavioral techniques.

generalization phase In this phase clients are prepared to transfer what they have learned in group to the natural environment. Extra-therapeutic assignments are designed to be carried out in the community.

intervention phase Situational analyses and goal setting are the primary foundations. Technical applications include correcting cognitive distortion, providing corrective information, exposure, modeling, and behavior rehearsal, with input from other group members.

Cognitive-behavior group therapy (CBGT) refers to a variety of different group approaches. What they have in common is that therapy occurs within the context of a group, and that intervention exploits various cognitive strategies, modeling techniques, and other behav-

ioral strategies as well. The goals of intervention are behavioral, cognitive, and/or emotional change. Specifically they aim at the reduction of stress and anxiety responses, depression, eliminating panic responses, reducing bulimic behavior losing weight, the resolution of phobic disorders, ameliorating agoraphobia, effective management of chronic pain, improving general social functioning, abstinence from risky sexual activity, and increasing self-control in the area of drug and alcohol abuse. (A comparable program has been described by Rose in 1998 for use with disturbed children and adolescents.) In the model proposed in this article the clients make use of the conditions of the group to enhance the clients' learning and motivation. Most CBGT models teach specific skills for coping with and resolving unique problem situations. Skills are usually developed for coping effectively with situations that trigger stress, anxiety, pain and/or anger through the use of various cognitive and behavioral procedures. In some cases where the goals are approaching anxiety-producing situations or phobic objects, the clients are gradually exposed to the phobic targets, often as a group. In almost all CBGT groups extragroup tasks (homework) are negotiated with the clients as a means of transferring learning to the real world. These tasks are monitored at a subsequent session. The therapist in CBGT, although presenting a highly structured program, in most cases involves the clients in many goal, task, and intervention decisions. Before we discuss CBGT in more detail, let us examine some of the research related to this approach.

I. OUTCOME RESEARCH ON CBGT

The research tends to provide support of the effectiveness of CBGT in the treatment of social phobias. For example, Heimberg in 1990 conducted a study comparing CBGT with a credible placebo control in the treatment for social phobias of 49 participants. Groups met weekly for twelve 2-hour sessions. The CBGT condition ($n = 25$) consisted of exposure to simulated phobic events, cognitive restructuring of maladaptive thoughts, and homework for self-directed exposure and cognitive restructuring between sessions. The educational supportive psychotherapy comparison group (ES) ($n = 24$), which acted as a control, consisted of lecture–discussion and group support. While both groups demonstrated significant pretreatment-to-posttreatment change, CBGT patients' phobias were rated as significantly less severe than those of ES patients at posttest assessment. Six-month follow-up data revealed a similar pattern.

In another study Mattick and Peters in 1988 conducted a study to assess the effectiveness of guided exposure in groups with and without cognitive restructuring in 51 subjects (24 male) with severe social phobia. The guided exposure model of CBGT emphasized the role of avoidance behavior in the etiology and maintenance of phobias and involved exposure to moderately difficult situations, the subjects being directed into increasingly difficult situations, and self-directed exposure homework assignments. The combined model of guided exposure and cognitive restructuring emphasized both avoidance behavior and the role of irrational thoughts in initiating and maintaining behavior and included systematic rational restructuring with elements of rational-emotive therapy as well as identifying, challenging, and altering maladaptive beliefs and attitudes. The combined methods group showed a significantly greater improvement than the exposure group from before to after treatment. Results from the self-report measures of target phobia avoidance rating indicated that the treatment resulted in greater approach to the phobic object.

Support for CBGT in the treatment of agoraphobia with panic disorder in intensive short-term CBGT (two all-day workshop) was provided by Evans, Holt, and Oei in 1991. They assigned 97 participants with the diagnosis of agoraphobia with panic attacks to either the treatment ($n = 74$) or the control wait-list group ($n = 23$). All subjects in the treatment condition attended the brief intensive CBGT, which consisted of lectures regarding agoraphobia, relaxation training, cognitive rehearsal of panic control messages, *in vivo* exposure, and group discussion. Waiting list participants were all consecutive re-

ferred to the clinic following the treatment phase. Results revealed that patients who received the treatment program had improved significantly at posttreatment and at follow-up and that significantly more patients were symptom-free or symptom-reduced following the CBGT treatment than the control group.

Lidren and colleagues in 1994 reported the results of a study that compared the effectiveness of CBGT in treating panic disorder (PD). Thirty-six men and women who met criteria of the DSM-III-R for PD were randomly assigned to one of three conditions: bibliotherapy (BT), group therapy (CBGT), or a waiting-list control (WL) group. Both groups were compared to a no-treatment control condition, and all three conditions contained 12 subjects. Results in terms of decreased panic attacks and lessening of severity of behavioral avoidance suggested the greater effectiveness of both treatment conditions over the wait list.

A number of studies support the effectiveness of CBGT in the treatment of eating disorders. For example, Telch, Agras, Rossiter, Willfley, and Kenardy in 1990 assessed the effectiveness of CBGT in treating binge eating disorders. Forty-four female patients who binged were randomly assigned to either CBGT ($n = 23$) for ten sessions or a waiting list control condition ($n = 21$). At posttreatment assessment, between-group comparisons revealed that subjects in the intervention group reported significantly reduced binge eating episodes compared with subjects in the waiting list control group. CBGT participants continued to binge significantly less frequently than at baseline. However, bingeing was usually not eliminated entirely.

Tanco, Linden, and Earle in 1997 conducted a study evaluating the effectiveness of a cognitive group treatment program on morbidly obese women. Sixty-two obese women were randomly assigned to either the cognitive program (CBGT), a behavior therapy weight loss program (BT), or a wait-list control condition (WL). Both treatment groups consisted of eight to 2-hour weekly sessions with the wait-list control condition lasting 8 weeks. However, results revealed that scores for the CBGT group improved significantly across time, while those for the BT group and the control group did not. The CBGT group and the BT group, but not the control group subjects, lost significant amounts of weight during the course of treatment. Analysis of body mass index (BMI) revealed a decrease with time in both the CBGT group and the BT group. Finally, the proportion of subjects in the CBGT group exercising regularly increased significantly over the course of treatment. Six-month follow-up data suggested that all treatment benefits were maintained.

A number of studies lend modest support to the use of CBGT in treating patients with hypochondriacal complaints or somatization. Lidbeck in 1997 conducted a study of the effectiveness of a short cognitive-behavioral group treatment model for somatization disorder in general practice. The CBGT condition consisted of six treatment groups with three groups of six patients and three groups of five patients making a total of 33 subjects receiving cognitive-behavioral therapy. The treatment included patient education to explain the psychological and physiological stress symptoms in order to enable cognitive restructuring, relaxation training, and homework consisting of one relaxation training session. CBGT consisted of eight 3-hour sessions. The control group consisted of 17 people: five groups of 3 patients and one group of 2 patients. Although no significant differences were found in dealing with social problems in either condition, reduction of illness behaviors was significantly greater in the CBGT condition than in the control condition, both at posttreatment evaluation and at the 6-month follow-up, and there was also a group difference reported for hypochondriasis at the 6-month follow-up. No significant differences were reported for anxiety, depression, or sleep disturbance, either at posttreatment or at the 6-month follow-up. Medical usage was significantly different between the CBGT and control conditions at the posttreatment evaluation and at the 6-month follow-up.

Avia and colleagues in 1996 also examined the effectiveness of CBGT with hypochondriacal patients. Seventeen participants were assigned to either the CBGT groups or the wait-list control group. The CBGT condition consisted of six weekly 1.5-hour sessions of general education covering inadequate and selective attention, muscle tension/bad breathing habits, environmental factors, stress and dysphoric mood, explanations given to the somatic signals, practical exercises implementing educational material, and homework to practice skills related to topic areas. The two CBGT groups were identical except for the assigned therapist. The waiting list control condition did not receive any form of treatment for the duration of the experiment. Results suggested a significant difference between CBGT and the control condition in the reductions of physical symptoms, bodily preoccupation, symptom interference, an overall reduction of the IAS, and also in their overall change in dysfunctional health beliefs. One year follow-up data reported that subjects maintained their reductions in their worry about illness and continued reducing symptom interference.

CBGT has found some support in the treatment of drug and alcohol abuse. Fisher and Bentley in 1996 conducted a study looking at the effectiveness of two

group treatment models, CBGT, disease and recovery approach, and a usual treatment comparison group. The CBGT condition consisted of interventions to enhance self-efficacy, provide more realistic and appropriate expectations about the effects of the abused substance on symptoms of personality disorders, increase adaptive coping skills, and enhance relapse prevention capacity. The disease and recovery group approach consisted of interventions to develop an "alcoholic" or "addict" identity, acknowledge a loss of control over the substance abuse and the effects of the personality disorder, accept abstinence as a treatment goal, and included participation in support group activities such as AA. Both experimental groups met for three 45-minute weekly sessions for 4 weeks. The usual treatment comparison group did not receive experimental interventions and met three times weekly in an open-ended group format. The analysis revealed that within the outpatient setting, the CBGT was significantly more effective than the disease and recovery group and the control group in reducing alcohol use, enhancing psychological functioning, and in improving social and family relations.

Eriksen, Bjornstad, and Goetstam in 1986 evaluated the efficacy of a CBGT model that used primarily social skill training procedures with patients who abused alcohol. Social skills training as part of inpatient treatment for patients with DSM III diagnosis of alcohol dependence delivered in a group format resulted in better outcomes than a traditional discussion group. Over the 1-year period after discharge, patients who had received social skills training were abstinent 77% of days, whereas control patients were abstinent 32% of days. In 1997, Vogel, Eriksen, and Bjoernelv also found support for the greater efficacy of the treatment of alcoholics in social skill groups over those in a control condition 1 year after the end of therapy.

Roffman and colleagues in 1997 assessed the effectiveness of CBGT to prevent HIV transmission in gay and bisexual men. Approximately 159 men were matched and assigned to receive either the 17-session group counseling ($n = 77$) or remain in an 18-week wait-list control ($n = 82$) condition. The CBGT condition was based on a relapse prevention model. Early sessions emphasized building group cohesion (one of the few studies that explicitly did so), HIV education, motivational enhancement, and goal setting. Middle sessions focused on determining antecedents to risky behavior and developing appropriate coping strategies that included coping skills training in high-risk situations that involved communication, cognitive activities, and behavioral strategies. Maintenance strategies for the preservation of safer behaviors were also included. This

study utilized one specific dependent measure: abstinence from AIDS-risk sexual activity over the 3-month period prior to reassessment. Data reveal men exposed to the treatment group had roughly 2.3 times the odds of success experienced by men assigned to the no-treatment control condition. Also, results indicate that the intervention appeared to be more effective with exclusively gay than with bisexual men.

Lutgendorf and co-workers in 1997 conducted a study of gay men diagnosed with HIV seropositive status to measure the psychological and immunological effects of a cognitive-behavioral stress management group (which could also be classified as CBGT) ($n = 22$) versus a wait-list control ($n = 18$). The CBGT group met for weekly 135-minute sessions that consisted of didactic components explaining physiological effects of stress, stress-immune associations, cognitive-behavioral theory of stress and emotions, identification of cognitive distortions and automatic thoughts, rational thought replacement, coping skills training, assertiveness training, anger management, identification of social supports, group discussion of personal examples, and homework.

Results of measures assessing relaxation practice and mood changes revealed a correlation between regularity of relaxation practice and changes in depression and anxiety, and in assessing immunologic effects. No changes, however, were found between groups at posttest or within groups over time in most of the immunological measures.

Adjustment of newly diagnosed cancer patients was found in a study by Bottomley, Hunton, Roberts, Jones, and Bradley in 1996. The groups compared were a CBGT condition ($n = 9$), a social support group ($n = 8$), and a wait list control condition ($n = 14$). Both treatment groups met for 8 weeks with sessions lasting 90 minutes. The cognitive-behavioral intervention focused on challenging dysfunctional thinking and learning coping skills while the social support group encouraged open and honest expression of ideas and employed topic-based discussions as primary treatment modalities. No significant differences were found between treatment groups at postintervention. However, differences in groups' scores on the Fighting Spirit subscale approached significance, suggesting that patients in the CBGT group received the most significant benefit in developing coping styles such as fighting spirit. However, at 3-month follow-up data indicate that the CBGT group significantly improved in their fighting spirit as compared to the other two groups. Also, a trend toward deterioration in the scores of the nonintervention condition was statistically significant in terms of increased helplessness and depression.

In the use of CBGT in the treatment of men who batter (see review by Tolman and Edleson in 1995), the results are mixed, although the authors note that consistent findings in varying programs, using various methods, seem to result in a large number of men stopping their violent behavior. In most studies they report that CBGT was more effective than a control group but not significantly more effective than alternative treatments.

In summary, the research cited earlier lends some evidence for the effectiveness of CBGT with a wide variety of presenting problems, although more research is needed. Often the group phenomena was confounded with the cognitive-behavioral procedures. The control groups were often not randomly assigned although the authors provided evidence for similarity of experimental and control conditions. In addition, it should be noted that in many of these and other studies, the number of subjects was low, and hence the power to reject the null hypothesis extremely small. It is in fact surprising that so many studies found a significant difference between control group and treatment conditions in spite of the small number. In all cases there was at least a no-treatment control group but often in the absence of a best possible alternative permitted only the conclusion that CBGT was better than nothing. In the several studies in which contrast groups existed, differences occasionally existed. No power analysis was reported prior to the intervention of most of the studies. The individual was in all cases the unit of analysis in spite of the fact that the treatment was in groups, thus incurring both statistical as well as psychological dependency.

One of the reasons for the modest methodological quality of research on small therapy groups is the complexity of such designs for groups and difficulty in recruiting sufficient subjects to meet quality design requirements. Second, because of the need to standardize treatment packages, individualization in experiments had to be ignored in contrast with actual practice. Third, most of the studies were field experiments that required special protections for the subjects that often worked against a strong design.

II. THE RELEVANCE OF THE GROUP IN CBGT

It is possible to do therapy in groups without making very much use of the group. Although most of the studies cited earlier do not include group interventions and group problems in their description, at the very least, all of them employed some form of group discussion

and member interaction. Unfortunately, the content and purpose of this discussion was not always made clear. This section describes the potential advantages as well as the difficulties, created by working with clients in a CBGT or any other group approach. Ways for dealing with some of the difficulties inherent in groups are also suggested. Many of the assumptions stated have been drawn from clinical practice. (For more details for adult groups see Rose's 1989 work and for groups of children and adolescents see Rose's 1998 research.)

A. Advantages of the Group

First, group membership commonly ends the sense of isolation many clients feel. It is difficult to maintain the feeling that you are the only person experiencing a particular problem when you are surrounded by other individuals who are dealing with similar issues. One of the potentially therapeutic factors in group treatment is the interaction with others who share common concerns (Yalom in 1985 referred to this as "universality"). Listening to others who describe and solve problems brings hope to the client that his or her problems are also manageable, which Yalom in 1985 also stated is a curative factor. These group phenomena are supported by the therapists who continuously permit members to help each other and create other conditions that increase the cohesion and work focus of the group. Helping others, a form of altruism and group cohesion, has also been described as curative factors by Yalom in 1985.

The group provides the client with a source of feedback about those behaviors that are irritating or acceptable to others and about those cognitions that can be viewed as distorted, self-defeating, and/or stress eliciting. As a result the group contributes to improved self-assessment for the individual client.

Another reason for using groups is the frequent and varied opportunity for mutual reinforcement. We have noted that clients find reinforcement from other group members more powerful than reinforcement from a single therapist. Reinforcement is a highly valued commodity in interpersonal relationships. As clients increase the frequency of reinforcing others, they note that they are reciprocally reinforced by others, and mutual liking increases. Each client is given the chance to learn or to improve his or her ability to mediate rewards for others in social interactive situations (with acquaintances, friends, family members, acquaintances in other groups, with other group members, etc.). The group therapist can create situations in which each client has frequent opportunity, instructions, and rewards for rein-

forcing others in the group. Special group exercises have been designed to train clients in mutual reinforcement, and extragroup tasks (homework assignments) are used to encourage clients, deficient in reinforcement skills, to practice them in the real world. The completion of these tasks is monitored by other group members.

In groups, a client must learn to deal with the idiosyncrasies of other individuals. Clients must wait while other people explain their problem. They must learn to tolerate what they perceive to be inadequate or even inane advice. Clients may be required to tolerate major differences with other group members and in some cases to deal with them. They must learn how to offer other clients critical feedback and advice in a tactful and helpful manner. By helping others, clients are likely to practice a set of strategies for helping themselves and learn a model of helping others that can be applied outside of the group. In this way they are likely to improve their relationships with others.

Therapy groups simulate the real world of natural friendship groups more accurately than does individual therapy if the therapist permits and even encourages such simulation. Individual therapy consists solely of a high-status therapist and a low-status client. Due to the greater similarity of the group to other social situations in the real world, the group setting facilitates transfer of newly learned behavior from the therapeutic setting to the community.

Groups create the opportunity for the group therapist to use an abundance of therapeutic procedures that are either unavailable or less efficient in individual treatment. Among these procedures are the "buddy system," numerous group exercises (see, e.g., Rose's work in 1998), multiple modeling, group feedback, group brainstorming, and mutual reinforcement. Groups also provide each client with a large number of models, role-players for overt and covert behavioral rehearsal, manpower for behavior monitoring, and partners for use in a "buddy system." By simulating the social world, the group provides a natural laboratory for learning, discussion, behavioral testing, and leadership skill development. All of these acquired skills are essential to form good social relationships in any setting.

In the process of interaction in therapy groups, norms (informal agreements among members as to preferred modes of action and interaction in the group) often arise, which serve to control the behavior of individual members. If these norms are introduced and effectively maintained by the group therapist, they serve as powerful therapeutic tools. The group, through group discussion of the implication of nonconformity to the norms, pressures deviant members to conform to such norms as

attending regularly, mutual reinforcement of assignment completion, self-disclosing, analyzing problems systematically, and assisting peers with their problems. Of course, if the group therapist is not careful, antitherapeutic norms also can be generated such as members coming regularly late, or having group members inappropriately or prematurely confronting one another.

In addition to modifying the norms of the group, the group therapist can facilitate the attainment of both individual and group therapy goals by such procedures as modifying the cohesiveness of the group, the status pattern, or the communication structure in the group. Group problems are also dealt with and resolved when they arise. Much of the power of group therapy to facilitate the achievement of therapy goals is lost if negative group attributes are permitted to fester.

B. Limitations of the Group as the Context of Therapy

Of course, groups are not without major disadvantages. Two mentioned earlier were that antitherapeutic norms occasionally develop and may be maintained if the therapist does not deal with such norms with the group members. Moreover, such phenomena as group contagion and mutual aggression can sometimes get out of hand in groups. In spite of such complications strategies for dealing with such group phenomena are available.

A relevant limitation to be concerned with is that it is more difficult to individualize each client in the group than in individual therapy. For efficiency, the group therapist is continually looking for common goals to pursue and may, therefore, overlook the unique needs of one individual. Within many complex group interactions, identifying the distinct needs of specific individuals requires a great deal of attention. Another threat to individualization is the fact that in order that everyone has a chance to participate actively in every session, restraints must be placed on people who talk more than their share. This is sometimes frustrating, but failure to limit excessive talking can result in the frustration of other members. The use of exercises with built-in restrictions depersonalizes the giving of structure and usually makes it more acceptable.

Confidentiality is more difficult to maintain in groups than in the therapeutic dyad. Confidentiality and the consequences of breaches need to be dealt with by the therapist in pregroup screening and early group sessions so that all group members conform to appropriate standards of conduct. Nevertheless, the participants are not professionally trained and abuses do occasionally occur and when revealed have to be dealt with in the group.

Finally, working with groups requires an extensive repertoire of skills and training to be minimally effective. Unfortunately, such training programs are not ubiquitously found in psychology, social work, counseling, psychiatry, or other professional training programs. However, training programs are available in the form of workshops. Exercises are available that can be used to develop in-service training (see Rose's 1998 discussion for more detail).

If the group therapist is aware of these limitations, all of the above potential problems can be avoided or, should they occur, dealt with. In this and the following sections the specific ingredients of CBGT are described. Since there are many models of CBGT, the focus is on the most eclectic approach, one that uses a wide variety of interventions and takes advantage of the group phenomena. How this model differs from other models is occasionally pointed out.

III. THE STRUCTURE OF THE CBGT GROUP

Before the interventions and phases of treatment are described, a number of practical questions need to be answered regarding number of participants, number and duration of sessions, number of therapists, and characteristics of members.

A. Size of the Group

The size of a group depends on its purpose, need for individualization, and practical considerations such as available space, length of stay in the institution, and available staff. Since individualization within a group is highly valued, the outpatient groups with which this approach has been used usually range in size from three to eight members. Generally, however, six members makes it possible to involve everyone at every session. Having a group with less than three members seems to lose many of the beneficial group attributes discussed earlier. A group larger than eight makes it difficult to allow every member to bring in a problematic situation at every meeting.

There are sometimes clinical practical reasons to modify this range. A limited number of staff may be available and a need for a group has been established. In some agencies groups of 12 or more clients have been carried out effectively, especially when all the clients share a common problem area, or if there are two therapists and the activities of the group are frequently carried out in subgroups. If there are two expe-

rienced therapists available, it would, based on my experience, be more efficacious to have two small groups than one large group. Often these larger groups have a more didactic than therapeutic goal purpose.

Institutional groups tend to be larger because they often overlap with the residential group. In order to facilitate greater individualization, the group may be divided into two subgroups, one led by the group therapist and the other by the residential worker or family worker or even a supervisor. Another reason for larger groups in institutions is that as a rule they meet much more frequently than outpatient groups. If a group meets every day, even if the group is large, each individual in the course of the several meetings a week will have the opportunity to focus on his or her problems.

B. Frequency, Length, and Duration of Group Sessions

Group size is also a function of the frequency, length, and duration of sessions. Most outpatient groups are time limited, and meet for approximately 2 hours a week for 6 to 18 weeks. In our review of the literature the modal number is 8, but most therapists prefer 12 to 18 sessions in order to achieve most treatment goals. Regular weekly sessions rather than the more variable schedule recommended later are the general pattern primarily because of the personal or work schedules of the families, of the clients, and of the group therapist rather than for any particular therapy rationale. Some have been able to follow 8 weekly sessions with 4 monthly ones as a way of providing the clients with more gradual fading of the intensity of treatment.

The exact number of sessions for outpatient groups depends on the purpose of the group, its composition, and certain practical limitations. In heterogeneous groups (members enunciating diverse presenting problems), in order to deal with a wide range of problems 14 to 18 sessions are usually required to meet treatment goals. When a highly specific and limited goal is pursued, a fewer number of sessions may suffice. In general, however, assuming major goals have been achieved after one set of therapy sessions, clients are referred to nontherapy groups such as at the YMCA/YWCA, yoga classes, bridge clubs, or sports groups to provide relatively safe opportunity to practice, unsupervised, what they have learned in therapy. Referral to individual therapy or support groups may also occur if clients have demonstrated increased motivation but are not yet ready to demonstrate their skills in the real world.

In institutions, transitional groups (groups that prepare the client to go back to the outside world) will

meet from 1 to 3 hours daily from their onset until termination, which is usually about 3 to 6 weeks. Only modest research exists to point the way to differences in the number of sessions. In adult groups in the therapy of social anxiety, D'Alelio and Murray in 1981 demonstrated that eight 2-hour sessions was significantly more effective in reducing social anxiety than four 2-hour sessions, perhaps because there is more extragroup time to practice what is learned in the group. In anger management groups for adolescents, Lochman in 1985 demonstrated the greater effectiveness of 16 sessions over 8 in increasing the control of anger by the youth.

As we mentioned earlier, although most outpatient groups are closed, some are also open-ended and have no set duration. In private practice especially, these groups of indefinite length tend to be organized. When the clients provide evidence that goals have been attained and a plan for generalization has been designed, the clients are helped by the other members to plan to terminate. Of course in such groups, termination of a given individual may also occur against the advice of the group therapist, as the attraction of the group fades for that individual without concurrent achievement of treatment goals.

In residential treatment, CBGT groups tend to meet every weekday or every other day for an hour and half for as long as the client is in the institution. Occasionally a client will miss sessions for such practical reasons as illness, doctor's appointments, court appearances, psychological testing, and special programs. Some institutions use CBGT only 2 or 3 of the 5 days, using the other days for more traditional methods.

C. Number of Group Therapists

As the number of group therapists in any one group increases so does the cost to the client, to the agency, or to the community. There is no evidence that two experienced group therapists are more effective than one, provided that the group therapist is experienced and trained. Thus, in most cases one group therapist is adequate and less costly than two or more. Moreover, two therapists often seem to amplify what the other says, which limits the time available for the clients to participate. There are, however, several situations in which more than one group therapist is required: if one of the therapists is in training, if both therapists are learning the method for the first time, if the group is larger than 10 persons, and if there are several acting-out persons in the group.

IV. PHASES OF CBGT

A. Beginning the Group

The structure of interaction in most models of CBGT can be divided into phases. Each phase overlaps with other phases, but in each phase the therapist focuses somewhat more on one set of behaviors than another. All have a "beginning the group" phase in which clients are oriented to the method, get to know each other, and the cohesion of the group is developed. Orientation involves explaining to clients what they can expect from the group experience and what is expected from them. The therapist usually describes the larger structure in the beginning and gradually fills in the details as the group progresses or as a new intervention is introduced.

Cohesion refers to the mutual liking of members with each other and with the therapist and their attraction to the program of the group. In our groups, the cohesion of the group can be enhanced by the use of group introductory exercises in which members interview each other in pairs and partners introduce their partner to the group. It is also a safe way of increasing broad participation and is the first step in self-disclosure. Cohesion is also enhanced by creating opportunities for continued broad participation, protecting members from premature and/or too harsh confrontation, keeping the interaction generally positive, using variation in the program, occasionally using humor, and developing opportunities for choice and self-decision-making by the members. The cohesion is continually monitored at the end of every session on one question of a postsession questionnaire (see later).

B. The Motivational Enhancement Phase

At the same time that the group begins and continuing into the later phases, in some models of CBGT the therapist focuses on increasing the motivation of the participants. (In most of the research cited earlier, this phase has not been explicated. One exception is found in the study by Roffman in 1997). When most clients enter a treatment group for the first time, they are often anxious, afraid of what others might think of them, and hesitant to expose their flaws to other people. They are often poorly motivated to work on the very problems that brought them to, or resulted in their being sent to, the group. This lack of motivation is particularly apparent in groups of involuntary clients such as men who batter, prisoners, and those who suffer from addictions.

However, even in voluntary groups, this ambivalence can often be detected. The type of behaviors often observed at the first session or even in the pregroup interview are a reluctance to speak, some anger about being in treatment, denial of any serious problems, setting themselves apart from the others in the group, speaking only to the therapist, an unwillingness to disclose anything about themselves, and an unwillingness to develop goals, treatment plans, or extragroup tasks.

Motivation has been operationally defined as the readiness of the client to participate actively in the treatment process (as discussed by Miller and Rollnick in 1991). This can be assessed by therapist's observations of the level of self-disclosure and other forms of participation of a self-report checklist. Strategies for enhancing motivation have been developed and are implemented throughout the treatment process to maintain the client's ever-changing commitment to change. Although in 1991 Miller and Rollnick viewed motivation as an individual characteristic, one often observes in groups a phenomenon in which motivation of each mutually influences the motivation of others. There appears to be a shared or prevailing group level of motivation. Miller and Rollnick identified a number of principles to be considered in the process of enhancing motivation. Some of these principles include normalizing ambivalence, contrasting costs and benefits of changing or resolving problems, eliciting and reinforcing self-motivational statements, and removing barriers to treatment. In addition, the therapist carries out a set of interviewing principles, such as supporting self-efficacy, avoiding argumentation, providing clear advice, and delivering continued feedback to the client. In groups the members are encouraged to respond in a similar fashion to each other.

C. Assessment Phase

Overlapping with cohesion building and orientation is the assessment phase. This actually begins with the client selecting a given group with a general theme in which she or he is interested or has major concerns (e.g., anxiety management, anger control, dealing with HIV infection). In the group and even in an intake interview, the particulars of the problem begin to be spelled out. Many practitioners make use of such paper and pencil tests as Beck's 1976 depression inventory, the fear survey schedule, and the fear questionnaire. Many other instruments are to be found in research summarized earlier. For practitioners a useful qualitative procedure often used is some form of situational analysis. Members can be trained by means of group

exercises and therapist modeling to identify and describe recent problematic or stressful situations in which they are dissatisfied with the responses. These situations are highly specific events that represent a sample of the more general complaint.

Client: Even though I am lonely most of the time and would like to meet people, I guess I don't do much to help myself (general problem).

Therapist: Can you give me a recent example of when you avoided doing something that would bring you in contact with others?

Client: That's easy; just this evening my brother called me to come for dinner, Friday. He said there would be some interesting new people there (situation). (This point is the critical moment.) The idea of meeting all those people scared the hell out of me (affective response) so I lied to him and told him I would have to be working that night (verbal response). I guess I'll never meet people that way (indicates dissatisfaction). But the people in this group have told me I'm a pleasant person and an interesting one, too (resources), so maybe this is something I can work on (goal).

Client 2: Sure, I have trouble controlling my temper (general problem). My dad was that way too (early background). But, Jeez, sometimes my wife, Shirley, really pushes my button with all her nagging (recent background). Thursday, when she told me to take the garbage out for the third time (situation) (at this point the critical moment), I thought, "there she goes again, nagging me" (cognitive response), then I really got teed off (affective response) and I let her have it (physical response). She called the cops (consequence) and I'm out on my own again (long-term consequence).

After the client provides a brief background, the situations are described in terms of what happened, where it happened, with whom it happened, and when it happened. Each client identifies a critical moment in the event and the behavioral, emotional, and cognitive response at the critical moment. (The critical moment is that instant in time that separates the triggering event from the response of the client.) The clients also state their level of dissatisfaction with the response and examine the long- and short-term consequences of their responses. In the assessment phase the group is used by having members evaluate each other's presentation as to how well the description meets the criteria.

Goal setting is also part of the assessment phase. Both individual treatment and common treatment goals are developed by each client, and, later in the process, group goals are formulated concerning group conditions requiring change. The attainment of group goals should

mediate the achievement of the individual treatment goals. As part of systematic problem-solving, specific treatment targets or goals are concrete behaviors, sets of actions, or identifiable cognitions that occur in response to a given specified problem situation. These behaviors and cognitions are specific to a given client and are identified in the interaction among members and in their description of problematic situations that they experience in their day-to-day social encounters. Since goal attainment is future oriented, the group therapist, group members, and each client together estimate a time frame for attaining the goal, which is incorporated into the formulation of the goal. Although clients identify unique individual goals, in groups common goals shared with some or all of the other group members are also identified. Common goals permit greater efficiency in terms of information to be provided, group exercises to be used, and problems to be solved. Most goals are developed over time, as members learn the language of therapy and begin to describe their problems in this highly specific terminology. When goals are not forthcoming from a given individual, the other members can "brainstorm" goals, based on earlier discussions, that might be considered by the reluctant client.

Group goals refer to a future change in interactive phenomena that occur in the group. An example of one group goal is "at the end of this session, all the members of the group will have actively participated in the role-plays." Another is "by the end of the next session, the members all establish a norm that extra-group tasks will be completed if agreed to at a prior session." A third example is "the attraction of the members to each other (as measured on a postsession questionnaire) will increase from the previous session to the end of this session." Although we urge formal goal setting as part of the treatment process, in some versions of CBGT the use of goals is more implicit than explicit. Group goals can sometimes be estimated by means of a postsession questionnaire distributed at the end of each session.

In the postsession questionnaire (PSQ) participants rate their own response to various aspects of each group session. A variety of group problems and group goals can be formulated in terms of these scales, which are in the form of 6 to 12 questions administered to all the members and the therapist at the end of every session. Some of the following are examples of PSQ items commonly used.

1. How useful was this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

2. How actively involved were the members in today's session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

3. How helpful were members to each other during this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

4. How much did the members reveal about themselves (their real thoughts, feelings, motivations, and or concerns) during this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

5. How close did the members feel to each other during this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

6. How upset or angry were the members during this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

7. How much did the members control the content and direction of this session?

1-----2-----3-----4-----5-----6-----7-----8-----9

not at all very little somewhat quite a bit extremely

Means, discrepancies among the members, and discrepancies between the mean of the members and the therapist's observations provide a rough estimate of some of the group phenomena as perceived by the members with the group. These data and member comments are discussed at the beginning of the subsequent session.

Group attainment scaling can also be used in group therapy as a way of estimating whether group goals are achieved. Group goals usually refer to a change in process such as broader participation, greater cohesion, increase in on-task behavior, greater decision making by members, and reduction of in-group conflict. A commonly used example of a Group Goal Attainment Scale (for more details on goal attainment scaling, see Kiresuk, Smith, and Cardi's 1994 discussion) in CBGT is the following:

Much less than expected (−2). Members talk almost exclusively to group therapist (91% or more).

Moderately less than expected (−1). Members talk primarily to group therapist (65%–90% of the time).

Expected level (0). Members talk about equally to other members and to group therapist (35%–64%).

Moderately more than expected (+). Members talk primarily to other members (10%–34% toward leader).
Much more than expected (+2). Members talk almost exclusively to each other (9% or less toward leader).

As observed in some of the research summaries presented earlier, individual and common treatment goals in CBGT have included a wide range of targets including managing pain, stress, anger, depression, or anxiety; reducing and/or eliminating the use of drugs, alcohol, or cigarettes; eliminating violence toward one's spouse and children; improving parenting skills; reducing the frequency of bulimic behavior; increasing safe sex practices; increasing positive life experiences in the face of personal tragedies; building more satisfying experiences; and reducing negative or self-defeating self-statements or avoidance behavior. Most of these goals can be broken down into even more specific short-term goals to be achieved by the end of one or two subsequent sessions.

D. Intervention Phase

Situational analyses and goal setting become the foundation for the intervention phase, which may involve correcting cognitive distortions implied in the situation, providing corrective information, exposure to the anxiety-producing object, systematic problem solving, modeling and rehearsing alternatives, reinforcing successful actions, and other interventions, most of which are carried out in the group with the help of the other group members. All of these interventions as they are applied in groups are described later.

E. Generalization Phase

In the generalization phase, which overlaps with the earlier phases, clients are prepared to transfer what they have learned in the group to the outside world and to maintain what they have learned in therapy beyond the end of therapy. In particular, extragroup tasks are designed for each member, usually at the end of every session, to be carried out in the community. Some of the other principles that are incorporated into treatment and that guide the planning for generalization are teaching the target behaviors in varied and multiple ways, finding opportunities for clients to teach what they have learned to others, encouraging clients to go public with their intervention plans and goals, gradually increasing the level of difficulty of expected behavior, preparing the clients for potential setbacks, having booster sessions following termination,

and encouraging membership in support or social recreational groups following group therapy.

V. INTERVENTION STRATEGIES

Almost all models of CBGT make use of a wide variety of interventions. Different models tend to emphasize different sets of interventions. These include cognitive change procedures, guided group exposure, modeling techniques, relaxation training, problem-solving techniques, operant procedures, community change strategies, relationship enhancement methods, and small group techniques, all of which are now discussed in more detail.

A. Cognitive Change Methods

Since the method is referred to as cognitive-behavioral, the major strategies employed focus on correcting distorted cognitions and replacing them with coping thoughts. Specifically, it includes such techniques as cognitive restructuring, cognitive modeling, self-instructional training, and realistic goal setting.

The most commonly used form of cognitive restructuring in groups is derived from the work of Aaron Beck in 1976. Bottomley, Hunton, Roberts, Jones, and Bradley in a 1996 study described earlier used Beck's method of challenging dysfunctional thinking of clients by the therapist. In groups the challenging may also be the responsibility of the other group members as they learn the correct techniques. In addition, the clients are helped to develop alternative cognitive coping skills and some behavioral alternatives as well (e.g., relaxation, recreational skills, social skills). The cognitive coping responses are often practiced in the group in role-plays (cognitive rehearsal). One technique proposed by Beck and Emery in 1985 that lends itself in particular to groups is "point counter point." In this technique a target client argues why his position is distorted or illogical, while another member or the group therapist try to support the illogical position. The discussion is first developed in pairs and then later presented to the entire group. The group members may coach the target client in his or her new role. The danger is that sometimes the group is too aggressively confrontative. To avoid this the group members are first trained through therapist modeling and explanation and a group exercise how to deliver and receive critical feedback.

Another version of cognitive restructuring as discussed by Meichenbaum in 1977 that we employ most

frequently as noted by Rose in 1998 is characterized by a set of procedures used to change self-defeating or illogical patterns of thinking to self-enhancing or logical ones. It is the first step used in improving cognitive coping skills. It is assumed that in a given set of circumstances cognitions partially mediate overt behavioral responses. These cognitions include how one values oneself and one's actions and how one specifically thinks or responds covertly in a given situation. The clients are trained to identify self-enhancing and self-defeating thoughts in case examples or exercises. Later they learn to identify their own self-defeating thoughts and try to change these to self-enhancing thoughts. They are taught through modeling initiated by the therapist and rehearsal by the client of the new cognition. Rehearsals may be carried out by all the group members, one after the other. Self-instructional training as described by Meichenbaum in 1977 combines cognitive restructuring and problem solving. It consists of the members being encouraged to make step-by-step verbalizations concerning the problem definition ("What's wrong with the way I'm thinking about this?"), problem focus ("What can I do about it?"), focusing of attention ("I should think about how that will get me in trouble"), coping statements ("If I keep relaxing I won't blow it!"), and self-reinforcement ("Wow! I did it! See, I can do it!"). To prepare for implementation of these strategies the group therapist or another client demonstrates (modeling) what might be said to oneself. This is followed by practice (rehearsal) by the client with the problem, first stating the coping statements aloud, then whispering, and eventually silently stating the coping statements to himself or herself. The group members serve as coaches for each other. This technique is often integrated into guided group exposure.

B. Guided Group Exposure

This technique has been primarily used in the treatment of agoraphobia, as described by Hand, LaMontagne, and Marks in 1974, although some practitioners and researchers have used it with other phobic objects usually in combination with cognitive restructuring and other techniques. The guided exposure involves exposure of the client in groups to feared situations *in vivo*, first together with other group members and then eventually alone. For example, a group of clients who suffered from agoraphobia went together to a department store after preparing by means of cognitive restructuring and the modeling sequence. The first trial was in the morning when the store was almost empty;

later they went at noon when it was more crowded; and the third time they went to the department store during a high volume sale. Later, they tried out the same exercises with partners from the group and eventually they performed them alone. Emmelkarnp and Kuipers in 1985 reviewed the commonly used procedures and the current research that lends support to these methods. As described earlier Mattick and Peters in 1988 conducted a study to assess the effectiveness of guided exposure with and without cognitive restructuring. The combined model of guided exposure and cognitive restructuring was significantly more effective than guided exposure alone. Evans, Holt, and Oei in 1991 reported on the long-term effects of a brief intensive CBGT in which group exposure methods combined with cognitive and other procedures were successfully used in treating agoraphobia. Heimberg and Colleagues in 1990, as described earlier, successfully used exposure methods and cognitive restructuring to significantly change the prosocial behavior of social phobics.

C. Modeling Methods

In our experience, symbolic modeling is one of the most effective strategies in group therapy. As we noted earlier, modeling by the therapist and the members for each other was an integral part of all of the other strategies described so far. Modeling strategies in groups have also been used in preventive and behavioral medicine with patients using the health care system (as described, for example, by Newton-John, Spence, and Schotte in 1995, and by Subramanian in 1991 and 1994). It has also been used successfully with mentally ill patients with social impairments, (as discussed by Daniels and Roll in 1998, and by Van Dam-Baggen and Kraaimaat in 1986). Modeling techniques are the central procedures in assertion training and play an important role in teaching clients how to cope with stress. In addition, because of the presence of many potential models and sources of feedback, modeling is especially useful in groups.

Symbolic modeling involves simulated demonstrations (role-playing) by group members, the group therapist, and/or special guests in the group. It may also include video or audio tapes of actors or real clients. The advantage of symbolic modeling over real-life modeling is that simulated modeling can be focused and developed systematically by the group and group therapist. It can be applied in simple situations with one critical moment or eventually in complex situations consisting of many critical moments. In symbolic modeling the group therapist can direct the action so that successful efforts

can be reinforced and unsuccessful ones terminated and redeveloped. The small group is especially well-suited to the use of symbolic modeling since it affords a rich source of ideas as to what the model should do, and multiple models and multiple sources of feedback to the person attempting to duplicate the role of the model. The techniques used in enhancing the modeling effects are drawn from the assumptions about and research on social learning, theory according to Bandura in 1977.

As in the earlier examples, most modeling is used solely by the therapist to demonstrate a given behavior or set of behaviors. However, modeling may be used as a major intervention package. In that case the modeling sequence in its entirety makes use of a number of steps.

1. The therapist orients the group to modeling and demonstrates the modeling steps (the first few times only).
2. Based on a situational analysis of an interactive situation, each client presents a situation he or she wants to have role modeled. The client clarifies the roles of model, target person, significant others, and observers.
3. A model is selected who demonstrates the desired behaviors. The model may be the therapist, a group member, or a guest invited for that purpose.
4. The target person rehearses or practices what she or he has observed, if necessary with some coaching or assistance from others (rehearsal plus coaching). If coaching is used the rehearsal is repeated without coaching.
5. The target person is provided with feedback from the other group members and the group therapist.
6. The practice is repeated as many times as time permits and the target person requires in order to be comfortable in his or her new set of behaviors. If necessary, additional practice may be carried out in pairs or triads to save time.
7. With the assistance of the group or a partner, each client designs an extragroup task to perform the modeled behavior in the real world or to practice again outside of the group.

D. Relaxation Methods

Relaxation is a way of teaching clients to deal directly with such strong emotions as anxiety, stress, pain, or anger for which no external coping behavior is possible or where cognitive coping behavior is insufficient (although the two procedures are often paired). This technique primarily involves teaching clients a

modified version of the system developed by Jacobson in 1929 and 1978 in which various muscle groups are alternately tensed and relaxed. This is often referred to as neuromuscular relaxation. In later phases, the tensing of muscles is eliminated. To make use of the group, after an initial demonstration by the therapist, the clients teach, monitor, and reinforce each other's efforts in the group for suitable performance and practice. Various alternatives uniquely suited to specific populations are also taught. Modest research support for the use of neuromuscular relaxation procedures for reducing anxiety and stress is to be found in studies by Stovya in 1977 and Lyle, Burish, Korzely, and Oldham in 1982. However, Heide and Borkovec in 1983 showed that relaxation may increase anxiety for some individuals. Meditation and breathing exercises can be taught as alternatives to neuromuscular relaxation depending on the preferences of the group members and the skills of the group therapist.

E. Systematic Problem Solving

Many models of CBGT make use of some form of systematic problem solving insofar as clients bring problems of concern to the group. The group, under the therapist's guidance, attempts to help find solutions to those problems. It is systematic insofar as the members follow specified steps, which include orienting the members to the basic assumptions of problem solving, identifying and defining the problem and client resources for dealing with the problem, generating alternative solutions, evaluating and selecting the best set of solutions, preparing for implementation, implementing the solution outside the group, and evaluating the outcome with the other group members at a subsequent session (as discussed by Heppner in 1978 and Goldfried and D'Zurilla in 1969). We have added the intermediate step called preparation for implementation. In this preparation, modeling, cognitive restructuring, or information giving may be used and an extragroup task is designed to be carried out prior to the next session. The tasks may involve small and gradually increasingly difficult steps toward performing the goal behavior.

Systematic problem solving is most effective as a group procedure, because in generating ideas for dealing with the problem, the many group members are a rich resource for potential solutions. Moreover, in evaluating these ideas the many group members provide varied life experiences on which to support or reject some of these solutions generated. The group is also a source of reinforcement and support for carrying out the task.

F. Operant Methods

These methods involve procedures in which the immediate consequences of a given behavior are followed in some systematic manner by a reinforcing event. It may also involve procedures in which the immediate conditions that lead to, or are parallel with, a given behavior are changed to create circumstances more amenable to the performance of a desired behavior. The latter is often referred to as stimulus control.

In groups, clients receive many kinds of reinforcement for the performance of prosocial group behavior and the completion of extragroup assignments or home tasks. With adults, this reinforcement takes the form of praise by the group therapist or other group members. Occasionally, it takes the form of smiles, applause, approving nods, and delighted laughter. Reinforcers are withheld in response to undesirable behaviors. This is referred to as extinction and is an occasional response in groups when someone is frequently off-task or complains a great deal. However, because in groups so many people are involved, it is a difficult procedure to manage.

Operant procedures, especially reinforcement, lend themselves to group conditions if the therapist trains and encourages members to reinforce each other and significant others outside of the group. Exercises have been developed to train members in effective use of praise and constructive criticism as communication skills in their own right.

Modifying the antecedent conditions or stimulus control was exemplified by a client in a weight-loss group who was urged by the others to eat only at a set table and with food that had been cooked. The group had a pot luck dinner in which the behavior was modeled. Two college students in a study skill enhancement program developed with each other a plan in which they only studied at a clean desk and did nothing but study at that desk. They monitored each other. They removed the telephone and food from the study room. Success was followed by group approval and self-reinforcement.

G. Community Interventions

Community interventions are used as part of the generalization process. It involves the client in dealing with other organizations or social systems in which they might find social support, social recognition, and reinforcement. For example, a group of parents of intellectually challenged children organized a float on which their children sat in a local parade as means of educating the public that they were not ashamed of their children.

This same group developed a little booklet for physicians on how to deal with the parents of special children and the children themselves as described by Kirkham, Schinke, Schilling, Meltzer, and Norelius in 1986. In working with clients with limited resources, referral to needed services may be considered. Ideas for community interventions may also come from the group.

H. Relationship Enhancement Methods

A number of skills have been identified as crucial to any helping relationship, (as discussed by Goldstein and Higgenbottom in 1991), regardless of whether this relationship is dyadic or within the structure of a small group. We have noted in our supervision of group therapists that in spite of high levels of technological skill, failure of group therapists to possess these relational or clinical skills results in high dropout rates from groups, disinterest on the part of the clients, and high levels of group problems.

Many of these skills are to be found in the other methods described earlier. For example, group therapists who can comfortably and frequently provide their members with high levels of reinforcement and protect the clients from premature or abusive feedback tend to establish sound relationships with group members. Similarly, group therapists who model self-disclosure (and all of the other skills that the members are expected to carry out) discover that the indicators of group problems (high levels of conflict, low cohesion, low satisfaction, exclusive pairing off, low group productivity) seldom arise.

Some skills are unique to relationship building. For example, the use of humor with clients is not addressed in the methods above. Yet, successful therapists must be able to play and joke with clients. Involving clients and the group in their own therapy is a skill that is essential for achieving generalization of change. This involves helping clients to take a chance at answering the questions of their fellow members, to make suggestions to each other for plans of action, to help each other to clarify the essential aspects of their problems, and to formulate appropriate goals. The process by which clients are involved is a vital relationship-building skill. Another skill is letting clients make their own decisions as much as possible concerning goals, extragroup tasks, and the extent of their participation. The more clients perceive themselves as deciding on what happens to them, the more likely it is that they will make use of interventions (similar to the ideas of Miller and Rolinick in 1991).

Listening to clients is a skill not discussed earlier, yet the absence of careful listening often results in choosing wrong change targets. Effective listening does not necessarily require seeing the underlying implications of the client's words, but rather has to do with grasping the obvious meanings. While hastening to carry out the items on a group's given agenda, for instance, therapists might interrupt or ponder next steps while a client is still speaking. This can cut off important interpersonal messages.

Attending skills refers to competency in observing nonverbal responses such as eye contact, body posture, and voice tone. Although these are nonspecific characteristics that are difficult to define, ratings by observers of group therapists in action tend to indicate whether such skills are indeed operating.

Setting limits on disruptive or off-task behavior is another relational skill that must be considered if the goals of change are to be pursued in a safe environment. This is one of the more difficult of the relational skills and one of the most frequently needed. It is not always clear when to set limits and when to ignore disruptive behavior. Skill in reinforcement and developing interesting and attractive program content often protects the group therapist from frequent application of limit setting.

I. Small Group Procedures

We have already discussed the unique opportunities as well as the limitations offered in therapy in small group settings. As mentioned earlier, interventions such as modeling, cognitive restructuring, and relaxation are administered in such a way as to encourage broad participation and high attraction among group members. In addition to the specific intervention strategies adapted from individual treatment mentioned earlier, there are some concrete group procedures that appear to contribute to helping clients move toward change. These group procedures include broad group participation, role-playing, the buddy system, subgrouping, leadership skill delegation, group exercises, and sociorecreational procedures. All of these techniques are described below. Combinations of these procedures are often applied to attain group goals or resolve group interaction problems.

Broad group participation refers to client-to-client verbal as well as client-to-therapist interaction in which all members participate extensively. It is the essential element by which problems are laid out and considered, solutions are shared and evaluated, decisions are formulated and affirmed, values are deliberated, and friendships are made. Maximum involvement of all group

members is essential for high cohesion and effective therapy. Broad group participation in the discussion is a necessary ingredient in the evaluation process, in problem solving, in assessment as members respond to other persons' stories, and in providing feedback to each other. Although not typical of many CBGT groups, issues sometimes arise that need to be discussed, such as stereotyping of persons with the client's problems and group problems (e.g., someone dominating the interaction). The therapist usually encourages such discussions but holds them to tight time constraints in time-limited groups.

Role-playing, in its most elementary form, can be defined as the practice of roles under simulated conditions. The group therapist, by acting as a guide and structuring the role-playing, contributes to the process and to the outcome achieved through role-playing. If the group therapist is clear about the purposes of role-playing, this technique can prove highly beneficial in promoting change, broadening participation, and in increasing cohesion. Role-playing may be used in assessment to discover how clients actually handled a given situation. In the modeling sequence, role-playing is used both to demonstrate specific skills and to practice them. Role-playing is also used to demonstrate and practice specific therapy skills such as giving and receiving feedback or showing empathy to others. Role reversal is a form of role-playing in which the client plays a significant person in his or her life and that person or another group member plays the client. It is a procedure that gives insight into how it feels to be the other person. Finally, role-playing is used to practice generalization strategies evolved in the group. Some clients are initially reluctant to role-play; however, the activity appears to eventually gain the enthusiastic cooperation of almost all members if it is implemented in a supportive, nonthreatening atmosphere.

Subgrouping is a simple procedure in which clients work in pairs, triads, or other sized subgroups to increase interaction among group members and provide them with an opportunity to work without the oversight of the therapist. It also may increase the amount of work that can be done in a given period of time. Subgrouping creates an opportunity for group members to practice leadership skills and afford clients the opportunity to help others while being helped themselves. The buddy system (as discussed by O'Donnell, Lydgate, and Fo in 1979) is a special subgrouping procedure for clients to work together outside of the group. In addition to the advantages mentioned earlier, it contributes to the transfer of learning from the group to situations outside of the group. The danger of

subgrouping is that the interaction occurs without the supervision of a therapist. In the group sessions the therapist can sample the interaction by floating from subgroup to subgroup. Moreover, subgroup activities are usually highly structured.

Group exercises refer to the use of structured interactive activities as ways of teaching clients the skills that mediate the achievement of therapeutic goals. For example, an introduction exercise is used in which a client interviews and is interviewed by at least one other client in the group and then introduces the partner to the others. Another exercise is one in which the clients study a case and discuss how each of them is different from the person in that case. Other exercises involve teaching clients how to give and receive both praise and criticism to a partner in the group. To be effective exercises are usually in writing and the goals as well as the activities are stated.

The therapist must make sure that the exercise is understood before they begin. Usually, at least one group exercise is carried out in every session. Other interventions, in addition to subgrouping, may be embedded within group exercises. For instance, a "round robin" exercise uses modeling and rehearsal at a fast clip in order to provide multiple trials of new behavior. In teaching how to ask for help, Pete asks Don for help, then Don asks Robin for help, then Robin asks Jerry for help, and finally, Jerry asks Pete for help.

VI. SOME CLOSING REMARKS

In this article the process of using cognitive behavioral and small group strategies in the treatment of individuals in groups has been described. Although the focus has been on adults, most of the same principles apply equally to group therapy for youth and children (Rose in 1998 provided a detailed account of this approach with youth). Where relevant literature was available, it was cited. However we have also drawn on our own experience and that of other practitioners for examples and practice principles. This article has stressed the use of procedures commonly used by various helping persons as they can be applied in groups. It should be noted that this chapter has drawn from practice, research, theoretical, and clinical literature produced by psychologists, social workers, psychiatrists, and others in the helping professions and social sciences. The therapists of the groups exemplified in this book come from diverse professional backgrounds. The label most commonly attributed to work with groups to achieve social-therapeutic goals has been "group therapy." In

many cases, the labels group treatment, group work, group training, or group counseling could have been used just as appropriately. We have referred to the individual who leads the process as group therapist—a label that cuts across all of the above fields. The group therapist might just as readily have been identified as group worker, group leader, or group counselor, since the activities of each overlap the others considerably. We have used the words, “clients” and “members” interchangeably to refer to the persons belonging to the groups.

As noted often, CBGT is not one approach but several similar ones. I have tried to point out some of the differences as well as similarities. Some stress one intervention strategy such as modeling, cognitive restructuring or guided imagery, while others use a wide range of interventions. The particular model stressed in this chapter is cognitive-behavioral interactive group therapy (CBIGT) because of its emphasis on the use of the group as the means as well as the context of therapy, along with a wide variety of both cognitive and behavioral procedures.

I. DESCRIPTION

Cognitive behavior therapy (CBT) incorporates principles associated with information-processing and learning theories. A basic assumption of CBT is the recognition that there is a reciprocal relationship between clients' cognitive processes (what they think) and their affect (emotional experience), physiology, and behavior. Although CBT treatments for individual disorders differ in both their form and application, they all emphasize the importance of changing cognitions and behaviors as a way of reducing symptoms and improving the functioning of the affected person.

CBT clearly defines roles for both the therapist and the client, both of whom are active participants in the therapy. The clinician assumes the role of educator, teaching the client about cognitive models that have been developed to understand the etiology and, more importantly, the maintenance of the client's specific problems. The clinician is also responsible for teaching clients the cognitive and behavioral techniques designed to alleviate their problems. The client is considered to be the expert on his or her personal experiences, and the two of them work together to overcome the client's difficulties.

The stance taken by therapists in CBT is quite different from that taken by therapists who employ different modes of treatment, most notably psychodynamic therapy. In CBT, therapists clearly communicate to clients that they do not have all of the answers and that they

GLOSSARY

- automatic thoughts** The self-critical or exaggerated negative self-statements that go through a person's mind and are accepted as true by the person without testing their accuracy.
- cognitive restructuring** A treatment technique that attempts to identify and modify negative or unrealistic thoughts or attributions.
- cognitive triad** A person's view of him- or herself, of the world, and the future, which may lead to depression when negative.
- exposure** A treatment approach in which clients systematically confront their feared objects or situations.
- exposure and response prevention** An approach to treatment for obsessive-compulsive disorder (and other disorders such as bulimia nervosa) in which the client is systematically and gradually exposed to his or her feared thoughts or situations while compulsive rituals or other behaviors are actively prevented.
- schema** An enduring and stable belief system that assists in explaining experiences, mediating perception, and guiding response.
- self-monitoring** A treatment technique in which clients systematically observe and record behaviors or responses and may be used to highlight subsequent changes in patterns of responses.

must collaborate to solve the client's problems. For clients to experience symptom relief, they must also actively seek out new experiences and must learn to look at the world in new ways. Clients are, in effect, taught over time to serve as their own therapists, to apply the principles of CBT with decreasing amounts of guidance from the therapist. Encouraging clients to take on this role might be part of the reason why gains experienced over the course of CBT tend to be maintained or even increased once treatment has ended.

A core assumption of cognitive behavioral approaches to understanding and treating mental disorders is that people are active processors of information. In Aaron Beck's original cognitive model of depression, three important concepts were introduced to help to explain the psychological underpinnings of the disorder, and these concepts have greatly informed our understanding of other disorders as well. First, Beck introduced the cognitive triad, a term to describe his contention that depressed people have negative views of themselves, their ongoing experiences, and their futures. The second core component of Beck's model is the schema. Each day, humans are barraged with numerous stimuli from the environment, and it would be impossible to attend to every single one. Furthermore, once a person actually attends to a stimulus, how he or she comes to understand and process it might be very different from how another individual might react to that same stimulus. Beck suggested that our reactions to stimuli are determined by relatively stable cognitive structures called schemas. Once activated, schemas can have effects reaching far beyond the immediate situation. For example, a relationship break-up might trigger a depressive schema (which might relate, for example, to the inevitability of the loss of all things good) and lead the individual to view unrelated events in a similar vein. For example, having an important piece of mail get lost might be interpreted as just one more example of how "no one cares for me," while prior to the break-up (and the activation of the depressive schema), that same event might have been interpreted in a more neutral and less hurtful way.

Finally, Beck also introduced the idea of faulty information processing. Specifically, depressed people tend to erroneously think in an "extreme, negative, categorical, absolute, and judgmental" fashion, not surprisingly leading to negative affect. According to Beck, these thinking errors maintain clients' negative beliefs about the self, their experiences, and the future, even in the presence of contradictory evidence.

Given that negative affect and behaviors are facilitated and maintained by faulty information processing, it makes sense that the main goal of cognitive behavior therapy is to fix errors in thinking. Thoughts can often be changed directly, in which case clients are instructed to be attentive to subsequent changes in their mood, physiology, and behavior. Conversely (as will be discussed in more detail below), clients are also taught that changes in behavior can result in subsequent changes in cognition. These behavioral changes can also have a profound impact on affect and physiology. In short, clients are encouraged to always keep the important reciprocal relationship between cognition and behavior in mind and to remember that alleviation of symptoms can come about via changes in thinking and/or changes in behavior.

An important component of treatment is to make clients aware of their negative automatic thoughts. Often, clients are so accustomed to having negative thoughts, and the thoughts come to them so quickly, that they are not even aware of having them. Furthermore, clients rarely come into treatment having a clear understanding of the ways in which negative thoughts impact affective, physiological, and behavioral processes. Therefore, a first step in treatment is to help clients to become more aware of their thoughts, primarily through self-monitoring exercises. In line with Beck's cognitive triad, important targets of CBT include beliefs and expectancies about oneself and one's future, about others, and about the world. Once clients become adept at this process, it is essential also to teach them to evaluate their thoughts and to restructure them to be more rational and adaptive, all the while being cognizant of how changing thinking patterns can influence feelings as well as patterns of behavior. Although cognitive restructuring is very effortful at first (and requires the guidance of the therapist), clients gradually become more adept at the process, and many remark that this new style of looking at the world becomes integrated into their internal thought processes.

As noted above, changes in behavior can also have a profound impact on thinking patterns. Behavioral exercises in CBT can take many forms. The client is encouraged to take the stance of a scientist, viewing dysfunctional beliefs as hypotheses that can be tested, rather than as facts. This process of hypothesis testing involves not only cognitive restructuring, but also behavioral exercises. An important assumption behind this scientific stance is that beliefs can only be changed if there is concrete evidence to support the integration of new ways of looking at the self, the world, and the future.

Behavioral techniques used in CBT are also greatly informed by the assumption that psychological difficulties are often maintained by dysfunctional patterns of behavior, including avoidance. As such, an important component of CBT is the use of exercises aimed at changing clients' expectancies about their ability to function in particular situations. For example, the key to treating a specific phobia of spiders is to actually expose the client to spiders. Through this experience, clients learn that their anxiety will habituate over time, that the terrible consequences that they associate with spiders are unlikely to occur (e.g., that the spider will have fangs that result in violent bites), and that they have the skills to deal with their anxiety in this feared situation.

Another behavioral technique used in the treatment of some disorders is exposure and response prevention (EX/RP). Here, clients are encouraged to resist the urge to engage in dysfunctional behaviors while exposing themselves to the stimuli that typically elicit these behaviors (e.g., refraining from bingeing after eating a bit of a fattening food in the case of bulimia nervosa; refraining from washing after touching something perceived by the client as contaminated in the case of obsessive-compulsive disorder). These exercises are again intended to test out the veracity of the client's beliefs (e.g., eating a bit of a forbidden food does not need to invariably result in a binge; touching something dirty will not result in something terrible happening), as well as to teach clients to use more effective coping strategies and to feel more in control of their behaviors.

An important component of CBT is relapse prevention. Throughout treatment, clients are encouraged to integrate CB techniques into their daily lives, with the intention that in doing so, CBT will remain effective after therapy ends. Some interventions, however, are specifically aimed at preventing posttherapy relapse. Specifically, clients are made aware of the fact that they might have difficult times in the future even following successful treatment. In line with cognitive-behavioral principles, they are encouraged not to interpret a single difficult event as a failure. Although the same difficult events might come up pre- and posttherapy, clients are reminded that they have come away from therapy with many useful skills that they did not previously have at their disposal. As already noted, an important goal of therapy should be to ensure that clients can apply cognitive and behavioral techniques on their own, with less reliance on the therapist over time, thus facilitating relapse prevention efforts.

CBT is a very versatile treatment, adaptable to both group and individual settings. It has been used with

children, adolescents, and adults across a wide range of cultural and socioeconomic backgrounds. CBT is also a time-efficient treatment, with most uncomplicated cases of anxiety or depression being treated in 4 to 14 sessions. This efficiency comes about for a number of reasons. First, the CBT therapist performs a thorough assessment prior to treatment that is aimed at identifying a principal problem that will be the focus of treatment. The clinician then develops a treatment plan that specifies how long the problem should take to treat and what should be accomplished during each session to meet that goal. This efficiency has been greatly aided by the development of CB treatment manuals, written for a range of psychological disorders. While these manuals help clinicians to structure treatment, they also encourage flexibility in terms of tailoring the treatment to suit the progress of the individual client.

Another factor in the time-limited nature of CBT is its focus on the "here and now." The CB view of symptom maintenance is greatly informed by learning theory. Simply put, difficulties are viewed as maladaptive "habits" that have been learned as a result of the association between certain stimuli and certain responses or as the result of reinforcement of specific responses in specific situations. Rather than looking back on why a particular problem developed (e.g., why a stimulus came to be associated with a particular response), focus is placed on developing new, more adaptive stimulus-response associations through the use of both cognitive and behavioral techniques.

CBT is an effective treatment for a wide range of client groups, although there are some contraindications. CBT is generally not indicated for people with thought disorders, although it should be noted that some researchers have explored the efficacy of CBT for schizophrenia (as reviewed recently by Faith Dickerson) and the research done to date suggests that the approach might be more promising than intuition would suggest. CBT is also not indicated for people with organic brain disorders or for people who do not have a good grasp of the language in which therapy is being conducted. Beyond these limitations, CBT has been used successfully with clients from a broad range of educational backgrounds.

Clients who embark on CBT must also be willing to accept the basic premise of the cognitive-behavioral approach to understanding and treating psychological disorders. Thus, clients who are very wedded to a particular theoretical or therapeutic approach and who are not willing to consider alternative perspectives might not do well in CBT. Furthermore, clients must be willing to

commit time and effort to their treatment. They are expected to work on their own between sessions, and research has suggested that adherence to homework assignments is predictive of good treatment outcome. As such, clients who are so impaired that they are unable to actively engage in treatment might not be good candidates for CBT until they experience some symptom relief from other approaches (e.g., medication).

II. THEORETICAL BASES

Cognitive-behavioral theories resulted from a gradual evolution of thought in the field of psychology that began as a reaction to the psychoanalytic theories that dominated clinical psychology and psychiatry in the 1960s. In its classical formulation, Sigmund Freud's psychoanalytic theory rested on the reductive analysis of the psyche, conducted from a scientifically detached posture. The main features of this theory included an emphasis on the unconscious, intrapsychic processes, and early childhood experiences. By its very nature, psychoanalytic constructs were not conducive to empirical investigation or validation. A growing dissatisfaction with the length and expense of psychoanalytic therapy and an ongoing controversy about its relative effectiveness led to a rise in treatments based on behavioral theories of psychotherapy.

Behavioral theories in the 1960s and early 1970s were based on the assumption that behavior develops and is maintained according to the principles of learning. One of the earliest influences on behavioral models of psychopathology was the seminal work of the Russian physiologist Ivan Pavlov on the principles of classical conditioning. His specific findings on animal learning processes, as well as his controlled methods of laboratory investigation, made important contributions to the study of behavior by prompting the view that a particular psychological symptom may be a response triggered by a specific stimulus or event. In one of the most significant investigations of learned behavior, John Watson and his colleagues demonstrated that specific fears could be both conditioned and deconditioned in human beings via the principles of classical conditioning. Using these and his own research findings, Joseph Wolpe developed a treatment for human anxiety referred to as systematic desensitization, wherein deep muscular relaxation is paired with images of anxiety-provoking situations. Over time, clients using this technique would experience less anxiety in response to the feared stimulus because the condi-

tioned relaxation response was incompatible with the physiological response of fear. B.F. Skinner explored another learning principle called operant conditioning. Theories based on operant conditioning rest on the notion that many behaviors are performed spontaneously and are controlled primarily by their consequences. Thus, the removal of a reinforcing consequence should decrease the frequency of an unwanted behavior and conversely, applying a reinforcing consequence should increase the frequency of a desired behavior.

This belief that psychological disorders arise from an inappropriate conditioning history led to the development of behavioral treatments based on the tenet that symptoms can be reshaped into adaptive behaviors through a program of response-contingent reinforcement. Behavioral therapy was compatible with experimental methodologies, was time-efficient and heralded success in reducing anxiety and overcoming maladaptive avoidance behaviors. However, criticism of strict stimulus-response behaviorism soon followed. Albert Bandura, a social learning theorist, showed that cognitive processes were critical to the acquisition and maintenance of maladaptive behaviors and emphasized a more reciprocal relationship between the person and the environment. Other limitations of strict behavioral therapy, including a neglect of affective processes and a lack of success in the treatment of depression, opened the way for a more cognitive approach to the theory and treatment of psychological disorders.

Albert Ellis has been credited for his pioneering work in formulating the first coherent system of cognitive behavior therapy called rational-emotive therapy (RET). RET uses direct cognitive debate, logical persuasion, and behavioral homework assignments to challenge irrational beliefs and negative thinking. The goal of this therapy was to modify the core cognitive dysfunctions that are the basis of psychological disturbance. Unlike strict behavioral theories, cognitive theories assert that individuals are active participants in their environments, judging and evaluating stimuli, interpreting events and sensations, and appraising their own responses.

As mentioned earlier, Aaron Beck has been a highly influential figure in the history of cognitive therapy. In contrast to earlier theorists, Beck placed a great deal of emphasis on the cognitive aspects of psychopathology, while also advocating the integration of established behavioral techniques.

The marriage of these two approaches provides the foundation for a cognitive-behavioral approach to psychotherapy, wherein overt behavior and covert cognition, along with the interaction between the two, are crucial

for explaining the development and maintenance of emotional distress. This approach attempts to integrate the rigors of a behavioral research methodology and performance-based exercises with the centrality of mediating information-processing factors in cognitive therapy. This therapeutic approach thus offers greater explanatory power through an integration of cognitive, behavioral, emotion-focused, and social aspects of change.

The field of cognitive-behavioral therapy has been increasingly specialized and refined since the early work of Beck and Ellis, and cognitive-behavioral treatments have been applied to a wide range of psychological conditions and problems. However, these treatment programs have a common core that belies their common ancestry.

III. EMPIRICAL STUDIES

Studies of the efficacy of CBT for the different disorders have generally sought to answer some common questions. Researchers often begin to explore whether CBT is an effective treatment for a particular disorder through “open-label” trials, wherein all participants in a study receive CBT and change is assessed from before to after treatment. Once it has been demonstrated that CBT is associated with improvement in the problem of interest, other essential questions with respect to its efficacy must be explored. First, is CBT more effective than no treatment? Second, how does CBT compare to other psychological treatments? Third, how does CBT alone compare to either medication alone or a combination of medication and CBT? Finally, if a treatment is shown to be effective, it is also important to establish whether it remains effective in the long term once active interventions (e.g., therapy sessions) have been discontinued.

A. Mood Disorders

As noted earlier, CBT was first developed as a treatment for depression. CBT for depression has been shown in numerous studies to be more effective than no treatment at all and more effective than nonspecific treatments (those not specifically targeted at depression). CBT has also been shown to be at least as effective as, or more effective than, other psychological and pharmacological treatments. Also of note, CBT seems to reduce the risk of experiencing subsequent depressive episodes following treatment.

Despite a long and relatively successful tradition of using CBT to treat depression, this approach does not

seem to be a “cure-all” and not all research studies have provided strong endorsements. The National Institutes of Mental Health (NIMH) Treatment of Depression Collaborative Research Program compared CBT to interpersonal psychotherapy (IPT) (a treatment developed specifically for depression by Myrna Weissman, Gerald Klerman, and colleagues that focuses on the relationship between mood and life events, particularly those related to interpersonal relationships), the tricyclic antidepressant imipramine, and pill placebo. All three active treatments performed equally well, with a little over 50% of participants who completed all 16 weeks of treatment experiencing a significant response. Although CBT was slightly more effective than the other active treatments for people with less severe cases of depression, it fared less well for people with more severe cases. Furthermore, the three active treatment groups did not differ in terms of relapse rates 18 months after treatment had ended. Although a greater percentage of responders in the imipramine group ended up relapsing as compared to responders in the CBT and IPT groups, it should be noted that these latter two groups relapsed at the same rate as participants in the placebo group.

In a more recent study, Steven Hollon and his colleagues compared the efficacy of 12 weeks of CBT alone, imipramine alone, a combination of CBT and imipramine, and 12 weeks of imipramine followed by another year of active drug treatment. After 12 weeks, the groups did not differ. At 2-year follow-up, the participants who had taken only 12 weeks of imipramine fared worse than all of the other groups. This study also demonstrated that CBT worked well, and its efficacy was not improved by the addition of imipramine. In contrast to the NIMH Treatment of Depression Collaborative Research Program described above, more severely depressed participants responded as well to CBT in this study as did the less depressed participants.

Although the use of CBT as the sole treatment for unipolar depression has certainly been advocated, CBT is viewed as an adjunct to pharmacotherapy in the treatment of bipolar disorder. At the current time, very few studies have been conducted, but researchers are taking a greater interest in the application of CBT to this disorder. Monica Ramirez Basco and John A. Rush have published a CBT treatment manual for bipolar disorder that should facilitate research. Furthermore, a federally funded, multisite study is currently under way that is exploring the relative efficacy of CBT, IPT, and family-focused therapy for bipolar disorder.

B. Anxiety Disorders

CBT, or components of it, have also been used for many years in the treatment of anxiety disorders. In general, CBT has been shown to be effective across the anxiety disorders. CBT is generally seen as *the* treatment of choice for specific phobia and has been used for this disorder for many years. Medication has not been shown to be effective for the treatment of specific phobias, nor have alternate psychological therapies.

Another successful application of CBT in the realm of anxiety disorders has been in the treatment of panic disorder. David M. Clark and his colleagues compared the efficacy of CBT, applied relaxation, and imipramine. Clients placed on a wait-list served as an additional comparison group to ascertain whether changes could be attributable to the simple passage of time. At the end of treatment, clients in all three active treatment groups were doing better than clients assigned to the wait-list control group, and CBT clients fared better than those who received applied relaxation or imipramine. Furthermore, at 15-month follow-up, the CBT group was still doing better than the other two treatment groups. The most notable finding was that between 6 and 15 months following treatment, 40% of the imipramine group relapsed, compared to only 5% of the CBT group.

In another large-scale study of the treatment of panic disorder, David H. Barlow, Katherine Shear, Jack M. Gorman, and Scott Woods compared the efficacy of CBT alone to imipramine alone and to a combined treatment (CBT and imipramine). The results of their study suggested that CBT and imipramine were both superior to pill placebo. Although imipramine produced a somewhat better quality of response than CBT, the latter was better tolerated and proved to be more effective in the long term. The combination of CBT and imipramine was not as promising as the investigators had expected. In fact, participants in the combination group experienced the highest relapse at follow-up, suggesting that the addition of CBT to drug therapy did not protect against the relapse that has been associated with withdrawal from drug therapy in past studies of panic disorder clients. It is interesting to note, however, that there are studies suggesting that CBT can be very useful in helping clients to withdraw from benzodiazepines, antianxiety drugs commonly used in the treatment of panic disorder. In short, CBT has been shown to be very effective in the treatment of panic disorder, particularly in terms of long-term efficacy. Recent studies have also suggested that a shorter course of CBT for panic disorder using

self-study modules may be as effective as longer courses of treatment.

CBT has also been shown to be as effective as alternative treatments for social phobia, when delivered in either individual or group format. Richard G. Heimberg, Michael R. Liebowitz, and their colleagues have compared the efficacy of cognitive behavioral group therapy (CBGT) to that of the monoamine oxidase inhibitor phenelzine. For comparison, some participants in this study were assigned to either pill placebo or to a psychotherapy control condition (educational supportive group therapy). The general finding from their study was that clients taking phenelzine improved more quickly than did clients who received CBGT, but CBGT seemed to be more effective in terms of long-term efficacy once treatment had ended. The same research team is now exploring the efficacy of combined treatment (CBGT and phenelzine) for social phobia.

A highly successful approach to treating obsessive-compulsive disorder (OCD) is through the use of exposure plus response prevention (EX/RP, described earlier). Since the utility of EX/RP was first explored in the late 1960s, the approach has gained ample empirical support, with the combination of exposure *and* response prevention proving to be more effective than either component alone. Although certain medications [particularly clomipramine and some of the serotonin reuptake inhibitors (SRIs)] seem to be modestly effective in the treatment of OCD, continued success depends on continued use, suggesting (as in other anxiety disorders) that CBT might be a more effective treatment than medication in the long term. Isaac M. Marks and his colleagues have explored the efficacy of combined treatments (clomipramine and EX/RP) for OCD. In general, his studies have suggested that EX/RP is a more powerful, and a more long-lasting treatment than clomipramine and that the combination of the two treatments has only a small and short-lived additive effect. The issue of the combined treatments in OCD is also being explored in an ongoing study by Michael Liebowitz, Edna Foa, and Michael Kozak. In line with Marks's findings, preliminary data suggest that EX/RP is superior to medication alone and the combination of medication and EX/RP does not seem to be superior to EX/RP alone.

In contrast to the other anxiety disorders, treatment for generalized anxiety disorder (GAD) is still in its infancy and furthermore, while treatment for GAD (including CB-type treatments) is more effective than no treatment at all, comparative studies have failed to find differences between active treatments. Many factors

have contributed to the relative slowness in the development of treatments for GAD. First, the diagnostic criteria for GAD have changed a great deal over time. Uncontrollable and excessive worry was not specified as the core feature of the disorder until 1994. As such, past treatments have included nonspecific interventions, such as relaxation training and biofeedback, rather than interventions specific to treating uncontrollable and excessive worry. In line with changes in the diagnostic criteria, there have also been major changes in the way that people understand the etiology and maintenance of GAD. Newer treatments place greater emphasis, for example, on the important role of emotion in GAD. These developments are greatly informed by current cognitive models of the disorder, like that of Tom Borkovec and his colleagues, which suggests that worry functions as a means of avoiding more emotionally laden, painful thoughts. Over the next few years, continued research into the nature of GAD may lead to the development of exciting new treatments for this disorder.

There have also been few controlled studies of CBT as a treatment for posttraumatic stress disorder (PTSD). However, various approaches based on CBT have been used to treat the disorder with encouraging results. These approaches have included stress inoculation training (SIT), a treatment originally developed by Donald Meichenbaum. In SIT, clients are first helped to make sense of the trauma that they endured and to understand the responses that they are experiencing to their trauma (in terms of cognition, behavior, and physiology). Clients are then taught coping skills to increase their sense of efficacy and to help them to feel that they have gained mastery over their fears. Coping skills are targeted at alleviating physiological symptoms (e.g., through muscle relaxation), cognitive symptoms (e.g., through guided self-dialogue), and behavioral avoidance (e.g., through modeling and role playing). Dean G. Kilpatrick and his colleagues found SIT to be effective in uncontrolled case studies but since this initial work, it has not been found to be superior to other treatments, particularly in the long term where exposure therapy seems to show greater efficacy.

Edna Foa and her colleagues have explored the use of exposure therapy for PTSD with particular focus placed on treating rape-related trauma. Their treatment, referred to as prolonged exposure, is premised on the assumption that PTSD occurs when people do not adequately process their rape experience. As such, treatment must involve processing the trauma by, in effect, exposing the client to the memories of the trauma until a fear response is no longer elicited. Foa and her col-

leagues have found that clients enrolled in prolonged exposure do better than clients on a wait-list and that prolonged exposure is more effective than SIT in terms of long-term efficacy. Patricia A. Resick and Monica K. Schnicke have also used a CB approach to treating PTSD in victims of sexual assault. Their cognitive processing therapy (CPT) involves both exposure and cognitive-restructuring techniques, with the latter based on the assumption that the experience of sexual assault is incongruent with schemas that were held prior to it. As such, CPT involves dealing with thoughts pertaining to such issues as danger, safety, intimacy, and competence. Studies have shown that clients enrolled in CPT do better than those on a wait-list, and CPT seems to have good long-term efficacy.

C. Bulimia

Bulimia nervosa has been treated with CBT for many years, beginning with the work of Christopher G. Fairburn in the 1970s. CBT has been associated with reductions in frequency of binge eating and purging, levels of dietary restraint, and concern over shape and weight. Furthermore, CBT for bulimia has been shown to improve general functioning (including social functioning) and to increase self-esteem. As in the case of the anxiety disorders, CBT for bulimia seems to be effective in the long term, suggesting that clients learn skills that they can continue to apply on their own once treatment has ended. In comparison studies, CBT has been shown to be more effective than alternative therapies, drug therapies or a combination of drug therapy and CBT. The one treatment besides CBT that seems to hold particular promise for individuals with bulimia is IPT (described above). Fairburn and his colleagues compared CBT and IPT and found that although CBT seemed to work more quickly than IPT, the efficacy of the two treatments evened out during the follow-up period. It is interesting to note that IPT in that study was (as in the treatment of depression) focused on interpersonal relations, not on the eating disorder, suggesting that there is more than one way to foster improvement in eating disorder symptomatology.

D. Alcohol Use Disorders

CBT has also been applied to the treatment of alcohol problems. Alcohol use is viewed as a learned behavior that can be modified once a clear understanding is reached of the antecedents and consequences of its use. Several successful treatments have been developed

with roots in CBT. Behavior self-control training (BSCT) is a treatment aimed at teaching clients self-regulation strategies. Although the goal of BSCT can be abstinence, the more common goal is moderation. Focus is placed on engaging in self-monitoring as a means of understanding motives underlying drinking, learning ways to cut back on drinking, and developing more adaptive coping skills with which to replace drinking. BSCT has been shown to be more effective than no treatment and at least as effective as treatments aimed at complete abstinence. William R. Miller and his colleagues also found that BSCT had good long-term efficacy for individuals with moderate drinking problems.

As mentioned earlier, RP is an essential part of CBT for all disorders, but the strategy was initially developed for the treatment of people with alcohol use problems by G. Alan Marlatt. Drawing from research on self-efficacy, RP is based on the premise that the probability of relapse can be predicted by client's perceptions of their abilities to handle difficult situations. RP can be easily integrated into other treatments. Over the course of RP, clients are taught to identify high-risk situations and to use cognitive and behavioral coping strategies when they find themselves in such situations. Furthermore, cognitive techniques are used to help clients deal with inevitable lapses. Clients are taught to view a lapse as a one-time mistake, rather than a sign that they have failed or that they are failures. If clients come to view lapses in this way, a single lapse will be unlikely to evolve into a full-blown relapse. James R. McKay and his colleagues explored the efficacy of RP in a sample of clients who had completed behavioral marital therapy, a CB treatment for alcohol abuse that includes the client's spouse. Their study showed that low self-efficacy at the end of behavioral marital therapy was related to a greater likelihood to relapse—but only in the group of clients that did not receive RP treatment as an adjunct to therapy.

E. Other Applications

Treatments based on CB approaches have also been demonstrated effective in the treatment of other psychological disorders (e.g., other substance use disorders, borderline personality disorder, sexual dysfunction) as well as other problems with living (e.g., couples distress). Interested readers can find more detailed information in books included in the Further Reading list.

IV. SUMMARY

Cognitive behavioral therapy is an integrative therapeutic approach that assumes that cognitions, physiology, and behaviors are all functionally interrelated. This model posits that client's emotional or behavioral distress is influenced by the manner in which they perceive, manipulate, and respond to information within their cognitive system. Treatment is aimed at identifying and modifying biased or distorted thought processes, attitudes and attributions, as well as problematic behaviors via techniques that actively involve the client's participation, such as self-monitoring, cognitive restructuring, and hypothesis testing. As such, the treatment goal is to develop a more rational and adaptive cognitive structure, which in turn is seen as a pathway to improving both affect and maladaptive patterns of behavior.

GLOSSARY

collaboration The practice in which health professionals from two or more disciplines cooperate in the diagnosis, treatment, and disposition of an individual patient.

co-location The collaborative model in which a behavioral health practitioner is actually located and functions within the primary care setting.

disease management The focus of a primary care team on a disease or diseases with the use of integrated programs of care (examples: asthma, depression, diabetes, hypertension, panic and anxiety disorder.)

hallway hand-off The term used for frequent, informal collaboration accorded by behavioral care providers being on co-location with primary care physicians.

integration, horizontal Programs that attempt to provide a general collaborative response to the diverse needs of the primary care population.

integration, vertical Programs that focus on a specific segment of the primary care population.

PCP A primary care provider who is usually a family medical practitioner, an internist, or a pediatrician. In some venues this term is extended to include nurse practitioners.

psychoeducational programs The term given to most vertical programs because they encompass a strong didactic component designed to inform the patient about the disease or condition.

referral The practice by a primary care physician of sending a patient to a specialist for diagnosis or follow-up services within that specialty.

specialist A physician or surgeon other than a primary care physician who has advanced training and standing in a specified area of practice, and is board certified in that field (examples: neurology, psychiatry, radiology, oncology, cardiology, psychology).

team The group of primary care physicians, behavioral health providers, nurse practitioners, and health educators serving the diverse needs of a primary care population (horizontal integration) or those that provide programs that are focused on a segment of that population (vertical integration).

triage The practice of determining the appropriate service, specialty, or community resource for an individual patient or segment of patients.

I. COLLABORATION AS A RANGE OF CONCEPTS

For the most part, collaboration is an occasional or infrequent occurrence. Defined as cooperation regarding the diagnosis and/or treatment of an individual patient

among two or more practitioners from different health fields, such laissez-faire arrangements fall short of today's expectations among those in medicine who advocate a closer working relationship among the various care disciplines. But even if this basic definition is accepted as valid, there is essentially an absence of collaborative care in the way medical practice is currently conducted. In most practices the primary care physician makes a referral to a specialist who then assumes responsibility for that aspect of the patient's care. Interaction with psychologists is usually a referral for psychodiagnostic testing, the results of which go back to the primary care provider (PCP) who makes the final disposition, or the patient is referred for psychotherapy to a separate mental health system. The relationship is usually from physician in independent solo or group practice referring to a mental health specialist also in solo or group practice. Some physicians who refer a patient for psychotherapy ask for occasional feedback, but most do not.

In the current managed health care climate there is considerable discussion accorded the concept of collaboration, but most of the movement toward a meaningful goal is largely lip service. The interest in the subject is usually sparked by psychologists and other mental health professionals who are looking for ways to expand their declining practices. Nonetheless, professional planning meetings will devote some time to the discussion of collaboration, often laughingly described as an unnatural act between two nonconsenting adults. Two organizations, however, were founded to promote collaboration. The first of these is the National Academies of Practice (NAP), founded in 1981 and composed of 10 Academies that are recognized by the federal and state governments for independent, reimbursable practice: Dentistry, Medicine, Nursing, Osteopathic Medicine, Optometry, Pharmacy, Podiatric Medicine, Psychology, Social Work, and Veterinary Medicine. Each Academy is composed of no more than 100 Distinguished Practitioners, chosen because they have received all the honors of their profession and are now prepared to disregard turf in the interest of the national health. The NAP essentially views collaboration as the cooperation among two or more professionals from different disciplines who are in independent, and most often solo practice. It publishes a journal on collaborative care, the *National Academies of Practice Forum*.

A smaller, but more activist organization is the Collaborative Family Healthcare Coalition that was founded recently and publishes *Families, Systems and Health*. It conceptualizes collaboration as the integration of behavioral health into primary care, as will be discussed below.

II. THE TRADITIONAL MODELS OF COLLABORATION
